Sudden changes in feedstuffs or feeding practices have been associated with triggering outbreaks of enterotoxemia in all affected species. Specific situations that make goats predisposed to this disease have included turnout to lush pasture, feeding of bread or other bakery goods, feeding of a bran/molasses mash to recently fresh does, excessive grain consumption after accidental access to feed storage sheds, and feeding of garden greens to goats unaccustomed to green feed (King 1980a). Feed changes, however, are not a prerequisite for enterotoxemia to occur. The author has observed an explosive outbreak of enterotoxemia in a herd of commercial antibody-producing goats that were fed an unchanging diet of hay and concentrate for many months before the outbreak.

Abrupt changes in weather have also been associated with onset of enterotoxemia in other species but this has not been well documented in goats. Nor has a strong seasonal pattern been identified. Intestinal tapeworm infections are believed to predispose feedlot lambs to enterotoxemia by slowing transit time of grain rations through the gut, allowing for more extensive proliferation of clostridia, but this association has not been reported in goats either.

While sporadic cases of caprine enterotoxemia are common, outbreaks of enterotoxemia in goat herds with high morbidity rates also occur. On some premises, the outbreak of enterotoxemia can become well established, with new cases occurring over several weeks or months. The epidemiologic factors contributing to this disease pattern are unknown. A buildup of *C. perfringens* type D in the environment from earlier diarrheic cases is probably contributory.

Pathogenesis

Specific studies on the pathogenesis of enterotoxemia in goats are limited. In other ruminant species it is believed that commensal *C. perfringens* type D organisms reside in the gut without producing much damage, because bacterial numbers are low and any toxins that are produced are moved quickly through the gut by normal peristalsis. Sudden ingestion of readily fermentable, carbohydrate-rich feeds permits more undigested starch to pass through the rumen to the abomasum and intestine where it serves as a nutrient substrate for rapid proliferation of the organism. Excess carbohydrate intake may also predispose to reduced motility. This proliferation of *C. perfringens* type D in conjunction with reduced peristalsis enhances the concentration and pathogenic potential of the epsilon toxin produced by the organism. Epsilon toxin, after being converted from the prototoxin by intestinal trypsin, increases vascular permeability in the gut, thereby facilitating its own absorption into the bloodstream. A generalized toxemia ensues. The toxin is necrotizing, and specifically neurotoxic. Death is attributable to damage of vital neurons, generalized toxemia, and shock (Kimberling 1988).

There is evidence that the pathogenesis of enterotoxemia in goats is different in terms of the intestinal effects. In field cases, diarrhea is a predominant clinical finding in goats relative to other species, and at necropsy, marked enterocolitis is often present (Blackwell and Butler 1992). This enterocolitis is an infrequent finding in lambs and calves.

The predilection of the gut as a target organ in caprine enterotoxemia has been demonstrated experimentally. Lambs and kids given broth infusions of *C. perfringens* type D intraduodenally via a cannula showed markedly different clinical and pathologic responses (Blackwell et al. 1991). In general, lambs showed lethargy, overt neurologic signs, minimal diarrhea, and death. Kids showed more prominent diarrhea and abdominal discomfort with fewer neurologic signs preceding death. At necropsy, intestinal lesions in lambs were limited to a moderate edema of the colon and watery gut content, while in kids, a severe necrotizing colitis was seen grossly and confirmed histologically.

More recent experiments involving introduction of epsilon toxin into ligated gut loops of lambs and kids has suggested a possible mechanism for the different clinical responses in sheep and goats. At two hours post inoculation, kids had accumulated much larger volumes of fluid and sodium in the small intestinal lumen than lambs. It was hypothesized that the more rapid endotoxin-induced accumulation of fluid in the small intestine of goats could more quickly flush away bacteria and toxin, moderating the intestinal toxin

absorption. In contrast, the delayed physiological response in the small intestine in sheep might result in greater absorption of epsilon toxin from the small intestine of this species, leading to the neurologic signs, brain lesions, and lung edema that is more commonly observed in naturally occurring cases of enterotoxemia in sheep as compared to goats (Fernandez Miyakawa and Uzal, 2003).

Clinical Findings

Three distinct clinical forms of enterotoxemia are recognized in goats, namely peracute, acute, and chronic. The peracute form occurs more frequently in young goats than adults. The clinical course is usually less than twenty-four hours and may go unnoticed. Finding one or more dead animals is often the first indication of peracute enterotoxemia in a herd. In milk-fed kids, it is frequently the larger, more robust, aggressively feeding individuals that are affected. In weaned kids, the history may reflect some recent change in feeding practices or an opportunity to overeat. Clinical signs include a sudden loss of appetite, profound depression, marked abdominal discomfort manifested by arching of the back and kicking at the belly, loud and painful screaming, and profuse watery diarrhea containing blood and shreds of mucus. Fevers of 105°F (40.5°C) are recorded. Affected goats quickly become weak and recumbent. They may show paddling or convulsions, but frequently they just lapse into a coma without excitatory signs. Death ensues within hours. Recoveries are rare, even with treatment. When the peracute form occurs in milking goats, the onset of signs may be foreshadowed by a sudden drop in milk production.

In the acute form, similar clinical signs are seen but with less severity. Abdominal pain and screaming may be absent or reduced. Feces may first turn pasty or soft, but then become watery. The clinical course lasts from three to four days. Severe dehydration and acidosis, caused by the profuse diarrhea, become complicating factors in these cases. Spontaneous recoveries may occur, but most animals die if not treated. The acute form more often affects mature goats. It can occur in herds with a solid history of vaccination against *C. perfringens* type D, so enterotoxemia should not be ruled out on the basis of previous vaccination. A history of recent feed changes may or may not be elicited.

In the chronic form, intermittent, recurring bouts of illness are observed over several weeks. Mature animals are usually affected. These goats are dull and listless with reduced appetite and milk production if lactating. There is progressive weight loss with intermittent episodes of pasty or loose feces. It has been emphasized that the chronic form is extremely difficult to recognize as enterotoxemia unless there is prior knowledge of acute or peracute cases in the herd (Shanks 1949).

Clinical Pathology and Necropsy

Reports on hematologic and clinical chemistry changes during caprine enterotoxemia are limited. The author has recorded complete blood counts on goats with the acute form of the disease. There is a distinct trend toward neutrophilic leukocytosis. In thirty-nine affected goats, the mean white blood cell count was 16,200/mm^3 with individual counts as high as 47,700/mm^3 recorded. Packed cell volumes as high as 57% were noted in cases with severe dehydration. Hyperglycemia, azotemia, and increased serum osmolarity may occur in the later stages of enterotoxemia (Blackwell et al. 1991) but they are not specific to this disease.

Reports on necropsy findings in caprine enterotoxemia also are limited. In a series of ten goat necropsies, enterocolitis was the most consistent finding in enterotoxemia (Blackwell and Butler 1992). The gut lesions were hemorrhagic, fibrinous, or necrotic in character. Enterocolitis was followed in frequency by pulmonary edema, renal tubular necrosis, and edema of mesenteric lymph nodes. Hydropericardium, a common finding in sheep, was seen in only one goat. Glucose may be detected in bladder urine of affected goats. If necropsy is performed shortly after death, the detection of soft or pulpy kidneys supports the diagnosis of enterotoxemia. However, if necropsy is delayed, the pulpy kidney loses its diagnostic significance, because kidney autolysis eventually occurs post mortem regardless of the cause of death. Gross lesions may be entirely absent in some cases of enterotoxemia (Blackwell 1983).

Cerebral microangiopathy has been rarely reported in caprine enterotoxemia, though it is a prevalent finding in sheep with the disease. This may reflect a failure to examine the brains of affected goats histologically since neurologic signs are not prominent clinically in caprine enterotoxemia. When tissues from two goats in Australia diagnosed with enterotoxemia where examined retrospectively, cerebral microangiopathy was noted in both goats (Uzal et al. 1997).

In experimentally induced type D enterotoxemia in goats, produced by administration of starch into the abomasum along with duodenal instillation of either whole cultures, culture supernatant, or washed cells, goats developed diarrhea and a necrotizing colitis, as is typical of the species. They also developed lesions similar to those found more often in ovine enterotoxemia, including lung edema and cerebral vasogenic edema (Uzal and Kelly 1998).

Abnormal appearing areas of bowel mucosa can be used to support the diagnosis of enterotoxemia. Impression smears of affected mucosa reveal a predominant population of large Gram-positive rods typical of *C. perfringens* (Figure 10.5). A similar
a
b

Figure 10.5. Gram-stained impression smear of intestinal mucosa of goat with enterotoxemia (Figure 10.5a). Note abundance of large Gram-positive rods compared to intestinal smear taken from a normal goat at necropsy (Figure 10.5b). (Courtesy of Dr. David M. Sherman.)

preponderance of large Gram-positive rods plus spores may be seen in smears made from diarrheic feces *ante mortem*.

Swabs from intestinal lesions can be submitted for anaerobic culture. Because *C. perfringens* type D may be isolated from the gut of normal goats, culturing the organism from the gut has been considered by some to have little diagnostic significance. However, survey studies of abomasal and intestinal culture from normal, healthy goats indicate that only 61% of goats sampled carried any type of enteric clostridial organism, and only 3% carried *C. perfringens* type D (Sinha 1970). Therefore, the isolation of the organism from swabs of necrotic intestine in animals dying of signs typical of enterotoxemia may have more diagnostic significance than is usually ascribed to it.

The most convincing indication of enterotoxemia, however, is the presence of epsilon toxin in diarrheic feces or intestinal content. At least 10 ml of intestinal content should be submitted, taken from the areas of the bowel exhibiting lesions. The toxin is fragile, so gut content should be sent to the lab refrigerated or frozen. When type D enterotoxemia is suspected, intestinal content should be collected as soon as possible after death and frozen for shipment because the epsilon toxin is especially labile.

Traditionally, toxin types have been identified by *in vivo* toxin neutralization assays using mouse lethality and guinea pig or rabbit dermonecrosis as endpoints. More recently, both ELISA and counter immunoelectrophoresis (CIEP) procedures have been described that eliminate the need for lab animals and have improved the availability of confirmatory testing. Both methods have been reported as comparable to mouse lethality tests (Naylor et al. 1987; Hornitzky et al. 1989). However, another study indicated considerable vari-

ability in sensitivity of a polyclonal ELISA, monoclonal ELISA, and CIEP when compared to the mouse neutralization test for detection of epsilon toxin in intestinal content and other body fluids. The study also urged that a final diagnosis be based not only on toxin testing but also clinical signs and post mortem findings (Uzal et al. 2003).

Beginning in the 1990s, polymerase chain reaction (PCR) tests have been developed that identify the presence of the bacterial genes responsible for the production of the various *C. perfringens* toxins, thus obviating the need for direct identification of toxin for typing the organism (Daube et al. 1994; Meer and Songer 1997). Multiplex PCR genotyping is now routinely available in some diagnostic laboratories and can be applied to identify and type *C. perfringens* strains present in the gastrointestinal content or feces of goats (Uzal et al. 1996) or from paraffin-embedded tissues of goats (Warren et al. 1999).

Diagnosis

Diagnosis is based on a combination of characteristic clinical history and signs, evidence of enterocolitis at necropsy, isolation of *C. perfringens* from the feces or gut lumen, and identification of epsilon toxin or the gene expressing epsilon toxin in *C. perfringens* cultures from feces or gut lumen content. It has been suggested that a presumptive antemortem diagnosis of enterotoxemia can be made by observation of clinical improvement in response to administration of *C. perfringens* type D-specific antitoxins (Guss 1977). However, this has been reported as unreliable by others (Blackwell and Butler 1992).

Differential diagnosis of the peracute form must include all causes of sudden death, with particular emphasis on plant and chemical toxicities. Peracute

deaths in kids younger than three weeks of age are not likely to be due to type D enterotoxemia because normal gut trypsin levels may be inadequate to activate the epsilon prototoxin. Type C enterotoxemia, however, can cause death in these young kids.

When diarrhea is present in peracute or acute disease, the differential diagnosis should include coccidiosis, salmonellosis, yersiniosis, and in younger animals cryptosporidiosis and colibacillosis.

In milking does, the early stages of the acute form of the disease may mimic milk fever or hypocalcemia, but favorable response to administration of parenteral calcium salts in cases of milk fever should clarify the diagnosis. The chronic form of enterotoxemia and chronic salmonellosis may be clinically undifferentiable and diagnosis depends on bacteriologic methods.

Treatment

The prognosis for recovery is guarded in caprine enterotoxemia, even with treatment. Aggressive intervention is required. Affected animals should be managed in a warm and dry hospital pen. Intravenous fluid therapy providing mixed electrolyte solutions with bicarbonate is indicated in peracute and acute cases to counter shock, dehydration, and acidosis. Nonsteroidal anti-inflammatory drugs such as flunixin meglumine (1 mg/kg intravenously every twelve hours) may be helpful in stabilizing animals in toxemic shock and will alleviate pain.

Commercially available type C and D antitoxins should be administered parenterally, preferably intravenously, in severe cases. Though recommended prophylactic doses are usually around 5 ml, therapeutic doses up to 100 ml have been administered. Because the antitoxin products are relatively expensive, a minimum effective dose is desirable. Fifteen to 20 ml has been effective in Australian practices (King 1980a). In those cases responsive to antitoxin, a rapid though sometimes temporary improvement may be noted within one to two hours. Equal or decreased doses can be repeated every three to four hours until the animal's condition has obviously stabilized. In the chronic form of the disease, 2 doses of 20 ml of antitoxin given four days apart was reported to be a reasonably effective treatment (Quarmby 1946). Diarrhea ceased in affected does and their milk production and body condition improved.

Decades ago, there were reports of allergic protein sensitivities to antitoxin observed in Saanen goats after repeated administration (Quarmby 1947). Though this may reflect impurities in older serum products, the potential for anaphylaxis, particularly in the Saanen breed, should be anticipated, and epinephrine (0.03 mg/kg intravenously) kept close at hand.

Antibiotic therapy may be helpful in reducing bacterial proliferation. Oral sulfas have been used success-fully. To ensure that the drugs reach the abomasum and intestine, pretreatment with 5 cc of copper sulfate solutions (1 tablespoon $CuSO_4$/liter of water) to close the esophageal groove followed rapidly by antibiotic administration has been recommended (King 1980a). Parenteral antibiotics including penicillin, tetracyclines, or trimethoprim-sulfa combinations may also be useful. *C. perfringens* isolates are often resistant to aminoglycosides (Songer 1996).

To limit the uptake and promote elimination of intestinal epsilon toxin, various cathartics and adsorbents have been given orally, including activated charcoal, magnesium sulfate, magnesium hydroxide, caffeine, and kaolin/pectin. Though the rationale for use is valid, therapeutic efficacy has not been proven.

In the face of outbreaks of enterotoxemia, all animals on the premises should be considered to be at risk. Previously vaccinated goats should be boostered, and unvaccinated goats should receive a prophylactic dose of antitoxin in conjunction with an initial vaccination to be boostered two to three weeks later. Any excessive feeding of carbohydrate should be curtailed immediately.

Control

Goats are considered highly susceptible to enterotoxemia and it is universally recommended that all goats be vaccinated against the disease as part of any basic caprine herd health program. At the same time, it is recognized that vaccination does not afford the same level of protection to goats that occurs in sheep, and that the persistence of serum antibodies against toxin at protective levels in goats is limited (Shanks 1949; Blackwell et al. 1983).

This species difference has been experimentally demonstrated. When sheep and goats were given equivalent doses of three different multivalent clostridial vaccines that included *C. perfringens* type D, levels of serum anti-epsilon toxin antibodies increased significantly in sheep and remained significantly higher than prevaccination levels at twenty-eight days after vaccination. In goats, only one of the same products produced a significant increase in serum anti-epsilon toxin antibody titers, and titers returned to prevaccination levels for all products by twenty-eight days (Green et al. 1987).

The required level of anti-epsilon toxin antibody in serum that protects goats from clinical enterotoxemia is not fully established, but recent research suggests that it is likely 0.25 IU/ml (Uzal and Kelly 1998; Uzal et al. 1998). In one study, goats vaccinated with an incomplete Freund's adjuvanted vaccine had high anti-epsilon antibody titers between 2.45 IU/ml and 230 IU/ml. They showed no clinical signs or post mortem lesions after intraduodenal administration of *C. perfringens* type D culture supernatant. In contrast,

goats receiving a commercially available aluminum hydroxide adjuvanted vaccine only produced antibody levels in the range of 0.22 to 1.52 IU/ml and four of five goats developed diarrhea and some evidence of colitis at necropsy, while unvaccinated control goats all developed severe enterocolitis (Uzal and Kelly 1998). It seems, therefore, that the occurrence of enteritis in vaccinated goats derives from the fact that conventional, commercial vaccines, which are generally approved for sheep, may not produce sufficiently high antibody responses in goats to effect protection against the enterocolitic form of the disease common in goats (Uzal and Kelly 1998).

In a second study, antibody levels were measured after vaccination with a standard commercial vaccine following a single injection alone or after booster injections given either twenty-eight days later or forty-two days later. In all three protocols, antibody levels had dropped below the putative protective threshold of 0.25 IU/ml in most of the goats by ninety-eight days after the initial vaccination (Uzal et al. 1998).

These findings support the recommendation that goats should be vaccinated at intervals of three to four months to maintain adequate protection against enterotoxemia using currently available vaccines, especially in herds where there is a history of enterotoxemia. At the least, goats should be vaccinated semi-annually. Initial vaccinations should be followed by a booster vaccination three to six weeks later and semi- or tri-annual vaccinations should be timed so that the last vaccination occurs two to three weeks before parturition in pregnant does. This enhances the protective effect of colostrum for suckling kids. Kids should be vaccinated initially at four to six weeks of age and certainly before weaning. They should also be boostered three to six weeks later, depending on product recommendation.

Vaccines limited to *C. perfringens* types C and D with or without tetanus may be preferable to the use of more complex, polyvalent clostridial vaccines commonly approved for sheep and cattle. These polyvalent vaccines may be more expensive and provide unneeded protection against clostridial diseases that occur uncommonly in goats. Furthermore, in at least one study, anti-epsilon toxin antibody titers were sometimes significantly lower in goats in response to a multivalent vaccine than to a bivalent *C. perfringens* types C and D vaccine (Blackwell et al. 1983). Few products are approved specifically for goats, and in general, sheep dosages are used.

There is a marked tendency for goats to develop local tissue reactions at the vaccine injection site. This is quite troublesome in show goats, and also complicates caseous lymphadenitis control because owners may have trouble differentiating between lymph node abscesses and injection site reactions. The occurrence

of sterile abscesses of 2 to 5 cm in diameter after clostridial vaccination is well documented and does not necessarily result from careless injection technique, but rather is intrinsic to some vaccine preparations (Smith and Klose 1980; Blackwell et al. 1983; Green et al. 1987).

Scrupulous vaccination technique should be observed when vaccinating show goats to avoid any implication that technique was at fault, should abscesses develop. Use a new needle for each vaccination. Subcutaneous vaccination in the loose skin on the chest wall behind the elbow is recommended as a site where reactions will be less visible in show goats. However, if reactions occur at this site and become secondarily infected, they may grow quite large before they are noticed. In commercial goats, therefore, vaccination on the neck is recommended. Practitioners should sample several vaccine products to determine which produces the least tissue reaction. No correlation between tissue reaction and immunogenicity has been demonstrated (Green et al. 1987).

In addition to vaccination, control of enterotoxemia depends on avoidance of sudden feed changes, vigilance against overeating, and guarding against accidental access to grains and other stored feeds.

Salmonellosis

Salmonellosis continues to be an important infectious disease for several reasons: changing patterns of infection and morbidity rates in virtually all domestic species of livestock and poultry, public health concerns regarding human illness from animal sources, increased occurrence of multiple drug resistance, and economic losses to producers and food processors caused by condemnations and adverse publicity relating to the zoonotic potential of the infection. These issues are all relevant to the goat industry.

Etiology

Salmonella are Gram-negative, nonspore-forming, rod-shaped bacteria in the family Enterobacteriaceae. There are more than 2,400 serotypes, also known as serovars. On a worldwide basis, the serovar *S.* Typhimurium is the most common cause of the diarrheal and septicemic forms of clinical salmonellosis in cattle, sheep, horses, and swine. This serovar has been associated with clinical salmonellosis in goats in the United States (Bulgin and Anderson 1981). In two British reports, however, *S.* Dublin was isolated from sick goats (Levi 1949; Gibson 1957), while in a Nigerian investigation of diarrheic kids, S. Poona was the sole isolate identified (Falade 1976). In an Australian outbreak, four serovars were isolated from goats dying with severe diarrhea: *S.* Adelaide, *S.* Typhimurium, *S.* Muenchen, and *S.* Singapore (McOrist and Miller 1981). Isolates from cases of gastroenteritis and septi-

cemia in goats in India include *S.* Typhimurium, *S.* Bere, *S.* Colombo, *S.* Newport, *S.* Tennessee, and *S.* Worthington (Janakiraman and Rajendran 1973). *S.* Enteriditis, *S.* Abony, and *S.* Cerro were cultured from cases of kid diarrhea in Greece (Zdragas et al. 2000).

Salmonella can also cause caprine abortion. Abortions may occur as a sequela to septicemia with any *Salmonella* serovar, but a specific epizootic abortion syndrome of goats and sheep caused by *S.* Abortusovis occurs in Mediterranean and Middle Eastern countries (Leondidis et al. 1984). S. Abortusovis may also cause enteric salmonellosis (Sanchis and Cornille 1980). *Salmonella* are an infrequent cause of mastitis in goats, gaining entry to the mammary gland through the teat canal from a contaminated environment.

Numerous *Salmonella* serovars have been isolated from the feces of healthy goats (Kapur et al. 1973; Abdel-Ghani et al. 1987) and more than forty serovars from the viscera of healthy goats at slaughterhouses around the world (Nagaratnam and Ratatunga 1971; Kumar et al. 1973; Gupta et al. 1974; Arora 1978; Nabbut and Al-Nakhli 1982; Subasinghe and Ramakrishnaswamy 1983; Faraj et al. 1983; Diaz-Aparicio et al. 1987; Woldemariam et al. 2005; Chandra et al. 2006). *S.* Paratyphi, the cause of paratyphoid in humans, has been isolated from mesenteric lymph nodes of slaughtered goats in the Middle East and Asia, suggesting that the goat can act as a source of infection for humans. In slaughterhouse surveys of viscera, *Salmonella* are most often isolated from mesenteric lymph nodes and gall bladders.

Epidemiology

The occurrence and outcome of salmonellosis in livestock can be influenced by a number of factors. These include the existence of host-adapted *Salmonella* serovars, the development of a carrier state, impaired immunity of the host, the occurrence of severe stress including prolonged transport or deprivation of food and water, intensive management practices, and exposure to contaminated feeds or infected animals. The role of all these various factors in caprine salmonellosis is not fully described.

There are no known host-adapted *Salmonella* serovars in goats. *S.* Dublin, which is considered to be host-adapted to cattle in Britain, caused clinical disease in goats but there was no indication that a carrier state or persistent shedding occurred in exposed or recovered goats based on repeated fecal cultures or tissue cultures at necropsy (Levi 1949; Gibson 1957).

Reports of naturally occurring salmonellosis indicate that latent carrier states occur in goats and that latent infections can progress to active fecal shedding of *Salmonella* or to overt clinical disease in response to stress of transport, excessive handling, feed or water deprivation, sudden feed changes, or parturition. The

frequent isolation of *Salmonella* from the organs of healthy goats at slaughter, as cited above, also indicates the existence of a carrier state.

A latent carrier state in goats has been demonstrated experimentally with *S.* Typhimurium (Arora 1983). Goats challenged orally showed peak fecal shedding at three days after challenge but all shedding ceased by two weeks. During the three subsequent weeks, no organisms were recovered from feces. However, when these goats were later stressed by transport, 60% resumed fecal shedding of S. Typhimurium. The organism was isolated from mesenteric lymph nodes, livers, and spleens at necropsy. In contrast, attempts to confirm the existence of a nasal carrier state in kids from premises with a history of salmonellosis were unsuccessful, though calves and piglets on the same premises yielded the organism (Garg and Sharma 1979).

Transmission is most commonly by the fecal-oral route. The introduction of unrecognized carrier animals into susceptible populations is of major importance in the spread of salmonellosis. Cross species infection can also occur as reported in the transmission of *S.* Dublin from calves to goats via fecal contaminated pens and bedding, and of *S.* Typhimurium from ducks to goats via consumption of contaminated water (King 1980). Other potential sources of infection for goats include raw sewage, contaminated feedstuffs, rodents, birds, and other livestock species, although documentation of such transmissions to the goat is rare.

Other factors that may predispose to clinical salmonellosis in goats include close contact with active shedders, excessive buildup of organisms in the environment caused by poor hygiene or poorly constructed feeders and waterers, concurrent disease, particularly severe gastrointestinal parasitism, stress of capture in feral goats, and in neonates, failure of passive transfer of antibody from the does' colostrum. There is little documentation that intensive management with many goats maintained in confinement housing increases the risk or spread of salmonellosis, although this is considered to be a major factor in regard to dairy cattle.

Human infections with *Salmonella* from goat products have been documented. Raw or undercooked goat meat can pose the risk of salmonellosis, but so can goat milk or goat milk cheese, especially if unpasteurized. Severe gastroenteritis and even fatalities can occur. In France in 1993, a commercial goat cheese made from unpasteurized goat milk led to 273 human cases of salmonellosis with one death. Though the processing plant derived milk from forty goat herds, the offending organism, *S.* Paratyphi B, was traced back to a single goat farm. Thirty-three tons (30 tonnes) of cheese stored at the plant had to be destroyed (Desenclos, et al. 1996). More recently, three brands of unpasteurized goat cheese derived from a single herd of 260 goats in

France were associated with fifty-two cases of human disease in seven European countries: France, Switzerland, Sweden, Austria, Germany, the UK, and the Netherlands. The causative agent was a relatively rare serovar, *S*. Stourbridge (Espié and Vaillant 2005). Milk samples from all goats in the source herd were cultured in the ensuing epidemiologic investigation and the organism was found in the milk of only one asymptomatic carrier. This outbreak underscores, among other things, how widely zoonotic disease can be disseminated under modern systems of marketing and trade.

Pathogenesis

The pathogenesis of enteric and septicemic salmonellosis has not been specifically studied in goats and is presumed to be similar to that described in other species (Radostits et al. 2007). After ingestion, the organism becomes established in the intestines, most commonly in the ileum. A marked enteritis develops, most likely as a result of release of endotoxin from dying organisms. Diarrhea results at least in part from the inflammatory enteritis, but the organisms may also elaborate enterotoxins that have a hypersecretory effect on villous epithelial cells leading to accelerated fluid and electrolyte loss from the gut.

Salmonella are invasive bacteria and can penetrate the mucosa, gaining entry to the lymphatics. Several outcomes are possible. In individuals with decreased disease resistance or severely impaired immunity, the organism can then gain entrance to the blood, producing a generalized septicemia with marked endotoxemia and usually death, while animals with a strong immune system may clear the infection entirely. In animals with moderate disease resistance, a transient bacteremia may occur with subsequent localization of the organism in liver, gall bladder, spleen, and mesenteric lymph nodes. These animals become latent carriers, and in the face of subsequent stresses they may develop clinical septicemia or enteritis, or they may remain subclinical but initiate fecal shedding of the organism, usually as a result of re-inoculation of the gut via the infection in the gall bladder. In carrier does that are pregnant, the stress of parturition may induce bacteremia and result in exposure of the kid either *in utero* or via the milk or by fecal contamination of the udder.

Animals experiencing infection may produce detectable antibodies against flagellar (H) and somatic (O) antigens of *Salmonella*. In goats experimentally infected with S. Typhimurium, antibodies to O and H antigens were detectable by five days post infection in one study (Sharma et al. 2001) and not until after seven days in another (Otesile et al. 1990). The flagellar antibodies appear to be more persistent in goats. The role of antibody in subsequent immunity is not clear. Immunity

to the same strains of *Salmonella* may develop after initial exposures, but cross immunity is limited. This fact has impeded the development of broadly efficacious vaccines.

Clinical Findings

Three age patterns of salmonellosis have been identified in goats, namely neonatal septicemia during the first week of life, preweaning enteritis in kids two to eight weeks of age, and enteritis/septicemia of mature goats. The prognosis is grave in the first, poor in the second, and guarded in the third.

In neonatal septicemia, kids usually appear normal at birth and may die acutely by thirty-six hours with no signs other than depression. Occasionally, signs of gaseous abdominal distension with pain or diarrhea may be seen.

In enteritis of older kids, there is an acute onset of depression and anorexia. A profuse, watery, foul-smelling, yellow to greenish-brown diarrhea develops, accompanied by fever up to 107°F (41.7°C). Affected kids rapidly become severely dehydrated, weak, and recumbent. Some may die within eight hours of the onset of diarrhea, with most dying within twenty-four to forty-eight hours. Fever may subside after twenty-four hours and temperature can become subnormal as animals develop shock. Morbidity and mortality rates can be high, particularly as kid births are often concentrated into a short period and numerous kids on the premises may be at risk.

The adult form of the disease tends to be more sporadic, with lower morbidity and mortality rates. Affected goats become acutely depressed, anorexic, and febrile, and develop a watery, foul smelling diarrhea that can be yellow, gray, or greenish-brown. Dehydration and weakness rapidly ensue and death can occur within twenty-four to forty-eight hours of the onset of signs. A chronic form of adult disease can also occur in which similar but milder signs are seen with subsequent recovery, followed by intermittent, recurring bouts of diarrhea. These animals tend to become progressively emaciated and may develop anemia.

In published cases of caprine salmonellosis, bloody diarrhea or fibrinous casts are rarely reported. This is in marked contrast to the disease as described in cattle or sheep.

Clinical Pathology and Necropsy

Goats with salmonellosis may have a marked leukopenia early in the course of disease followed by a rebound leukocytosis, with neutrophilia and a left shift in animals that do not die acutely. Severe metabolic acidosis can be expected along with losses of sodium and potassium caused by diarrhea. Liver-specific enzymes may be elevated in septicemic salmonellosis

due to foci of infection in the liver. In chronic salmonellosis, anemia and hypoproteinemia may be observed. In neonates, serum immunoglobulin levels may be low if failure of passive transfer of antibody from the dam has predisposed to clinical salmonellosis. Bacterial culture of the doe's milk and feces is also indicated to identify the dam as the possible source of infection.

For a definitive antemortem diagnosis in enteritis cases, repeated attempts at fecal culture should be made. Appropriate enrichment media should be used. In some cases, attempts to culture the organism from diarrhea are unsuccessful, but positive culture results may be obtained from formed feces after the diarrhea has resolved. Subsequent biochemical characterization and serotyping of isolates at a reference laboratory are recommended because of the different zoonotic implications of various *Salmonella* serovars. Blood cultures may be attempted on septicemic cases before antibiotic therapy, and antibiotic susceptibility testing of isolates should be requested because the occurrence of antibiotic resistance in *Salmonella* is increasing.

Serology may be of some value in the diagnosis of acute salmonellosis, particularly in evaluating a herd outbreak. In outbreaks of *S.* Dublin infection, goats had strong persistent antibody responses to flagellar H antigens of homologous *S.* Dublin for several months after exposure. Nonexposed control goats had background agglutination titers up to 1:80, whereas exposed goats had titers as high as 1:20,480.

At necropsy, kids dying acutely of septicemia may show minimal gross lesions consisting of some hemorrhage on serosal surfaces, increased pericardial and peritoneal fluid, and gas distended bowel. Histologically, edema of the abomasum and dilation of the tips of the intestinal villi have been observed. Culture should be attempted from multiple organs.

In older kids and adults with enteritis, gross lesions can be more apparent and include petechial hemorrhage of serosal surfaces, pericardial and peritoneal effusions, enlarged and edematous mesenteric lymph nodes, congestion of the lungs and liver, edematous thickening of the gall bladder, and marked, diffuse inflammation of the intestinal mucosa. The small and large intestines can be involved and the inflammation can range from catarrhal, to hemorrhagic, to necrotic, with diphtheritic membranes present in more prolonged cases. In chronic cases, lack of abdominal fat, miliary nodules in the liver, and hepatic lipidosis may also be seen.

Histologically, the intestinal inflammation is confirmed. The small intestine may show dilated mucosal crypts containing cellular debris and neutrophils, submucosal infiltrates of neutrophils and lymphocytes, and edema of the lamina propria. There may be small foci of hepatic necrosis containing aggregates of mononuclear cells. It is reported from experimental infection in goats with *S.* Typhimurium that histological lesions in mesenteric lymph nodes may be severe, even when enteric lesions are not conspicuous (Sharma et al. 2001). In goats, the mesenteric lymph nodes are the most promising source for bacterial isolation. Intestinal content, spleen, liver, and bile may also be cultured successfully.

Diagnosis

In newborn kids, starvation, hypothermia, lethal congenital defects, and colisepticemia must be considered in the differential diagnosis. In older kids with acute enteritis, the major differential diagnoses are coccidiosis, cryptosporidiosis yersiniosis, enterotoxemia caused by *Clostridium perfringens* type D, and, if pastured, gastrointestinal nematodiasis. In adult animals, enterotoxemia and gastrointestinal nematodiasis should be ruled out. Peste des petits ruminants and rinderpest must be considered in countries where they occur.

Treatment

Treatment should be directed at rehydration and maintenance of circulatory volume, correction of acid-base and electrolyte imbalances, amelioration of endotoxic effects, and the control of bacteremia when present. Intensive fluid therapy is indicated, and it is unlikely that any route other than intravenous will be of value. Balanced electrolyte solutions supplemented with sodium bicarbonate and potassium are indicated. In septicemic neonates, glucose supplementation is also advisable. If neonates are hypogammaglobulinemic, whole blood or preferably plasma transfusions are desirable. Nonsteroidal anti-inflammatory drugs such as flunixin meglumine administered parentally can be helpful.

The use of antibiotics in the treatment of salmonellosis is controversial because in other species it is associated with prolonged fecal excretion of bacteria, increased likelihood of developing a carrier state, and the promotion of drug resistance in the organism. These associations have had limited investigation in the goat. Two goat isolates made in India, *S.* Typhimurium and *S.* Weltevreden, were shown to possess R-factor that imparted multiple drug resistance to tetracycline, oxytetracycline, and chlortetracycline (Kumar and Misra 1983). An abattoir survey of 204 slaughtered goats in India yielded sixty *Salmonella* isolates with forty patterns of antibiotic resistance. All isolates were susceptible to chloramphenicol and imipenem, while 70% were resistant to nitrofurantoin and 52% to amikacin. Multiple resistance to three or more drugs occurred in 52% of the isolates while only 8% of isolates were sensitive to all drugs tested. Thirteen percent were resistant to gentamicin and 18% to tetracycline (Chandra et al. 2006).

It is unlikely that septicemic kids have any chance of survival without the use of antibiotics. In addition, it is extremely difficult to establish clinically if there is a component of septicemia in advanced cases of enteritis where severe dehydration and electrolyte imbalance lead to weakness and recumbency, suggestive of endotoxic shock. The use of antibiotics in these cases is justified. The major concern is that antibiotic-treated animals should not be subsequently introduced into naïve herds because it is impossible to be sure that the carrier state has not developed.

Where its use is permitted, chloramphenicol, at a dose of 10 mg/kg intravenously every twelve hours, has proven to be a drug to which most caprine isolates of *Salmonella* are susceptible. Caprine isolates are also frequently susceptible to cephalothin, the aminoglycosides gentamicin and kanamycin, and trimethoprim-sulfonamide combinations. The aminoglycosides must be used cautiously in these cases because the severe dehydration that is often present can aggravate the inherent renal toxicity of these drugs.

Gentamicin is given intramuscularly or subcutaneously at a dose of 1 mg/kg every eight hours, and kanamycin at 5 mg/kg every eight hours. Trimethoprim is rendered inactive by rumen degradation and therefore trimethoprim-sulfa combination drugs must be given intravenously or subcutaneously to adults. They should also be given intravenously to septicemic neonates to provide rapid plasma concentrations. They may be given orally to young preruminant kids with enteritis. The dose is 30 mg/kg orally once a day or 15 mg/kg intravenously every twelve hours. Sensitivities to tetracyclines, nitrofurantoin, sulfonamides, neomycin, streptomycin erythromycin, and ampicillin are more variable. Resistance to penicillin is typical (Nabbut et al. 1981; Mago et al. 1982; Kumar and Misra 1983). In outbreaks, mass medication with sulfonamides or tetracyclines can be helpful if the isolate is susceptible to these drugs. Drugs should be added to the water rather than the feed, because many affected animals will not eat but may continue to drink.

Control

To prevent introduction of *Salmonella* into a naïve herd, purchase of outside animals should be discouraged. If purchases are made, they should be directly from healthy source herds and not through sales barns or markets. Because the stress of transport and introduction to new surroundings may trigger fecal shedding or overt clinical disease, newly purchased animals should be isolated from the herd for at least three weeks after purchase and, if practical, bacterial cultures of feces should be performed, particularly if the animal develops diarrhea during isolation.

In the face of an outbreak, it is important to identify the source of infection. Because the source of *Salmonella* can be contaminated feed or water, subclinical carrier animals, newly introduced livestock, or other animals on the premises, including rodents and birds, extensive animal and environmental sampling may be necessary to identify and remove the offending source.

Affected animals and their cohorts should be isolated away from the rest of the herd and rigorous hygienic measures should be practiced when dealing with these animals. If affected animals have been moved from the original site of the outbreak, those premises should be thoroughly cleaned, repeatedly disinfected, and allowed to remain unused for several weeks. Common household bleach is an inexpensive and effective disinfectant as long as organic material has been removed from floors, pens, feeders, and waterers.

When sporadic cases or recurrent outbreaks of salmonellosis continue to occur in a herd, the presence of carrier animals must be considered. Repeated herd-wide fecal culture testing with culling of shedders may be costly but effective. Strict attention must be paid to ensuring that kids receive adequate colostrum and that kidding facilities and feeding equipment are kept clean. Kids should be reared in a separate facility away from adults and preferably in individual pens or hutches rather than in groups.

Vaccination can play an important role in the control of *Salmonella* infection in ruminant livestock, but at present the options are limited for goats, because there are no vaccines approved specifically for use in this species. A bivalent killed bacterin containing *S.* Typhimurium and *S.* Dublin is available for use in cattle in many countries, including the United States, but the effectiveness of whole cell killed *Salmonella* bacterins is limited. Vaccines based on the core lipo-polysaccharide (LPS) common to Gram-negative bacterial cell walls are also commercially available for cattle and may offer better cross protection between serovars, because the repeat polysaccharide units of the LPS which confer serotype specificity are not present in the vaccine.

There is active research on the development of new vaccine technologies to improve cellular and humoral responses and especially to overcome the general lack of cross protection provided by monovalent vaccines against heterologous *Salmonella* serovars. One promising advance has been the development of a vaccine that produces antibodies against siderophore receptor sites and porin proteins found on the outer cell membrane of Enterobacteriaceae, including *Salmonella*. The receptor sites and proteins are necessary for the transfer of iron into the bacterial cell, a requisite for bacterial multiplication and survival. The receptor site structures are conserved across various *Salmonella* serovars, so cross protection against multiple serovars by using this approach can be significant. A commercial vaccine

based on this technology is now available in the United States but is limited to use in cattle (Stevens and Thomson 2005). At present, the use of autogenous bacterins made from *Salmonella* isolated on the premises can be considered for control of infection in known infected herds of goats.

Yersiniosis

Yersiniosis has emerged as a common cause of enteritis and death in goats in New Zealand, where it appears to have become enzootic. It is also sporadically associated with enteritis, abortion, mastitis, internal abscesses, and mortality caused by septicemia in goats throughout the world. Yersiniosis is a zoonotic disease.

Etiology

Yersinia spp. are Gram-negative, aerobic and facultatively anaerobic, nonlactose-fermenting coccobacilli of the family *Enterobacteriaceae*. They grow readily on blood agar and MacConkey's agar, but may be quickly overgrown, particularly when isolating from fecal specimens.

There are three pathogenic species in the genus *Yersinia. Y. pestis* causes plague in humans and rodents and will not be considered further except to note that there are recorded cases of human plague traced to the slaughter, skinning, and butchering of sick goats. The goat is considered a sentinel animal in plague epidemics (Christie et al. 1980).

Y. enterocolitica and *Y. pseudotuberculosis* are pathogenic for humans and a range of animal species including goats. *Y. enterocolitica* is ubiquitous in the environment. *Y. pseudotuberculosis* is a common inhabitant of the gut of many domestic and wild animals. The conditions caused by either of these two species are known collectively as yersiniosis.

Different serotypes are recognized, based primarily on somatic O antigens. There are six main serotypes (I to VI) of *Y. pseudotuberculosis.* Serotypes I and especially III are most often associated with disease in goats (Hubbert 1972; Jones 1982; Hodges et al. 1984; Slee and Button 1990; Seimiya et al. 2005). Serotype III produces an exotoxin that may be a virulence factor.

Yersinia enterocolitica isolates are classified according to biotype, which refers to their biochemical characteristics, and serotype, which refers to their antigenic characteristics, mainly associated with somatic O antigens. Because some antigens are common to both pathogenic and nonpathogenic isolates, ideally, organisms should be described by first their biotype and then serotype, though these full descriptions are not always included in the earlier literature. There are five main biotypes or biovars of *Y. enterocolitica*, and many serotypes or serovars. Biotype 5 serotype O:2,3 has been associated with caprine enteritis in Norway (Krogstad et al. 1972) and was also associated with enteric disease of goats and sheep in Australia and New Zealand (Slee and Button 1990a).

In standard serological tests, such as the microagglutination test, *Y. enterocolitica* serotype O:9 is cross-reactive with *Brucella abortus* and can confound surveillance in brucellosis control programs. It was demonstrated in Canada that normal goats may be infected with serotype O:9 and possess antibody that leads to false positive brucellosis test results when using *B. abortus* antigen (Mittal and Tizzard 1980). More recently, an ELISA technique using refined antigens from *B. abortus* has been reported to serologically differentiate *Brucella* infected animals from those with *Yersinia enterocolitica* O:9 (Erdenebaatar et al. 2003).

Epidemiology

Many sporadic episodes of yersiniosis have been reported in animals and humans throughout the world for most of the twentieth century. In recent years, gastrointestinal illness in humans caused by *Y. enterocolitica* is increasing and links to animal contact and animal food sources are often suspected or confirmed (Nesbakken 2006). *Y. enterocolitica* has been isolated from raw goat milk offered for sale in Northern Ireland and Australia (Hughes and Jensen 1981; Walker and Gilmour 1986), and yersiniosis in a goat keeper was recorded in Norway during an epizootic of diarrhea in goats with *Y. enterocolitica* biotype 5 serotype O:2,3, possibly as a result of animal or fecal contact (Krogstad et al. 1972).

Nevertheless, goats are not considered to be significant carriers of human pathogens (Nesbakken 2006). A recent sampling survey of 575 goats in twenty-four goat herds in northern Germany yielded seventeen *Y. enterocolitica*-positive fecal samples from five herds. All isolates were biovar 1A, which is considered to be nonpathogenic, and it was concluded that milk, cheese, or meat from these goats did not represent a risk of human yersiniosis (Arnold et al. 2006). However, a serosurvey in the same region of Germany during the same time frame indicated that sera from 66% of 681 goats from twenty-eight farms had antibodies to *Yersinia* outer proteins (Yop) generally associated with pathogenicity (Nikolaou et al. 2005). One possible explanation is that goats are indeed often exposed to subclinical infections with pathogenic *Yersinia* but mount effective immune responses which eliminate these infections. This explanation is supported by the findings of a longitudinal study in New Zealand wherein pathogenic *Yersinia* cultured from the feces of young goats could not be identified again on subsequent monthly samplings from those same goats (Lãnada et al. 2005).

Epizootics in lab animal colonies and aviaries due to *Y. pseudotuberculosis* have been the most common

form of the disease in animals, but livestock epizootics also occur (Obwolo 1976). Stress, overcrowding, and sudden cold weather can be predisposing factors. Birds and rodents are considered reservoirs of infection and may introduce virulent strains into susceptible herds by contaminating feedstuffs. Swine are a carrier source of *Y. enterocolitica* and may infect ruminant species when commingled. Because *Yersinia* organisms are often present in the gut of normal animals, factors that compromise gut mucosal integrity, such as concurrent parasitism, or coarse feed-related abrasions or ulcerations can predispose to septicemic yersiniosis.

Yersiniosis has been increasingly recognized as a cause of various disease problems in goats in the past two decades. Abortion and post-parturient deaths in goats because of *Y. pseudotuberculosis* have been reported from Germany (Albert 1988), India (Sulochana and Sudharma 1985), Japan (Morita et al. 1973), and the United States (Witte et al. 1985). Liver abscesses and granuloma formation in goats because of *Y. pseudotuberculosis* have been documented in the United States, Japan, and Australia (Hubbert 1972; Morita et al. 1973; Slee and Button 1990). Chronic mastitis in does caused by *Y. pseudotuberculosis* has been reported from California (Cappucci 1978) and the UK (Jones 1982). Clinical mastitis caused by *Y. enterocolitica* has not been reported in goats, and efforts to induce it experimentally were unsuccessful (Adesiyun and Lombin 1989).

Yersiniosis has become enzootic in goats in New Zealand. In a large study of goat mortality on the North Island, yersiniosis, mainly due to *Y. enterocolitica* biotype 5, was the fourth most common documented cause of death, and the most prevalent infectious cause (Buddle et al. 1988). It was also the most common bacterial cause of caprine enteritis identified in diagnostic laboratories (Vickers 1986). The disease occurs mostly in late autumn or winter and has been linked to the stress of transport, excessive handling of feral goats, nutritional deprivation, winter shearing, cold and wet weather, inadequate shelter, and, in one outbreak, contact with pigs (Orr et al. 1987). Young goats are more often affected but all ages are at risk. *Y. enterocolitica* is more frequently identified than *Y. pseudotuberculosis* (Thompson 1985). Enteric yersiniosis also has been reported in goats in Norway (Krogstad et al. 1972) due to *Y. enterocolitica*, in Australia due to *Y. enterocolitica* and *Y. pseudotuberculosis* (Slee and Button 1990, 1990a), and most recently in Japan due to *Y. pseudotuberculosis* (Seimiya et al. 2005).

A cohort study of *Yersinia* infection in goats in New Zealand indicated a clear seasonal and age related pattern of infection in goats, with most fecal excretion of pathogenic biotypes of *Y. enterocolitica* and *Y. pseudotuberculosis* occurring in the colder winter months

and dropping off in summer, while excretion of non-pathogenic or environmental *Yersinia* spp. (e.g., *Y. frederiksenii*) showed a more persistent temporal pattern. The shedding of pathogenic *Yersinia* was highest in goats less than one year of age, with pathogenic strains rarely isolated from adults (Lãnada et al. 2005). It is likely that young goats normally experience subclinical infections due to environmental exposures and develop immunity, but if they are stressed during those infections, they may manifest clinical disease (Orr et al. 1990)

Pathogenesis

Infection is usually via the oral route, though in the case of mastitis, entry via the teat canal is more likely. The two *Yersinia* spp. causing yersiniosis are known to contain two plasmid-mediated virulence factors, the V and W antigens, similar to those of *Y. pestis*. In addition, some *Y. pseudotuberculosis* serotype III organisms produce an exotoxin that may enhance virulence (Obwolo 1976). *Yersinia* organisms multiply in the intestine, producing enteritis, but the organisms also produce bacteremia via the portal circulation and lymphatics, leading to internal abscesses, abortions, and acute deaths.

Clinical Findings

The enteric form of yersiniosis occurs most often in kids between one and six months of age, but all ages and breeds can be affected. In an outbreak in Japan, for instance, twenty-nine of one hundred adult lactating does developed diarrhea, but no kids, males, or dry does on the premises became ill (Seimiya et al. 2005). The initial signs were anorexia and a significant drop in milk production followed by depression and a watery diarrhea containing mucus one or two days later that lasted for four to six days. The case fatality rate was 13.7% (four of twenty-nine). There was no fever recorded in any affected animals but fever has been associated with enteric yersiniosis in other reports. In young animals, cases of sudden death without diarrhea may occur along with cases of diarrhea. The diarrhea is watery and not bloody. The course of diarrhea may be short, up to several days, and is often fatal. A more prolonged illness with dehydration and weight loss also may be seen.

In the abortion form, spontaneous abortions may occur in a herd in conjunction with the birth of weak, term kids that die shortly after birth. The cotyledons on placentas from affected does may be entirely white or have focal white spots on their surfaces (Witte et al. 1985). An abortion rate of 24% was recorded in one affected herd over a period of ten days and affected does died (Albert 1988).

Both acute and chronic forms of mastitis occur. There is udder swelling and clots in the milk in the

acute form and there may be blood in the milk in the chronic form. Induration of the udder may persist for weeks after infection is cleared.

Clinical Pathology and Necropsy

Goats with enteritis may show a pronounced leukocytosis with neutrophilia and a marked left shift (Seimiya et al. 2005). There may also be laboratory evidence of hemoconcentration due to dehydration from diarrhea. The causative organism can be isolated from diarrheic feces, mastitic milk, and uterine discharges. Because the organism may be present in feces as a normal gut inhabitant, serotyping is necessary to confirm the isolate as a likely pathogen. Serologic testing can be used to support a diagnosis of yersiniosis. Goats with diarrhea caused by *Y. enterocolitica* may show marked increases in agglutination titers between sera taken at the time of diarrhea and two to three weeks later (Krogstad 1974).

At necropsy, goats with the enteric form of yersiniosis are thin and often emaciated. The large, multiple, internal abscesses (pseudotuberculosis) characteristic of the disease in laboratory animals are not reported in goats, though occasional, single, abscesses have yielded *Y. pseudotuberculosis*. The most consistent gross finding is enlargement and edema of the mesenteric lymph nodes. Gross lesions in the intestines may be limited to hyperemia or edema of the mucosa or a catarrhal enteritis, but careful inspection of the mucosal surface frequently reveals small focal areas of necrosis visible as small, whitish, circular lesions 1 to 2 mm in diameter. Histologically, there are microabscesses in the superficial mucosa or lamina propria of the intestine that contain colonies of Gram-negative bacteria surrounded by neutrophils (Vickers 1986). Gross thickening of the cecum and proximal colon and mucosal ulceration and fibrin plaque formation have also been observed in at least one goat with intestinal yersiniosis (Slee and Button 1990). Microabscesses in the small and large intestines are strongly suggestive of *Y. enterocolitica* infection (Slee and Button 1990a).

In the abortion form of the disease, the uterus may be hemorrhagic or filled with pus. Goats that die with the abortion form of the disease may also have swollen, edematous mesenteric lymph nodes. Splenomegaly, renal infarcts, and swelling of the intestinal mucosa with edema also have been noted. *Yersinia* organisms can be cultured from mesenteric nodes and uterine content.

Diagnosis

Because of the zoonotic potential of yersiniosis, definitive diagnosis by bacteriological or serologic methods should be attempted whenever human exposure is a concern. In the enteric form of the disease, all potential causes of diarrhea must be considered. In the age group most often affected, kids one and six months of age, coccidiosis and nematode parasitism are the most likely causes of diarrhea and must be ruled out. Salmonellosis and enterotoxemia are also likely to produce diarrhea in conjunction with sudden deaths. The differential diagnosis for abortion is discussed in Chapter 13, and for mastitis, in Chapter 14. Internal abscesses in goats are most likely caused by *Corynebacterium pseudotuberculosis*, but yersiniosis, tuberculosis, and melioidosis must also be considered as potential causes.

Treatment

Yersinia are generally susceptible to a wide range of broad-spectrum antibiotics. Most reports of successful treatment, however, have involved use of tetracyclines. Tetracycline was effective in halting outbreaks of both the enteric and abortion forms of the disease (Orr et al. 1987; Albert 1988;). Antibiotic therapy is most successful when initiated early in the course of disease. In severe diarrhea cases, supportive fluid therapy may improve outcome. Antibiotic sensitivities were conducted on the *Y. pseudotuberculosis* serotype III isolates associated with diarrhea in lactating goats in Japan. All were sensitive to enrofloxacin, ceftiofur, gentamicin, tetracycline, oxytetracycline, colisitin, and fosfomycin (Seimiya et al. 2005).

Control

Because the epidemiology of caprine yersiniosis is incompletely understood, control recommendations are largely empirical. In New Zealand, it is suggested that to minimize stress, hair goats normally sheared in winter be well fed before shearing and have good shelter available immediately afterwards. It is also recommended that newly captive feral goats not be sheared at all their first winter to avoid compounding their stress (Thompson 1985). Other general recommendations include avoidance of overcrowding and other stressors, provision of adequate nutrition and feeder space, separation of goats from swine, good nematode parasite control, and good rodent and bird control in intensive housing and feeding arrangements. Water supplies should be tested for the presence of pathogenic *Yersinia*. There are no commercial vaccines available for *Y. enterocolitica* or *Y. pseudotuberculosis* in livestock.

Paratuberculosis

Paratuberculosis, also known as Johne's disease, is an economically important infectious disease of domestic and wild ruminant animals primarily affecting the digestive tract. Infection leads to gradual debilitation and death through a mechanism of digestive dysfunction that is not completely understood.

Because the disease has been studied most intensively in cattle, many aspects of the bovine disease traditionally have been assumed to hold true for goats. However, this is not the case. Diarrhea, which is the cardinal sign in cattle, is an uncommon clinical sign in goats. Caprine paratuberculosis is characterized mainly by chronic, progressive weight loss in adults.

Etiology

Paratuberculosis is caused by the bacterium formerly known as *Mycobacterium paratuberculosis* (also previously called *M. johnei*). Based on advances in the molecular characterization of the organism that occurred in the 1990s, the organism has since been reclassified as a subspecies of *Mycobacterium avium* and is referred to as *M. avium* subsp. *paratuberculosis (Map)*. The characterization and molecular epidemiology of *Map* have been reviewed (Harris and Barletta 2001). Analysis of *Map* strains from different geographic locations and different host species using various molecular techniques indicates that there are two main groups of strains. The C, or cattle, strains occur mainly in cattle but are also the predominant strains in goats. The C strains also occur in deer and, rarely, sheep. The S, or sheep, strains occur mainly in sheep but also in farmed deer and sometimes goats. The presence of S strains in goats, though less frequent than the C strains, occurs mainly when goats are commingled with infected sheep. Restriction endonuclease analysis and DNA hybridization studies indicate that there may be a unique *Map* strain that is isolated from Norwegian goats that falls neither in the C nor S strain groups (Collins et al. 1990), but other studies could not distinguish Norwegian goat strains from cattle strains (Thoresen and Olsaker 1994). Previous experimental challenge studies indicated that the Norwegian goat strain has little or no pathogenicity for cattle (Saxegaard 1990). However, further evaluation of goat strain pathogenicity for cattle is ongoing, and there are indications that infection and shedding in cattle may in fact occur (Holstad et al. 2003).

Map is a small mycobacterium (0.5 × 1 microns) compared with other pathogenic mycobacteria. It demonstrates typical acid fastness with Ziehl-Neelsen stain. In tissues, the organism tends to be found in clumps inside macrophages rather than as individual bacteria. The bacterium is very resistant to environmental degradation and can persist in barnyards and in manure spread on pastures for longer than one year. Shade on pastures prolongs the survival time and there are indications that *Map* may be genetically capable of dormancy, i.e., being able to enter a viable but noncultivable state and later reverting to a vegetative form (Whittington et al. 2004). Disinfectants capable of eliminating the organism from the environment include cresylic compounds diluted 1:64 and sodium orthophenylphenate diluted 1:200.

The C strain of *Map* is a fastidious, slow-growing organism *in vitro*. Positive cultures are rarely identifiable before six weeks and should be held at least twelve weeks for confirmation of negative cultures. The cultivation of field isolates of *Map* requires supplementation of the culture media with mycobactin, an iron-chelating substance found in other *Mycobacterium* spp. Mycobactin dependence has long been considered a distinguishing culture characteristic of the paratuberculosis organism. However, it is now known that certain strains of *M. avium* subsp. *avium* and *M. avium* subsp. *sylvaticum* (formerly known as the wood pigeon mycobacterium) also demonstrate mycobactin dependence and may sometimes infect ruminants. These other mycobactin-dependent species can be distinguished from *Map* by molecular techniques based on the fact that *Map* contains multiple copies of the genetic insertional sequence IS900 while the other species contain the genetic insertional sequences IS901 (*M. avium* subsp. *avium*) or IS902 (*M. avium* subsp. *sylvaticum*).

Until recently, the S strains of *Map* could not be grown using the standard culture techniques successfully employed for cultivation of the C strains. Reliable growth is now possible by use of liquid modified BACTEC 12B medium. Solid media (modified Middlebrook 7H10 and 7H11 agars) can also support growth but may be less sensitive (Whittington et al. 1999).

The interspecies infectivity of *M. paratuberculosis* was established in 1913 when clinical paratuberculosis was produced in a goat with a bovine-derived inoculum (Twort and Ingram 1913). In general, when different ruminant species are managed together on a single farm premises and one species is infected, the risk of cross-infectivity is considerable. The development of paratuberculosis in feral goats in New Zealand after introduction into paddocks with known paratuberculous cattle has been documented (Ris et al. 1988).

Epidemiology

Paratuberculosis was first definitively described in cattle in 1895 (Johne and Frothingham 1895) and in goats in 1916 (McFadyean and Sheather 1916). It has traditionally been considered a disease of temperate regions with sporadic occurrence in tropical environments, primarily as a result of importation of infected livestock from endemic areas. Today, paratuberculosis is generally considered a disease of worldwide distribution. However, accurate details on the geographic distribution of caprine paratuberculosis are difficult to ascertain, because statistics on goat disease are often reported together with sheep by governments and international agencies.

Caprine paratuberculosis has been specifically described in numerous countries representing all con-

tinents but Antarctica. These countries include the Sudan (Chaudhari et al. 1964) in Africa; India (Rajan et al. 1976), Nepal (Singh et al. 2007), and Korea (Lee et al. 2006) in Asia; Turkey (Alibasoglu et al. 1973), and Israel (Shimshony and Bar Moshe 1972) in the Middle East; Cyprus (Polydorou 1984), France (Yalcin and Des Francs 1970), Greece (Xenos et al. 1984), Norway (Government of Norway 1985), Spain (Leon Vizcaino et al. 1984), and Switzerland (Tontis and König 1978) in Europe; Canada (Morin 1982; Moser 1982), the United States (West 1979; Sherman and Gezon, 1980; Ullrich et al. 1982), and Mexico (Ramirez et al. 1983; Estevez-Denaives et al. 2007) in North America; Chile (Kruze et al. 2007) in South America; and Australia (Lenghaus et al. 1977; Straube and McGregor 1982) and New Zealand (Thompson 1986).

The prevalence of caprine paratuberculosis is not well documented and presumably it may vary widely between countries because of local management conditions, infectivity of *Map*, and other factors. The prevalence is likely to be higher in intensively managed goats than in extensively managed goats. For example, in Norway, where goats are kept intensively for dairying and a goat-specific strain of the organism is recognized, nationwide prevalence was as high as 53% before the introduction of a vaccination program. In India, with generally smaller herds and more extensive management, a thirteen-year necropsy study indicated a prevalence of only 5.2% (Kumar et al. 1988).

A significant development in the epidemiology of paratuberculosis over the past twenty years has been the suggestion of a putative association between *Mycobacterium avium* subsp. *paratuberculosis* and Crohn's disease, a granulomatous enteritis of humans. Paratuberculosis was proposed as a possible model for the study of Crohn's disease in 1972 because of the clinical and histopathologic similarities of the two conditions, but at that time there was no suggestion that the *Map* organism itself might be involved in the pathogenesis of the human disease (Patterson and Allen 1972). However, in 1984 the *Map* organism was identified in tissues of four Crohn's disease patients (Chiodini et al. 1984), suggesting an etiologic role for the organism. This also suggested that paratuberculosis might be a zoonotic disease, potentially transferable by contact with infected livestock or by consumption of food products from those animals.

Since then considerable research has been carried out on the possible role of *Map* in the pathogenesis of Crohn's disease and that literature has been reviewed (Hermon-Taylor et al. 2000; National Research Council 2003). A body of research has also evolved relative to the potential for zoonotic transmission from infected animals, meat, milk, or milk products, and this also has been reviewed (Grant et al. 2001; Grant 2006). Concerns about the risk of dairy products were heightened

when it was demonstrated in the UK that *Map* in milk can survive standard high temperature—short time pasteurization of 161.6°F (72°C) for fifteen seconds (Grant et al. 1999). This prompted regulators and processors to extend the pasteurization time to twenty-five seconds. Still, *Map* could be identified in containers of pasteurized milk offered for sale at the retail level (Grant et al. 2001; O'Reilly et al. 2004).

A comprehensive study by the National Research Council published in 2003 concluded that "there remains insufficient evidence to prove or disprove that *Mycobacterium avium* subsp. *paratuberculosis* is a cause of some or all cases of Crohn's disease in humans" (National Research Council 2003). However, it was also concluded that a causal link between paratuberculosis and Crohn's is plausible and a new research approach is needed to definitively establish or disprove that relationship. Nevertheless, there are members of the human medical community who believe quite strongly that sufficient evidence exists to make that link and they call for a strong and immediate public health response (Hermon-Taylor and Bull 2002). Others believe that the evidence for involvement of *Map* in Crohn's disease remains unconvincing (Eckburg and Relman 2007). In the meantime, public perceptions have spurred regulators and producers to take the control of paratuberculosis in cattle, sheep, and goats far more seriously than in decades past.

Pathogenesis

The primary mode of transmission of paratuberculosis is fecal-oral, with the organism shed in the manure of infected adults and ingested by susceptible young stock, particularly when animals are overcrowded and sanitation is poor. An age-related resistance to infection is well known to exist in cattle, and this appears to hold true for goats as well (Levi 1948). Neonates are considered most susceptible to new infections, particularly when their own dam is an active fecal shedder and the kid is allowed to remain with the doe. However, age-related resistance is not absolute, and it is probable that adult animals may remain at risk for new infection if kept in overcrowded, heavily contaminated environments.

In utero infection of the fetus is considered a less common form of transmission, but is documented in cattle (McQueen and Russell 1979) and sheep (Tamarin and Landau 1961). The role of *in utero* transmission in the goat remains unknown, although the organism has been recovered from the uterus and fetal organs of some experimentally infected goats (Goudswaard 1971). If fetal infections were shown to occur naturally in goats, then currently accepted disease control practices would require modification.

As with cattle and sheep, goats are most likely infected at an early age by ingestion of the organism.

Following ingestion, the organism localizes in the mucosa of the small intestine and associated lymph nodes. The organism is transported across the intestinal mucosa by M cells associated with the Peyer's patches or by enterocytes (Sigurðardóttir et al. 2005). While some exposed individuals may develop resistance to chronic infection, many infected goats subsequently carry the infection in a dormant state in the Peyer's patches of the intestine and the mesenteric lymph nodes for a variable period into adulthood. At some point, triggered by stress or other ill-defined factors, some infected animals begin to shed the organism in the feces. They may begin to show clinical signs concurrently or at a later time. These signs include diarrhea and weight loss in cattle, and progressive weight loss without diarrhea in sheep and goats.

It is not known why diarrhea is the distinguishing characteristic in bovine paratuberculosis but an infrequent finding in the caprine and ovine forms of the disease. Because small ruminants normally produce a drier feces than the cow, it may require a more severe derangement of colonic water resorption capacity in the goat or sheep to produce evidence of clinical diarrhea than in the cow.

In general, small ruminants with paratuberculosis tend to have less severe lesions of granulomatous enteritis than affected cattle. There have been a number of recent studies of experimental paratuberculosis infection in goats aimed at gaining a better understanding of the pathogenesis of the disease at a cellular level and the associated cell mediated and humoral immune responses (Storset et al. 2001; Valheim et al. 2002, 2004; Sigurðardóttir et al. 2005; Munjal et al. 2005; Stewart et al. 2006). A standard experimental challenge model for caprine paratuberculosis has been proposed (Hines et al. 2007).

There is experimental evidence that bacteremia occurs in goats with clinical paratuberculosis based on isolation of the organism in blood cultures and numerous tissues at necropsy, including the udder and uterus (Goudswaard 1971). This suggests that offspring born to clinically infected does have a very high likelihood of infection through the birth process or when suckling, if not already infected as fetuses.

Because of the prolonged dormancy of infection, the persistence of the organism in the environment, and the endemic nature of the disease, all goats in a known-infected herd must be considered at risk of infection. Goats in an infected herd may fall into one of four categories: resistant or non-infected individuals; infected, non-shedders; subclinically infected, inapparent-shedders; and clinically affected, apparent-shedders. Only individuals in the last group can be identified as abnormal on physical examination, although a definitive diagnosis can never be made on physical examination alone. The subclinical infection rate in an infected herd is likely to be much higher than the rate of clinically apparent cases.

Clinical Findings

Overt clinical disease rarely occurs before one year of age and is most common in goats two and three years of age. Clinical disease is often triggered by some episode of stress, such as parturition or recent introduction into a new herd. Affected individuals begin a course of progressive weight loss, which may extend from weeks to months and can lead to dramatic emaciation (Figure 10.6). Appetite may remain intact initially, but decrease later on, and the animal becomes increasingly lethargic and depressed. A rough hair coat and flaky skin are common. Animals in the advanced state of disease may become immunologically anergic. Advanced cases eventually succumb to debilitation, inanition, exposure, or secondary infections.

Unlike cattle, goats rarely show persistent watery diarrhea, except possibly in the terminal stages of disease. When it occurs, diarrhea may actually be due to concurrent parasitism, although sometimes it may be directly because of paratuberculosis. Soft stool, like dog feces in appearance, may occur intermittently through the course of disease, but normal pelleted feces are the rule.

As the disease progresses a moderate anemia of chronic infection may develop and clinical evidence of hypoalbuminemia such as intermandibular edema may be seen. The nonspecific nature of these clinical signs makes a definitive diagnosis of paratuberculosis by clinical examination impossible.

Clinical Pathology and Necropsy

Anemia and hypoalbuminemia are likely to be present in advanced clinical cases, but are not specific for paratuberculosis. Hypergammaglobulinemia and hypocalcemia have also been reported in affected goats (Schroeder et al. 2001). Definitive diagnosis of paratuberculosis requires bacteriologic or serologic testing and/or histopathologic examination of tissues.

Infection with paratuberculosis slowly evolves in such a way that no single diagnostic test can possibly detect all infected animals at any given time in the course of the disease. The earliest detectable reactions to develop involve the cell mediated immune (CMI) response. Humoral immune response, with the production of circulating antibodies, occurs after the CMI response, later in the course of subclinical infection. The detection of infection by culture of organisms from the feces can only occur in animals that are actively shedding the bacteria. This usually occurs after or concurrent with the development of the antibody response, though some subclinically infected animals with a detectable antibody response may remain non-shedders for a significant period of their infection. One

recent experimental study illustrates the progression of the goat host response to *Map* infection. The CMI response, as measured by the lymphocyte proliferation test, was detectable at sixty days post infection (dpi); fecal shedding of *Map* began between 150 and 180 dpi; and antibody response, measured by ELISA and AGID, became detectable at 180 dpi (Munjal et al. 2005).

During clinical disease, tests of cell mediated and humoral immunity as well as fecal culture can be employed for diagnosis but in the advanced stages of clinical disease, anergy may occur in some individuals and cell mediated and humoral immune responses may be lost, yielding false-negative results. Furthermore, even when tests are applied at the appropriate times, there is no single bacteriological or serologic test with sufficient sensitivity to identify all clinical and subclinical cases of caprine paratuberculosis or with sufficient specificity to avoid some false-positive results. For these reasons, more than one type of test needs to be applied for implementation of herd control programs that are based on testing and culling of infected animals.

Traditionally, the CMI response has been assessed by *in vivo* intradermal skin test using johnin purified protein derivative (PPD-J) or the intravenous johnin test. These *in vivo* assays have largely been replaced by newer techniques involving the identification of cytokines released by immune cells, such as the production of gamma interferon (IFNγ) produced *in vitro* by stimulation of peripheral blood mononuclear cells with mycobacterial antigens, and then measured using a sandwich enzyme immunoassay (Rothel et al. 1990). The IFNγ assay was used to monitor the progression of paratuberculosis in a naturally infected herd of pygmy goats along with fecal culture, ELISA, and AGID. The IFNγ assay produced both false positive (one of three) and false negative (three of ten) results in live animals based on the true infection status determined subsequently by necropsy and culture of *Map* from tissues (Manning et al. 2003). In experimentally challenged goats, CMI was measured by IFNγ assay, but also by interleukin 2 receptor expression and by lymphocyte proliferation test (Storset et al. 2001). CMI responses were detectable by nine weeks post inoculation and persisted with variation through the two years of the study, though responses were stronger in the first year.

The tests currently in use for identification of antibody responses in goats are the complement fixation (CF) test, the agar gel immunodiffusion (AGID) test, and the ELISA test. In general, when applied to goats, these tests have a sensitivity in the range of 85% to 100% when applied to clinical cases but only 20% to 50% when applied to subclinical cases (Stehman 2000).

The CF test is probably the least commonly employed but remains in use because a number of countries require a negative CF test for importation of ruminant livestock. One problem with the CF test is that anticomplementary activity with goat serum may confound interpretation of the test, yielding neither clear positive nor negative results (Stehman 1996).

Specificity may also be reduced in the CF test due to cross reactions with other mycobacteria or *Corynebacterium pseudotuberculosis* as discussed further below in relation to the ELISA test.

The AGID test is very effective in confirming suspect clinical cases of caprine Johne's disease, with a sensitivity of 86% or greater, and it provides results within twenty-four to forty-eight hours. It can also identify subclinical shedders with moderate reliability, but sensitivity falls dramatically when the test is applied to subclinically infected non-shedders. Agar gel immunodiffusion tests performed as well as fecal culture when both tests were used for several years in a large, naturally infected goat herd (Sherman and Gezon 1980). Precipitating antibody was detectable in infected goats at approximately the same time that the animals began to shed the organism in their feces. Similar results were reported independently in a large goat herd studied for three years in England, where fecal culture and the AGID test proved more useful than intradermal and complement fixation tests for detecting infected individuals (Thomas 1983). Nevertheless, false-negative AGID test results do occur in subclinically infected goats and a single negative test should not be presumed to indicate non-infected status (Ramirez Casillas et al. 1984).

The application of ELISA tests for the diagnosis of paratuberculosis emerged in the 1990s and since then a number of studies have reported its use specifically in goats (Milner et al. 1989; Molina et al. 1991; Molina Caballero et al. 1993; Burnside and Rowley 1994; Rajukumar et al. 2001; Whittington et al. 2003; Dimareli-Malli et al. 2004; Munjal et al. 2004; Gumber et al. 2006). Differences in performance are noted, often as a result of the type of antigens that are employed in the assay. In general, these ELISA tests have sensitivity in the range of 54% to 88%; they are more reliable for confirmation of clinical cases than detection of subclinical cases. In experimentally infected goats, enzyme-linked immunosorbent assay and agar gel immunodiffusion test were found to be 100% sensitive from 180 and 210 dpi onward, respectively (Munjal et al. 2005).

The specificity of ELISA tests may suffer because of the occurrence of cross reactions. *Map* is known to share common antigens with other *Mycobacterium* spp., *Nocardia* spp., and *Corynebacterium* spp. Corynebacterial infections may produce cross reactivity in serologic tests used to diagnose *Map* infection (Ridell 1977). This is of particular concern in goats because caseous lymphadenitis caused by *C. pseudotuberculosis* is a common disease in the species. The problem of cross reaction occurs mainly with ELISA and CF tests, while the AGID test is not influenced by antibodies to *C. pseudotuberculosis* (Van Metre et al. 2000). In one study comparing specificity of two paratuberculosis ELISA kits and the AGID test, 344 goats with known exposure to *C. pseudotuberculosis* but with negative fecal cultures for *Map* were tested. The AGID gave no false-positive results. One ELISA kit gave five false-positive results (1.5%), while the second kit gave eighty-nine false positive results (25.9%)(Manning et al. 2007). Clearly, if the infection status of a herd is not known relative to paratuberculosis and caseous lymphadenitis, the ELISA test would not be a wise choice for screening the herd to determine the prevalence of paratuberculosis.

Commercial test kits for performance of the ELISA are available. Until recently, the kits available in the United States were approved only for use in cattle to test serum and plasma. In Europe, and more recently in the United States, an ELISA (Paracheck®) is marketed that is approved for serologic diagnosis of paratuberculosis from cattle, sheep, and goat serum or plasma as well as from bovine milk. The comparative performance of a commercial ELISA has recently has been evaluated for goat milk and serum from the same animals. Sensitivity of the milk ELISA was lower than for the serum ELISA, but the specificity was higher than that of the serum ELISA (Salgado et al. 2005, 2007).

There have been some notable advancements in techniques for identification of the organism in the feces or tissues of infected animals. Conventional fecal cultures on solid media grow slowly. Positive cultures can take six weeks or more to develop and culture tubes have to be held for a minimum of twelve weeks to ensure that they are negative. The use of liquid media has allowed for faster cultivation. Radiometric techniques for culture of mycobacteria on liquid media have been adapted for growth of *Map* and provide more rapid results with equal or greater sensitivity than conventional culture on solid media (Collins et al. 1990a; Sockett et al. 1992; Eamens et al. 2000). The use of radiometric liquid medium has also enabled laboratories to culture the S strain of *Map* from sheep (Whittington et al. 1999). Because goats can be infected with either the C or S strain of *Map*, use of radiometric culture should be considered, especially when there is clinical or serologic evidence of paratuberculosis, and fecal cultures on conventional solid media are negative.

Molecular probes and PCR techniques have also been developed to confirm the presence of *Map*-specific genetic material in feces or tissue samples, in an effort to bypass the need for culture. However, inhibitors in feces and inefficient DNA release from clinical samples have hampered the general application of these techniques, particularly with regard to fecal samples.

Most laboratories with the capacity to culture *Map* still offer the conventional solid media technique as the main or sole method for detection of *Map* in feces. Radiometric culture is increasingly available but can be more expensive. Expense is an issue in herd-wide testing for paratuberculosis and may be an obstacle in getting herd owners to undertake testing either to establish herd prevalence or to follow through with test and cull programs for control. One approach to reducing costs has been the use of pooled fecal cultures to determine a herd's infection status. This is done by combining samples from groups of animals of the same age for testing. The sensitivity of this method depends on the prevalence of infection in the herd and the intensity of shedding among herd members. There is one report from Australia on the use of pooled samples for culture of *Map* in goats. Based on the conditions prevailing in that study, pools of twenty-five samples were considered to be suitable for producing meaningful test results (Eamens et al. 2007).

Because clinical caprine paratuberculosis is invariably a terminal disease, necropsy provides the opportunity for definitive diagnosis. Gross lesions are more variable in occurrence in the goat as compared with cattle. Therefore, histologic examination of tissues and bacterial culture of selected organs also should be performed.

The gross and microscopic lesions of caprine paratuberculosis are well described (Levi 1948; Harding 1957; Nakamatsu et al. 1968; Fodstad and Gunnarsson 1979). The prominent, accordion-like, corrugated thickening of the intestinal wall and mucosa commonly seen in cattle is not often observed in goats. When gross lesions are present in small ruminants, they usually present as focal or diffuse thickening or edema of the ileum, cecum, or spiral colon. Adjacent lymph nodes may be enlarged and edematous, and caseation of nodes with focal calcification occurs more often in goats than cattle. Emaciation is a constant finding, although persistence of abundant mesenteric fat deposits is not unusual in goats, even when the general body condition is one of emaciation. Calcification of the aorta often occurs in goats with prolonged paratuberculosis, though the pathogenesis is unknown.

Histologically, paratuberculosis produces characteristic granulomatous lesions in the intestinal tract, lymph nodes, and possibly liver. At a minimum, tissues submitted for microscopic examination should include a section of the ileocecal junction and adjacent ileocecal lymph node, ileum, spiral colon, and another mesenteric node. Where available, PCR can be applied to paraffin embedded tissues to detect the IS900 insertional sequence characteristic of *Map*. Otherwise, acid-fast Ziehl-Neelsen or immunohistochemical staining should be requested on these samples when paratuberculosis is suspected. Bacterial culture of fresh or frozen tissues is also possible. In areas where both tuberculosis and paratuberculosis occur in goats, microbiological diagnosis is imperative because necropsy lesions may be similar.

Diagnosis

The differential diagnosis of paratuberculosis in goats is essentially the differential diagnosis of chronic weight loss. The causes of this common presenting sign in goats are covered in detail in Chapter 15.

Treatment

There are no known effective treatments for the elimination of *Map* infection and none are specifically approved for the treatment of paratuberculosis. Various antimycobacterial drugs have been used with limited effect in goats. Attempted unsuccessful therapies have included isoniazid, isoniazid plus rifampin, isoniazid plus ethambutol, or all three drugs together (Gezon et al. 1988). However, some treatment regimens have alleviated clinical signs in individual cases as long as therapy is continued. Nevertheless, the organism can still be isolated from cultures prepared from tissues at necropsy. One such regimen is daily streptomycin sulfate (0.5 g intramuscularly) plus isoniazid (25 mg by mouth) plus sodium aminosalicylate (850 mg by mouth) for six months (Zahinuddin and Sinha 1984). A second regimen is daily dihydrostreptomycin (0.5 g intramuscularly) plus rifampin (300 mg by mouth) and isoniazid (300 mg by mouth) twice daily (Slocombe 1982). Long-term administration of monensin has been reported to have some therapeutic effect in cattle, reducing the severity of paratuberculous lesions in the digestive tract (Brumbaugh et al. 2000) and reducing fecal shedding of *Map* in calves (Whitlock et al. 2005), but no trials in goats have been reported. Treatment has little economic application in goats except for the possibility of keeping known infected, high-quality, breeding does in good health long enough to achieve embryo transfers or to prolong the life of pet goats. However, in light of the putative connection between paratuberculosis and Crohn's disease, owners of pet goats should be made aware of that link before deciding to treat and maintain a known infected goat as a pet.

Control

Interest in the control of paratuberculosis has increased in recent years, mainly for two reasons. The first is increased understanding of the economic losses associated with the disease, particularly in dairy herds. In dairy cattle, losses are associated with decreased milk production, decreased milk fat and protein, premature culling, reduced slaughter weight at culling,

decreased fertility, reduced feed efficiency, and increased incidence of mastitis (Radostits et al. 2007). Losses have been estimated to be as high as $200/cow/year in high prevalence herds. While similar types of loss could be expected in goat dairies, no specific findings on the economic impact have been reported.

The second major stimulus for control of paratuberculosis is the much publicized zoonotic potential of the disease relative to Crohn's disease in humans, which has caused concern among public health officials, regulatory veterinary agencies, and livestock producers about public perception of milk and meat as wholesome foods. As a result, numerous countries have initiated or expanded their paratuberculosis control programs in recent years. Most programs focus on cattle, but some may include sheep and goats. Readers should contact their own regulatory veterinary authorities to determine the status of goats in existing paratuberculosis control programs. In the United States, for example, there is now a national Voluntary Bovine Johne's Disease Control Program that focuses on control of the disease in cattle. Johne's programs for sheep and goats are administered through the individual states rather than at the national level. In 2006, six states responded to a survey indicating that they have some activity, albeit limited in some cases, related to control of goat paratuberculosis. The states were Illinois, Nebraska, New York, Ohio, Wisconsin, and Wyoming.

Paratuberculosis is almost always a herd problem rather than an individual animal problem, unless the individual goat diagnosed with paratuberculosis was recently introduced into the herd. When a clinical case is diagnosed from within a long established herd, the herd almost inevitably includes additional subclinical shedders and infected, non-shedding goats. These subclinical infections are likely to be present in far greater numbers than the clinical cases, often in the range of one to five subclinical cases for each clinical case, depending on herd size, how long the herd has been in existence, and various management factors that affect the level of bacterial contamination on the farm.

There are three basic elements to consider in developing a strategy for eliminating paratuberculosis from infected herds: identifying and removing infected individuals from the herd; reducing the rate of new infections in susceptible kids through improved sanitation and modified kid-rearing techniques; and vaccinating to increase host resistance to new infections. It is unlikely that any one of these components of the control program taken alone will effectively eliminate paratuberculosis, but the emphasis on each component in the overall control program will vary with local conditions. On the national level, paratuberculosis has

been controlled in Norway largely through vaccination (Saxegaard and Fodstad 1985). At the local level, elimination of paratuberculosis in a large commercial herd in the United States was achieved without vaccination by testing and culling in conjunction with altering management procedures (Gezon et al. 1988). In another dairy goat herd, infection in adult goats was significantly reduced over a two-year period by serological testing with ELISA and AGID, culling of positive animals, and improving herd management practices (Hutchinson et al. 2004).

The best techniques currently available for identifying infected goats are the bacterial culture of feces and the AGID or ELISA tests. Because these tests do not reliably identify all infected non-shedders, testing must be carried out at frequent intervals to assure that infected non-shedders are rapidly identified as they convert to subclinical, inapparent-shedder status. Testing at intervals of at most six months is recommended. In aggressive eradication programs, all offspring of positive test animals are culled in addition to the positive animal itself. This reflects the belief that kids of infected dams are also very likely to be infected.

Improved management and sanitation help reduce the incidence of new infections in young stock. In intensive dairy operations, kidding pens should be cleaned or rebedded between kiddings. Kids should be taken immediately from the does and raised in separate facilities on heat-treated colostrum and pasteurized milk or milk replacer. Kids should not commingle again with adult animals until they themselves have kidded. Adult animals should not be overcrowded, manure should be removed frequently from the pens, and feed and water should be provided in a manner that does not allow for fecal contamination. If manure is spread on pastures, goats should not be allowed to graze those pastures for at least one year. The use of pastures in general may be problematic as it has become clear that wildlife reservoirs exist for *Map* which may contaminate pastures, even when paratuberculous livestock have been kept off those pastures. An association between *Map*-infected wild rabbits on farms in Scotland and paratuberculosis in cattle on those farms has been reported (Greig et al. 1999). Wild ruminants are often seen in pastures in North America, and *Map* has been isolated from a number of species, including whitetail deer, mule deer, bison, and elk (Harris and Barletta 2001).

Management recommendations for extensively managed goat herds are more difficult to make. At the least, does should be turned out on clean, uncontaminated pastures before kidding so they can spread out to kid and minimize cross contamination. Herd-wide testing by culture of feces or AGID tests to identify infected dams should be performed before the

Figure 10.7. Persistent granulomatous reaction (arrows) at site of vaccination for paratuberculosis with live vaccine. (Courtesy of Dr. David M. Sherman.)

kidding season begins. Infected dams should either be culled or segregated from the non-infected animals before kidding.

Vaccination of goats for paratuberculosis in Norway has been extremely effective in reducing the national prevalence of caprine paratuberculosis (Saxegaard and Fodstad 1985). The vaccine employed is a live, attenuated, adjuvanted vaccine containing two strains of *Map* and is given to goat kids between two and four weeks of age. Post mortem evaluation of vaccinated and unvaccinated goats over a fifteen-year period indicated that the infection prevalence was reduced from 53% in 1966 to 1% in 1982, primarily through the use of vaccination. The majority of infected goats identified in 1982 were not vaccinated. Because caprine paratuberculosis in Norway may involve a unique caprine-specific strain of *Map*, this success with vaccination may not be transferable to all situations worldwide.

Currently, data on extensive field experience from other nations is lacking. More recently, it was reported that a killed vaccine administered to adult goats in a known infected herd was very useful in the control of paratuberculosis. Half the goats were vaccinated and the other half left unvaccinated and all goats culled for any cause were necropsied to determine the presence of paratuberculosis. By the end of two years, three times as many goats had been culled from the unvaccinated group as the vaccinated group, and three times as many of the cases culled in the unvaccinated group were cases of paratuberculosis (Corpa et al. 2000). This killed vaccine is now registered in or available for use

by special permit in Australia, Cyprus, Germany, Greece, India, the Netherlands, New Zealand, Norway, Spain, South Africa, the United Arab Emirates, and the UK (Colmeiro, 2008).

Two potential drawbacks to the use of all vaccines containing *Map* are the appearance of a granulomatous nodule at the site of vaccination (Figure 10.7) and the fact that animals vaccinated against *Map* may develop cross-reactivity to standard tuberculosis tests, thus complicating the testing procedures for regulatory programs designed to control tuberculosis. Implementation of paratuberculosis vaccination, then, may be restricted by regulatory agencies in countries where tuberculosis is monitored or still endemic. Under the new Voluntary Bovine Johne's Disease Control Program in the United States, some vaccination may be permitted with regulatory approval and supervision in herds actively involved in Johne's control that have been shown to be free of tuberculosis. Vaccination is limited to cattle and not all states allow vaccination. An additional caution involves accidental injection of live vaccines into the vaccinator. A serious, persistent granuloma can result at the accidental injection site in people.

PROTOZOAL DISEASES

Coccidiosis

Coccidiosis is the most likely cause of diarrhea in young goats between three weeks and five months of age, particularly when young goats are group-housed in confinement.

Etiology

Coccidiosis is caused by protozoal parasites of the genus *Eimeria.* In the past, the *Eimeria* species infecting goats and sheep were presumed to be the same. In 1979, however, well-controlled experiments using *E. ninakohlyakimovae* and *E. christenseni* demonstrated that each small ruminant host has its own host specific *Eimeria* species that are not readily cross-infective (McDougald 1979). This led to a reexamination of *Eimeria* morphology and a renaming of species thought to be cross-infective. The current nomenclature for the recognized *Eimeria* of goats is given in Table 10.6, with information on comparable sheep species, oocyst morphology, pathogenicity, geographic distribution, and prevalence in goats (Norton 1986; Soe and Pomroy 1992).

Historically, the *Eimeria* have been classified based on phenotypic characteristics such as morphology, ultrastructure, life cycles, and host specificity. However, more recent molecular phylogenetic studies of *Eimeria* spp. have called into question the accuracy of some of these classifications. Readers should be aware that as a result, names of *Eimeria* spp. affecting goats may be subject to change (Tenter et al. 2002). Furthermore, additional new species of *Eimeria* are being identified in goats such as *E. minasensis* reported from Brazil (Silva and Lima 1998) and *E. sundarbanensis* reported from India (Bandyopadhyay 2004).

The typical life cycle of the various *Eimeria* spp. is as follows. Oocysts passed in the feces sporulate in the goats' environment to produce infective sporocysts containing sporozoites. These sporocysts are ingested

Table 10.6. The *Eimeria* species infecting goats (*Capra hircus*).

Current name	Comparable *Eimeria* species in sheep	Morphologic characteristics of oocysts (length × width in µm)	Prepatent period (days)	Pathogenicity	Distribution; occurrence
E. alijevi	E. parva	Spherical to subspherical; 16 × 14 µm; no micropyle, no cap; yellow to yellow-green wall	16–17	Mild	Worldwide; very common
E. apsheronica	E. faurei	Ovoid; 29 × 21 µm; distinct micropyle, no cap; brownish yellow to pink wall	20	Mild	Worldwide; very common
E. arloingi	E. bakuensis (E. ovina)	Ellipsoidal to ovoid; 27 × 18 µm; distinct micropyle and cap	?	moderate to severe	Worldwide; most common
E. capralis	Unknown	Ellipsoidal; 29 × 20 µm micropyle and cap; smooth wall	?	?	New Zealand only
E. caprina	None	Ellipsoidal; 32 × 23 µm; distinct micropyle, no cap; yellow brown outer wall, inner wall clear	?	Moderate to severe	Known in US, UK, Brazil; common
E. caprovina	Same species infects sheep	Ellipsoidal to ovoid; 30 × 24 µm; distinct micropyle, no cap; yellow-brown inner wall, outer wall clear	14–20	Moderate	Known in US, UK; uncommon
E. charlestoni	Unknown	Ellipsoidal; 23 × 17 µm; indistinct micropyle; no cap	?	?	New Zealand only
E. christenseni	E. ahsata	Ovoid; 38 × 25 µm; distinct micropyle, dome-shaped cap	17	Moderate to severe	Worldwide; very common

Current name	Comparable Eimeria species in sheep	Morphologic characteristics of oocysts (length × width in µm)	Prepatent period (days)	Pathogenicity	Distribution; occurrence
E. hirci	E. crandallis	Spherical to ellipsoidal; 23 × 19 µm; flat, saucer-shaped micropylar cap	?	Nonpathogenic	Worldwide likely; common
E. jolchijevi	E. granulosa	Ellipsoidal to urn-shaped; 29 × 21 µm; distinct micropyle and cap; brownish-yellow wall	?	?	Known in US, UK, Australia; uncommon
E. kocharli	E. intricata	Ellipsoidal; 47 × 32 µm; distinct micropyle and light-colored cap; very thick wall	20–27	Mild	Known in India, Africa, Russia; uncommon
E. marisca	Same species may also occur in sheep	Ellipsoidal; 19 × 13 µm; faint micropyle, shallow, domed cap; polar granule, colorless to pale yellow	14–16	Mild	Reported in Spain only
E. masseyensis	Unknown	Ellipsoidal to ovoid; 22 × 17 µm; micropyle and cap	?	?	New Zealand only
E. minasensis	Unknown	Ellipsoidal; 35 × 24.5 µm; micropyle and cap; two-layered wall; inner brown, outer colorless	19–20	?	Recently reported from Brazil
E. ninakohlyakimovae	E. ovinoidalis	Ellipsoidal to ovoid; 23 × 18 µm; no micropyle or cap; faint brownish-yellow wall	15–17	Most severe	Worldwide; very common
E. pallida	Same species may also occur in sheep	Ellipsoidal; 14 × 10 µm; micropyle indistinct, no cap; yellowish green wall	?	Nonpathogenic	Known in U.S., Turkey, India, Sri Lanka; uncommon
E. punctata	Questionable status in sheep and goats	Subspherical to spherical, 21 × 17 µm; micropyle and small cap; obvious pitting in wall and greenish tint	?	Nonpathogenic	Reported in Germany and Zimbabwe
E. sundarbanensis	Unknown	Pyriform, 28 × 20 µm, micropyle and cap; yellowish, two-layered wall	?	?	Newly reported from India

by other goats. Ingested sporocysts release their sporozoites which then enter host cells to form schizonts. Schizonts undergo asexual reproduction to produce a first generation of daughter merozoites. Depending on the species of *Eimeria*, anywhere from a few dozen to one hundred thousand merozoites may be formed by each schizont. The merozoites then break from the disrupted host cell and each is capable of invading a new host cell to form a second generation of schizonts. The number of cycles of schizogony varies among *Eimeria* spp. The final cycle of schizogony leads to the differentiation of merozoites into male and female gametes. Male gametes (microgametes) then are released from host cells to fertilize female gametes (macrogametes) within their host cells. Zygote formation results in oocyst formation with release of oocysts from disrupted host cells and subsequent passage in the feces.

Epidemiology

Eimeria spp. have been isolated from goats on all continents. Prevalence studies throughout the world demonstrate that *Eimeria* oocysts are widely present in the feces of both normal and diseased goats, with a reported range of 38% to 100% of all goats infected (Lima 1980). Concurrent infection with multiple *Eimeria* spp. is the rule. For example, in a survey from Iran of 150 goats, 110 animals were infected with at least one species, but ninety-three of these (84.5%) were infected with multiple species (Razavi and Hassanvand 2007). Similarly, in Zimbabwe, in a survey involving more than 1,000 goats, 89.9% of adults and 94% of kids were found to be infected. All had multiple infections, with the number of species ranging from two to eleven. Just over 75% were infected with six to eight different *Eimeria* spp. (Chhabra and Pandey 1991). It is reasonable to assume that where there are goats, there are coccidia; however, it is important to discriminate between infection with coccidia and disease caused by coccidiosis.

All ages of goats may be infected with *Eimeria*, but numerous factors contribute to the highest incidence of clinical disease occurring in young goats between three weeks and five months of age. These include host, parasite, management, and environmental factors.

Host Factors. Age-related resistance to clinical coccidiosis is reported in all ruminant species. The resistance is immunologic in nature and is maintained by continuous exposure to coccidial infection. Immunity is relative and not absolute because it does not eliminate infection, but effectively checks the rate of coccidial reproduction in the host intestinal tract. This is reflected in a good correlation of oocysts shed in feces with age of infected goats. There is a steady decline in oocyst numbers from six months through six years of age, followed by an increase in goats seven years and older as immunity begins to wane in older goats (Kanyari 1988).

Complete elimination of coccidial infection may lead to a failure of immunity and the development of clinical disease on reexposure to pathogenic *Eimeria.* The immunity that develops is specific for a given *Eimeria* species and animals of any age may develop clinical disease if exposed to a population of *Eimeria* spp. not previously encountered. In most management situations, goats become resistant to clinical disease at approximately five months of age. Resistance may be impaired, however, by stresses such as concurrent illness, lactation, transport, feed changes, weather changes, increased levels of exposure, or exposure to new species of *Eimeria*. Therefore, sporadic outbreaks of clinical coccidiosis may occur in a variety of unexpected settings besides the predictable occurrence in confined weanlings. Breed variation may exist in resistance to coccidia. In Australia, Angora goats and feral goats are considered more susceptible to clinical coccidiosis than dairy breeds (Howe 1984). However, a study of fecal oocyst counts in three Australian breeds showed approximately equal counts for Angoras and Anglo-Nubians, and significantly lower counts for Saanens (Kanyari 1988).

Parasite Factors. Oocysts are quite resistant to environmental degradation, and are even more resistant when sporulation occurs. Overwintering of sporocysts is not uncommon, and many disinfectants, including 5% formalin, do not destroy them. Sporulation depends on a combination of oxygen availability, temperature, and moisture conditions. In general, with adequate moisture and oxygen, sporulation of oocysts occurs optimally within two to five days at temperatures between 75°F and 90°F (24°C to 32°C) and readily at temperatures down to 53.6°F (12°C). Synchronous sporulation can occur among oocysts accumulating in a contaminated environment when optimal conditions prevail. This means that susceptible goats may be challenged by massive numbers of infective sporocysts under appropriate conditions of warmth and humidity.

Some of the more pathogenic *Eimeria* spp. such as *E. ninakohlyakimovae* produce thousands of merozoites per schizont during asexual reproduction inside the goat intestine. The various species may also differ in the number of cycles of schizogony involved in reproduction. The more merozoites produced, the more intestinal epithelial cells are disrupted because every merozoite potentially can invade a target host cell. Prepatent periods also vary among goat *Eimeria* spp., and oocysts may be shed by kids as young as two weeks of age when kids are exposed to sporocysts at birth. This means that abdominal pain or diarrhea caused by coccidiosis may occur as early as one week of age, although this is not common.

MANAGEMENT AND ENVIRONMENTAL FACTORS. Clinical coccidiosis occurs more often in intensive management situations than in extensive ones because of the concentrating effects of confinement on both host and parasite. Dairy goat kids are commonly at risk when removed from their does at an early age and confined to group pens indoors. Most outbreaks of clinical coccidiosis occur around the time of weaning, particularly if kids are weaned abruptly and not offered solid feed *ad libitum* before termination of milk feeding.

Several factors may increase exposure to infective sporocysts at this time. Feeding young goats on the ground promotes ingestion of sporocysts. Poorly designed feeders in which goats can stand, climb, or defecate lead to contamination of feed and water sources. Watering systems that leak or overflow readily contribute to environmental moisture, which promotes sporulation. Overcrowding of pens or failure to segregate kids by age augments exposure to sporocysts and increases disease risk. When goats are kept on solid floors, the failure to maintain clean, dry bedding is a major factor in outbreaks of clinical disease. Even when floors are scraped clean, well-intentioned spraying or hosing of the pens may actually aggravate the problem because of the amount of moisture added to the atmosphere. If troughs and waterers are situated or hung so that they impede floor scraping, foci of heavy oocyst/sporocyst concentration may persist under or around them between cleanings.

Buildings that do not admit adequate sunlight also contribute to the persistence of oocysts, particularly in the winter months in temperate regions when days are short. Hot, humid weather is particularly conducive to sporocyst development and outbreaks of clinical coccidiosis are common in temperate regions during summer, especially because spring-born kids are being weaned during the hot, humid months.

Even when goats are managed extensively and the risk of coccidiosis is ostensibly less, it is important to scrutinize management practices for evidence of temporary mobbing that can predispose to outbreaks of coccidiosis. For example, Angora goats in Texas are managed extensively on range but coccidiosis can be a major problem in weaned kids. Kids are removed from dams, placed on solid feed for the first time, and housed in large pens. Despite the spaciousness of the pens, the stressed kids flock together in one area, leading to excessive buildup of oocysts and outbreaks of coccidiosis with mortality rates as high as 15% (Craig 1986). Outbreaks in adult Angoras are also seen when inclement weather occurs after shearing, and shorn goats are confined for two weeks to prevent losses due to hypothermia. In South Africa, the incidence of clinical coccidiosis is aggravated by drought when great numbers of grazing animals are transferred to small irrigated pastures or congregate to consume supplemental feed and water provided for them (van Tonder 1975).

In general, most exposures to coccidia cause subclinical infection and the acquisition of a protective though relative immunity. Most clinically affected individuals recover from clinical disease after a period of diarrhea as long as two weeks, and mortality rates do not usually exceed 10% when exposure to sporocysts has been gradual and continual before disease. When exposure to coccidial sporocysts is abrupt and intense, however, mortality rates in young goats can reach 50%. While the costs of treatment and death loss can be high, the major economic impact of coccidiosis in production animals may be reduced growth rates and weight gains after clinical or subclinical infection. In dairy goats, coccidiosis in weanlings can inhibit growth sufficiently so that spring-born kids will not reach breeding size by the fall of the same year and must be held over an additional year. It has been reported that the oral administration of the coccidiostat decoquinate (1 mg/kg bw) to young dairy goats from eight days prior to weaning through seventy-five days after weaning produced higher body weights at seven months of age and higher first lactation milk production at 100 and 200 days than controls (Morand-Fehr et al, 2002). In Angora goats, coccidiosis in weanlings may manifest as poor growth, poor hair coat, and increased susceptibility to pneumonia and other potentially fatal conditions.

Pathogenesis

The adverse effects of *Eimeria* infection in goats result from destruction of the gastrointestinal epithelium as these intracellular parasites progress through their complex life cycle in the digestive tract of the host. Multiple cycles of asexual and then sexual reproduction in the digestive epithelium result in successive waves of host cell disruption.

There are species-specific differences in the location of host cells invaded by various *Eimeria* spp. during their development cycles. For example, sporozooites of *E. ninakohlyakimovae*, considered the most pathogenic of the goat species, enter basal epithelial cells in the crypts of Lieberkuhn in villi of the small intestine. Many thousands of merozoites are produced in each schizont. These merozooites then invade epithelial cells in the large intestine. The subsequent gametogonous stages invade the ileum, cecum, and large intestine, where oocysts are produced. Because multiple infections are common in goats, disruption of gastrointestinal epithelium can be very widespread.

Diarrhea results from disruption and inflammation of the intestinal mucosa. In massive infections, severe hemorrhage into the intestinal lumen can result in death caused by blood loss. In the more typical acute

form of the disease, fluid and electrolyte loss result from a compromise of the normal resorptive potential of the intestinal epithelium as well as leakage of plasma and lacteal constituents from the inflamed and disrupted mucosa. When extensive, these losses can lead to fatal systemic sequelae of dehydration, acidosis, and serum electrolyte derangement. Disruption of the mucosal integrity may also lead to increased susceptibility to secondary bacterial infection and resultant septicemia, thus increasing mortality rates. The ill thrift and poor growth commonly seen in the aftermath of clinical coccidiosis are manifestations of prolonged malabsorption and maldigestion associated with permanent damage to the intestinal mucosa. In many cases, regeneration of a normal epithelial lining is not complete and evidence of mucosal scarring or villous atrophy may be observed at necropsy in poorly doing animals.

Clinical Findings

Most goats with clinical coccidiosis are between three weeks and five months of age. However, cases have been confirmed in adults as old as seven years of age. Coccidiosis often occurs in conjunction with nematode infections, so attribution of clinical signs specifically to coccidiosis may be problematic because signs of gastrointestinal parasitism due to nematodes can be similar (Valentine et al. 2007).

Subclinical coccidiosis should be suspected when complaints of poor growth, weight loss, or loss of fecal pellet formation are reported for young, susceptible animals in management situations conducive to the persistence and multiplication of coccidia.

Clinical coccidiosis may develop within one to two weeks of ingestion of a large dose of infective sporocysts. Peracute cases, caused by severe blood loss in the intestinal lumen, may present as sudden death before signs of diarrhea or abdominal discomfort are seen. The intestinal lumen may be filled with blood due to massive destruction of the intestinal mucosa.

In acute cases, early signs include decreased appetite, listlessness, weakness, and abdominal pain that may be manifested by crying and frequent rising up and lying down. The feces may first be unpelleted, then pasty, and then, a watery yellowish-green to brown diarrhea develops. Fresh blood or melena may be seen. Tenesmus is less common than reported in cattle or sheep. The hindquarters and tail become stained and feces-coated as diarrhea persists. If dehydration becomes severe, animals become recumbent with cold extremities and subnormal temperature. They eventually become moribund and die. In Australia, polioencephalomalacia is reported to be a common sequela to coccidiosis in goats (Howe 1980). That disease, producing signs of neurological dysfunction, is discussed in Chapter 5.

Very young, highly susceptible animals may die of acute coccidiosis within one or two days of onset. Older or more resistant animals may exhibit diarrhea and weakness with resultant weight loss for as long as two weeks before spontaneously recovering. Animals that have recovered from clinical coccidiosis may develop ill thrift. They may be stunted, show a poor hair coat, and develop a pot-bellied appearance.

Clinical Pathology and Necropsy

The hemogram in coccidiosis may be normal, but a marked leukocytosis is possible when intestinal mucosal damage is extensive. Anemia is variable, depending on severity of disease, and may be masked by an increased packed cell volume caused by hemoconcentration associated with dehydration. Varying degrees of hyponatremia, hypocalcemia, hypophosphatemia, and metabolic acidosis can occur. Hyperkalemia has been reported in goats with coccidiosis and this may be caused by compensatory efforts to counter acidosis.

The use of fecal flotation methods to detect oocysts, though often useful, is not a wholly satisfactory approach to diagnosis of clinical coccidiosis. When oocysts are not found in the presence of active diarrhea, it may be because the affected individuals are in an early stage of infection. Intestinal disruption with resulting diarrhea can occur during the schizogony that precedes oocyst formation. In these cases, direct fecal smear instead of fecal flotation is employed to identify merozoites. Conversely, oocysts may be found routinely in the feces of all normal goats older than two to three weeks of age. Therefore, finding oocysts in the feces of diarrheic goats does not confirm coccidiosis as the cause of illness. Performing oocyst counts is of limited value, unless the oocysts of pathogenic species are morphologically identified and quantified, because some of the less pathogenic *Eimeria* spp. are prolific egg producers (Aumont et al. 1984; Yvore et al. 1985). If oocyst counts are undertaken, a modified McMaster technique should be used, with a flotation solution made of magnesium sulfate at a density of 1.18 (Yvore and Esnault 1987).

Necropsy examination offers more reliable indications of clinical coccidiosis (Figure 10.8). Gross lesions of enteritis seen in the gut mucosa may range from a mild catarrh to overt hemorrhage or necrosis. In peracute cases, the intestinal lumen may contain fresh blood. Thickening of the intestinal wall caused by edema is not uncommon. The most consistent and characteristic lesion is the occurrence of multiple raised, white nodules measuring between 1 and 6 mm in diameter on the intestinal mucosa, which may be apparent even when the intestine is viewed from the serosal side. These nodules represent sites of active gametogony and on smears or histologic examination

contain numerous macrogametes and oocysts. Lesions of enteritis and nodules may be seen in subclinical, peracute clinical, and acute clinical cases. The extent and severity of the lesions in conjunction with the history must be considered in establishing coccidiosis as the cause of death.

Lesions associated with coccidial infection have sporadically been reported in the abomasum of goats. Cysts, which appear on the mucosal surface as small whitish dots up to 1.5 mm in diameter, have been described and the condition has been referred to as globidiosis (Soliman 1960; Mehlhorn et al. 1984). Originally, *Globidia* was thought to be a distinct protozoal genus. It is now recognized that the protozoal structures seen histologically in the abomasa of goats and sheep are in fact large schizonts of an *Eimeria* species, most likely *E. gilruthi.* Some early reports attributed diarrhea, dehydration, and death in goats to abomasal

globidiosis (Mugera and Bitakaramire 1968), but the infection is also recognized to occur in normal, healthy goats (Abdurahman et al. 1987). A recent report of clinical disease in a sheep with coccidial abomasitis due to *Eimeria* (*Globidium*) *gilruthi* suggests that the organism may indeed have pathogenic potential for goats as well (Maratea and Miller 2007).

Sporadic cases of hepato-biliary coccidiosis have also been reported in goats (Dai et al. 1991; Mahmoud et al. 1994; Schafer et al. 1995; Oruc 2007). Two types of lesions may be seen. In the biliary type, coccidial oocysts, schizonts, gametes, and gametocytes can be seen in the epithelium of the bile duct and the bile duct wall shows fibrosis. In the hepatic type, granulomata composed of oocysts and macrophages encapsulated in a fibrous capsule are present in the liver (Mahmoud et al. 1994).

Liver lesions may be severe, with large focal areas of necrosis reported (Schafer et al. 1995). Several species of *Eimeria* have been associated with these lesions. Clinical signs of diarrhea were reported in some of these cases, but since coccidial lesions were also present in the intestines, it was difficult to attribute the clinical disease to the liver involvement. A non-pathogenic coccidium has been identified in the gall bladder of a goat (Dubey 1986).

Diagnosis

The diagnosis of coccidiosis is presumptive, based on an appropriate signalment, history, clinical signs, and necropsy findings. In very young kids between one week and one month of age, other causes of abdominal pain and acute diarrhea must be differentiated. These include cryptosporidiosis, colibacillosis, enterotoxemia, salmonellosis, yersiniosis, viral enteritis, and dietary diarrhea. Abdominal pain alone would suggest abomasal bloat, mesenteric torsion, or other intestinal accidents if diarrhea does not develop. In cases of peracute death due to coccidiosis, the differential diagnosis includes enterotoxemia, bacterial septicemias, and plant and chemical toxins.

In weanlings two to five months of age, particularly those with access to pasture, kid yards, or poorly drained dry lots, helminthiasis is the major differential diagnosis for diarrhea. Gastrointestinal nematodiasis and paramphistomiasis should be considered. In fact, multiple parasitic infestations are common and it may be difficult to attribute diarrhea or ill thrift to coccidiosis alone. Other causes of diarrhea in this age group include simple indigestion and acute carbohydrate engorgement due to sudden feed changes or excessive grain feeding, as well as salmonellosis and enterotoxemia.

In subclinical coccidiosis, or after severe clinical coccidiosis, ill thrift or poor growth may be the primary clinical complaint in growing kids. Selenium deficiency or cobalt deficiency must be considered in these cases,

particularly where soil deficiencies of these minerals are known to exist. Chronic helminthiasis must also be ruled out.

Treatment

Supportive care is the principal therapeutic intervention in active cases of coccidiosis. Diarrheic goats should be removed from the group and given oral or parenteral balanced electrolyte solutions depending on the degree of dehydration. In preweaned kids, milk should be fed only in small amounts, because disruption of the intestinal mucosa produces maldigestion and may promote osmotic diarrhea from undigested lactose. Weaned kids should be offered good quality grass hay and brought back on full feed gradually. Severely anemic kids with acute intestinal blood loss may require blood transfusions. Broad-spectrum antibiotics are indicated in severe cases to prevent bacterial septicemia secondary to disruption of the intestinal mucosal barrier. Probiotics have been recommended to help re-establish the normal gut flora (Bath et al. 2005).

The use of anti-coccidial drugs in active clinical cases may have limited value. Most anti-coccidial drugs are coccidiostats that inhibit but do not eliminate coccidial reproduction. These drugs usually act on early stages of the reproductive cycle. Animals already showing diarrhea have often progressed beyond the stages of infection where coccidiostats may prove beneficial. Nevertheless, goats are commonly infected with multiple species of *Eimeria* and some of these may still be in the early stages of development. In these cases, the duration of clinical disease may be shortened by treatment.

The main goal in administering coccidiostats is to reduce the number of additional cases developing in a group of animals at risk, rather than curing existing cases. Drugs reported for use in the treatment of caprine coccidiosis include sulfonamides, nitrofurazone, ionophores, amprolium, toltrazuril and diclazuril. Dosages and treatment regimens reported specifically for goats are summarized in Table 10.7

The sulfonamides and nitrofurazone may offer the added benefit of control of secondary bacterial infections. Because goats with clinical coccidiosis are often dehydrated, the sulfonamides must be used with care because nephrotoxicity can result from poor renal perfusion and decreased urine output. Sulfonamides are the oldest class of drugs used as coccidiostats and it is generally considered that resistance to sulfonamides is widespread among *Eimeria* spp. However, efficacy continues to be reported in some goats treated with sulfonamides. Sulfa drugs are available for oral and parenteral use. A variety of oral preparations can be given as boluses or added to feed or water. Nitrofurazones can produce neurotoxicity when overdosed, as

Table 10.7. Coccidiostats used in the treatment or prevention of caprine coccidiosis.

Drug used	Treatment regimen	Prophylaxis regimen	Comments	References
Sulfonamides				
Sulfadimethoxine	75 mg/kg bw orally for 4–5 days			Yvore 1984
	250 mg/kg bw orally once using a sustained-release bolus		Releases 50 mg/ kg bw per day for 5 days	Yvore et al. 1986
Sulfadimidine	135 mg/kg bw orally for 4–5 days	55 g/ton of feed for at least 15 days		Yvore 1984, Radostits et al. 2007
Sulfaguanidine	280 mg/kg bw orally for 4 days			Vujic and Ilic 1985
Sulfaguanidine (or Sulfaquinoxaline) followed by Sulfathiazole (or Sulfadimethoxine)	1.3 g/kg bw orally for 4 days 1.1–2.2 g/kg bw orally for 4 days		Poor absorption from digestive tract	Guss 1977
Sulfamethazine		50 g/ton of feed		Shelton et al. 1982
Antibiotics				
Nitrofurazone	10–20 mg/kg bw orally for 5–7 days		No longer permitted for use in food producing animals in the US	Tarlatzis et al. 1955, 1957
Amprolium	10–20 mg/kg bw orally for 3–5 days			Yvore 1984
	50 mg/kg bw orally for 5 days			Swarup et al. 1982
		25–50 mg kg bw orally in feed or water continuously from 2 weeks to several months of age		Smith 1980
Ionophores				
Monensin		15–20 g/ton of feed		Shelton et al. 1982, Foreyt 1990
Lasalocid		20–30 g/ton of feed (1.1– 2.2 mg/kg bw/day) continuously		Williams 1982
Salinomycin		100 ppm in concentrate fed for 3 weeks after weaning		Yvore 1984
Quinolones				
Decoquinate		0.5–1 mg/kg bw orally in feed; may be fed continuously		Foreyt et al. 1986
Triazinons				
Toltrazuril	20 mg/kg bw orally once	20 mg/kg bw orally once every 3–4 weeks		McKenna 1988
Diclazuril	1 mg/kg bw orally once	1 mg/kg bw orally once every 3–4 weeks	Recommended for use in goats but no dose given. Lamb dose provided here.	Harwood 2004
Clopidol and methylbenzoquate		12 mg/kg bw clopidol and 1 mg/kg bw methylbenzoquate/ day for 5 weeks		Polack et al. 1987
Dapsone	80 mg/kg bw orally for 4 days			Devillard 1981
3,5, Dinitro-*O*-toluamide	100 mg/kg orally for 5 days			Dash and Misra 1988

ppm = parts per million.

may occur if the medicine is not properly mixed into milk or solid feeds. This drug is rarely used anymore in coccidiosis control. Note that in 2002, as a public health measure, all nitrofurans, including nitrofurazone, were banned in the United States for use in food-producing animals, because the nitrofurans have been identified as potential carcinogens.

Amprolium is a thiamine antagonist and works as a coccidiostat by blocking utilization of thiamine by coccidia. If amprolium is used for too long or at excessive doses, there is the potential for producing polioencephalomalacia in goats, though this should not discourage its proper usage. Polioencephalomalacia of ruminants may result from thiamine deficiency, as discussed further in Chapter 5. Amprolium is for oral use and is available as a liquid for addition to milk, milk replacer, or water, and in solid forms for addition to feeds.

The ionophores include monensin, lasalocid, and salinomycin; all have been used in goats. They are used mainly in solid feed in weaned animals. While monensin is used widely in poultry, cattle, and sheep, it is known to be toxic in horses and is potentially toxic in ruminants if overdosed. The lethal dosage LD_{50} in sheep is reported to be 12 mg/kg; in cattle, 22 to 80 mg/kg; and in goats 26.4 mg/kg. Muscle weakness and myoglobinuria are the clinical signs of toxicity in sheep (Langston et al. 1985). The cardiotoxicity of ionophores is discussed further in Chapter 8.

A new class of coccidiocidal drugs known as the symmetric triazinons emerged in the 1980s. They can disrupt all intracellular developmental stages of *Eimeria* and therefore can be more effective in the treatment of clinical coccidiosis than the coccidiostats, while also being useful for prophylaxis. Two drugs in this class are used in ruminants, toltrazuril and diclazuril, though neither is specifically approved for use in goats at this time. There are several reports on the use of toltrazuril in goats. In the earliest report, a single oral dose of 20 mg/kg produced a rapid, significant reduction in oocyst shedding that remained low for two to three weeks, suggesting that all developmental stages of the coccidia present were killed (Anonymous 1988a). In a later study, toltrazuril was administered orally at a dose of 25 mg/kg for two consecutive days to seven-week-old kids with clinical coccidiosis. Oocyst shedding was virtually eliminated and all treated kids became clinically normal (Ocal et al. 2007). In another study, the drug was given to four- to five-week-old kids at a lower dose of 10 mg/kg bw for two consecutive days (Slosarkova et al. 1998). Though oocyst counts in feces were reduced, considerable numbers of oocysts continued to be shed over the following three weeks and by five weeks were at higher levels than the pretreatment counts. Therefore, the higher doses of 20 to 25 mg/kg appear to be more effective in kids.

It is not clear that a second consecutive daily dose is required. In calves, a single dose of 20 mg/kg bw is considered to provide a full therapeutic effect. Diclazuril has been recommended for prophylactic use in goats. It is available as an oral suspension and is given as two doses two weeks apart (Harwood 2004). In lambs, the therapeutic and prophylactic doses of diclazuril are the same, 1 mg/kg bw, given at four to six weeks of age, with a second dose administered three weeks later for prophylactic use where there is high infection pressure.

In addition to the use of coccidiostats, implementing management changes is important in controlling outbreaks of coccidiosis. Attempts should be made to reduce exposure to infective sporocysts by removing contaminated bedding and feed, reducing the stocking rate, and moving animals to a new, uncontaminated environment.

Control

Under management conditions where outbreaks of coccidiosis can be reliably anticipated, measures should be taken to control coccidiosis before the observation of clinical disease. Proper control is a balancing act. The goals are to reduce oocyst numbers in the environment sufficiently to avoid massive challenge to susceptible animals while allowing sufficient exposure so that immunity and resistance can properly develop. This is accomplished by combining sound management and hygiene practices with the use of coccidiostats. In production systems where group housing of weanlings is unavoidable, control of coccidiosis without the use of coccidiostats is rarely achieved, even when management is excellent.

In attempting to maximize the immunologic resistance of the host, it is important to consider the mode of action of the various coccidiostats. The host immune response appears to be most stimulated by active schizogony, while most coccidiostats inhibit reproduction earlier in the infective cycle.

Sulfonamides, amprolium, and ionophores have been used as prophylactics and as therapeutics in goat-rearing programs with mixed success. The sulfonamides are folic acid antagonists, and are most inhibitory during the second schizogony. This late action allows for development of host immunity. However, as already mentioned, resistance to sulfas may be widespread. The ionophores primarily inhibit the early, asexual stages of coccidial development. However, they offer an added benefit of improved weight gains above and beyond their action as coccidiostats (Shelton et al. 1982). Unfortunately, outbreaks of clinical coccidiosis have been observed in young goats being fed lasalocid in their ration. This has been attributed to uneven consumption by individual goats, possible resistance to the drug, and failure to maintain

good hygiene, in addition to feeding coccidiostats. Monensin was approved for use in nonlactating goats in the United States in 1989 as a feed additive at 20 grams/ton.

Decoquinate, a quinolone not used for treatment, has been found to be effective in preventing caprine coccidiosis. It works early in the *Eimeria* life cycle by inhibiting sporozoite development. Dose ranges from 0.3 to 4 mg/kg bw have been evaluated. All doses prevented clinical coccidiosis and allowed equal rates of weight gain. Doses at the higher end, however, resulted in a more rapid and pronounced decrease in the number of oocysts shed (Foreyt et al. 1986). In 2002, decoquinate was approved for use in non-lactating goats in the United States as an additive to milk replacers or feeds to be administered at a dose of 0.5 mg/kg bw (22.7 mg/100 lbs bw) for a minimum of twenty-eight days to control coccidiosis due to *E. ninakohlya-kimovae* and *E. christenseni* (Vaughn 2002).

Coccidiostats are most often used between the ages of one and four months, usually in conjunction with grain feeding. However, in some intensive management situations, it may be necessary to begin use in the milk or milk replacer of pre-weaned kids. As discussed above in the treatment section, oral toltrazuril or diclazuril can also be highly effective for prevention of clinical coccidiosis in young kids if given at three- to four-week intervals through weaning.

Good hygiene and thoughtful management are essential to effective coccidiosis control. Weaning should be as unstressful as possible. To minimize weaning shock, kids should have access to grain well in advance of weaning. Whenever possible, dairy kids should be raised away from adults and housed individually or in small groups, segregated by age, and provided feed and water in devices that minimize contamination with feces. They should never be fed on the ground, and waterers must not leak or be liable to spillage.

Housing that allows shelter with ready access to sunlight is preferred. A successful system of weaned kid management using movable hutches is shown in Figure 10.9. No matter what type of housing is used, ground, floors, and bedding should not be allowed to become excessively wet. Adequate ground drainage, frequent floor scraping, and regular provision of clean bedding are necessary. Scraping floors and allowing them to dry is probably more effective in coccidia control than scraping followed by scrubbing or hosing because disinfectants are generally not effective, and excess moisture promotes sporulation. If disinfectants are used, products containing ammonia, particularly quarternary ammonium compounds, are the most effective.

In general, when proper control methods are implemented and goats are not exposed to new species of

Figure 10.9. Movable hutches used in coccidiosis control. Fencing and hutches are moved every several weeks to minimize weanling exposure to oocyst buildup on the ground. (Courtesy of Vincent and Christine Maefsky, Poplar Hill Dairy Goat Farm, Scandia, Minnesota.)

Eimeria not previously experienced, immunity to reinfection is usually achieved by five months of age. Coccidiostat feeding may be terminated and, if possible, kids should be moved to uncontaminated housing at this time.

No vaccines are currently available for control of coccidiosis in ruminant animals, though live, multivalent, attenuated, coccidial oocyst vaccines are commercially available for poultry. There has been active research into the development of subunit vaccines for protozoa of veterinary importance, including the *Eimeria*, and these efforts have been reviewed (Jenkins 2001).

Cryptosporidiosis

First reported as a cause of fatal enteritis in goats in 1981, cryptosporidiosis has emerged as a major cause of diarrhea in kids younger than one month of age, particularly under intensive management conditions. Cryptosporidiosis is a zoonotic disease and has become an important and serious infection of patients with acquired immunodeficiency syndrome (AIDS) or other conditions involving immunosuppression.

Etiology

Cryptosporidiosis is caused by *Cryptosporidium* spp. which are small, protozoal parasites in the family Cryptosporidiidae in the phylum Apicomplexa. Though long considered to be members of the class

Coccidea, they are no longer considered to be coccidian parasites (Xiao and Cama 2007). The taxonomy of the *Cryptosporidium* genus is in flux as new molecular criteria become available to augment or replace the more traditional morphologic criteria of classification. Currently, fifteen *Cryptosporidium* species have been identified which infect a wide range of vertebrate hosts, including all the mammalian domestic livestock species; birds, including domestic poultry; reptiles, and fish. These fifteen species tend to be, but are not exclusively, host-specific. *C. parvum* infects domestic ruminants, including goats, sheep, and cattle as well as humans, and is the major focus of this discussion. Overviews of the taxonomy of the *Cryptosporidium* genus are available elsewhere (Fayer 2004; Xiao et al. 2004; Xiao and Cama 2007).

It is known that cryptosporidial oocysts are very resistant to environmental degradation, and many common disinfectants are reported to be ineffective in destroying them. Oocysts remained infective after eighteen hours of contact with iodophores, cresylic acid, sodium hypochlorite, benzalkonium chloride, and sodium hydroxide. Only 5% ammonia and 10% formol saline destroyed infectivity of oocysts (Campbell et al. 1982). Ammonium hydroxide, hydrogen peroxide, and chlorine dioxide are now also recognized to be effective disinfectants.

Epidemiology

Cryptosporidiosis occurs worldwide. In goats, kids from two days to three weeks old are mainly affected but older animals may also be affected. In outbreaks, especially in intensively managed herds, kid morbidity can approach 100% and mortality up to 40% has been reported.

The first reported field case of diarrhea attributed to cryptosporidiosis in a goat involved a four-week-old kid in Australia in 1978 (Mason et al. 1981). This was followed by a second Australian report in 1982 in which twenty-one of twenty-nine grazing goat kids developed diarrhea and three died. All kids examined were shedding cryptosporidial oocysts and tests for enteric viruses and K99+ *E. coli* were negative (Tzipori et al. 1982).

In Hungarian studies on the causes of diarrhea in kids younger than one month of age in large commercial dairy goat herds, cryptosporidia were isolated more frequently than rotavirus, coronavirus, adenovirus, or enterotoxigenic *E. coli*. In these studies, cryptosporidia were not identified in the feces of any normal goats, while all of the other agents mentioned were identifiable one or more times in non-diarrheic kids (Nagy et al. 1983, 1984). In a French survey, twenty-eight of forty-eight diarrheic kids (58%) on nine different premises had cryptosporidia detectable in feces or intestinal scrapings (Polack et al. 1983). A more exten-

sive kid survey on twenty-four intensively managed dairy goat farms in France demonstrated an overall mortality rate from diarrhea of 10.3%, mostly during the first two weeks of life. Cryptosporidia were identified in feces of virtually all fatal diarrhea cases, but not in any non-diarrheic animals, save those recovering from diarrhea or those that subsequently developed diarrhea (Yvore et al. 1984). In contrast, cryptosporidia have been reported from feces of healthy kids in Tanzania (Matovelo et al. 1984) and Nigeria (Ayeni et al. 1985).

In diagnostic laboratory accessions seen from 1981 to 1985 in New Zealand, cryptosporidia were identified more frequently than any other single infectious agent, save *Eimeria* spp., in diarrheic kids younger than one month of age (Vickers 1986). Cryptosporidia also have been reported in association with diarrhea in a six-month-old goat in the Netherlands, four- to twenty-five-day-old kids in Italy, and a seven-day-old kid in conjunction with *Clostridium perfringens* in the United States (Ducatelle et al. 1983; Gialletti et al. 1986; Card et al. 1987). The author has confirmed cryptosporidiosis as a significant cause of diarrhea in young, intensively managed kids in a large goat herd in New York. More recently, major outbreaks of cryptosporidiosis affecting kids by the hundreds have been reported in herds from Oman (Johnson et al. 1999) and Turkey (Sevinc et al. 2005). In the Turkish incident, subclinically infected adult goats, insufficient colostrum intake in kids, and contamination of the kidding area were considered to contribute to the dramatic evolution of the outbreak.

Transmission is by the fecal-oral route from oocysts shed in the feces, and infections can spread quickly through group-housed kids once introduced into the group. It has been shown that goats may be infected with cryptosporidia isolated from calves and humans (Contrepois et al. 1984; Nagy et al. 1984). Colostrum-deprived kids develop more severe disease and a higher rate of mortality than colostrum-fed kids (Naciri et al. 1984). It is not yet clear if this is directly associated with *Cryptosporidium*-specific immunoglobulins or with other nonspecific nutritional or immune factors available from colostrum. The severity of disease does not appear to be affected by the state of the intestinal flora (Contrepois et al. 1984). While cryptosporidia are found infrequently in non-diarrheic kids during field investigations, experimental challenge can result in oocyst shedding in diarrhea-free kids, indicating that subclinical infections may occur (Nagy et al. 1984).

Pathogenesis

Cryptosporidium spp. are obligate, intracellular parasites. The only stage that occurs outside the host is the oocyst stage. The life cycle is similar in outline to the Eimeriidae, with some notable differences. Transmis-

sion is by the fecal oral route. Susceptible hosts ingest infective, sporulated oocysts which excyst and release sporozoites that invade intestinal enterocytes and undergo rapid asexual multiplication or schizogony. Meronts produced by schizogony release merozoites which invade new enterocytes. Sexual multiplication or gametogony also occurs in enterocytes, producing zygotes. Zygotes may form either thin-walled sporulated oocysts which rupture within the small intestine to release sporozoites that can further invade new host enterocytes (autoinfection) or a thick-walled sporulated oocyst that is passed in the feces as a source of infection to other animals.

Initially, these parasites of the gastrointestinal tract were considered to be extracellular, observed in close association with the brush border of the intestinal epithelial cells. Electron microscopic studies have confirmed that they are in fact intracellular, but extracytoplasmic, residing underneath the brush border of intestinal epithelial cells in a parasitophorous vacuole created from the host cell microvillous and plasma membranes.

The pathogenic effects of cryptosporidial infection are most likely due to the impairment of enterocyte function and integrity resulting from the rapid, cyclic reproduction of cryptosporidia that occurs within the brush border of enterocytes. In goats, infection leads to increased senescence of epithelial cells and villous atrophy in the ileum. The severity of these effects is related to the degree of infection (Matovelo et al. 1984). This can lead to both malabsorption and maldigestion, resulting in the clinical diarrhea observed. Prolonged weight loss may be associated with malabsorption. Steatorrhea caused by maldigestion has been documented in experimentally infected lambs (Contrepois et al. 1984). That diarrhea has been observed in kids as young as three to four days of age reflects the short life cycle of cryptosporidia. The prepatent period has been reported to be two to seven days in calves and two to five days in lambs (Radostits et al. 2007). Age-related immunity probably occurs, as clinical disease is far less common in older animals, but this immunity is not complete as oocysts are found in the feces of healthy adult goats (Castro-Hermida et al. 2007). Such goats can serve as a source of infection for kids. In ewes, it has been reported that there is a periparturient increase in the excretion of oocysts.

Clinical Findings

The most common presentation of cryptosporidiosis is an acute, white to yellow, watery diarrhea in kids younger than two weeks of age. The diarrhea may last from several days to two weeks, and may be mild to severe, presumably depending on the magnitude of the initial exposure to oocysts. Diarrhea may be persistent or recurrent. In addition to diarrhea, kids may

show depression, inappetence, and a rough hair coat. Sequelae of dehydration, electrolyte imbalance, acidosis, and death may occur, depending on the severity of diarrhea and the time of intervention. Spontaneous recovery can also occur.

Explosive outbreaks of diarrhea with mortality rates of 10% to 20% have been observed in intensively managed dairy goat kids housed in groups indoors. Some of these outbreaks have begun toward the end of the kidding season, suggesting that environmental buildup of oocysts is contributory (Delafosse et al. 2006).

Two other syndromes of cryptosporidiosis have been reported from France (Polack and Perrin 1987). Progressive emaciation without diarrhea has been observed starting in one-week-old kids, and diarrhea has been noted beginning in six-week-old goats.

An atypical presentation of caprine cryptosporidiosis was reported from Oman (Johnson et al. 1999). Distinguishing features included clinical disease in adult goats as well as kids, and the limitation of cryptosporidiosis to goats, even though sheep, cows, and buffalo were in close proximity on the farm. No other enteric pathogens were identified during the outbreak. Morbidity approached 100% in goats under six months of age and mortality was high, with 37.8% of goats up to four weeks of age and 34.4% of goats between five and eight weeks of age dying.

Clinical Pathology and Necropsy

Current evidence suggests that cryptosporidial oocysts are not commonly shed in large numbers in the feces of healthy goats. Detection of oocysts in feces of diarrheic goats therefore is useful in supporting a diagnosis of cryptosporidiosis.

Direct fecal smears have been routinely used for examination because they are quick and easy to prepare. Oocysts, however, may be sparse, difficult to discover in fecal debris, or hard to distinguish from yeasts. Fecal flotation and sedimentation methods are preferable. Centrifugal flotation techniques including the use of potassium dichromate/saturated sucrose (sp. gr. ≥ 1.10), sucrose/phenol (sp. gr. = 1.27), and potassium iodomercurate (sp. gr. = 1.44) solutions have been reported. Yeasts do not float in the potassium dichromate/saturated sucrose solution (Willson and Acres 1982).

Concentrated oocysts can be viewed stained or unstained using direct light- or phase-contrast microscopy. The sample for examination should be taken from the meniscal surface using a wire loop, put on a slide, and covered with a coverslip. It is advisable to use high-power magnification, search the edges of the coverslip, and focus just below the coverslip because oocysts float up to its underside. A semi-quantitative flotation technique for counting oocysts in feces has

been reported for use in calves (Anderson 1981) and applied to goats (Contrepois et al. 1984). Sedimentation using formalin-ethyl acetate solution with centrifugation at 1,700 × g or more also effectively concentrates oocysts (Kirkpatrick and Farrell 1984).

Numerous staining techniques have been used to assist in identifying cryptosporidia oocysts in feces. Currently, acid fast staining with modified Ziehl-Neelsen stains is generally favored. Oocysts stain pink to red with interior blue granules against a blue-green counterstained background. Auramine fluorescent stains or fluorescein isothiocyanate-labelled monoclonal antibodies are also being used. With these stains, oocysts display a yellow green fluorescence against a black background. Antigen based ELISA tests and PCR techniques are also available for detection of *C. parvum* oocysts in feces (Wright and Coop, 2007). Immunoassays are also available, but are more appropriate for surveillance studies than for case diagnosis because clinical disease generally precedes the immune response.

Gross lesions are nonspecific and unremarkable and may be limited to a mild to moderate enteritis most commonly located in the ileum. Smears should be made of the ileal mucosa for microscopic examination to detect oocysts. Histologically, sections of intestine reveal numerous small, round basophilic bodies of various sizes along the mucosal surface. These are the different endogenous stages of developing cryptosporidia in the brush border of the enterocytes. Free oocysts may also be seen in the intestinal lumen. Infection is accompanied by marked villous atrophy and villous fusion in the ileum and possibly the jejunum and large intestine. For accurate diagnosis, it is essential to fix fresh tissues in formalin immediately after death because autolysis of developing cryptosporidia and associated enterocytes is rapid. Oocysts in feces are more hardy, although freezing destroys them. If necessary, they may be preserved as long as 120 days by mixing one part feces with two parts of 2.5% potassium dichromate solution.

Diagnosis

A presumptive diagnosis of cryptosporidiosis is based on identifying oocysts in feces or various endogenous stages of the organism in intestinal smears or histologic sections. Since cryptosporidia may be present in association with other etiologic agents capable of producing diarrhea, laboratory evaluation for the various other bacterial, viral, and protozoal causes of kid diarrhea is indicated before a definitive diagnosis can be made. These are discussed later in the chapter in the section on the neonatal diarrhea complex, and a list of likely etiologic agents is provided in Table 10.3. Careful history taking is necessary to rule out dietary causes of diarrhea.

Treatment

Currently, treatment of cryptosporidiosis is limited to supportive care, particularly oral or parenteral fluid therapy, based on the severity of fluid and electrolyte loss. Nutritional management is an important consideration because maldigestion may be present. Diarrhea in cryptosporidiosis can last as long as two weeks. It is not possible to withhold milk for that period but regular milk feeding may result in aggravation of the diarrhea due to the osmotic influence of undigested lactose. Therefore, it is recommended to reduce the volume of milk fed per feeding while increasing the frequency of feeding. Lactose intolerance has been documented in a young goat in association with clinical cryptosporidiosis and feeding of lactase treated goat milk was reported to aid in recovery of the affected kid (Weese et al. 2000). Parenteral nutrition, though costly, could be considered in pet goats or other valuable individuals.

Reportedly, more than fifty anticoccidial, antibacterial, and antiparasitic drugs have been tested for therapeutic efficacy against cryptosporidiosis in numerous species and *in vitro,* and none were found effective (Tzipori 1983). More recently, some possible treatment options have emerged for use in goats and other ruminants, notably halofuginone lactate and paromomycin sulfate. Neither drug is approved for use in goats in the United States.

Preliminary results from a French field trial indicated that the anticoccidial drug halofuginone lactate was effective in arresting diarrhea and eliminating shedding of oocysts in goat kids with cryptosporidiosis (Naciri et al. 1989). The drug was given orally at a dose of 0.5 mg/kg daily for three to five days and the therapeutic response was marked compared with affected kids in the same flock treated with sulfonamides. Since that time, the therapeutic efficacy of halofuginone in cryptosporidiosis has been more widely recognized and the drug is now commercially available and approved for use in newborn calves in Europe for control of cryptosporidiosis. Available as an oral solution, it is given at a dose of 0.1 mg/kg bw for seven days beginning on the first or second day of life.

A cautionary note on the use of halofuginone is warranted. This drug has a very narrow margin of safety. It can be fatal when administered at three times the dose used. Animals should be weighed when possible to calculate an accurate dose and animals should be adequately hydrated before administration.

Paromomycin sulfate is an aminoglycoside antibiotic similar in structure to neomycin. It has been shown to have efficacy against *C. parvum* and is being used in human AIDS patients with cryptosporidiosis.

Several efficacy trials have been specifically carried out in experimentally infected (Mancassola et al. 1995)

and naturally infected goats (Chartier et al. 1996; Johnson et al. 2000). In all studies, the drug was administered orally to kids at a dose of 100 mg/kg bw but for varying durations of ten, eleven, or twenty-one days. In all cases, there were marked reductions in oocyst shedding and clinical manifestations as compared to controls. When used for twenty-one days, in the face of a severe natural outbreak, treated animals showed no diarrhea and were negative for fecal oocysts on the day following cessation of treatment, while untreated controls in the same environment all developed diarrhea and had oocyst positive fecal samples (Johnson et al. 2000). Because the drug is given orally and is poorly absorbed from the alimentary tract, concerns about nephrotoxicity and ototoxicity associated with aminoglycoside administration, especially in diarrheic or dehydrated animals, are minimized.

There are also reports that decoquinate can reduce the severity of *C. parvum* infection and the number of oocysts shed in feces, though it does not prevent the development of clinical disease (Mancassola et al. 1997; Naciri et al. 1998; Ferre et al. 2005). In all these studies, the drug was administered orally to young kids for a period of twenty-one days at a dose of 2.5 mg/kg bw. In one study, however, the drug was also given to a group of pregnant does during their last three weeks of pregnancy, rather than to their kids. The positive effect on cryptosporidiosis in their kids was equivalent. The explanation was that treatment of the does suppressed the periparturient rise in oocyst shedding and therefore reduced environmental contamination and exposure of the newborn kids. Decoquinate is approved for use in the United States as an additive to feed or milk replacer for controlling coccidiosis in non-lactating goats as discussed in the preceding section of this chapter on coccidiosis.

The non-reducing oligosaccharide alpha-cyclodextrin has also been evaluated as a treatment for cryptosporidiosis in goats. In an experimental model, kids given 500 mg/kg bw orally for six days beginning on the day of experimental infection had a longer pre-patent period, a reduction in the patent period, a decrease in the intensity of infection, and far fewer cases of diarrhea as compared with untreated neonatal kids (Castro-Hermida et al. 2004).

Control

The thrust of cryptosporidiosis control is in improved management and hygiene. Kids should be separated from does at birth and fed colostrum in clean nipple bottles. Goats that do not receive colostrum are more likely to develop cryptosporidiosis. Kids should be housed away from the adult herd and housed individually or in small groups. When kids are housed in groups, affected kids should be isolated at the first sign of diarrhea to reduce oocyst contamination of the environment. The author has had excellent results in checking the spread of cryptosporidiosis in groups of young kids at risk by practicing early removal and strict isolation of affected kids at the first sign of diarrhea. Outbreaks can be stopped without the use of drugs.

Excellent sanitation in housing, bedding, and feeding utensils is probably most critical in controlling the spread of cryptosporidiosis among susceptible kids (Thamsborg et al. 1990). Rodent control may also be indicated because there is evidence that oocysts derived from goats can infect mice, which in turn shed oocysts as well (Noordeen et al. 2002). In problem herds, water supplies should also be checked for contamination with *C. parvum* oocysts, because the risk of water-borne infection is recognized (Watanabe et al. 2005). Personnel handling diarrheic kids should not handle healthy kids. Hands should be washed thoroughly after handling sick kids because of the zoonotic potential of cryptosporidiosis. Because common disinfectants do not destroy cryptosporidia, steam cleaning or high pressure cold water spraying of pens or hutches between uses is recommended. No vaccine is currently available, though this is an area of active research (Sagodira et al. 1999; He et al. 2002). While no drugs are specifically approved for prophylactic use in goats, published reports indicate that halofuginone, paromomycin, or decoquinate can help control the disease in young kids, as discussed above in the treatment section.

HELMINTH DISEASES

Nematode Gastroenteritis

Nematode infection of the gastrointestinal tract is one of the most significant causes of wastage and decreased productivity in goats worldwide, especially under grazing conditions. The natural history of caprine nematodiasis is in many ways similar to that seen in cattle and sheep. Studies in the goat, however, suggest some important species differences in terms of parasite susceptibility, age-related immunity, and the pharmacokinetics of anthelmintic therapy. These differences must be understood and taken into account for effective control of nematode parasites in goats.

Etiology

A multitude of nematode parasites are at home in the gastrointestinal tract of goats. The major genera are first presented here in taxonomic family groups to facilitate discussion of common and distinct aspects of their life cycles. Subsequently, the individual species are discussed according to their locations in the caprine alimentary tract so that their pathophysiologic effects

can be better understood. More detailed information about the biology of the various nematodes is available in standard veterinary parasitology texts (Soulsby 1982).

TRICHOSTRONGYLIDAE. The trichostrongyles are responsible for most of the disease and economic loss associated with nematode parasites in goats. Genera in this family include *Haemonchus*, *Trichostrongylus*, *Cooperia*, *Nematodirus*, *Marshallagia*, *Mecistocirrus*, *Ostertagia*, *Teladorsagia*, and *Camelostrongylus.* All have a direct life cycle. Adult nematodes in the alimentary tract of the host produce ova that are passed in the feces. First-stage larvae develop in ova within one day of passage to the external environment. For most species, first-stage larvae then break out of ova and molt to second-stage larvae. These molt one more time and become infective third-stage larvae. Development to the infective stage usually takes seven to ten days under favorable conditions but can vary according to environmental factors, mainly temperature and moisture.

Nematodirus spp. are distinguished from the other genera in that development to infective third-stage larvae occurs within the ova during the three-week period after passage in the feces. This adaptation enhances survivability over periods of adverse weather. In *Marshallagia* spp., larvae develop to the second stage before hatching from the ova.

Infective larvae of all genera are ingested by the host during consumption of contaminated feed. When goats are at pasture, infective larvae migrate to the tops of grasses during mornings and evenings, enhancing ingestion by grazing hosts. After ingestion, the larva travels to its predilection site in the alimentary tract. The larva then burrows into mucosal folds or digestive glands and molts within one to two days to a fourth-stage larva. This larva may remain in place for as long as ten days, and then returns to the mucosal surface to finally molt into an adult capable of producing ova to complete the life cycle. The average prepatent period is between three and four weeks.

Recently, two cases of human trichstrongylosis were reported in two suburban goat keepers in Australia who presented with abdominal pain and diarrhea. Eggs of *Trichostrongylus* spp. were identified from the patients and larvae of *T. colubriformis* from the goats. One patient had used goat manure as fertilizer on his vegetable garden (Ralph et al. 2006).

TRICHURIDAE. These parasites also have a direct life cycle. In *Trichuris* spp. of this family, known as whipworms, development to the third larval stage occurs within the egg and release of the larva does not occur until after ingestion by the host. Embryonation within the egg occurs after passage in the feces, taking three weeks or longer, depending on temperature and moisture conditions. Ingested eggs release larvae that penetrate the small intestine. Larvae develop for two to ten days before moving to the cecum for maturity to the adult stage. The prepatent period is seven to nine weeks.

OXYURIDAE. The members of this family that affect goats are *Skrjabinema* spp., referred to as pinworms. The life cycle is direct. Eggs ingested by the host hatch in the small intestine and larvae migrate to the large intestine to become adults within twenty-five days of infection. Eggs are fully embryonated and are deposited by the adult female pinworm on the perianal skin of the host.

STRONGYLIDAE. *Oesophagostomum* spp. in the family Strongylidae are referred to as nodular worms. They have a direct life cycle similar to the Trichostrongylidae except that infective larvae penetrate deep to the submucosa of the alimentary tract, reaching the lamina propria for development to fourth-stage larvae. This can occur anywhere from the pylorus to the rectum. After the molt, fourth-stage larvae return to the mucosal surface and migrate to the colon to develop into adults. The prepatent period is approximately six weeks. The characteristic nodules that occur in the intestine of affected animals due to *O. columbianum* are associated with a host reaction to the deeply burrowed infective larvae, not the surface feeding adults. The third-stage larvae of *Chabertia* spp. develop deep in the intestinal wall, but nodule formation is not a characteristic of chabertiosis. The prepatent period is approximately seven weeks.

ANCYCLOSTOMIDAE. This family includes the hookworms of goats, in the genera *Bunostomum* and *Gaigeria.* These nematodes have a direct life cycle, but a different route of transmission than the Trichostrongylidae. Infective larvae penetrate the skin or oral mucosa of the host. Such larvae enter the bloodstream via capillaries and end up in the lungs. They disrupt pulmonary capillaries and enter the alveoli, where they molt to fourth-stage larvae. These larvae are coughed up and swallowed. Migration to the small intestine and development of adults then occurs. The prepatent period is approximately nine to ten weeks, but adult worms may be present and feeding in the goat colon by four weeks after infection (Arantes et al. 1983).

STRONGYLOIDIDAE. *Strongyloides papillosus* is the sole caprine pathogen in this family. The life cycle is unique among the gastrointestinal nematodes. *S. papillosus* is parthenogenic—either free-living or parasitic development can occur. Under adverse environmental conditions, ova produced by parthenogenic females are passed in the host feces and develop only to infective third-stage larvae. Under more favorable environmental conditions, the free-living cycle is more common.

Ova are passed in the host feces again, but develop rapidly into sexually mature free-living males and females. After copulation, the females produce a single

generation of infective larvae. In both cases, the resulting infective larvae must enter a suitable host to complete a subsequent life cycle. Infection of the host may occur by penetration of the skin, or the oral or esophageal mucosa. Penetrating larvae enter the bloodstream and localize in the lungs, where they enter the alveoli, migrate up the airways, and are swallowed. They mature to adults in the intestine. The prepatent period is six to seven days. In addition, transmission of infective larvae to neonates via the milk of infected dams has been documented to occur in goats, though transplacental transmission was not demonstrated (Moncol and Grice 1974; Yvore and Esnault 1986). Very young kids infected via milk or colostrum can pass ova in the feces, and *S. papillosus* may be the only gastrointestinal nematode found in preweaned kids.

Gongylonematidae. *Gongylonema* spp. of the family Gongylonematidae (superfamily Spiruroidea) have an indirect life cycle. Eggs passed in feces of primary hosts such as the goat hatch after ingestion by coprophagous beetles. Infective larvae develop within the beetles for about thirty days. Goats are infected by eating beetles containing infective larvae.

Location of Nematodes in the Host

Nematodes of the Esophagus and Rumen. Nematodes of the genus *Gongylonema*, *G. pulchrum*, *G. verrucosum*, and *G. monnigi* exist in the esophagus and forestomachs of the goat. Adult worms may be visible embedded in the mucosa and submucosa of the esophagus and rumen, but these parasites are essentially nonpathogenic and are of little clinical significance. Trematode parasites of the rumen, mainly *Paramphistomum* spp. and *Cotylophoron* spp., are more pathogenic, and are discussed later in this chapter.

Nematodes of the Abomasum. The abomasal worms of goats regularly associated with morbidity, mortality, and production losses on a worldwide basis are *Haemonchus contortus*, *Teladorsagia circumcincta*, and *Trichostrongylus axei*. *H. contortus* is generally considered the most seriously pathogenic in goats. It is distinguished from the others in that the fourth-stage larvae and adults are voracious blood suckers. *Mecistocirrus digitatus*, like *H. contortus*, is an aggressive blood feeder and is a serious pathogen of goats in Central America and Southeast Asia.

Certain other abomasal worms affecting goats are less pathogenic or have a more limited geographic distribution. *Haemonchus longistipes* is a stomach worm of camelids in North Africa and India that occurs naturally in goats commingled with camels (Hussein et al. 1985). Pathogenicity for goats has been demonstrated experimentally (Arzoun et al. 1983). *H. placei*, usually associated with cattle and sheep, is found in the abomasum of goats in the Philippines (Tongson et al.1981).

Teladorsagia (*Ostertagia*) *trifurcata* often occurs in conjunction with *T. circumcincta.* Several species of *Ostertagia*, which are mainly associated with cattle, show variable infectivity for goats (Bisset 1980). *O. lyrata* has been found to occur naturally in New Zealand feral goats (Andrews 1973). Angora goats in Australia are readily infected with *O. ostertagi* when grazing contaminated paddocks (Le Jambre 1978). This parasite is also known to occur in goats in Chile, Cyprus, and the Ukraine.

Teladorsagia davtiani occurs primarily in goats in temperate regions. *Marshallagia marshalli* occurs in tropical and subtropical regions. *Marshallagia mongolica* infects goats, sheep, and camels in central Asia. *Camelostrongylus mentulatus* is a common, non-pathogenic abomasal worm primarily of camels in the Middle East and Australia that also can infect goats. All four species are morphologically similar to the *Ostertagia* and are considered to be minor pathogens.

Trichostrongylus axei is one of several important *Trichostrongylus* spp. to infect goats, but it is the only one found principally in the abomasum. It may also be found infrequently in the small intestine of the goat as well (Tongson et al. 1981; Akkaya 1998).

Nematodes of the Small Intestine. The major pathogens of the small intestine of goats recognized worldwide are the black scour worms *Trichostrongylus colubriformis* and *T. vitrinus*, the small intestinal worm *Cooperia curticei*, the thin-necked worms *Nematodirus filicollis* and *N. spathiger*, and the hookworm *Bunostomum trigoncephalum.* This hookworm is an active blood sucker and may contribute significantly to the development of anemia. This is also true of the hookworm *Gaigeria pachyscelis*, which occurs in Indonesia, India, and Africa. As few as two dozen *G. pachyscelis* feeding in the proximal small intestine can lead to acute death from blood loss. *Strongyloides papillosus*, the threadworm of the small intestine, is moderately to markedly pathogenic in goats. In South Africa, field observations followed by experimental studies indicated that *S. papillosus* may be associated with severe clinical disease in young goats up to twelve months of age. Some of the signs observed were typical of gastrointestinal parasite infection such as abnormal feces or diarrhea, anorexia, cachexia, and dehydration, but other more dramatic and unexpected signs were also present including ataxia, stupor, nystagmus, and head pressing, as well as rupture of the liver (Pienaar et al. 1999).

Other nematodes of the caprine small intestine are geographically restricted or of limited pathogenicity. *Nematodirus oiratianus* and *N. abnormalis* are common caprine pathogens in cold regions of central Asia (Neiman 1977). *N. battus* has emerged as an important pathogen of lambs in the United Kingdom and North America, but there are no reports yet of disease in goats. *N. battus* was found in 5.8% of goat alimentary

tracts examined at an abattoir in Nigeria (Nwosu et al. 1996). *Trichostrongylus falculatus* and *T. rugatus* infect goats in South Africa and Australia. *T. longispicularis* is primarily a parasite of cattle, but has been reported from a goat in Brazil (Lima and Guimaraes 1985).

Nematodes of the Cecum. The whipworm *Trichuris ovis* occurs worldwide in goats, but is not considered a primary cause of disease or production loss. It occurs commonly in mixed infections and may contribute to poor condition. Infections of goats with *T. ovis* and/or other *Trichuris* spp. have been reported to be more common during dry seasons in Brazil and Nigeria (Travassos et al. 1974; Okon 1974). *Trichuris* spp. burrow into the cecal mucosa and pierce vessels with their styletted mouth parts, subsequently feeding on the pools of blood created. The cecal worm *Skrjabinema ovis* occurs worldwide in goats but is generally considered nonpathogenic. A separate species, *S. caprae*, occurs in the United States. Adult forms of these small, nonpathogenic pinworms are sometimes present around the anus of goats, where they deposit their eggs. If observed, they may cause concern to owners.

Nematodes of the Colon. Adult *Oesophagostomum columbianum* reside in the colon, but the nodular lesions produced by infective larvae occur throughout the intestines. The parasite occurs worldwide. The remaining *Oesophagostomum* spp. that infect goats are not known to produce the characteristic intestinal nodule and are considered non-pathogenic. Experimental infection of goats with *O. venulosum* was reported to produce small nodular lesions in goats but this is generally not observed in natural infections (Goldberg 1952; Chhabra 1965). *Chabertia ovina* can contribute to clinical parasitism in goats worldwide. Morbidity caused by *Chabertia* infection alone is uncommon. However, in experimental challenge studies, *C. ovina* worm burdens of more than 800 were fatal to four- to six-month-old kids (Kostov 1982).

Epidemiology

The successful infection of goats by gastrointestinal nematodes and the completion of the parasitic life cycle depend on a variety of environmental, parasitic, and host-related factors and interactions.

Environmental-host Interactions. The feeding behavior of ruminant species is a major factor in the development of parasitism. Animals such as sheep and cattle that graze close to the ground are exposed to massive numbers of infective larvae. Free-ranging goats are less exposed to infective larvae because their feeding behavior includes a large component of browsing at levels well above the ground. In surveys of infection intensity in sheep and goats, where the animals are allowed to follow their natural feeding behaviors, sheep have been shown to carry heavier worm burdens than goats (Le Riche et al. 1973). Domesticated goats,

however, are often managed in situations where access to browse is restricted and pasture grazing is obligatory. Under these conditions, goats may have equal or greater risk of nematode parasitism; this has been demonstrated experimentally in Australia (Le Jambre and Royal 1976).

Elimination characteristics also play a role. Splattering of naturally fluid cow feces when it hits the ground facilitates the dissemination of nematode ova on pasture. The fecal pellets of goats and sheep are not as accommodating, but natural disintegration of the feces with spreading of ova or larvae by heavy rain, melting snow, trampling by hooves, and the action of coprophagous beetles can achieve the same result, albeit more slowly. In addition, goats on lush pasture in spring, a time of increased ova production, often develop a more fluid manure that loses its pelleted character. Overt diarrhea caused by clinical parasitism also facilitates the dissemination of ova on herbage.

Lush, dense pasture in turn provides a protective umbrella for developing larvae, screening out direct sun to reduce desiccation. Direct sunlight has been shown to reduce the survival time of nematode larvae contained in goat fecal pellets (Tongson and Dimaculangan 1983). Survival time of infective larvae may also decrease in very hot weather due to the increased metabolic rate experienced by the larvae.

Overstocking and/or overgrazing of pastures generally promote increased parasitism. While intensive, rapid consumption of herbage may reduce survivability of ova and larvae by eliminating the protective plant growth, the total number of ova produced and deposited on the pasture each day increases directly with the number of animals present. Wild ruminants using pastures may also transmit nematodes to the goat, as demonstrated with *Camelostrongylus mentulatus* and *Trichostrongylus probolurus* transmitted to goats from blackbuck antelope (Thornton et al. 1973).

Management systems also play a role in the type and intensity of caprine nematodiasis, and a well-recognized advantage of confined housing systems is the marked reduction in nematode parasite loads. In a survey of forty-nine dairy goat farms in France, indoor housing was associated with a low incidence of clinical parasitism, attributable mainly to *Chabertia* and *Oesophagostomum.* In goats with access to yards, ostertagiasis was more common, and in pastured goats, haemonchosis was the predominant problem (Cabaret et al. 1986).

Environmental-parasite Interactions. Nematodes have evolved a number of adaptive strategies for surviving severe environmental stresses such as freezing, overheating, and desiccation. These include deep burrowing of larvae into soil during adverse seasons, delay of ova hatching until optimal conditions of temperature, moisture, and season are met, development of the

infective larvae within the protective shell of the ova as is seen in *Nematodirus* spp., and the production of huge numbers of ova by a single female as is seen in *H. contortus*, which produces up to 10,000 eggs per day.

The most dramatic adaptation to hostile environments is hypobiosis, or arrested development. In hypobiosis, infective larvae consumed by the host during periods of environmental adversity remain voluntarily dormant and progress to adulthood only when environmental conditions favor development and survival of larvae outside the host. Host factors may also trigger renewed development as discussed below. In temperate regions, decreasing temperatures may signal the larva's commitment to hypobiosis, while in tropical regions with distinct seasons, hypobiosis is triggered by the onset of hot, arid conditions (Chiejina et al. 1988). Hypobiosis of *Haemonchus contortus* in goats in association with the hot, dry season has been reported from Kenya (Gatongi et al. 1998) and Togo (Bonfoh et al. 1995). Even in tropical regions where temperature and humidity conditions can support free-living larvae year-round, some degree of hypobiosis may occur in response to increasing moisture content of the soil (Ikeme et al. 1987).

Synchronous resumption of larval development in the host can lead to clinical disease, referred to as type II disease. Type II ostertagiasis has been reported in goats in Israel, with a significant increase in fecal egg counts occurring at the end of the hot dry summer and continuing through the subsequent cooler rainy season (Shimshony 1974). Type II infection also has been reported in goats in Spain with clinical signs occurring in January and February (Tarazona et al. 1982).

Environmental temperature is an important factor in the survival of nematode ova and free-living larvae. Various nematode ova in the feces of goats all died within six days at a temperature of 104°F (40°C). Ova survived and hatched optimally within eight to nine days at temperatures between 86°F and 95°F (30°C and 35°C). Hatching was delayed for fourteen days at temperatures between 68°F and 77°F (20°C and 25°C). At 32°F (0°C), ova remained alive but still did not hatch after thirty days (Tripathi 1980).

Some nematodes are best suited to tropical and subtropical conditions, notably *Haemonchus* spp., *Mecistocirrus digitatus*, and *Oesophagostomum columbianum. H. contortus* is representative of this group. No hatching of ova or larval development occurs when temperatures are 50°F (10°C) or below. The optimal conditions for development of *H. contortus* from ova to infective third-stage larvae are reported to be 28°C (82.4°F) with humidity greater than 70% (Rossanigo and Gruner 1995).

The ova are highly susceptible to desiccation and do not survive in regions where hot, dry summer follows winter rainfall, or where winters are intensely cold. Infective larvae, when developed, are more resistant to weather and can survive repeated periods of desiccation. Warm, humid regions of the world with summer rainfall and temperate regions with mild winters are conducive to development of infective larvae on pasture.

In *H. contortus*, hypobiosis largely replaces overwintering of free larvae as a means of survival for the species. This is true not only for tropical countries but also for cold, temperate regions. A recent report from Sweden indicated that *H. contortus* in sheep showed almost 100% arrested development in the early fourth larval stage as early as mid-summer, thus evolving a strategy to survive the long, cold winters entirely within the host as the arrested larval stage, and relying on the ewe to complete its life cycle with the periparturient resumption of egg-laying in the spring (Waller et al. 2004). The pattern of development of *Oesophagostomum columbianum* is similar to that of *H. contortus.*

Bunostomum trigonocephalum and *Gaigeria pachyscelis* are best suited to humid subtropical and warm temperate regions. They thrive under management conditions where housing and bedding are allowed to remain continuously damp because early larval stages are particularly susceptible to desiccation. Percutaneous penetration of larvae on the feet and legs of livestock is facilitated by grazing in wet herbage or housing in damp conditions.

Nematodes better adapted to cooler, temperate climates include *Teladorsagia* (*Ostertagia*) spp., *Trichostrongylus* spp., and *Chabertia ovina. Teladorsagia circumcincta* is the prototype of this group. *Trichostrongylus* spp. are more resistant to cold and desiccation than *H. contortus*, and are capable of overwintering. Ova accumulate on pasture until suitable conditions of moisture and temperature occur, at which time large numbers of infective larvae develop. Development occurs within four to six days at 80.6°F (27°C) but can take as long as one month when temperature and humidity are unfavorable. *Trichostrongylus* fare poorly in very hot, dry summer conditions. They are capable of hypobiosis as a survival mechanism.

Teladorsagia (*Ostertagia*) spp. are broadly adaptable, tolerating both colder winters and hotter, drier summers than *Trichostrongylus* spp. Overwintering of *Teladorsagia* (*Ostertagia*) larvae is successful as long as winters are not excessively dry. Survival is enhanced by slow release of infective larvae from disintegrating fecal pellets. This permits some larvae to persist on pasture as long as one year. Nevertheless, the *Teladorsagia* (*Ostertagia*) readily undergo hypobiosis when necessary. In regions of cold winter, larvae are conditioned to arrested development in the late autumn. In regions of hot, dry summer, larvae are conditioned in the spring.

Nematodirus spp. are well adapted to cold climates. They produce low numbers of ova, but survival rate is enhanced by the adaptation of larval development within the protective shell of the egg. They are extremely resistant to cold and dryness, and survive drought conditions. Hatching of ova of *N. filicollis* can begin in late autumn and continue through spring (Boag and Thomas 1975). *N. spathiger* does not show delayed hatching and behaves on pasture more like *Trichostrongylus* spp.

HOST-PARASITE INTERACTIONS. Two phenomena in the host-parasite relationship favor success for the parasite. These are hypobiosis and the periparturient egg rise phenomenon. The goat is not totally defenseless, however, and some host mechanisms are known to limit parasite infection. These are immunity, the phenomenon of self cure, and genetic resistance.

With regard to hypobiosis, environmental cues can trigger arrested development, as discussed in the preceding section. However, host factors may also trigger arrested development of ingested larvae. Host factors include immunity acquired from previous nematode infections, ingestion of large numbers of infective larvae, or a sizable pre-existing adult worm burden. Resumption of larval development also may be triggered by host factors, including depression of host immunity, removal of adult worm burdens by anthelmintic therapy, pregnancy-induced changes in hormone levels, and increased prolactin levels related to lactation. The latter two signals also are related to the phenomenon of periparturient egg rise.

The periparturient egg rise commonly observed in sheep results from maturation and ova production by previously arrested larvae, particularly of *H. contortus* and *T. circumcincta.* In temperate regions, when lambing occurs in the spring, ova deposited during the periparturient egg rise are largely responsible for the infections of grazing lambs that occur in summer. Overwintered larvae are usually killed off by the time lambs or kids are actively grazing. Lambs and kids in turn are more susceptible to infection than their older, possibly resistant dams. Lactation after pregnancy is a strong stimulus for renewed development of arrested larvae. Periparturient egg rise in goats has been documented. Fecal ova counts were highest in does one week after parturition and remained elevated for four weeks. This was independent of the season when they kidded, and no changes in fecal ova counts were observed in infected male goats sampled concurrently (Okon 1980). Increasing prolactin levels in goats have been reported to be associated with the periparturient egg rise (Chartier et al. 1998). It has also been postulated that a reduction in parasite-specific IgA antibodies in the dam associated with the transfer of maternal antibody to the colostrum around parturition may also facilitate the periparturient egg rise (Jeffcoate et al. 1992).

Immunity is an important host defense. While the neonate is immunologically naïve to parasites and colostral antibody does not appear to be protective, immunologic resistance to nematode parasites can develop over time and is enhanced by the continuous exposure to parasites. The development of resistance to infection with *Trichostrongylus colubriformis* in goats exposed to decreased weekly doses of infective larvae has been demonstrated experimentally (Pomroy and Charleston 1989).

The intensity of immunity with advancing age and parasite experience varies among domestic ruminant species. Goats show the weakest degree of immunity, sheep somewhat more, and cattle the most resistance to infection as adults. It is postulated that selection pressure on goats to develop parasite resistance is not as intense as in cattle and sheep because their browsing behavior in natural settings or under extensive range management systems does not demand strong resistance to parasite infection.

The greater susceptibility of goats is manifest in numerous studies. Significant worm burdens have been observed much earlier in kids than lambs, with worm burdens of more than 17,000 noted in kids between three and four weeks of age (McKenna 1984). When Merino sheep and Angora goats grazed the same contaminated pasture for four months, the goats had higher worm burdens of all species of gastrointestinal nematodes present except *Nematodirus* spp. (Le Jambre and Royal 1976). Adult goats carried mixed worm burdens similar in intensity to kids and yearlings in a survey of forty-seven dairy goat farms in New Zealand (Kettle et al. 1983). No difference in intensity of worm burdens or fecal egg counts was apparent between years one and two of pasturing when feral goats in New Zealand were pastured. In addition, when compared with sheep infections, worms infecting goats were more fecund, producing increased numbers of eggs per worm, and the return of high fecal egg counts was much quicker after anthelmintic therapy in goats than sheep (Brunsdon 1986). These findings suggest that direct extrapolation of sheep parasite control measures to goats may often be ineffective because of species differences in response to parasite infection. One practical consideration of these differences between goats and sheep is that adult goats represent a significant risk for the contamination of pastures and that goat parasite control programs, to be effective, must account for this risk (Hoste and Chartier 1998).

Any immunity to parasites that does develop in goats likely involves a complex interaction of mucosal and humoral antibody responses and cell mediated responses. For example, it was demonstrated that CD4+ T lymphocytes in goats contribute to immunity against *H. contortus* gut antigens, but that antibody works syn-

ergistically with the CD4+ T lymphocytes to confer this immunity (Karanu et al. 1997). Nonspecific inflammatory mediators can also play a role (Smith 1988).

Immunity to parasites is not absolute. It predictably declines in the periparturient period, and may also be impaired by concurrent illness or malnutrition. It has been demonstrated by experimental challenge with *H. contortus* that goats on a low plane of nutrition subsequently pass more ova in the feces than better-fed goats (Preston and Allonby 1978). Goats with paratuberculosis are predisposed in increased worm burdens, and in Africa, goats with *Trypanosoma congolense* show increased susceptibility to *H. contortus* infection (Griffin et al. 1981).

The phenomenon of "self-cure" is known in sheep that ingest large numbers of infective larvae of *H. contortus* and subsequently expel their existing adult worm populations. Because these animals usually become immediately re-infected, the adaptive significance in terms of parasite control is unclear. Nevertheless, it does serve as an indicator of the potency of the immune response of the host to infection. There are two reports suggesting that self-cure is observed in goats (Fabiyi 1973; Preston and Allonby 1978). However, more recent and extensive field observations, as well as experimental studies, suggest that if self-cure does occur naturally in goats, the response is weaker and less reliable than that seen in sheep (Kettle et al. 1983; Brunsdon 1986; Watson and Hosking 1989). The failure of self-cure in pastured goats may lead to increased levels of sustained fecal egg counts and a resulting increased intensity of pasture contamination compared with sheep.

A final host defense against parasites is genetic resistance, the existence of which has been studied extensively in sheep (Courtney 1986; Gruner and Cabaret 1988). Evidence for genetic resistance in goats to helminths has been reported as well. In East Africa, imported Saanen goats showed more resistance to challenge with *H. contortus* than either of two indigenous breeds, the Galla and East African (Preston and Allonby 1978). It was postulated that the European dairy breed has been selected for resistance to *H. contortus* through generations of grazing behavior, while the indigenous breeds, as innate browsers, have not. In a later study, the Small East African goat breed was shown to be more resistant than the Galla breed based on significantly lower fecal egg counts in the post weaning period (Baker et al. 2001). In India, during a natural outbreak of haemonchosis after unexpected heavy rains, small grazing or pen-fed breeds such as the Black Bengal goat were far less affected than large, browsing goats such as the Beetal and Jamunapari (Yadav and Sengar 1982). Thai native goats demonstrated greater resistance to *H. contortus* infection based on fecal egg counts and worm counts on necropsy than

Thai native (50%)-Anglo Nubian (50%) crosses (Pralomkarn et al. 1997).

In addition to breed differences, selection within breeds can also lead to greater resistance as indicated by long term studies involving large numbers of Creole goats in Guadeloupe (Mandonnet et al. 2001, 2006). Another extended study with cashmere goats in Scotland naturally exposed to mainly *Teladorsagia circumcincta* concluded that selection for reduced fecal egg counts was possible in breeding programs (Vagenas et al. 2002). Breeding for helminth resistance in small ruminants has been reviewed (Gruner, 1991; Baker 1998).

Hemoglobin type in sheep has been associated with resistance to helminth infection and this has also been studied in goats. Five hemoglobin phenotypes were identified in Red Sokoto goats in Nigeria and helminth egg counts on feces during the rainy season were correlated with these types. Significant differences in infection rates were observed, and hemoglobin types associated with high infection rates were less frequent in the older goat population than in the kid population, suggesting increased mortality among the more parasite-susceptible phenotypes (Buvanendran et al. 1981).

In summary, the development of gastrointestinal parasitism in goats depends on a complex interrelationship of parasite, host, and environmental factors, many known and some unknown. In general, the types and degree of parasitism that develop in goat populations may be predicted on the basis of geographic and climatic location, management system, and prevailing weather conditions. Nematodes, by evolving diverse strategies and rates of development, different mechanisms for feeding, and different predilection sites in the host alimentary tract, appear to have maximized their exploitation of the host, while minimizing competition among each other. This diversity encourages development of multiple nematode infections, which are the rule in goats.

The outcome of infection depends on host resistance, level of infection, variety and types of parasites involved, the development of parasite resistance to anthelmintics, and the extent of appropriate therapeutic intervention. Acute death, clinical disease, or subclinical infection with adverse effects on growth and lowered productivity are all possible outcomes. Worldwide, numerous studies on the causes of wastage in goats, particularly young goats, have confirmed that clinical gastrointestinal nematodiasis is a major cause of morbidity and mortality. However, specific studies concerning the impact of subclinical gastrointestinal nematodiasis on production parameters in dairy, fiber, and meat goats are comparatively scarce.

The impact of nematode parasites on dairy goat production is beginning to become clearer. One French

study indicates that elimination of gastrointestinal nematodes in lactating does by treatment with thiabendazole resulted in a 17.6% increase in milk production compared with untreated control goats (Farizy and Taranchon 1970). More recent studies have revealed a number of interesting findings. Subclinical parasitism with *H. contortus* and *T. colubriformis* in lactating does resulted in a decrease in body condition score as well as a persistent decrease in milk yield ranging from 2.5% to 10% as compared to uninfected controls. However, when the highest producers were assessed separately from other infected does, reductions in milk output ranged between 13% to 25.1% and had lower fat content. It was concluded that high producing goats had less resistance and/or resilience to parasite infection than lower producing goats, leading to more severe depression of milk output (Hoste and Chartier 1993). Further studies reinforced these observations that resistance to parasite infection differed according to level of milk yield in lactating does (Chartier and Hoste 1997; Hoste and Chartier 1998a).

Pathogenesis

Various pathogenic mechanisms are involved in gastrointestinal nematodiasis depending on the genera involved. The principal effect of hematophagous worms on the host is a progressive debilitating anemia. Blood feeders include *Haemonchus contortus* and *Mecistocirrus digitatus* in the abomasum, *Bunostomum trigonocephalum* and *Gaigeria pachyscelis* in the intestine, and *Trichuris* spp. in the cecum. Each *H. contortus* adult in the abomasum may be responsible for the loss of 0.05 ml of blood per day, either by active feeding or by moving to new feeding sites and leaving old sites to continue hemorrhaging. Death caused by acute blood loss is possible when infection rates are high (more than 10,000 adults per host) and development of large adult populations is synchronous, as can happen after arrested development.

In less severe infections, three stages of anemia may be recognized in infected hosts (Dargie and Allonby 1975). In the initial stage of blood loss, packed cell volume (PCV) may decrease markedly because intraluminal blood loss in the alimentary tract is not a strong trigger for hematopoiesis. In experimental haemonchosis of goats the PCV decreased from a mean of 29% to 16% within nineteen days of infection with 9,000 to 12,000 larvae (Al-Quaisy et al. 1987). In the second stage, regenerative erythropoiesis begins and the PCV stabilizes, albeit at less than the normal level, for as long as six to fourteen weeks. During this time, however, iron stores in the host are reduced by loss in the feces. In the final stage, the PCV begins to decrease again as erythropoiesis is impaired by the progressive iron deficiency. Concurrently, a steady loss of serum proteins occurs as a result of parasite feeding. Serum albumin levels may be maintained initially due to replacement by tissue catabolism, but hypoalbuminemia eventually develops, accompanied by cachexia and clinical evidence of hypoproteinemia such as intermandibular edema.

The remainder of the nematode parasites of the caprine alimentary tract are not primarily blood feeders, though blood constituents are gradually lost in the process of feeding during chronic or large-scale infection. In these cases, anemia does not occur acutely or reach the severity seen with the blood feeders. In the field, however, this distinction may not be evident because mixed infections of hematophagous and non-hematophagous parasites often occur.

Infective larvae of *Trichostrongylus axei* develop to adults within the abomasal mucosa and the adults feed there and lead to erosion of the mucosal epithelium, catarrhal inflammation, hyperemia, edema, and diarrhea. Plasma loss from the mucosal damage contributes to the hypoproteinemia seen with this infection.

Infective larvae of *Teladorsagia (Ostertagia) circumcincta* enter the gastric glands of the abomasum to undergo the third and fourth molts to adulthood. When synchronous maturation of large numbers of arrested larvae occurs (type II ostertagiasis), a severe gastritis results. Gastric glands become hyperplastic, intercellular tight junctions are weakened, hydrochloric acid secretion diminishes, and the pH of stomach content increases. One result of the pH change is that pepsinogen is not converted to pepsin and pepsinogen may leak across the abomasal mucosa to the circulating blood. Increases in blood pepsinogen support a diagnosis of Type II ostertagiasis. Other plasma proteins also are leaked from the abomasum. Hypoproteinemia and diarrhea are cardinal signs of ostertagiasis.

The *Trichostrongylus* spp. that infect the intestine tunnel under the mucosal epithelium to feed. This results in a protein-losing enteropathy accompanied by diarrhea. Larval stages can be as destructive as adult worms. Over time, marked villous atrophy occurs. The pathogenesis of *Nematodirus* spp. is similar.

Oesophagostomum columbianum presents a unique situation in small ruminants. Infective larvae burrow into the submucosa of the small intestine, encyst for the third molt, and then return to the intestinal lumen to migrate to the colon for the final molt. In first-time infections, this process occurs unremarkably. In previously exposed, sensitized hosts, however, encysted third-stage larvae produce a dramatic local inflammatory response around the cyst, leading to the formation of caseating nodules. The larvae inside may die or resume migration at a much later time. Nodules may occasionally rupture serosally, causing peritonitis, adhesions, and partial or complete obstructions of the

intestine. Even without rupture, widespread nodular formation may impair digestion, absorption, and passage of excreta. In addition, adult nodular worms can produce a severe catarrhal colitis with much mucus production. Diarrhea with mucus, weight loss, and hypoproteinemia occur in severe infections.

Anorexia with reduced feed intake is the most consistent finding in all forms of intestinal nematodiasis, and is accompanied by poor growth, decreased productivity, and weight loss. The causes of these host responses are complex and not fully understood. Failure of muscle growth in young animals results from a decrease in skeletal muscle synthesis, with a shift to increased albumin production by the liver to counteract ongoing protein loss. Muscle wasting in severely affected animals may be associated with muscle catabolism. In fiber-producing animals, fiber growth is also impaired by the shift in protein synthesis. In growing goats, bone growth is also compromised, possibly as a result of decreased intake of calcium and phosphorus and depletion from bones (Fitzsimmons 1966). The pathophysiological adaptations of the host to gastrointestinal parasitism have been reviewed (Hoste 2001).

Clinical Findings

Mixed parasitic infections are common and often it is not possible to attribute clinical signs to a single parasite. In general, infections with *Trichostrongylus*, *Teladorsagia (Ostertagia)*, *Cooperia*, and *Nematodirus* spp. produce a similar clinical picture. Young, grazing animals are most likely to be affected, particularly after weaning. A gradual, progressive loss of condition, poor growth, a dull attitude, and a decrease in feed intake are the most consistent findings. In more severe infections, a dark green to black diarrhea is evident, with staining of the hair and skin of the tail and perineal region. When the course is prolonged, intermandibular edema may develop secondary to hypoproteinemia. Chronically infected animals also develop a pot-bellied appearance, a rough, dry hair coat and flaky skin. Evidence of anemia is usually not pronounced. Deaths may be reported, and are usually spread out over a period of days or weeks. A more acute presentation may also be seen with type II disease when maturation of parasites resumes after arrested development.

Nodular worm (*O. columbianum)* infection may result in signs of abdominal pain such as hunched back and reluctance to move when nodule formation occurs and localized peritonitis results. Affected animals may be febrile. Occasionally, nodules may abscess and rupture. Pus may be passed per rectum if the rupture is intraluminal. Diffuse peritonitis may result if the rupture is intra-abdominal. In sheep, intussusceptions are reported sometimes in association with intestinal

nodules, but this has not been reported in goats. When nodule formation is minimal, as in first time exposures, signs of *O. columbianum* infection may be limited to diarrhea in young kids, or in older animals, intermittent passage of soft, mucus-laden feces flecked with blood and progressive loss of condition. Excessively mucoid feces with occasional blood is also associated with *Chabertia ovina* infection. Anemia is uncommon.

When hematophagous parasites such as *H. contortus* infect goats, clinical evidence of anemia predominates. When infections are massive, peracute haemonchosis can occur, with animals dying of gastric hemorrhage. Acute and chronic forms are more common. Affected animals exhibit marked pallor of mucous membranes and conjunctivae, and respiratory and heart rates may be increased. Hemic murmurs may occasionally be heard. Intermandibular edema, or "bottle jaw," is common. Weakness, reluctance to move, and exercise intolerance are observed. Constipation is more common than diarrhea in uncomplicated haemonchosis. In prolonged disease, weight loss is also a common finding.

Diarrhea may be seen after constipation in hookworm infections. Restlessness and pruritus, particularly on the legs, may accompany skin penetration and migration of hookworm larvae in the host.

Clinical Pathology and Necropsy

In goats with clinical gastrointestinal nematodiasis, serum albumin is consistently below 2.5 g/dl and often less than 1.5 g/dl. Total serum or plasma protein is also usually low, but in chronic cases, may be normal due to concurrent hypergammaglobulinemia. Anemia is a variable but important finding. Packed cell volumes below 9% can occur in severe haemonchosis. In less severe or chronic infections, PCVs in the range of 15% to 25% are likely and red cells may by hypochromic due to iron deficiency. A mild to moderate anemia may occur during severe or prolonged infections with non–blood-feeding nematodes.

When larvae of abomasal nematodes develop in the gastric glands and cause gastric inflammation, serum pepsinogen levels may be increased. Serum pepsinogen levels between 400 and 3,500 mU tyrosine were measured in naturally infected goats with mixed trichostrongylid burdens, including some with type II ostertagiasis (Tarazona Vilas 1984). In experimental ostertagiasis, serum pepsinogen in non-infected goats remained below 800 mU while levels between 1,000 and 1,500 mU were seen beginning fifteen days after infection. In experimental haemonchosis, serum pepsinogen in non-infected control goats also remained less than 800 mU while infection produced levels between 1,000 and 3,500 mU three days after larval challenge (Kerboeuf and Godu, 1981). Because clinical disease may occur in type II infections before adult nematodes pass eggs in the feces, the estimation of

pepsinogen may be a helpful diagnostic tool. These elevations can be highly variable in affected individuals, so several suspected animals should be tested to establish the presence of type II disease in the affected population. A slaughter house study in Sri Lanka demonstrated a strong correlation between increasing *H. contortus* abomasal worm burdens and increasing serum pepsinogen concentration in goats (Paranagama et al. 1999).

Baseline values for serum pepsinogen from normal, strongyle-free French Alpine and Saanen dairy goats have been reported (Chartier et al. 1993). Mean baseline serum pepsinogen for French Alpine goats under six months of age was 490 ± 175 mU tyr and for adults (more than twelve months of age) 825 ± 414 mU tyr. For Saanen goats it was 397 ± 135 mU tyr in young goats and 709 ± 274 mU tyr in adults. In addition to age and breed, farm and duration of lactation were identified as sources of variation. In general terms, serum pepsinogen levels above 1,000 mU tyr are indicative of significant abomasal strongylosis in goats.

Microscopic examination of feces for parasite ova by direct smear, flotation techniques, or quantitative methods can aid in diagnosis. Fecal specimens should be fresh or refrigerated. Most of the gastrointestinal nematodes have ova of approximately equal size (60 to 90 um long) and morphology, making specific etiologic diagnosis difficult. This requires *in vitro* cultivation of larvae and morphologic identification. Some infections, however, can be distinguished by ova structure. *Nematodirus* and *Marshallagia* spp. ova are distinctly larger than the rest, with average length of 160 to 180 um. *Trichuris* ova are barrel shaped, with obvious bipolar caps or plugs. *Skrjabinema ovis* and *S. papillosus* ova are smaller than average and contain fully developed embryos.

Ova may be counted by methods such as the McMaster technique, but direct correlations between egg counts and severity of infection do not always exist. The obvious example is type II disease in which serious damage to the abomasum may occur before adults even develop to produce ova. In severe *T. colubriformis* infection, marked clinical illness can result from larval feeding before patency of infection occurs (Fitzsimmons 1966). There also may be wide variation in the number of eggs produced by different species, and some prolific egg producers are not always the most serious pathogens. Precise parameters for ascribing significance to ova counts from goats, or using them as a basis for triggering therapeutic intervention, are not established, but a generally accepted guideline is that 0 to 500 eggs per gram (epg) represents a low parasite burden, 500 to 2,000 epg a moderate burden, and more than 2,000 epg a heavy burden. In a study from New Zealand, there was reasonable correlation between fecal egg counts and worm burdens in individual lambs within these three categories (McKenna 1981). In a Venezuelan study, a 10% to 30% mortality rate in goats was associated with *H. contortus* infection when fecal egg counts were in the range of 650 to 4,100 eggs per gram (Contreras 1976).

At necropsy, nematodiasis in general is suggested by emaciation with reduced fat reserves or serous atrophy of fat around the heart and kidneys. Subcutaneous edema may also be observed, especially in the intermandibular space, when hypoproteinemia is marked. In haemonchosis, the characteristic red- and white-striped females can be seen on the abomasal mucosa with careful inspection, although they may be absent in the extremely anemic goat at the time of death. Multiple sites of hemorrhage, ulceration, or both may be present. In *Teladorsagia* (*Ostertagia*) infection, the wall of the abomasum is edematous, and the mucosal surface has a grainy, "Moroccan leather" appearance caused by distension of gastric glands with developing larvae. An increase above the normal pH range of the abomasal content supports a diagnosis of severe type II disease.

For most of the intestinal worms, gross findings at necropsy are nonspecific, consisting only of catarrhal inflammation. The worms themselves are very difficult to see, especially in the small intestine, but may be larger in the large intestine. Preparation of mucosal impression smears and staining with aqueous iodine solution helps to establish the presence and intensity of the worm burden. A catarrhal enteritis and soft, unformed dark feces in the colon are consistent with most forms of nematodiasis. Transmural nodular lesions anywhere along the intestinal tract support the diagnosis of *O. columbianum* infection. Blood staining of intestinal content, particularly in the proximal small intestine, is suggestive of hookworm infection. Petechiation in the colon with edema and thickening of the colon wall are suggestive of *Chabertia ovina* infection. Extensive mucus covering the colonic mucosa is associated with adult *Oesophagostomum* spp. infection.

Diagnosis

Any combination of clinical signs of anemia, edema, poor body condition, and diarrhea should suggest gastrointestinal nematodiasis in goats. Evidence of increased fecal egg counts, heavy worm burdens in necropsied herd mates, or in the case of type II disease, characteristic Moroccan leather-type lesions of the abomasal mucosa, a preponderance of arrested fourth stage larvae, and/or increased serum pepsinogen levels, supports the diagnosis. When anemia is a predominant sign, various hemoparasites, hepatic fascioliasis, and cobalt or copper deficiency must also be considered in the differential diagnosis. Causes of anemia in goats are discussed in Chapter 7. In young goats, coccidiosis is the most important cause of diar-

rhea that must be differentiated from nematodiasis, but giardiasis and cryptosporidiosis should also be ruled out.

In certain regions, particularly Africa and southeast Asia, concurrent hemoparasite, gastrointestinal nematode, and liver trematode infections commonly occur in goats, so the clinician must look beyond gastrointestinal nematodiasis as the sole explanation for the clinical signs.

Subclinical parasitism often presents as poor growth in young animals or prolonged weight loss in adults with few additional clinical findings except in lactating goats, where a drop in milk production may be apparent. The differential diagnosis of progressive weight loss in goats is complex and is discussed separately in Chapter 15.

Treatment

Clinically affected individuals require supportive care to reverse the process of parasitic debilitation as well as anthelmintic therapy to eliminate existing infections. In severely debilitated goats, anthelmintics of low toxicity such as thiabendazole, fenbendazole, or ivermectin should be used because animals may be more susceptible to the adverse effects of drugs with a narrower margin of safety such as levamisole or organophosphate compounds.

Even when packed cell volumes are less than 10%, blood transfusions may not be a necessary aspect of therapy as long as animals are kept in quiet conditions of confinement with food and water provided. Perhaps more significant than anemia is the hypoalbuminemia. If serum albumin is below 1.5 g/dl, development of edema and anasarca will progress unchecked unless plasma or whole blood transfusions are administered to increase total serum protein. A good-quality, digestible hay or forage of high protein content should be fed during convalescence with a gradual supplementation of concentrate when available to restore body condition. Parenteral administration of iron as iron dextran may promote erythropoiesis because iron deficiency often results from prolonged parasitism.

A wide variety of anthelmintics have been used for treatment and prevention of gastrointestinal nematodiasis in goats. Some of the older drugs, notably the chlorinated hydrocarbons and organophasphates, are now rarely used because of toxicity and environmental safety issues. Other drugs are no longer available because markets for the products were limited and their distribution discontinued. Table 10.8 presents the anthelmintics that are currently in general use for goats, grouped according to anthelmintic class. Dosages appropriate for oral treatment of goats are given, because this is the preferred route of administration to delay development of resistance. Many of these anthelmintics, notably the benzimidazoles, also are useful in the treatment of cestode and trematode infections, nematode lungworm infections, and, in the case of the

Table 10.8. Dosages for various anthelmintics used orally in goats to treat gastrointestinal nematodiasis. (Dosing information for goats provided by Dr. Ray M. Kaplan, University of Georgia.)

Anthelmintic	Goat oral dose (mg/kg)	Comments
Benzimidazoles		
Thiabendazole	44	No longer marketed in US, but approved for use in goats.
Fenbendazole	10	
Oxfendazole	10	Basically the same drug as fenbendazole.
Albendazole	20	The recommended dose for nematodes is 20 mg/kg split into two equal doses (10 mg/kg each) given 12 hours apart. This is more effective than a single dose.
Macrocyclic lactones		
Ivermectin	0.4	
Doramectin	0.4	Doramectin has little efficacy advantage over ivermectin but has much longer persistence and can therefore promote resistance so its use in goats is discouraged.
Eprinomectin	0.4	Eprinomectin is available in the US only for topical administration.
Moxidectin	0.4	
Imidazothiazoles		
Levamisole	12	
Tetrahydropyrimidines		
Morantel tartrate	10	
Pyrantel tartrate	25	

macrocyclic lactones, arthropod parasites of the skin. The dosages and indications for these other infections are discussed in more detail in the pertinent sections of this book.

In most countries, the approved use of various anthelmintics in food producing animals is regulated by relevant government agencies. The list of drugs approved for use in goats varies considerably between countries as do the restrictions regarding slaughter withholding times and milk discard times after use.

In the United States, for example, only three anthelmintics, thiabendazole, fenbendazole, and morantel tartrate are approved for use in goats. Only thiabendazole is approved for use in lactating goats, with a milk discard time of ninety-six hours, but it is no longer marketed. In France, fenbendazole, oxfendazole, and febantel are approved for use in lactating goats with no milk discard required when prescribed doses are used. When resistance to these drugs has been documented by a veterinarian, then it is permitted for the veterinarian to use anthelmintics that are approved for use in lactating cattle with no withdrawal time, such as eprinomectin. However when used in goats, it is necessary to observe a seven-day milk withholding time in accordance with European Union "prescribing cascade" regulations. These regulations are akin to off-label, minor species drug use rules in the United States aimed at limiting the occurrence of drug residues in foods of animal origin.

BENZIMIDAZOLES AND PRO-BENZIMIDAZOLES. The benzimidazoles are a useful group of broad-spectrum anthelmintics, with the parent compound being thiabendazole. The pro-benzimidazoles, febantel, and thiophanate are broken down metabolically to benzimidazoles by the host. Both fenbendazole and the pro-benzimidazole febantel are metabolized in the goat to oxfendazole. In general, where resistance has not developed, these drugs are highly effective against adult and active immature stages of *Haemonchus*, *Teladorsagia* (*Ostertagia*), *Trichostrongylus*, *Cooperia*, and *Chabertia* spp., moderately effective against *Oesophagostomum*, *Nematodirus*, *Bunostomum*, *Gaigeria*, and *Strongyloides* spp., and poorly effective against *Trichuris* spp. (Bali and Singh 1977; Kirsch 1979; Sathianesan and Sundaram 1983).

Importantly, the newer compounds oxfendazole, febantel, fenbendazole, and albendazole are highly effective against arrested larvae of *Teladorsagia* (*Ostertagia*) and are useful in the control of type II disease. The benzimidazoles are ovicidal as well. This means that transfer to clean pastures after treatment can be made with minimal risk of contamination and subsequent re-infection.

The benzimidazoles, often referred to as "white drenches" due to their color, are only available for oral use, but a number of oral formulations are available including boluses, pastes, drenches, and feed or salt supplements. The spectrum of activity of these drugs can be a function of dose. Fenbendazole is effective against tapeworms in goats at 15 mg/kg but not at the usual sheep and cattle nematode dose of 5 mg/kg. Parbendazole is effective against *Oesophagostomum* and *Trichostrongylus* spp. at 10 mg/kg, *Teladorsagia* (*Ostertagia*) and *Strongyloides* spp. at 20 mg/kg, and *Nematodirus* spp. at 30 mg/kg (Theodorides et al. 1969). Whipworms that are not commonly killed at recommended doses of benzimidazoles often may be removed by doubling the recommended doses. Albendazole administered either in a single dose of 7.6 mg/kg or two daily doses of 3.8 mg/kg was highly effective against *Teladorsagia* (*Ostertagia*) and *Trichostrongylus* spp., but the latter dose regimen was less effective against *Oesophagostomum venulosum* and neither regimen was effective against *Nematodirus* spp. (Pomroy et al. 1988). A slow-release capsule formulation of albendazole has been evaluated in dairy goats (Chartier et al. 1996a). The capsule contains 3.85 g of the drug and is designed to release 36.7 mg/day for 105 days. This would provide at least 0.5 m/kg of albendazole for goats under 70 kg, which is sufficient to control *Teladorsagia circumcincta*, the dose-limiting species. For non-resistant parasite strains, the treatment eliminated 92% to 99% of existing infections and prevented new infections for eighty-five to ninety-one days post treatment.

As a group, these drugs are quite safe. Thiabendazole has been used safely in goats at doses up to 100 mg/kg (Bell et al. 1962). In toxicity studies of Angora goats, a death loss of 20% was observed at doses of 815 mg/kg (Snijders 1962). It has been suggested that the benzimidazoles can enhance the activity of thiaminase in the gut, thereby increasing the risk of polioencephalomalacia, but field confirmation is limited (Roberts and Boyd 1974). There is concern that overdosing with oxfendazole and its precursors, albendazole, fenbendazole, or febantel, can produce teratogenic effects, particularly if given in the first forty-five days of gestation; fetal defects have been observed in rats. Goats given either febantel or fenbendazole at 50 mg/kg during early pregnancy, however, had no embryotoxic or teratogenic effects (Savitskii 1984). Cambendazole and parbendazole have produced teratogenic effects in sheep in early gestation. This has not been substantiated in goats. However, cambendazole may be toxic when administered to goats on a high grain ration. Grain should be withheld for twenty-four hours before treatment (Howe 1984). Thiabendazole has antimycotic properties and is partially cleared in the milk. It can inhibit inoculation molds used in cheese making.

The pharmacokinetics of at least some benzimidazoles and thus the dose rates are different in goats than in sheep. At an oral dose of 5 mg/kg fenbendazole is absorbed relatively poorly from the gut of goats, with 43% of the dose excreted unchanged in the feces.

Peak mean plasma concentration was 0.13 µg/ml compared with 0.40 µg/ml in sheep (Short 1987). At a dose of 5 mg/kg, fenbendazole was undetectable in the milk of lactating does by forty-eight hours, and by seventy-two hours at a dose of 25 mg/kg (Waldhalm et al. 1989).

MACROCYCLIC LACTONES. The macrocyclic lactone anthelmintic class is comprised of avermectins and milbemycins, all of which are derived from soil microorganisms of the genus *Streptomyces*. They are often referred to as the "clear drenches." The commercially available products with use reported in goats include the avermectins ivermectin, doramectin, and eprinomectin, and the milbemycin moxidectin. Despite a comparatively high cost, avermectins are very popular with livestock owners because they have a very broad-spectrum of action against gastrointestinal and pulmonary nematodes including adult worms, infective larvae, and arrested or hypobiotic larvae, as well as activity against some ectoparasites, including mange mites and sucking lice. They also have a persistent effect, continuing to control new infections of gastrointestinal nematodes for up to several weeks following administration.

Ivermectin is the oldest compound in this class, the most studied and most widely used. The drug is available for oral, subcutaneous, or topical use. Pharmacokinetic studies indicate that the bioavailability of ivermectin in goats is less than that of sheep and cattle (Alvinerie et al. 1993; Lanusse et al. 1997; González et al. 2006). Accordingly, the current recommended dose for goats is 300 to 400 µg/kg bw, which is one and a half to two times the cattle and sheep dose (200 µg/kg). A double sheep dose requires an extension of the meat withdrawal time to fourteen days and a milk withdrawal of nine days (Baynes et al. 2000). The drug has a wide margin of safety. There are anecdotal reports of goat owners giving an entire tube of ivermectin paste formulated for an adult horse to a goat with no ill effect. Ivermectin, however, may be highly irritating to some individual goats when given subcutaneously. These goats may run around frantically after injection and attempt to rub the injection site vigorously against available objects. If the injection is given in the neck, they may throw their heads back, giving the suggestion of opisthotonos. However, the reaction invariably subsides within several minutes and no lasting local or systemic effects have been reported. The drug is highly lipophilic and as such, it concentrates in milk. Therefore it cannot be used in lactating animals, and if given subcutaneously in error, a meat withdrawal time of 35 days and milk withdrawal of 40 days are recommended (Baynes et al. 2000).

Eprinomectin is the least lipophilic of the macrocyclic lactones. Because of its partitioning profile between serum and milk, only 0.1% of the total topical dose is eliminated in the milk of cows and it is approved for use lactating dairy cattle with no milk withholding time worldwide. By contrast, 2.9% of the total subcutaneous dose of doramectin was recovered from milk, while 5.7% and 22.5% of an oral or subcutaneous dose of moxidectin were recovered from milk in goats (Carceles et al. 2001). Pharmacokinetic studies indicate that the systemic availability of eprinomectin is significantly lower in goats than in cattle (Alvinerie et al. 1999). Also, it has been noted that the mean residence time for the presence of eprinomectin in the lactating goat is markedly less (2.67 days) than in non-lactating goats (9.42 days) and that 0.3% to 0.5% of the total drug dose given is recovered in the milk with residues never exceeding the maximum acceptable limit set for cattle (Dupuy et al. 2001).

There is good evidence that the effective dose of eprinomectin in goats is 1 mg/kg, which is twice the established cattle dose of 0.5 mg/kg. In one study, at the dose of 0.5 mg/kg, applied topically, the drug had limited effectiveness against *T. colubriformis* in experimentally infected goats (Chartier et al. 1999), while in another study of naturally infected goats, fecal egg counts were reduced only 59.5% in adults and 89.9% in yearlings after topical treatment with the cattle dose (Gawor et al. 2000). In contrast, eprinomectin was 100% effective in eliminating existing worm burdens of *T. circumcincta* and *T. colubriformis* when given at a topical dose of 1 mg/kg (Chartier and Pors 2004). In an Italian study, reduction in fecal egg counts for naturally infected goats at seven days post treatment was 90% for goats receiving 0.5 mg/kg topically and 99.5% for goats receiving 1 mg/kg (Cringoli et al. 2004). Though eprinomectin is available only as a topical formulation, studies indicate that subcutaneous administration is two and a half times more efficient than topical administration in terms of the amount of drug present in the goat (Lespine et al. 2003). Moxidectin, though not approved in goats, has been reported to be effective at a dose of 0.2 mg/kg bw (Pomroy et al. 1992; Praslicka et al. 1994). At that dose, the subcutaneous route is preferred to the oral route in goats due to a superior pharmacokinetic profile of the parenteral route. If given orally to goats, the dose should be doubled to 0.4 mg/kg (Kaplan 2006).

A notable aspect of the macrocyclic lactones for use in grazing animals is their persistence of efficacy. Some studies have been done specifically on the persistence of eprinomectin in goats. In naturally infected goats in Italy with mixed infections of *H. contortus*, *T. circumcincta*, *T. colubriformis*, and *O. venulosum*, topical treatment with eprinomectin at 1 mg/kg resulted in fecal egg count reductions of 99.5% at seven days post treatment, 99.6% at fourteen days, 99.7% at twenty-one days, and 96.7% at twenty-eight days (Cringoli et al. 2004). In a Polish study, fecal egg count reductions of 97.6% in adult goats and 88.5% in yearling goats were recorded at fifty-six days after topical dosing at 1 mg/kg (Gawor et al. 2000).

Persistence of anthelmintic effect has also been assessed for doramectin and moxidectin in goats. Moxidectin given orally at 0.2 mg/kg bw was 99.7% effective against *H. contortus* at twenty-nine days post treatment and 100% at twenty-two days. There was also a high degree of protection at twenty-nine days (94.9%) against *Teladorsagia circumcincta* but no protective effect at all was seen against *Trichostrongylus colubriformis* (Torres-Acosta and Jacobs 1999). A failure to protect completely against *T. colubriformis* was also noted in goats with eprinomectin (Chartier et al. 1999). Doramectin at a dose of 0.2 mg/kg SQ protected goats against *H. contortus* for fourteen to twenty-five days post treatment. This was about half the time of protection recorded in cattle, suggesting that the proper doramectin dose for goats requires further calibration (Molina et al. 2005). While persistence of efficacy may be deemed desirable by producers because it potentially reduces the frequency of treatments, the downside of persistence is that it may contribute to the selection of resistant parasites.

Nematode resistance to the macrocyclic lactones in goats is now widely reported. Ivermectin- and moxidectin-resistant *Trichostrongylus* spp. and *Teladorsagia* (*Ostertagia*) spp. were identified by fecal egg count reduction tests and larval cultures in goats in Australia (Veale 2002). In another report from New Zealand, *Teladorsagia* (*Ostertagia*) spp. in goats were resistant to ivermectin and moxidectin each given orally at 0.2 mg/kg bw (Leathwick 1995). Resistance to eprinomectin has been recorded in *H. contortus* in dairy goats in Brazil. While eprinomectin had never previously been used in the herd, ivermectin and moxidectin had been used, indicating the development of cross resistance to this relatively new drug within its class (Chagas et al. 2007).

CHOLINERGIC AGONISTS. There are two separate classes of anthelmintics that function as cholinergic agonists by interruption of nicotinic acetylcholine receptor functions in the nematode. These are the imidazothiazoles and the tetrahydropyrimidines. Levamisole, an imidazothiazole, is the most widely used drug in this group and may be commonly referred to as the "yellow drench." The spectrum of activity of these drugs against gastrointestinal nematodes is similar to that of the benzimidazoles and may be better than some of the benzimidazoles against *Nematodirus* and *Bunostomum* spp. However, there is minimal effect against arrested larvae and they are not ovicidal. They also have no activity against trematodes or cestodes. Levamisole is the L-isomer of tetramisole, which contains equal amounts of the D and L forms. Only the L form has anthelmintic properties. The racemic mixture was originally marketed as tetramisole at a recommended dose of 15 mg/kg. Currently, levamisole is marketed in the pure levo (L) form at a recommended dose of

8 mg/kg. The drug is available for either oral or subcutaneous use. An oral dose of 12 mg/kg has been established as the effective dose in goats (Coles et al. 1989).

The margin of safety is narrow for levamisole so it must be administered carefully. Even at recommended doses, some goats may demonstrate transient symptoms of depression, muscle fasciculation, salivation, or frothing at the mouth. Clinical signs of intoxication were consistently produced in Angora goats at a dose of 32 mg/kg and deaths occurred at 64 mg/kg (Smith and Bell 1971). Signs of overt toxicity include head shaking, lip smacking, increased salivation, muscle tremors, incoordination, hyperesthesia, clonic convulsions, increased respiratory rate, dyspnea, increased urination and defecation, collapse, and death. Many of these signs may be reversed by administration of atropine sulfate at intravenous doses up to 3 mg/kg, but death may still occur despite this intervention (Hsu 1980). Abortion has been ascribed to levamisole usage in goats at therapeutic levels but no direct link has been substantiated. Administration of levamisole orally at the recommended dose rate of 12 mg/kg bw is highly effective and not associated with any signs of toxicity (Chartier et al. 2000).

The pharmacokinetics of levamisole in goats are notably different than in sheep. Peak plasma concentrations are roughly equivalent in both species after subcutaneous or intramuscular administration but are only 59% of the ovine level in goats after oral administration. Subsequent plasma clearance is two to four times faster in the goat, depending on route of administration (Galtier et al. 1981). These differences have been cited as the cause of so-called treatment failures in the field (Gillham and Obendorf 1985). The elimination half-life of levamisole in goats is 222 minutes. The majority (55%) is excreted in urine, and 30% in feces. Less than 1% of the total dose is excreted in the milk (Nielsen and Rasmussen 1983). Goats exhibit a genetic polymorphism regarding the clearance rate of levamisole that may affect efficacy in field use (Babish et al. 1990).

The tetrahydropyrimidines include salts of pyrantel and morantel. Pyrantel tartrate at a dose of 25 mg/kg in goats was reported to be 98% to 100% effective against *Trichostrongylus*, *Ostertagia*, *Nematodirus*, *Bunostomum*, and *Strongyloides* spp., 97% effective against *Cooperia*, 91% against *Haemonchus*, and 70% against *Oesophagostomum* (Martinez Gomez 1968). However, in another experimental study in goats, the drug was highly effective against the abomasal worms *H. contortus* and *T. circumcincta*, but only 55% effective in goats against the intestinal worm, *T. colubriformis*, even at a dose of 40 mg/kg. This was due to host factors and not resistance in the parasite (Chartier et al. 1995). Morantel is a methyl analog of pyrantel and has become more

commonly used. It can be used at a lesser dose than pyrantel (12.5 mg/kg) with equivalent efficacy against gastrointestinal nematodes (Anderson and Marais 1972). In experimental infections of goats and sheep, morantel citrate at an oral dose of 10 mg/kg was less effective against *Teladorsagia* (*Ostertagia*) spp. and *Trichostrongylus* spp. in goats than in sheep, suggesting that dosages specific for goats need to be established by pharmacokinetic studies (McKenna and Watson 1987; Elliot 1987). Morantel tartrate given orally at 10 mg/kg to goats was highly effective against *Haemonchus*, *Bunostomum*, and *Oesophagostomum* spp. but showed little effect against *Strongyloides papillosus* and *Trichuris* spp. (Chandrasekharan et al. 1973). Morantel is available as a sustained release bolus for continuous parasite control in cattle on pasture, but this formulation should not be used in goats or sheep.

When resistance is encountered to levamisole, it is presumed that such nematodes are also resistant to morantel; however, the converse may not be true. In an Australian study, trichostrongyles resistant to morantel remained susceptible to levamisole. It was recommended that morantel should be used in deworming programs until resistance is detected, at which time levamisole may be substituted for improved efficacy (Waller et al. 1986).

ORGANOPHOSPHATES. Haloxon, coumaphos, and naphthalophos are the organophosphate anthelmintics that have received the most attention in goats. These drugs are most effective against *Haemonchus*, *Teladorsagia* (*Ostertagia*), and *Trichostrongylus* spp., moderately effective against *Nematodirus* spp., and have little or no efficacy against other gastrointestinal nematodes (Andersen and Christofferson 1973; McDougald et al. 1968). They have been available in drench, paste, bolus, and feed-additive formulations for oral use only. Coumaphos is also available as a topical pour-on, which should not be used in lactating does.

When used at prescribed doses, the acute toxicity potential of these compounds is low. However, haloxon has been demonstrated as a cause of delayed neurotoxicity in sheep, particularly Suffolk sheep and other breeds that may lack an esterase necessary to degrade haloxon. The condition manifests as progressive ataxia and paresis several weeks after administration of the drug. Since this discovery, haloxon has fallen into disfavor and has been removed from the market in many countries. There is no definitive evidence that the same syndrome occurs in goats, although there is the suggestion that it has been observed in Angora goats in Texas (Wilson et al. 1982).

SALICYLANILIDES. These compounds, which include closantel, oxyclosanide, and rafoxanide, have efficacy primarily against trematodes and not nematodes and are discussed in more detail in the section on trematode infections of the liver. They are mentioned here because many show some efficacy against *H. contortus.* Because *H. contortus* resistance to other classes of broad-spectrum anthelmintics is increasing, salicylanilides may be useful in control of haemonchosis. In the humid tropics, haemonchosis and fascioliasis may be the primary parasite problems, making salicylanilides an appropriate therapeutic choice where resistance has not developed. Regarding toxicity, blindness caused by degeneration of the optic tracts has been reported in kids overdosed with closantel at four to thirteen times the recommended dose rate of 7.5 mg/kg (Button et al. 1986).

MISCELLANEOUS ANTHELMINTICS. Phenothiazine is one of the oldest drugs used in control of caprine nematode infection and it has been largely replaced by newer drugs. The drug is administered orally in a micronized form because small particle size increases efficacy. Bolus, drench, and powdered forms have been available and the powder has been incorporated into salt blocks for extended administration to inhibit nematode ova production. However, anthelmintic resistance is promoted by the practice and resistance of *H. contortus* in goats to phenothiazine was reported as early as 1967 (Colgazier et al. 1967).

Phenothiazine can produce photosensitization and abortion in goats. Phenothiazine sulfoxide produced in the alimentary tract is the photosensitizing agent. It is normally detoxified by the liver. However, in liver damage or with overdosing, the sulfoxide may concentrate in the skin and aqueous humor. Even at therapeutic doses, healthy Saanens and other light-skinned goats may show erythema and edema of the cornea and eyelids if exposed to direct sunlight after treatment. The same may occur to people handling the drug for administration to goats. The metabolites of phenothiazine excreted in urine and milk impart a pinkish color to these fluids and may stain the hair when animals lie in urine-soaked bedding. Abortion has been reported in goats given phenothiazine during the last three weeks of pregnancy (Osweiler et al. 1988).

Anthelmintic Resistance

Unfortunately, at present, there are no assurances that use of the anthelmintics just discussed will provide effective therapy for goats with clinical gastrointestinal nematodiasis. Parasite resistance to anthelmintics is widely recognized as a growing problem in the treatment and control of gastrointestinal nematodiasis in small ruminants (Coles 1986; Waller 1987; Wolstenholme et al. 2004; Kaplan 2006; Fleming et al. 2006). It has received more attention in sheep but is increasingly identified in goats. Early reports of the problem in goats were from Australia (Barton et al. 1985), New Zealand (Kettle et al. 1983), the United States (Uhlinger et al. 1988), France (Kerboeuf and Hubert 1985), and the United Kingdom (Scott et al. 1989).

In New Zealand surveys, the prevalence of nematode resistance was much higher on dairy goat farms than on sheep farms, as was the number of resistant species found. Based on post drenching larval cultures, resistant parasites included *Haemonchus*, *Teladorsagia* (*Ostertagia*), and *Trichostrongylus* spp. On some premises, the nematodes were resistant to anthelmintics in both the benzimidazole and cholinergic agonist classes. The degree of resistance on farms was positively correlated with the frequency of drenching, which was, on average, 12.5 times a year for kids and 13.4 times a year for adults (Kettle et al. 1983).

The anthelmintic resistance problem in goats has grown even more serious since the 1990s, with additional reports of benzimidazole resistant *Teladorsagia (Ostertagia)* spp. and *H. contortus* in goats in Scotland (Jackson et al. 1992) England and Wales (Hong et al. 1996), benzimidazole resistance for multiple trichostrongyles in goats in France (Beugnet 1992; Chartier et al. 1998a, 2001), avermectin resistance in *Teladorsagia* (*Ostertagia*) spp. of Angora goats in New Zealand (Badger and McKenna 1990) and trichostrongyles of dairy goats in Argentina (Aguirre et al. 2002).

Of greatest concern is the increased documentation of multiple anthelmintic resistance on goat farms involving two or more of the three major classes of broad spectrum anthelmintic drugs: the benzimidazoles; the cholinergic agonists such as levamisole (an imidazothiazole) and morantel (a tetrahydropyrimidine); and/or, the macrocyclic lactones, such as ivermectin (an avermectin) and moxidectin (a milbemycin).

Multiple resistance of one or more trichostrongyles to all three classes of broad-spectrum drugs has been reported in Saanen dairy goats (Watson and Hosking 1990) and purebred goats of unspecified breed in New Zealand (West et al. 2004), Angora goats in the United Kingdom (Coles et al. 1996), mixed breed meat goats in Virginia (Zajac and Gipson 2000), Spanish meat goats and Nubian cross dairy goats in Georgia (Terrill et al. 2001), and meat and dairy goats in Georgia and South Carolina (Mortensen et al. 2003).

In Kenya, resistance of *H. contortus* in goats was documented against benzimidazoles, levamisole, and a different third class of anthelmintic, the salicylanilides, represented by rafoxanide, while ivermectin remained effective (Waruiru et al. 1998). Notable with regard to the implications for international trade in livestock is a report of resistance to the three major classes of anthelmintic for *Trichostrongylus* spp. and *Teladorsagia (Ostertagia)* spp. in cashmere and Angora goats imported into the former Czechoslovakia from New Zealand (Varady et al. 1993). There is also a report from Switzerland on resistance of *H. contortus* to benzimidazoles and ivermectin in Boer goats imported from South Africa (Schnyder et al. 2005).

Some presumed cases of anthelmintic resistance may be in fact treatment failures that occur when anthelmintics are under dosed, or when doses prescribed for sheep are assumed to be effective in the goat. In an Australian study, *Haemonchus*, *Trichostrongylus*, and *Teladorsagia* (*Ostertagia*) nematodes in naturally infected dairy goats demonstrated marked apparent resistance to albendazole, fenbendazole, levamisole, morantel, naphthalophos, and phenothiazine used at prescribed sheep doses. However, when the surviving larvae were cultured and introduced into worm-free sheep, infections were effectively cleared by these same anthelmintics at the same doses (Hall et al. 1981). Similarly, in France, grazing goats treated with benzimidazoles continued to pass ova of *Haemonchus*, *Trichostrongylus*, and *Ostertagia*, while identically treated, commingled sheep had a total suppression of egg output (Kerboeuf and Hubert 1985). In the United States, thiabendazole administered at the same dose to commingled sheep and goats was moderately effective against *Haemonchus* in sheep but totally ineffective in goats (Andersen and Christofferson 1973). Similarly, the bioavailability of oxfendazole is reported to be less in goats than in sheep after a single equivalent oral dose (Bogan et al. 1987). Differences in pharmacokinetics and bioavailability between sheep and goats for other anthelmintics have been documented as well, such as for levamisole (Galtier et al. 1981), fenbendazole (Short 1987), albendazole (Hennessy et al. 1993), closantel (Hennessy et al. 1993a), and the macrocyclic lactones (Chartier et al. 2001a).

These results indicate that many anthelmintics do not achieve therapeutic levels in goats at commonly used sheep dosages. In fact, one study has definitively demonstrated that *Trichostrongylus* presumed to be resistant to levamisole in goats were indeed sensitive to levamisole *in vitro*. The presumed resistance was in essence a treatment failure because levamisole given to goats at the sheep dose of 7.5 mg/kg did not maintain adequate plasma levels for sufficient duration to be effective against this particular parasite (Gillham and Obendorf 1985).

The pharmacokinetic differences between sheep and goats for common anthelmintics have become widely acknowledged. Many authorities now routinely suggest that when goat doses for an anthelmintic are not specifically given, the sheep dose should be increased by one and a half to two times for use in goats, with the caveat that potentially toxic drugs such as levamisole should be given to goats only at a maximum of one and a half times the sheep dose per oral route (Smith 2005).

Over time, treatment failures contribute to the development of anthelmintic resistance, as suboptimal dosing favors the selection and survival of subpopulations of resistant parasites. Nematode parasites are

also capable of developing an intrinsic resistance to anthelmintics that is genetically based. The mechanisms by which parasite resistance develops against different classes of anthelmintics in different species of nematodes are not fully understood, but some are known. Resistance to avermectins by *H. contortus* for example, is reported to be controlled by an autosomal, completely dominant gene in larvae, but in adult worms, its expression is sex-influenced, with males having lower resistance than females (Le Jambre et al. 2000). Benzimidazole resistance in trichostrongyles of small ruminants involves a mutation of phenylalanine to tyrosine at residue 200 of the isotype 1 β-tubulin gene and is a recessive trait (Elard and Humbert 1999).

It is clear that the use of any anthelmintic selects for populations of nematodes that can resist its lethal effects and that repeated use of that anthelmintic over time in a herd or flock results in the emergence of parasite populations that are widely resistant to that anthelmintic. The severity of the problem is exacerbated by the fact that when a population of parasites has evolved that shows resistance to a given anthelmintic, that population generally manifests resistance to all drugs in that anthelmintic class because they share a similar or identical mechanism of action. It is therefore necessary to switch to drugs from a different class to overcome a resistance problem, although there is no guarantee that populations resistant to other classes of drugs have not also evolved. In fact, as discussed above, there are already numerous reports of parasite populations in goats that have developed resistance to all three major classes of anthelmintic drugs.

Regrettably, anthelmintics have become a victim of their own success. When modern anthelmintics emerged in the 1960s and 1970s, they were so effective and relatively inexpensive that many producers came to depend on anthelmintics as the sole or predominant tool for parasite control, often applying frequent, repeated dosing on a calendar basis without regard to strategic or tactical justification. Such indiscriminate use was an engine driving the development of anthelmintic resistance, because repeated use of an anthelmintic selects for the survival of parasite populations that are resistant to it. There are now serious concerns that if anthelmintic resistance continues to spread, effective products will no longer be available in the near future. This concern is exacerbated by the fact that development of new classes or types of anthelmintics for use in ruminant livestock no longer appears to be a priority of the veterinary pharmaceutical companies (Geary et al. 1999). Therefore, many authorities are emphasizing techniques and practices that can be employed to slow the development of anthelmintic resistance and promote wise use of the anthelmintics

that are still effective (Kaplan 2006; Van Wyk et al. 2006). A summary of these suggestions follows.

MANAGE THE INTRODUCTION OF NEW STOCK. Resistant parasites are most often introduced into a herd or flock via the purchase of new stock. All new animals should be dewormed with double doses of broad-spectrum, non-toxic anthelmintics from at least two different classes before adding them to the existing herd or flock. They should be held in a dry lot for at least three days after treatment so that infective eggs not killed by non-ovicidal drugs are passed before turnout to pasture. Ideally, they should be held out for ten days until a follow-up fecal examination confirms that egg counts approach zero. These animals should be turned out to a dirty pasture so that any eggs from resistant worms that they may still be carrying will be diluted by eggs/larvae already on pasture.

DETERMINE THE RESISTANCE PROFILE OF THE HERD. Given the current extent of anthelmintic resistance, particularly with regard to benzimidazoles, rational and effective use of anthelmintics requires knowledge of existing resistance patterns in a herd or flock. Several tools are available to accomplish this and the subject has been reviewed (Taylor et al. 2002; Coles et al. 2006). The most commonly used tests in small ruminants are the fecal egg count reduction test (FECRT) and the larval development assay (LDA) (Kaplan 2006).

As the name implies, the FECRT involves counting of parasite ova in feces before treatment with a specific class of anthelmintic, and then again at a prescribed time following treatment to determine response to therapy based on significant reduction of egg counts. The test is conducted as follows (Coles et al. 2006).

- Distribute goats into groups either randomly or balanced based on preliminary egg counts.
- Use animals three to six months of age or, if older, with egg counts greater than 150 eggs per gram (epg). Identify animals individually.
- Use at least ten animals per group if possible. The number of groups depends on the number of classes of anthelmintic to be tested. An untreated control group should be included to account for natural changes in egg counts possible during the period of the test.
- Collect 3 to 5 g of feces from each animal into separate containers, identifying samples to correlate with specific animals.
- Count eggs using the McMaster technique as soon as possible after collection.
- Only store at 4°C (39.2°F) for no more than twenty-four hours if samples will also be used for larval culture.
- Individually weigh animals and give the established or presumed caprine dose orally over the base of the tongue.

- Collect post treatment fecal samples at the following intervals: Levamisole group, three to seven days; benzimidazole group, eight to ten days; macrocyclic lactones group, fourteen to seventeen days, as discussed further below.
- Count eggs using the McMaster technique as soon as possible after collection.
- Greater than 95% reduction in fecal egg counts for a group indicates susceptibility of the parasites present and that the anthelmintic tested should still be useful for parasite control in the herd.
- When resistance is encountered, a composite fecal sample of 50 g from group members should be collected for larval culture and identification to determine the resistant species of parasites.

With regard to the timing of the post treatment collection of fecal samples, the intervals indicated above were proposed to make allowances for the temporary suppression of egg production which sometimes occurs after treatment even if adults are not killed. However, these proposed intervals are acknowledged to be best guesses (Coles et al. 2006). Where more than one anthelmintic type is being evaluated in a herd, the longer interval of fourteen days should be used with the understanding that levamisole does not have a high efficacy against intestinal L4 stages of nematode parasites. A post treatment interval of ten to eleven days may be best for assessment of levamisole by FECRT if multiple drugs are being evaluated simultaneously.

An alternative to FECRT is the microagar larval development assay (LDA), which is akin to antibiotic sensitivity testing. Eggs are harvested from the fecal sample and larvae are cultured from the eggs in microtiter plates with different anthelmintics added to the wells. Inhibition of larval growth indicates effectiveness of the anthelmintic, while development of the larvae indicates resistance. Surviving larvae are then identified by species. The LDA is more convenient for owners and practitioners because a single composite fecal sample from ten to twenty goats in the herd can be submitted one time for evaluation. The mean fecal egg count in the sample should be greater than 350 epg, but samples with a mean greater than 500 epg are preferred.

The one time cost for the LDA is fairly high, but when weighed against the time and expense of multiple sampling and egg counting needed to test for all three major anthelmintic classes using the FECRT, the cost is reasonable. In the United States, the LDA is offered by the University of Georgia under the original Australian marketed name, Drenchrite®, and information about the test and sample submissions is available at the website of the Southern Consortium for Small Ruminant Parasite Control (SCSRPC), www.scsrpc.org.

ADMINISTER AND DOSE ANTHELMINTICS APPROPRIATELY. The persistence of infection after anthelmintic therapy is not always caused by the development of anthelmintic resistance. Inadequate or improper dosing is a major cause of treatment failure and may be due to several causes. Ideally, anthelmintics should be administered on a per weight basis to each animal. Practically, this is not commonly done, because weights are guessed or average doses administered when large numbers of animals require treatment. To minimize this problem, animals should be grouped according to size for drenching and the weight of the largest animal in the group accurately determined. All animals in the group should be given the dose calculated for the largest individual in the group. Doses specific for goats should be used when known based on scientific reports or proven, goat-specific manufacturers recommendations. However, if goat specific dosages are not available, then it is suggested that sheep dewormers be used at one and a half to two times the recommended sheep dose to account for pharmacokinetic differences in the two species (Smith 2005). For anthelmintics with potential toxicity, such as levamisole or moxidectin, only a one and a half time increase should be used.

Automatic dosing or drenching equipment should be checked before use to ensure the accuracy of doses dispensed. The tip of the drenching instrument should be carefully placed so that the anthelmintic is deposited over the base of the tongue. This facilitates passage of the drug directly into the rumen. If dispensed more anteriorly in the mouth, closure of the esophageal groove may be triggered and the drug will bypass the rumen, thus reducing its efficacy, especially in the case of benzimidazoles and macrocyclic lactones.

Holding animals off feed for twenty-four hours before drenching with benzimidazoles also helps to ensure that the drug is distributed properly and with the desired contact time. However, withholding feed is not advised for pregnant does due to the risk of inciting pregnancy toxemia. There is no added benefit to withholding feed with oral administration of levamisole or moxidectin (Kaplan 2006). Fasting for thirty-six hours before treatment was reported to not have any affect on the kinetic disposition, bioavailability, or retention time of ivermectin in goats (Escudero et al. 1997).

Another technique for extending contact time may be to repeat dosages of the anthelmintic at twelve-hour intervals, particularly when using benzimidazoles. In one study, two 10 mg/kg oral doses of fenbendazole given twelve hours apart produced a 92% reduction in fecal egg counts, whereas a single dose given to the same herd seven months earlier produced only a 50% reduction (Zajac and Gipson 2000).

These practices are important because the site of deposition of the drug can affect anthelmintic efficacy, particularly with the benzimidazoles. The effect of benzimidazoles is correlated with the contact time of parasite with drug. When these drugs are administered in the rumen and slowly absorbed into the bloodstream, the distribution and excretion phases are of appropriate length to ensure anthelmintic activity at prescribed doses. If the esophageal groove closes during administration of these drugs and they are deposited into the abomasum, then the periods of distribution and excretion, and hence, contact time with the parasites, are shortened and efficacy suffers.

MINIMIZE NUMBER OF TREATMENTS. The number of treatments administered during the course of a year should be kept to a minimum level because it has been demonstrated that the development of resistance correlates directly with the frequency of dosing. This underscores the importance of identifying and using strategic and tactical treatments based on the ecology of parasites and actual assessments of parasite burdens by techniques such as fecal egg counts rather than deworming simply on a calendar basis.

CONSIDER GIVING TWO ANTHELMINTICS AT THE SAME TIME. While drugs are still effective, treating simultaneously with two drugs from different classes of anthelmintics may delay the development of resistance (Kaplan 2006). Even when some resistance is present, there are reports that drugs may act synergistically to provide some protection even when alone, they are ineffective. In a report from Texas, Angora goats infected with *H. contortus* having known resistance to all three major classes of anthelmintics were treated with fenbendazole alone, levamisole alone, and the two in combination. Based on FECRT, the drugs together produced a 62% reduction in epg while fenbendazole alone produced a 1% reduction and levamisole alone a 23% reduction (Miller and Craig 1996). In another study of fiber goats in the former Czechoslovakia, resistance to all three classes of anthelmintic was well documented, but combination treatment of albendazole and levamisole completely cleared infections in Cashmere goats while a combination of albendazole, levamisole, and ivermectin completely cleared infection in Angora goats. The resistant nematodes were *Trichostrongylus* spp. and *Ostertagia* spp. (Varady et al. 1993).

TREAT SELECTIVELY. A new emerging strategy for reducing the rate of development of anthelmintic resistance in a herd is to target specific animals within the herd for anthelmintic treatment rather than treating the whole herd. There are two key principles underlying this approach. The first is that only a comparatively small percentage of animals in any given herd is responsible for the bulk of the parasite load, with an estimated 20% to 30% of the animals harboring 80% of the worms (Kaplan 2006). The second is that by not treating the remainder of the herd, the untreated animals will deposit significant numbers of eggs from parasites not selected for resistance by treatment onto pastures and thereby dilute the population of eggs and infective larvae from resistant worms. These populations of non-resistant eggs and infective larvae are referred to as refugia and are considered by some to be the most potent factor in mitigating the development of anthelmintic resistance (Van Wyk 2001).

Because the animals harboring the largest number of worms are the most likely to develop signs of parasitism, various techniques may be employed to identify those animals in the herd and treat them selectively. In the case of *Haemonchus contortus*, which produces anemia in affected animals, a screening system based on assessment of the color of the conjunctiva was developed in South Africa, known as the FAMACHA© system. The development, application, and impact of the FAMACHA© system have been reviewed (Van Wyk and Bath 2002). The system was specifically designed for use with sheep. A laminated card depicts the color of sheep ocular mucous membranes representing five different categories of anemia from none to severe associated with membrane colors from red (1) to white (5). The card is brought to the field and animals' membranes are matched to the card. Only sheep having scores consistent with anemia—scores of 4 and 5 or 3, 4, and 5, as reported in different studies—are treated. The assessment may be repeated during the grazing season with treatments repeated on anemic animals. This selective deworming based on clinical signs leaves the clinically unaffected and less infected animals to continue to shed eggs of mainly non-resistant parasites onto pastures, and contribute to the pasture load of eggs and larvae in refugia. In South African reports, relatively few individual animals require repeated treatments within a flock over one season and those that do are candidates for culling if efforts to select for parasite resistance are undertaken.

The FAMACHA© scoring card has been evaluated for use in goats by comparison of scores with packed cell volumes and/or fecal egg counts and its reliability in goats has been validated in South Africa (Vatta et al. 2001; Jeyakumar 2007), the United States (Kaplan et al. 2004; Burke et al. 2007), Germany (Koopmann et al. 2006), Kenya (Ejlertsen et al. 2006), Brazil (Molento et al. 2004), and Guadeloupe (Mahieu et al. 2007). The FAMACHA© system has been recognized as particularly useful for the southern United States where *Haemonchus contortus* is the predominant pathogenic nematode confronting the growing meat goat industry. Use of FAMACHA© in the southern United States is being strongly promoted by the Southern Consortium for Small Ruminant Parasite Control (SCSRPC) and the

group provides access to abundant information about FAMACHA© and other aspects of parasite control to minimize anthelmintic resistance at their Website www.scsrpc.org.

Veterinarians must work closely with producers, who should be specifically trained on the use of FAMACHA©. Faulty interpretation of charts and improper selection of animals for treatments could lead to unexpected deaths if severe anemia is overlooked. In addition, in some areas, hemoparasites may also contribute to anemia, thereby confounding the interpretation of anemia scores and diminishing the expected response to anthelmintic therapy. Producers also must understand that the system applies only to gastrointestinal parasitism caused by *H. contortus*. The other clinically important trichostrongyles are not hematophagous and therefore do not produce anemia as a criterion for selection. In those cases, if the principle of selective treatment is going to be applied, then other parameters for selection must be used, such as individual fecal egg counts, total protein measurements, body condition scores, or the presence of diarrhea in animals unlikely to have other gastrointestinal diseases.

For dairy goats, it may be possible to apply selective treatment on the basis of age and production level. Epidemiologic studies in France indicate that in dairy herds, goats in first lactation and multiparous does with the highest level of milk production before the beginning of the grazing season have the highest burdens of and impact from parasitism compared to herd mates (Hoste and Chartier 1993, 1998a). In a controlled trial, a dairy herd was divided into two balanced groups with all goats in one group treated once with oxfendazole during the grazing season but only first lactation does and heavy producers treated similarly in the second group, with the groups grazed on separate pastures after treatment and monitored monthly. The results indicated a similar level of egg excretion in the two groups as well as similar milk production for both years of the experiment, indicating that similar benefits were achieved by selective treatment with the added benefits of lower treatment costs and some mitigation of the development of parasite resistance in the herd (Hoste et al. 2002).

ROTATE DEWORMERS RATIONALLY. Finally, despite a widespread conviction that rotation of anthelmintics reduces the development of resistance, experimental data suggest that resistance occurs as rapidly with use of multiple anthelmintics as with a single anthelmintic (Le Jambre et al. 1978). Therefore, it is suggested that only a single anthelmintic be used during the entire course of a seasonal exposure to infective larvae. Where larvae are present throughout the year, the anthelmintic may be used until evidence of resistance appears. When subsequent changes are made, the change should be to an anthelmintic of a different chemical class.

Prevention and Control

Over the years, much emphasis has been placed on the strategy of modifying livestock management practices to minimize the animals' exposure to parasites, based on knowledge of life cycles and ecological behavior of those parasites (Baker 1975; Schillhorn van Veen 1982). A seminal notion of parasite control is that gastrointestinal nematodes are primarily a disease of pastures that also involve livestock. With this concept in mind, grazing management control strategies are often developed with the goal of reducing the build up of infective larvae on pasture or when possible, eliminating animal contact with pasture. The role of epidemiological knowledge and grazing management for helminth control in small ruminants has been reviewed (Barger 1999; Waller 2006).

Total confinement or zero-grazing systems are the most aggressive strategy for eliminating the use of pasture. They are most suitable to intensive management systems, such as goat dairying, under conditions in which adequate volumes of stored feed can be grown, processed, and brought to confined goats under economically favorable conditions. When zero grazing is carried out, goats should be housed in a roomy, comfortable, well lit barn or have access to dry lots for general welfare, exercise, and exposure to sunlight. In tropical and subtropical regions, where infective larvae may be continuously present on herbage, goats are often housed in pens with slatted floors, raised off the ground (Figure 10.10). This system reduces parasite exposure, predation, and theft. Many of these animals, however, are fed with fresh herbage cut and carried

Figure 10.10. In the tropics, goats are often housed in raised pens on slatted floors as a means of controlling gastrointestinal parasitism. If the goats are fed fresh-cut herbage, however, they may still be exposed to infective larvae. (Courtesy of Dr. David M. Sherman.)

daily by caretakers. These feedstuffs may be contaminated with infective larvae from free-ranging goats, sheep, or cattle, and it cannot be safely assumed that penned goats are in fact parasite-free. A Brazilian study has indicated that maintaining goats on raised, slatted floors did not reduce worm burdens compared with goats maintained in corrals with beaten earth floors (Alberto Fagonde Costa and Da Silva Vieira 1987). To be effective, forages must be stored or processed to eliminate the presence of viable larvae. At the least, sun drying of fresh cut grasses before feeding may reduce viable larvae on herbage and improve its dry matter content (Siamba 1990).

In intensive management systems in temperate regions, goats are often continuously housed in barns on solid floors, fed stored feeds such as hay and silage, and allowed exercise in well-drained dry lots. Under these conditions, goats, in most cases, can be maintained relatively free of gastrointestinal nematode parasites, although certain species, e.g., *Skrjabinema*, *Trichuris*, and *Capillaria*, are adapted to successful transmission away from moist herbage. To be totally effective, confinement should be absolute for all age groups in the herd. However, a drawback of total confinement systems is that, if not carefully managed, the advantages gained by controlling nematodiasis may be lost to an increase in coccidiosis and respiratory problems.

Many small dairy herd owners practice only semi-confinement rearing, turning goats out on pasture after winter confinement. These pastures may contain some level of overwintering parasite larvae if stocked with goats the year before. Harsh winters with extended periods of cold or freezing weather sharply reduce larvae on pasture, but even under such conditions, a small proportion of larvae may still survive. After mild winters, the population of overwintering larvae is greater and goats turned out in spring can become infected. By late summer, when weaned kids begin grazing in earnest, pastures can be heavily infected.

Under conditions of seasonal pasturing, two strategic worming interventions may be justified and beneficial, based on the prevailing herd situation. Pregnant does should be dewormed within one month of kidding to minimize the exposure of kids to infective larvae associated with the periparturient egg rise, and all goats, including kids, should be treated with anthelmintics before turn out in the spring. Drugs employed should be effective against both adult and arrested larval stages. When possible, in temperate climates, spring turnout should be onto pastures not grazed by goats or sheep for a full year. In tropical climates, a few months may suffice. Monitoring of infection levels by fecal egg counts from composite fecal samples should be done periodically during the grazing period to determine the need for tactical anthelmintic therapy.

Some strategies for pasture management can reduce parasite burdens and risk to goats in spring. Pasture rotation is important and should be practiced when there is sufficient pasture area available. Avoid using the same pastures for goats two years in a row. Grazing cattle or horses the preceding year, growing and harvesting a hay or grain crop or leaving the land fallow are some options to reduce the risk of dangerous overwintering larvae on a given pasture. Other tools include: maintaining forage height greater than two inches, providing areas of browse within pastures or along fence lines for goats, maintaining a low stocking rate, grazing goats along with cattle, avoiding creation of wet patches associated with leaky waterers, and fencing off of naturally occurring wet patches in pasture (Hale et al. 2007)

In some situations, goats are grazed year-round, but confined at night in corrals for protection. In such a system in Tanzania, with a single rainy season, significant, superior weight gains were achieved in grazing goats when a strategic anthelmintic treatment was administered at the end of the rainy season (Connor et al. 1990).

In extensive grazing systems, continuous or prolonged grazing is the fundamental management scheme, as is often the case in fiber or meat goat production. The extent and severity of parasite infection depends on multiple factors including stocking rates, herbage quantity and quality, season, and weather conditions. For example, Angora goats on the Edwards Plateau in west Texas exhibit a low prevalence of *H. contortus* infection, probably because range is extensive, browse is abundant, and rainfall is limited. When these goats are moved to east Texas and forced to graze intensively on improved pasture with little browse, and much more rainfall, clinical haemonchosis is widespread (Craig 1982).

Careful observation and monitoring of body condition, fecal consistency, and fecal ova counts are advisable in grazing animals to identify the effects of management and weather changes on the incidence of parasitic infection. In the case of haemonchosis, if 5% to 10% of the herd have fecal egg counts of 500 eggs per gram of feces or more, then tactical treatment is justified before the onset of clinical signs. Where *H. contortus* is the principal concern, FAMACHA© scores can be used for monitoring and/or planning intervention.

When the predominant parasites and their behavior are well known, problems may be anticipated without monitoring. In Texas, tactical anthelmintic therapy has been automatically given to grazing Angora goats after heavy rains on the reasonable presumption that acute haemonchosis is likely to ensue because of rapid, synchronous larval development. The use of tactical treatments must be weighed against concerns of promoting

anthelmintic resistance. For best effect, tactical treatments should be accompanied by movement of stock to clean pastures to avoid immediate re-infection on contaminated herbage. If strip grazing is practiced, care must be taken that restricted grazing areas are of sufficient size for the animal population. Otherwise, the rate and intensity of larval buildup may be severe enough that the presumed beneficial effect of strip grazing is negated. The smaller the strip, the more frequently animals should be moved.

Drought affects the use of pastures. Management changes made in response to drought, such as congregation of animals for supplemental feeding and watering, may precipitate an increased incidence of parasitism. Supplemental feed should be fed in feeders, not from the ground, and should be provided at multiple sites, spread out to avoid the intensification of parasite ova in places of high animal density. This is even more important with point source water supplies. If runoff or seepage from tanks or troughs is not properly avoided or drained away, heavy contamination of the soil with infective larvae can occur at points where goats congregate to drink.

In tropical regions, extensive grazing is often practiced and the lack of seasonal changes in temperature and humidity allows infective larvae to be continuously present in the environment. In this situation, the frequent, regular use of anthelmintics is often practiced to limit resident worm populations and minimize the effects of parasitism in goats. This approach is labor-intensive and costly, and can accelerate the development of drug resistance. If such suppressive treatment regimens are necessary, it may be helpful to use limited-spectrum anthelmintics when the local parasite population permits it. For example, salicylanilides could be useful where the primary nematode problem is *H. contortus* and broad-spectrum therapy is not required. Three week treatment intervals are suggested so that larvae ingested since the preceding treatment will not have yet matured to adulthood and begun producing ova. Rotation of anthelmintics among the different classes of available drugs should be kept to a minimum, because too frequent rotation of drugs within an active season or cycle of parasite development can itself promote resistance. Also, when haemonchosis is the main concern, as it often is in tropical environments, selective deworming based on FAMACHA© scores can help keep parasites under control while reducing the use of anthelmintics and increasing the proportion of larvae from non-resistant larvae on pasture (in refugia). Whenever local conditions allow, producers should be encouraged to raise goats in confinement in raised pens on slotted floors, and not feed them fresh cut herbage. Effective grazing systems have been developed for the tropics wherein small ruminants are moved to a new area of pasture after three to four days of grazing and not returned to the previous area for about one month (Barger 1999; Waller 2006). A longer rest period is required in cooler climates, because the larvae survive longer on pasture.

Where grazing of goats is practiced, mixed grazing of different livestock species is being recommended as a means of parasite control on the presumption that even though cross-species transmission can occur, the parasites infecting one species are less suited to an alternative host and will therefore result in a less severe infection. The net effect is one of dilution of the parasites most infective for each host species. Another effect is less competition for available herbage and browse among grazing animals with different feeding preferences, leading to a better plane of nutrition for all. In Texas, goats make up 20% to 40% of the grazing population and may be mixed with sheep, cattle, deer, or any combination of the three. Mixed grazing, however, does open the door to potential cross transmission of other diseases such as paratuberculosis.

In the face of growing anthelmintic resistance, other approaches to parasite control are also being adopted or explored. Selective deworming is one such approach, aimed at increasing the number of non-resistant parasites in refugia, as discussed above. Other approaches include breeding and selecting stock for parasite resistance, using forages with anthelmintic properties, administering copper oxide wires, and using antinematodal fungi. They are discussed briefly as follows.

Resistance can be defined as the ability of an animal to suppress establishment and/or subsequent development of worm infection. As discussed earlier, there is good evidence of a genetic basis for helminth resistance in small ruminants and some heritability estimates have been reported for different breeds of goats relative to different parasites under a variety of environmental conditions. At present, there is little documentation in the literature that farmers are applying selective breeding to their herds and flocks for improved parasite control, but the experimental evidence indicates that it has potential as a useful parasite management tool and no doubt some are practicing it. Owners can select a breed with known resistance characteristics, or they can attempt selective breeding for resistance within their own herds. Veterinarians can work with farmers on the development of these breeding programs. In the published studies, various criteria or markers were used as a basis for selection, including fecal egg counts; packed cell volume; total protein; serum pepsinogen; body condition scoring; or FAMACHA© score based on the type of goat, production system, predominant parasites, and other factors. One important caveat in such an undertaking is that correlations of parasite resistance to other desirable

production traits have not been well studied in goats and the risk exists that selection for parasite resistance might also select for loss of desirable production traits. Breeding schemes for small ruminants relative to the development of resistance or resilience to endoparasites in the tropics have been reviewed (Baker and Gray 2004).

Host nutrition can play a significant role in mitigating the effects of parasites. Adequate and proper nutrition, particularly the provision of supplemental protein, can boost host resilience in the face of parasite infestation, and help minimize the adverse affects of the parasite burden (Coop and Kyriazakis 2001). Furthermore, some feeds may have a direct anthelmintic effect, for example, forages high in condensed tannins such as sulla (*Hedysarum coronarium*), birdsfoot trefoil (*Lotus corniculatus*), big trefoil (*Lotus pedunculatus*), sainfoin (*Onobrychis viciafolia*), and sericea lespedeza (*Lespedeza cuneata*). Several controlled studies have demonstrated the capacity of condensed tannin forages to produce an anthelmintic effect on trichostrongyles in goats compared to other forages. These studies include the grazing of sericea lespedeza at pasture in Oklahoma (Min et al. 2004) as well as the feeding of sericea lespedeza as pellets or hay in Georgia (Shaik et al. 2006; Terrill et al. 2007). The latter work indicated that the anthelmintic effect is retained through drying, pelleting, and storage of the forage. The mitigating effects produced included a direct anthelmintic effect on the adult worms in the gastrointestinal tract as well as a reduction in parasite egg viability and/or larval development in feces (Shaik et al. 2006). Sericea lespedeza is well suited to the growing conditions of the southern United States and offers a possible adjunct to anthelmintic therapy for parasite control in that region, where the number of goats raised for meat has increased dramatically in recent years, along with a growing problem of gastrointestinal nematodiasis.

Other studies demonstrating anthelmintic effects against trichostrongyles in goats involved the feeding of sainfoin as hay in France (Paolini et al. 2003, 2005) and the feeding of dried leaves of *Acacia karoo* in Zimbabwe (Kahiya et al. 2003).

Another aspect of nutrition with the potential to be exploited for parasite control relates to observations that macrominerals and trace elements may modify the host-parasite relationship. In particular, copper, in the form of copper oxide wire particles (COWP), was demonstrated to have anthelmintic activity against some nematodes in experimentally infected sheep, notably *H. contortus* (Bang et al., 1990). Subsequently a number of studies with COWP have been carried out in goats (Chartier et al. 2000a; Martínez Ortiz de Montellano et al. 2007; Burke et al. 2007a). A recent summary of the outcome of COWP trials in the United States is available on the Internet (Hale et al. 2007).

The source of COWP in these studies is generally a commercially available 2 g gelatin capsule containing COWP with a 1.7 g copper metal content that is marketed for control of copper deficiency and congenital swayback in lambs. Others have used 12.5 or 25 g COWP boluses marketed for cows, but the boluses are repackaged into small gelatin capsules to produce a dosage suitable for small ruminants (Hale et al. 2007). The results of these studies have been varied. The main anthelmintic effect is directed against *H. contortus* as measured by reductions in fecal egg counts or parasite counts at necropsy. Little or no effect has been reported against other abomasal or intestinal trichostrongyles such as *Teladorsagia circumcincta* or *Trichostrongylus colubriformis* in goats. Duration of effect in pastured goats appears to be about three to four weeks, possibly up to six weeks, and the effects are more evident in young goats than adults.

Potential toxicity is a concern, though goats are less susceptible to copper toxicity than sheep. Copper oxide is preferred over other copper salts because of its limited absorption from intestine, thus reducing the risk of toxicity. Dosage is empirical but is generally reported as 0.5 grams for kids and 2 grams for adults. Dosing can be repeated during the grazing season in kids up to a maximum of 2 g total dose. It has been suggested that COWP be administered selectively to heavily parasitized goats based on FAMACHA© scores or other parameters rather than dosing the whole flock because of concerns for development of resistance to COWP. However, the mechanisms of action for COWP are unknown, so risk of resistance is unclear. What is clear is that COWP can be a useful adjunct to parasite control where *H. contortus* is the main concern, but it must be coupled with other interventions in an integrated parasite management program to be most beneficial.

Biological control of parasitic nematodes using nematophagous fungi is another tool currently under evaluation. A number of such fungi, which naturally occur in soil and feces, are known to kill infective third-stage and second-stage larvae, thus reducing the larval burdens in pastures. Some of these fungi, most notably *Duddingtonia flagrans*, are also capable of surviving passage through the alimentary tract of livestock. Therefore, research has been conducted in a variety of livestock species to determine if feeding spores of *D. flagrans* can reduce the number of free living stages of gastrointestinal nematodes in feces and therefore pastures.

Results in species other than goats have been variable but promising. Several experimental studies have now been carried out in goats in the laboratory or in pilot trials (Paraud and Chartier 2003; Waghorn et al. 2003; Terrill et al. 2004; Paraud et al. 2005) which indicate, in general, that the fungus is capable of reducing

the number of developing larvae of important parasitic nematodes in the goat. In a field trial (Paraud et al. 2007), young grazing goats in France were given a daily oral dose rate of 10^6 spores/kg body weight for just over three months via inclusion in a mineral mix. Compared to controls, kids receiving the spores showed lower fecal egg counts and serum pepsinogen levels at the end of the grazing season as well as a higher growth rate. Technical challenges regarding the growth of fungal spores in sufficient quantities for commercial markets and challenges in how to reliably and conveniently administer the fungus have slowed the development of marketable, commercial products.

As the prospects for reliable anthelmintic efficacy continue to decline in the face of growing anthelmintic resistance, producers and their veterinarians will have to develop integrated parasite management plans that use a variety of strategies, tools, and practices which are appropriate to the management system, environment, climate, and production goals of the farm under consideration.

Currently, no vaccines are available for controlling gastrointestinal nematodiasis in goats, although the area is one of intense research investigation. One promising focus is the use of parasite gut membrane proteins as antigens for control of *Haemonchus contortus* and other trichostrongyles (Knox, 2000; Knox et al. 2003). There are also preliminary reports on new classes of anthelmintically active compounds. The cyclooctadepsipeptides have a distinctly different mechanism of action than the existing anthelmintic classes (Harder and Samson-Himmelstjerna 2002). Two compounds from this new class have been shown experimentally to possess resistance-breaking properties against benzimidazole-, levamisole- and ivermectin-resistant *H. contortus* from sheep (Samson-Himmelstjerna et al. 2005). Another new class of anthelmintic with a novel mechanism of action, the amino-acetonitrile derivatives, has recently been described and shows efficacy against a broad range of nematodes, including those resistant to existing classes of anthelmintics (Kaminsky et al. 2008). It is not clear if or when commercial products based on these newly reported classes might be available or if resistance will develop against them.

Paramphistomiasis

Paramphistomes are trematode parasites commonly referred to as rumen flukes, stomach flukes, or conical flukes. Adult flukes may be present in the rumen of goats in large numbers, but are essentially nonpathogenic. Clinical paramphistomiasis is associated primarily with the immature forms that feed voraciously in the small intestine before moving to the rumen to mature.

Etiology

Numerous genera in the family Paramphistomatidae infect domestic ruminants. In goats, *Paramphistomum cervi*, *P. explanatum*, *Fischoederius elongatus*, *Gastrothylax crumenifer*, and *Cotylophoron cotylophorum* are found. More recently, *C. travassosi*, *C. bareilliensis*, and *C. fullerborni* also have been reported from goats in Brazil (Cavalcante et al. 2000) and *Paramphistomum daubneyi* from goats in France (Silvestre et al. 2000). These trematodes all have a similar, indirect life cycle involving water snails as intermediate hosts (Soulsby 1982). The size of mature flukes ranges from 5 to 20 mm, making them visible to the unaided eye. They are pink to red. One paramphistome of Asia, *Gigantocotyle explanatum*, migrates to and matures in the bile ducts. It is essentially non-pathogenic, and should not be confused with the pathogenic liver fluke *Dicrocoelium dendriticum.*

Adult paramphistomes inhabit the rumen and lay clear, operculated eggs that are passed in the feces. When feces are passed into water, miracidia develop from these eggs over a period of twelve to twenty-one days, depending on temperature. Swimming miracidia enter water snails of various genera, including *Planorbis*, *Bulinus*, *Lymnaea*, and others. Mature sporocysts containing rediae develop in snails over a period of eleven days. Rediae are released within the snail and after an additional maturation of ten days, contain multiple cercariae. In turn, cercariae are released from rediae and mature within the snail for approximately thirteen more days. Mature cercariae are released from snails into water under stimulation of strong sunlight. Liberated cercariae attach to herbage and encyst as metacercariae, remaining viable for as long as three months.

When ruminants ingest contaminated herbage, metacercariae excyst in the small intestine where they feed aggressively and mature for a period of six to eight weeks. Young flukes then migrate anteriorly to the rumen where they undergo additional maturation after attachment to the rumen mucosa, begin laying eggs, and complete the life cycle. Migration to the rumen and subsequent development in that organ can be delayed or prolonged up to several additional months when fluke infestations are heavy.

Development of flukes varies in goats, cattle, and sheep. After experimental infection of the three ruminants with metacercariae of *P. microbothrium*, migration of maturing flukes from the intestine to the rumen was virtually complete in sheep and cattle by thirty-four days after challenge, but was just beginning in goats at that point, and subsequent egg laying began two weeks later in goats than cattle or sheep (Horak 1967). This prolonged residence of maturing paramphistomes in the small intestine may contribute to increased pathogenicity of the fluke in the goat.

Epidemiology

Though paramphistome infection of domestic ruminants occurs throughout the world, reports of clinical disease have been limited to Africa, Asia, Australasia, eastern Europe, Russia, and the Mediterranean countries (Horak 1971). While most reports involve cattle and sheep, reports of caprine paramphistomiasis from India (Katiyar and Varshney 1963; Chhabra et al. 1978; Rao and Sikdar 1981), Sardinia (Deiana et al. 1962), Bulgaria (Denev et al. 1985), and Pakistan (Mohiuddin et al. 1982) suggest that goats are at risk wherever sheep and cattle are affected. However, one abattoir survey from Iran (Moghaddar and Khanitapeh 2003) identified paramphistome infection in sheep up to 4% but no infection in goats, while a survey in the former Zaire (Chartier et al. 1990) showed an infection rate of 54% in sheep but only 14.8% in goats, so species differences in exposure or response to exposure may occur.

In general, outbreaks of paramphistomiasis are increased during dry seasons when snail and livestock populations become concentrated around shrinking natural water sources with restricted grazing and browsing (Horak 1971). Animals grazing in low-lying, poorly drained, swampy areas or with access to irrigation ditches and other standing water supplies are at high risk of infection caused by increased contact with metacercariae produced by water snails.

In north central India, most outbreaks are seen in small ruminants between late September and January after the rains that promote increases in snail populations. During subsequent dry periods of decreased forage availability, goats may be fed rice paddy straw and other grasses grown underwater that contain large numbers of metacercariae. The disease can be costly. Morbidity rates in goats in India during such outbreaks have been reported in the range of 35% to 79% and fatality rates in the range of 45% to 88% (Katiyar and Varshney 1963). Slaughterhouse surveys in the region show that mature rumen fluke burdens are highest from March to October and lowest from November to February, while immature fluke burdens are highest from September to April, the time period correlating to clinical outbreaks (Gupta et al. 1985).

Pathogenesis

The immature fluke developing in the upper small intestine is most responsible for the pathologic effects of paramphistome infection. These immature flukes embed deeply in the intestinal mucosa via suckers and feed by drawing a plug of mucosa into the sucker. This mucosal plug becomes necrotic and sloughs, leaving an erosion and petechiation. The pathogenicity of the paramphistomes is correlated directly with the immature fluke burden. It is estimated that attachment of 50,000 immature flukes would completely denude the upper 3 m of small intestine, where most paramphistome infections are confined during the developmental stage. Worm burdens of this intensity occur under natural conditions. Large numbers of simultaneously feeding, immature flukes cause marked intestinal irritation and mucosal disruption, leading to hypoproteinemia, diarrhea, and general debilitation.

Clinical Signs

The clinical signs of paramphistomiasis are similar to those of nematode gastroenteritis and the two diseases commonly occur together. Young goats are more frequently and seriously affected than older goats. Affected goats are listless and have diminished appetite. They may be polydipsic, and stand for long periods with their muzzles in the water. They will show a fluid diarrhea that may be projectile at first but later may just drip from the rectum, staining the hindquarters. The diarrhea may contain mucus, epithelial shreds, and immature flukes. It has a characteristic and pronounced fetid odor. Intermandibular edema is pronounced and may extend over the face and brisket. Anemia, if present, is usually mild or moderate. The course of the disease is approximately five to ten days in goats. During that time the animals lose weight, get progressively weaker, and eventually die. They may pass nothing but copious mucus from the rectum in the terminal stages. A prolonged form may occur where animals survive but persist in the cachexic state.

Clinical Pathology and Necropsy

Marked hypoproteinemia and hypoalbuminemia occur. Anemia may also be present. Because clinical disease is caused by immature non-egg laying flukes, fecal sedimentation techniques for egg identification have little value because false-negative results would be common. As an alternative to checking for ova, diarrheic feces can be passed through a sieve with 53 μ apertures and the residue examined either microscopically or macroscopically against a black background for immature flukes that are commonly passed in the feces. The immature flukes are pinkish-white with a large prominent sucker (Horak 1971).

At necropsy, the carcass is thin and the hindquarters are soiled with diarrheic feces. Subcutaneous edema, ascites, hydrothorax, hydropericardium, and lung edema may be present. Significant gross lesions of the alimentary tract are limited to the pyloric portion of the abomasum and the first 2 to 3 m of the small intestine. The abomasal folds are enlarged and edematous and immature flukes may be seen attached to the mucosa, which also contains numerous erosions and petechia. The affected intestine is thickened and

edematous. The pitted mucosal surface is covered with catarrhal exudate. Careful inspection may reveal flukes deeply embedded in the mucosa, with only the external ends present in the lumen. The mucosa in this affected region appears corrugated with many elevated ridges and multiple foci of hemorrhage. Immature flukes may also be found free in the gut lumen. Mature flukes may be present in the rumen and omasum. Multiple intestinal diverticula measuring 2 cm in diameter have been reported as an unusual finding associated with paramphistomiasis (Prajapati et al. 1982).

Histologically, affected areas of intestine show hypertrophy, edema, inflammatory cellular infiltrates, and fibrosis in the mucosa and submucosa (Sharma Deorani and Katiyar 1967). Histopathologic effects of adult flukes in the rumen are limited to epithelial desquamation of the papillae (Singh et al. 1984).

Diagnosis

Presumptive diagnosis is difficult because of the clinical similarity of paramphistomiasis to nematode gastroenteritis. Haemonchosis is more likely to produce anemia and less likely to produce diarrhea. However, other trichostrongyle infections may mimic paramphistomiasis exactly. Definitive diagnosis depends on ruling out nematode gastroenteritis by fecal flotation or necropsy and ruling in paramphistomiasis by identification of immature flukes in feces or at necropsy. Chronic fascioliasis must also be considered in the differential diagnosis. It occurs under similar environmental circumstances and may appear similar to the chronic form of paramphistomiasis.

Treatment

Elimination of the immature flukes with appropriate anthelmintic therapy is the major therapeutic objective and is life saving if treatment is started early in the course of disease. Animals must be removed from the source of infection before treatment or they will be immediately reinfected. Morantel citrate at a dose of 6 mg of morantel base/kg bw has recently been shown to be 99.5% effective against immature paramphistomes (Srivastava et al. 1989). Other drugs with a reported efficacy of more than 95% against immature flukes in sheep and goats include bithionol (25 to 100 mg/kg), niclofolan (6 mg/kg), niclosamide (50 to 100 mg/kg), and resorantel (65 mg/kg) (Rolfe and Boray 1988). Resorantel is also 100% effective against adult paramphistomes in goats (Sahai and Prasad 1975). Oxyclozanide (15 mg/kg) has a slightly less consistent efficacy range of 85% to 100% against immature flukes, but is also 100% effective against adult flukes. A new tertiary butylbenzathiole has been shown to be 99.7% effective against immature flukes and 100% effective against mature ones (Rolfe and Boray 1988). In general, the benzimidazoles are minimally effective against paramphistomes despite their relative effectiveness against liver flukes. Bithional may be toxic to goats at the higher end of the effective dose range (Boray 1985).

Directing treatment toward adult flukes is controversial. It has no direct benefit in the face of clinical outbreaks. Elimination of adult flukes reduces fecal egg counts and subsequent infection of snails, thereby reducing the general environmental burden of paramphistomes. Elimination of adult flukes, however, may also reduce the level of immunity that they induce in infected hosts, thereby increasing the risk of clinical disease in subsequent exposures (Horak 1971).

Control

The major thrust in the prevention of paramphistomiasis is to keep grazing animals away from areas with heavy concentrations of infected snails and from herbage contaminated with metacercariae. This means avoiding low-lying, poorly drained, or swampy areas, ponds, ditches, and paddy fields. Small ruminants should not be grazed with cattle under such circumstances, because the latter are known to shed large numbers of eggs and promote increased infection of snails.

Forages from contaminated areas can be used safely if ensiled or made into hay before feeding. When local conditions do not permit restricted grazing or harvesting, molluscicides may be used to reduce snail populations, but the relative cost-effectiveness of this remains to be proven. Water for drinking can be pumped from contaminated areas, treated with molluscicides, and provided in raised troughs, but this too is capital-intensive.

Strategic use of anthelmintics can be helpful in controlling paramphistomiasis. In India it is recommended that livestock be treated in June and August to reduce mature fluke burdens and thereby reduce egg laying, and in November, January, and March to control immature flukes (Gupta et al. 1985).

Though not yet available for widespread practical application, immunization may be a major future tool in paramphistomiasis control. Oral vaccination with irradiated metacercariae significantly reduced paramphistome burdens in goats on subsequent challenge compared with unvaccinated control goats (Horak 1967; Hafeez and Rao 1981).

Intestinal Cestodiasis or Tapeworms

Intestinal tapeworms occur in goats throughout the world. Relative to gastrointestinal nematodiasis, cestodiasis in goats usually has little clinical or economic significance. However, goat owners are often keenly aware of tapeworms because the proglottids, or egg packets, shed by the adult worm in the goat's feces are visible to the naked eye.

Etiology and pathogenesis

The major intestinal tapeworm of goats worldwide is *Moniezia expansa*, though other *Moniezia* spp. may also infect goats. *Avitellina* spp. occur in goats in Europe, Africa, and Asia, often in conjunction with *Moniezia* spp., and are sometimes the predominant cestode (Raina 1973). *Thysaniezia giardi* infects goats in Europe, the former USSR, Africa, India, and North America. *Stilesia globipuncta* occurs in goats and other ruminants mainly in tropical regions of Africa and Asia. It is potentially the most pathogenic of the ruminant tapeworms, producing inflammatory nodules at the sites of attachment in the duodenal and jejunal mucosa that can lead to enteritis and diarrhea. Nevertheless, clinical illness in goats attributable to *Stilesia* infection is poorly documented.

Another *Stilesia* tapeworm, *S. hepatica*, occurs in the bile ducts of ruminants in Africa and Asia and several new or additional *Stilesia* spp. have been identified from goats in India in recent years. *Thysanosoma actinioides*, the fringed tapeworm, can be found in the small intestine, though it is more commonly located in the bile and pancreatic ducts. It occurs only in western North America and South America. Principally a tapeworm of sheep and deer, its prevalence in goats is poorly documented. There is one slaughter survey from Mexico in which the fringed tapeworm was found on average in about 1.5% of the livers of goats examined as compared to about 15% for sheep livers (Cuéllar Ordaz 1980). It has been cited as a caprine parasite in the United States as well (Guss 1977). The liver tapeworms are discussed in detail in Chapter 11.

These anoplocephalid tapeworms all use ruminants as definitive hosts and various species of oribatid or psocid mites as intermediate hosts. Adult tapeworms developing in the goat intestine can be up to several meters long (Figure 10.11). They consist of a head or scolex and short neck followed by a long, segmented body composed of proglottids. The most posterior proglottids are packed with eggs. These gravid segments separate from the worm and are passed in the feces. These egg packets are white and 1 to 1.5 cm in length. They are visible in the fecal pellets and have the appearance of rice (Figure 10.12). The proglottid casing gradually disintegrates and oribatid or psocid mites, common in soils and on herbages, ingest the eggs. Infective cysticercoids develop within these arthropod intermediate hosts over a period of four months. Infective mites are consumed by ruminants while they feed. Cysticercoids are released from the ingested mites in the intestine and mature tapeworms begin to develop. The prepatent period in the goat is around forty days for *Moniezia* spp.

The goat also serves as an intermediate host for a number of cestode parasites that use canids as defini-

Figure 10.11. Adult Moniezia tapeworm from the intestine of a goat. (Courtesy of Dr. T.P. O'Leary.)

Figure 10.12. Tapeworm proglottids in goat feces. (Reproduced by permission of Dr. C.S.F. Williams.)

tive hosts. In many cases, these infections are more economically and clinically significant than the adult tapeworm infections just listed above. All of these intermediate metacestode infections are addressed elsewhere in this text, in conjunction with the organ system most often affected. A summary overview of the various cestode infections is given in Table 10.9.

Light infestations of goats by the common tapeworms are generally nonpathogenic (Soulsby 1982; Williams and Schillhorn van Veen 1985). This is largely because tapeworms do not feed destructively with active mouthparts, but rather absorb nutrients from the intestinal lumen through their integument. In goats, at least fifty worms are required to produce deleterious effects. Several hundred may be present in an individual goat (Guss 1977). They may compete significantly for nutrients with the host, leading to ill thrift. They may produce luminal distension in the intestine resulting in a distended, pot-bellied appearance. Their presence may prolong transit time of

Table 10.9. Overview of cestode infections of goats.

Cestode	Definitive host	Intermediate hosts	Form in goat	Locations in goat	Impact
Moniezia expansa, other Moniezia spp.	Goats, other ruminants	Mites	Adult tapeworm	Intestine	Usually nonpathogenic
Avitellina spp.	Goats, other ruminants	Mites	Adult tapeworm	Intestine	Usually nonpathogenic
Thysaniezia spp.	Goats, other ruminants	Mites	Adult tapeworm	Intestine	Usually nonpathogenic
Stilesia globipunctata	Goats, other ruminants	Mites	Adult tapeworm	Intestine	Occasionally diarrhea
Stilesia hepatica	Goats, other ruminants	Mites	Adult tapeworm	Bile ducts	Liver condemnations
Thysanosoma actinoides	Goats, other ruminants	Mites	Adult tapeworm	Bile ducts	Liver condemnations
Taenia multiceps	Canids	Goats, other ungulates, humans	Metacestode cysts	Brain, spinal cord, muscle	Coenurosis, lameness, trim at slaughter, zoonosis*
Taenia hydatigena	Canids	Goats, other ruminants, pigs	Metacestode cysts	Liver, mesentery, omentum	Liver condemnation, trim at slaughter
Taenia ovis	Canids	Goats and more commonly sheep	Metacestode cysts	Heart, diaphragm, other muscle	Trim or condemnation at slaughter
Echinococcus granulosus	Canids	Goats, other ungulates, man	Metacestode (hydatid) cysts	Liver, lungs, CNS, bone, muscle	Liver disease, slaughter condemnation, zoonosis*

*Zoonotic potential of these cestodes does not derive from contact with goats or other intermediate host ruminants but from contact with feces of definitive host canids.
CNS = central nervous system.

ingesta in the gut. In feedlot lambs on grain rations, this is believed to promote the development of clostridial enterotoxemia. A similar interaction has not been described in goats. Massive tapeworm infections may sometimes even occlude the intestinal lumen. This results in signs of colic and may lead to spontaneous rupture of the intestine in young lambs and kids with dire consequences.

Epidemiology

Infections are most often observed in young kids at pasture during their first summer grazing season. Pasturing is not a prerequisite for infection, however, because the infective mites may be present in the barnyard or on carried forage. The pattern of infection may vary with climate and geography. In Nigeria, no seasonal variation was seen in the incidence of sheep and goat tapeworms in the dry savannah and desert regions, while the incidence was increased during the rainy season in the rain forest zone (Enyenihi et al. 1975). A natural resistance to cestode infection devel-

ops with age, and in populations of goats with constant exposure to tapeworms, worm burdens are always less severe in older goats.

Because tapeworms are often derived at pasture, heavy tapeworm burdens may also be a sentinel for heavy nematode infections. Therefore, when owners notice tapeworm proglottids in goat feces, deworming for tapeworms may be used as an opportunity to treat more serious nematode infections when broad-spectrum anthelmintics are used. Multiple parasitic infections are the rule, not the exception, in goats.

Clinical Signs

When clinical disease is associated with tapeworms, it usually involves young goats under six months of age. Affected animals may show poor growth rates and a pot-bellied appearance. Proglottids are present in voided feces that are usually normal in appearance, but may be soft or unpelleted. Constipation may also occur. In complete luminal obstruction caused by tapeworms, kids have symptoms of colic and decreased

fecal output. Animals that have ruptured the intestine may be profoundly depressed, or found moribund or dead.

Clinical Pathology and Necropsy

In addition to proglottids in the feces, characteristic tapeworm eggs may be detected by fecal flotation methods because proglottids sometimes degenerate before being shed. *Moniezia expansa* ova are distinctly triangular. There are no other specific clinical chemistry or hematologic abnormalities associated with tapeworms.

At necropsy, the long, white-segmented tapeworms are strikingly obvious in the lumen of the small intestine. In obstructions, they pack the lumen, and may be free in the abdominal cavity when rupture of the intestine has occurred.

Diagnosis

Tapeworm infections are definitively diagnosed by the presence of proglottids in the feces or worms in the intestine. Attributing disease to tapeworm infection is more problematic. It is essential that nematode parasitism, paramphistomiasis, and liver fluke disease all be thoroughly ruled out before clinical disease is ascribed to tapeworms.

Treatment

A wide range of anthelmintics are currently available for eliminating adult tapeworms in goats. Oral niclosamide (50 mg/kg bw) is highly effective and has a wide margin of safety; it is nontoxic at five times the recommended dose. Praziquantel (5 mg/kg bw) is also effective, but the injectable form can be highly irritating to goats at the injection site. Oral febantel (5 mg/kg) is effective against *Moniezia expansa* and a range of nematodes. The newer benzimidazoles are also effective against tapeworms and nematodes. These include mebendazole (15 mg/kg), fenbendazole (15 mg/kg), cambendazole (20 mg/kg), and oxfendazole (10 mg/kg). Albendazole (10 mg/kg) is effective against tapeworms, nematodes, and the adult liver fluke *Fasciola hepatica*. Cautions associated with the use of benzimidazoles are discussed in the section on treatment of nematode gastroenteritis.

Older treatments for tapeworms in goats include copper sulfate, nicotine sulfate, and phenothiazine with lead arsenate. Though reasonably effective, these compounds all are potentially toxic if misused or improperly dosed, and their use is discouraged.

Control

It is difficult to justify a preventive program aimed at adult tapeworm control on economic grounds because the clinical impact on goats is usually minimal. When the appropriate broad-spectrum anthelmintics are used for nematode parasite control, however, tapeworm control can be included in the program as a bonus. The group of major concern in both cases is the young goat on pasture for the first time. Given current concerns about the development of anthelmintic resistance in nematode parasites, it would not be prudent to administer benzimidazoles expressly for the control of tapeworms unless there was also some strategic or tactical justification for their use against gastrointestinal nematodes at the same time.

Controlling the intermediate host mites is difficult because these arthropods are ubiquitous and often present in enormous concentrations. Plowing and reseeding are considered to reduce mite populations at pasture, but the overall effect on tapeworm populations in goats is questionable. Pasture rotation with at least a one-year layoff may be helpful because mite populations decrease over winter.

METABOLIC DISEASES

Bloat

Ruminal tympany, or bloat, is less common in goats than cattle and sheep. When it occurs, however, it must be considered a medical emergency as in other ruminant species. Frothy (primary, or nutritional) bloat is more likely to be encountered than free gas (secondary) bloat.

Etiology and Pathogenesis

Gas production is a normal outcome of rumen fermentive activity. Ordinarily, gas rises to the dorsal sac of the rumen and is discharged by the orderly process of rumination and eructation. Frothy bloat derives from nutritional causes. Under certain dietary conditions, such as the feeding of legumes or finely ground grains, gas bubbling through the rumen content can no longer freely coalesce in the dorsal sac but rather is trapped in a stable foam in the liquid phase of the rumen content. Certain species of bacteria that proliferate in the rumen when carbohydrate-rich diets are fed can produce an insoluble slime that increases rumen fluid viscosity and helps trap rumen gas in the stable foam (Radostits et al. 2007). Stable foam cannot be freely eructated and a progressive distension of the rumen ensues as additional gas becomes trapped. This progressive ruminal distension can be fatal as a result of subsequent respiratory and cardiovascular compromise. Experimentally in goats it has been documented that ruminal insufflation leads to decreased cardiac output, increased blood pressure, and increased total peripheral resistance due to obstruction of venous return by the distended rumen (Reschly and Dale 1970).

Free gas or secondary bloat occurs when gas accumulating normally in the dorsal sac of the rumen cannot be expelled because of extraruminal

obstructions to outflow. When free gas cannot be eruc- tated, progressive ruminal distension ensues with con- sequences similar to those just described.

Epidemiology

Bloat occurs in goats throughout the world. All goats with a mature functional rumen are at risk. Factors that have been identified as predisposing goats to frothy bloat include unaccustomed ingestion of lush legumes such as clover or alfalfa, either as green feeds or as new hay, recent turnout to legume pastures, and even turnout to grass pastures if they are wet. As such, bloat may have a seasonal occurrence in the spring. Feeding of garden greens as treats to goats on a dry hay diet is a frequent cause of bloat in Australia (King 1980b). Sudden access to grain either as concentrate feed or from gleaning of grain fields can also lead to frothy bloat. Turnout to grain fields results in a sea- sonal increase of bloat in the fall.

Free gas bloat occurs only sporadically in goats, usually secondary to esophageal choke. Pieces of apple or carrot are common foreign bodies. A cud can lodge in the esophagus, particularly in debilitated or sick animals and in animals with inadequate water supply. Internal abscesses in the anterior abdomen or medias- tinum associated with caseous lymphadenitis or other causes can also produce secondary or free gas bloat by compression of the cardia or esophagus.

Clinical Signs

Frothy bloat can occur within hours of exposure to the offending feed or feeding situation. Many cases of bloat are first recognized by finding animals dead at pasture. In the initial stages of the disease, affected animals become anxious and uncomfortable and stop eating. The most characteristic sign is a progressive distension of the abdomen, particularly apparent on the left side and high in the left paralumbar fossa. Percussion of this area reveals the tight, tympanic feel of the distended rumen and a drum-like sound. As the distension progresses, animals become more uncom- fortable, stamping their feet, vocalizing, salivating, urinating frequently, and moving with a stilted gait. Without intervention, these animals become recum- bent, exhibit marked, labored respiration, and die within one hour.

In free gas bloat, signs are similar. Salivation is more pronounced if the esophageal obstruction is high and complete and saliva cannot be passed to the rumen. If intraluminal obstruction is not complete, or if the pres- sure of accumulating gas in the rumen can override an extraluminal obstruction, gas is intermittently expelled and the abdominal distension caused by the rumen may be less pronounced with less severe tympany. Such cases often result in a prolonged bloating that is not immediately life-threatening.

Clinical Pathology and Necropsy

Because of the acute nature of bloat, laboratory investigations are not performed. Necropsy is com- monly employed in the diagnosis of bloat because the condition often proceeds to the fatal stage without detection. In a fresh necropsy of a case of frothy bloat, the ruminal distension is obvious and large amounts of froth are present within the rumen. In free gas bloat, rumen distension is present but the rumen does not contain froth. Careful inspection of the alimentary tract and surrounding structures from the mouth through the forestomachs should identify the source of secondary obstruction leading to free gas bloat. When animals are found several hours after death, diagnosis becomes more problematic, particularly in warm weather. Rumen distension with gas caused by the continued fermentive action of rumen flora after death eventually produces bloat in all carcasses. Froth also breaks down after death, causing frothy bloat to appear as free gas bloat. Examination of the carcass may help to establish the presence of antemortem bloat. In bloat cases, there is congestion of tissues in the anterior por- tions of the carcass and blanching or paleness of tissues in the caudal portions, reflecting peripheral vascular changes induced by the distended rumen. A line of demarcation "bloat line") between red congested esophageal mucosa in the cervical region and pale mucosa in the thoracic esophagus may be noted.

Diagnosis

Bloat is easily confirmed by physical examination. It is important to determine whether the condition is primary or secondary because this affects treatment and subsequent management decisions. The difficulty in the diagnosis of bloat comes when animals are found dead. Because bloat may be a normal post mortem change, it is necessary to rule out all possible causes of sudden death under the circumstances that the animal is found.

Treatment

Timely intervention is essential. Simple passage of a stomach tube, though often effective in relieving free gas bloat, does not correct frothy bloat unless the foam is first broken down. Cooking oils or mineral oil given orally in a dose range of 100 to 200 cc can be effective but may not work as rapidly as some of the commer- cial anti-frothing agents available. If given as a drench, care must be taken to avoid aspiration pneumonia. Linseed oil should not be used because it is associated with indigestion in goats. Oil of turpentine is a common home remedy. Though effective, it can taint meat and milk for five days after use.

There are a number of commercial, surface-acting (surfactant) agents that are also effective in degrading

foam and results may be seen within minutes. Poloxalene is available as a concentrate to be diluted for use as a drench. It is dosed at a rate of 100 mg of poloxalene per kg bw. Dioctyl sodium sulfosuccinate (DSS) (15 to 30 ml dose), polymerized methyl silicone (10 to 15 ml dose), and docusate sodium (1.4 g dose) are other effective compounds. When large numbers of animals are affected and treatment time becomes a critical factor, anti-frothing agents can be injected directly into the rumen through the distended left paralumbar fossa using an 18-gauge needle rather than administering them orally by stomach tube. Polymerized methyl silicone works more effectively than poloxalene when given by this route. The newer, alcohol ethoxylate detergent products are more effective in controlling frothy bloat associated with grain ingestion than poloxalene and the other products, which perform best with legume-induced bloat.

Forced exercise after administering oils or surfactants helps break down foam and promotes expulsion of gas. If animals are recumbent, rolling the goat or massaging the rumen may help distribute the oil and break down the foam. A stomach tube should be passed to facilitate gas removal as the foam breaks down.

Trocharization of the rumen through the left paralumbar fossa can be life saving in goats in the terminal stages of bloat. However, this invasive treatment should be reserved for the most advanced cases due to the potential sequelae of peritonitis and prolonged rumen dysfunction. Goats trocharized for relief of bloat should be placed on a three- to five-day course of broad-spectrum antibiotic therapy after the procedure.

Control

Because goats are generally not managed in feedlots, control of feedlot bloat is not a major concern. When goats are fed grain, concentrate feeds should not be too finely ground and should not be abruptly introduced into the ration. For goats that show a tendency to bloat when fed grain, top dressing of the grain with vegetable oils can be helpful, as can the addition of poloxalene to mineral supplements or mineral blocks.

If grazing of legume pastures is an integral part of the goat management system, the risk of bloat can be high. A number of interventions have been described for cattle and/or sheep to reduce that risk. They include daily drenching of individual animals with oils before turn out, including anti-frothing agents such as poloxalene in feed or mineral supplements, feeding the ionophores monensin or lasalocid or administering a sustained release monensin capsule, and spraying oils or fats directly onto pasture. Managing the pasture itself can also be of value; interventions include sowing grasses with legumes, using forage types high in condensed tannins, strip grazing, and swathing and wilting alfalfa for twenty-four hours before turning animals out onto pasture. All these techniques and interventions are discussed in more detail elsewhere (Radostits et al. 2007).

The most fundamental intervention for controlling pasture bloat in goats is to adapt them gradually to pastures in spring, turning them out initially for short periods on a full stomach of hay to limit pasture consumption. A similar recommendation applies to animals turned out to glean grain fields in the fall. Whenever green feeds are fed, dry hay should be available simultaneously to avoid overconsumption of green feeds. To help control pasture bloat, poloxalene can be added to feed or mineral supplements to achieve a dose of 10 to 20 mg/kg bw. The supplementation should begin one to two weeks before turnout on pasture. If goats are being fed monensin or lasalocid for control of coccidiosis at recommended doses, they may appreciate some additional benefit in bloat control, as the ionophore antibiotics can reduce the incidence of bloat. The ionophores inhibit rumen bacteria, which produce large amounts of gas-trapping mucus and increase the rumen production of propionic acid, resulting in a decrease in the acetate:propionate ratio and a reduction in the amount of carbon dioxide and methane produced.

Rumen Impaction

Rumen distension secondary to impaction has been caused in the goat by sand ingestion and by prolonged feeding of low-energy, high-fiber diets, such as horse feed containing more than 25% oats in conjunction with poor quality grass hay (Guss 1977). It has also been associated with the feeding of bread, pollard, pellets, wheat, corn, or barley in excessive proportions of the total ration (King 1980). In northern India, rumen impaction in goats and other ruminants is more common in the hot, dry summer season when green fodders are unavailable, water is scarce, and the diet is composed mainly of low-grade, dry roughages (Prasad and Rekib 1979). The distension is primarily on the left, in the ventral abdomen, and ballotment reveals a firm, doughy consistency to the rumen content.

In recent years, the global proliferation of plastic bags in commerce and their careless disposal in the environment have become an important cause of ruminal impaction in goats. This is particularly the case in developing countries where flocks of goats may be brought to trash bins or garbage dumps to forage or when drought drives goats to eat items in the environment not normally consumed. Reports of rumen impaction due to plastic bags in goats have come from Nigeria (Otesile and Akpokodje 1991; Remi-Adewunmi et al. 2004), Jordan (Hailat et al. 1998), the Sudan (Abdel-Mageed et al. 1991), and South Africa (Donkin

and Boyazoglu 2004). There is some indication that goats develop pica for plastic bags and consume them preferentially (Abdel-Mageed et al. 1991). Other foreign materials reported in association with rumen impaction in goats include cloth, leather, twine, and rope.

In addition to developing a firm, distended rumen, animals with rumen impaction become dull and listless, appetite is reduced, and milk production falls off. Cud chewing ceases, there may be mild bloating, and the feces may become scant, dry and mucus-covered. Progressive weight loss and debilitation ensue if the condition is not recognized and treated.

For sand impaction, one week of daily drenching with 60 g of magnesium sulfate is recommended. Each drench should be followed by manual kneading of the lower left abdomen to break up impaction. If impaction persists, rumenotomy may be required. Up to 20 pounds (9.1 kg) of sand have been removed from a goat rumen (King 1980b). Animals should be fed in racks or troughs off of the ground when possible. For fibrous impactions, daily oral dosing with mineral oil and dioctyl sodium sulfosuccinate (DSS) may soften impactions, but rumenotomy may be necessary. When fibrous impactions are diagnosed, the ration needs to be evaluated and corrected to provide more digestible energy and less fiber. Rumenotomy is required for the treatment of goats with rumen impaction due to plastic bags.

DISEASES OF MIXED ETIOLOGY

Neonatal Diarrhea Complex

Etiology and Epidemiology

Diarrheal disease is documented as a very frequent cause of kid loss throughout the world (Sherman 1987). A high incidence of diarrheal disease is associated with intensive rearing of kids under conditions of overcrowding and poor sanitation. Though less common under extensive management conditions, the incidence can increase when kidding seasons coincide with periods of extreme weather conditions, especially excessive heat, excessive cold, or heavy rains.

Much has been and continues to be presumed about the causes of neonatal kid diarrhea, based on the widespread information available from calf and lamb studies. As a result, colibacillosis, caused by *E. coli*, is often considered to be the most common cause of diarrhea in young kids. The few epidemiologic studies actually carried out in kids, however, suggest that the nature and frequency of the various etiologic agents of diarrhea may differ considerably in the goat compared with calves and lambs, or remain unknown. In a New Zealand study, up to 72% of the diarrhea cases in kids younger than one month of age remained undiagnosed regarding specific etiology (Vickers 1986).

The generally held presumption that *E. coli* is a major cause of diarrhea in kids is challenged by several studies (Nagy et al. 1983; Yvore et al. 1984; Polack et al. 1989; Muñoz et al. 1996). In these field surveys and diagnostic laboratory investigations, cryptosporidiosis is the most commonly diagnosed cause of diarrhea in kids younger than one month of age, and particularly in kids younger than fifteen days of age. The organism is rarely isolated from nondiarrheic kids. Cryptosporidiosis can occur alone or in conjunction with other presumed pathogenic bacteria, viruses, and protozoa.

The virulence attributes of gastrointestinal *Escherichia coli* isolates of veterinary significance have been reviewed (DebRoy and Maddox 2001). There are four main types of *E. coli* that can potentially be associated with diarrhea in kids: enterotoxigenic *E. coli* (ETEC); enteropathogenic *E. coli* (EPEC); enterohemorrhagic *E. coli* (EHEC); and necrotoxigenic *E. coli* (NTEC). Their characteristics and role in neonatal diarrhea complex of goat kids are as follows.

The enterotoxigenic *E. coli* (ETEC) are characterized by the production of heat stable and heat labile enterotoxins and the possession of adherence structures, known as pili or fimbriae, which allow the bacteria to colonize the intestinal lining where the enterotoxin can exert its effect on villous and crypt epithelial cells, producing a hypersecretory diarrhea. The ETEC are noninvasive and produce minimal lesions in the gut.

Though a major cause of diarrhea in neonatal calves, ETEC have been infrequently identified as a cause of neonatal kid diarrhea. In a Hungarian study, the adherence pilus K99 (now also referred to as F5), that is most frequently associated with ETEC in calves, was rarely identified in kids, though it was actively screened for. In fact, it was found in non-diarrheic kids more often than in diarrheic kids (Nagy et al. 1987).

More recently, a number of studies from Spain have provided additional information on the relationship of various *E. coli* types and diarrhea in kids. In one study, 210 strains of *E. coli* were cultured from diarrheic kids up to three weeks of age on fourteen farms. None of the strains produced the F5 or F41 fimbrial antigens associated with ETEC in calves. Eighteen of the isolates produced F17 fimbrial antigen, but none of these F17 isolates produced enterotoxin (Cid et al. 1993). A subsequent report indicated that F17-positive *E. coli* isolated from diarrheic kids and lambs in Spain had the phenotypic characteristic of septicemic strains and not enterotoxigenic strains (Cid 1999). In another study, no *E. coli* possessing either the F5 or the F41 fimbriae typical of ruminant ETEC were identified from fecal samples of seventeen diarrheic kids up to four weeks of age on seven farms (Orden et al. 2002). In a different investigation, only three of fifty-five *E. coli* isolates from fifty-five diarrheic kids produced toxins of any kind. One was a verotoxin and two were cytotoxic

necrotizing factor 2 (CNF2), generally associated with septicemic strains. None of the isolates produced enterotoxin and it was concluded that most *E. coli* associated with diarrhea in kids were non-toxigenic (Cid et al. 1996).

There is one Spanish study in which fimbriated *E. coli* were found frequently in diarrheic kids and lambs but their significance was unclear because the same organisms were recovered with similar frequency from non-diarrheic kids and lambs and none of the fimbriated isolates produced enterotoxins (Muñoz et al. 1996). Furthermore, the fimbriated *E. coli* were present in kids and lambs at approximately equal frequencies among the age groups—one to five days, six to ten days, eleven to fifteen days, and sixteen to forty-five days—whereas in calves, ETEC are most often found in the first few days of life. Notably, the predominant pathogen isolated from diarrheic kids in this survey was *Cryptosporidium parvum*. It occurred mainly in kids one to ten days of age and was not isolated from any non-diarrheic kids.

In contrast to the Spanish studies, there are reports from Greece which suggest that ETEC are a common cause of diarrhea in newborn kids (Kritas 2002; Kritas et al. 2003). Isolates from kids on dairy goat farms with diarrhea in the first few days of life were confirmed as having F5 (K99) and F4 (K88) fimbriae. However, the isolates were not tested for enterotoxin and the presence of other possible pathogens, e.g., rotaviruses, was not investigated, so the etiologic role of ETEC in these outbreaks was not definitively established. The most convincing evidence offered for ETEC as the etiologic agent was that vaccination of does with a subunit vaccine containing K88 and K99 pilus antigens substantially reduced the occurrence and severity of diarrhea in newborn kids receiving colostrum as compared to kids of unvaccinated does in a controlled study (Kritas et al. 2003). More goat-specific epidemiologic investigations and laboratory confirmations are required to better clarify the role of ETEC in neonatal diarrhea of kids.

The enteropathogenic *E. coli* (EPEC) are also known as adhering and effacing *E. coli* (AEEC). They are characterized by the possession of the *eae* gene which encodes intimin, an outer membrane protein that mediates intimate bacterial adhesion to host enterocytes. A second *espB* gene may also be involved in adhesion but is not present in all isolates containing the *eae* gene. The adhering and effacing *E. coli* produce characteristic attachment and effacing lesions of the gut mucosa, involving destruction of the brush border of enterocytes, but are usually non-invasive.

Spanish studies on the prevalence and characteristics of AEEC in goats indicate that healthy kids and adults have a higher prevalence of AEEC than diarrheic kids, but there are differences in the characteristics of the AEEC organisms. AEEC from healthy kids and adults possess both the *eae* and *espB* genes and produced verotoxin, while the isolates from diarrheic kids possessed only the *eae* gene and did not produce verotoxin. All kids sampled were ≤ four weeks old and the prevalence of AEEC was highest in diarrheic kids eight to fourteen days of age (Cid et al. 1996; Fuente et al. 2002). Six types of the *eae* gene are known, and the AEEC associated with diarrhea in kids most often possessed the *eaeβ* type (Orden et al. 2003). In Canada, an AEEC was identified in a ten-day-old diarrheic kid from a herd of French Alpine dairy goats in which twenty-one of thirty-four kids died over a period of three weeks with profuse diarrhea and dehydration beginning at one week of age. The organism did not possess fimbrial antigens nor did it produce either enterotoxins or verotoxin, but it was *eae* gene positive (Drolet et al. 1994).

The enterohemorrhagic *E. coli* (EHEC) are characterized by production of verotoxin, a toxin similar to the shiga toxin of *Shigella dysenteriae*. Some but not all EHEC are also attaching and effacing and possess the *eae* gene. Those possessing the gene are considered more likely to be pathogenic to humans. Virulence factors and the epidemiology of EHEC have been reviewed (Caprioli et al. 2005).

Though sometimes associated with diarrhea in ruminant hosts, the greater significance of the EHEC is in their zoonotic potential. *E. coli* O157:H7 is the most well known EHEC, although there are numerous other enterohemorrhagic serotypes as well. *E. coli* O157:H7 is associated with diarrhea, hemorrhagic colitis, thrombocytopenic purpura, and hemolytic uremic syndrome in humans. Cattle are considered the main reservoir of the organism and there is widespread public health concern about the transmission of *E. coli* O157:H7 to humans through foods of bovine origin. However, other livestock, including goats, can harbor verotoxigenic *E. coli*.

E. coli O157:H7 has been isolated from goats on commercial farms (Dontorou et al. 2004) and tourist farms (Pritchard et al. 2000), at agricultural fairs (Keen et al. 2006), and in petting zoos (DebRoy and Roberts 2006). It has been associated with hemorrhagic colitis and hemolytic uremic syndrome in humans through foods of caprine origin, including unpasteurized milk (Bielaszewska et al. 1997; McIntyre et al. 2002) and fresh unpasteurized goat cheese (Espié et al. 2006) and possibly by direct contact with goats or goat feces (Pritchard et al. 2000; Heuvelink et al. 2002).

EHEC serovars other than O157 are found more commonly in goats. For instance, a fatal case of diarrhea in a two-month old goat was confirmed as being due to a verotoxic *E. coli* serotype O103:H2 (Duhamel et al. 1992). In a German study, seventy verotoxin-producing strains were isolated from ninety-three

healthy goats from six farms. None was O157 and only one possessed the *eae* gene (Zschöck et al. 2000). In another German study, thirty-seven of sixty-six healthy goats yielded verotoxin-producing strains and none was 0157. The predominant serotype (70%) was O5:H⁻ with single isolates of O82:H8, O87:H21, O5:H10, and O74:H⁻, as well as nine untypeable strains also recorded (Beutin et al. 1993). In a Spanish study of healthy and diarrheic goats, verotoxin-producing *E. coli* were isolated more frequently from the feces of healthy goats than diarrheic goats. No O157 serotypes were identified but 12% of the isolates from goats represented serotypes known to be pathogenic for humans: O5:H⁻, O26:H11, O91:H⁻, O128:H2, and O128:H⁻. It was concluded that verotoxigenic *E. coli* are not strongly associated with diarrhea in kids, but that goats can serve as an important source of EHEC infection for humans (Orden et al. 2003a). In a survey of twelve dairy goat farms in Spain, verotoxigenic *E. coli* were more prevalent in adult goats than kids, no strains were *eae* positive, and 16% of the strains isolated from healthy goats belonged to serotypes associated with disease in humans, again indicating that goats can be an important reservoir of EHEC (Cortés et al. 2005).

Other pathogenic *E. coli* that can infect ruminant neonates are primarily associated with septicemia rather than enteritis. Some of these may be necrotoxigenic strains of *E. coli* (NTEC) that produce cytotoxic necrotizing factor. Others may belong to known invasive serotypes. In colisepticemia, invasive strains of *E. coli* gain entrance to the bloodstream and produce clinical disease through the effects of bacteremia and endotoxemia. Diarrhea may be part of the clinical syndrome, but is not the primary problem. Colisepticemia occurs most commonly in neonates that have not received adequate passive immunity through consumption of the dam's colostrum. The condition is discussed further in Chapter 7 in the section on failure of passive transfer of maternal antibody.

A poorly understood disease known locally as "chevreau mou" in France or "floppy kid syndrome" in North America was first recognized as a cause of diarrhea in kids in intensive management systems in winter in France. Affected kids were usually three to four days of age and showed severe generalized weakness, distension of the forestomachs with undigested milk, and sometimes diarrhea (Garcin 1982). The condition was originally thought to be a form of colisepticemia because of its similar clinical presentation to the condition known in lambs in the UK as "watery mouth" (Savey 1985; Eales 1986). However, a similar condition was later observed in Canada in kids nine to ten days old and reported to be associated with metabolic acidosis without dehydration (Tremblay et al. 1991). Currently, floppy kid syndrome is recognized as a form of metabolic acidosis associated with high con-

centrations of D-lactate in the plasma (Bleul et al. 2006) and diarrhea is no longer considered to be part of the case definition (Rowe 2006). The underlying cause of the syndrome remains unknown but there is currently no evidence that it has an infectious etiology. The condition is discussed further in Chapter 19 as a metabolic disease.

In a New Zealand study, *Clostridium perfringens* types C and D were rarely identified as causes of diarrhea in kids. Enterotoxemia is considered to more commonly assume the neurologic or sudden death forms than the enteric form in New Zealand (Vickers 1986).

Rotaviruses have been identified from diarrheic kids for thirty years, and serologic surveys indicate a high prevalence of infection in goats in some countries—for example 60% in Japan (Takahashi et al. 1979), 41% in Turkey (Gumusova et al. 2007), and 25.7% in Italy (Iovane et al. 1988). It is reported to be the most common enteric virus of goats in New Zealand, and it is believed to cause profuse diarrhea either alone or in combination with *E. coli* and/or cryptosporidia (Thompson 2001).

However, the epidemiology of rotavirus as a cause of neonatal diarrhea in kids still requires further clarification. In an early report from the UK rotavirus particles were identified from the diarrheic feces of several four-month-old goatlings (Scott et al. 1978). If the virus was indeed responsible for the diarrhea, this would be in marked contrast to rotavirus infection in calves and lambs, where clinical diarrhea is unusual in individuals older than three weeks of age. In France, rotaviruses were identified readily from non-diarrheic kids with almost equal frequency as diarrheic kids, raising questions about their pathogenicity in goats (Yvore et al. 1984).

Rotaviruses are now known to belong to seven different serogroups, A through G, based on the cross reactivity of antibodies to the major inner capsid protein, VP6. Group A rotaviruses are most commonly associated with diarrhea in farm animals. Rotavirus A was identified as the cause of diarrhea in twelve- to sixteen-week-old Saanen kids in South Africa (Costa Mendes et al. 1994). The presence of rotavirus A was also confirmed in Canada in one- to two-week-old goat kids with diarrhea in conjunction with cryptosporidial infection. Rotavirus A was considered to be contributory to the diarrhea because villous atrophy was more pronounced histologically in kids with dual infection than in kids with cryptosporidiosis alone (Sanford et al. 1991). In contrast, no association between group A rotavirus and diarrhea in kids could be made in a Spanish goat herd where rotavirus was identified in the feces of five times as many normal kids as diarrheic kids (Muñoz et al. 1994).

Group B rotavirus was identified in Spain as the sole cause of severe diarrhea, dehydration, and prostration

in kids two to three days of age and affecting 22.6% of kids on the farm (Muñoz et al. 1995). In a broader survey of diarrheic and healthy kids on sixteen goat farms in Spain, group A, B, and C rotaviruses were identified. Group A rotaviruses were identified in healthy kids more often than diarrheic kids, while group C rotavirus was identified in healthy kids only. An association between infection and diarrhea was established only for the group B rotaviruses (Muñoz et al. 1996).

Coronavirus is a major cause of diarrhea in calves, but information on coronavirus infection in goats is limited. A seroprevalence study in five provinces in Turkey found 41% of goats sampled positive for bovine coronavirus (Gumusova et al. 2007). There are no published reports of diarrhea outbreaks in kids confirmed as due solely to coronavirus. Some disease investigations in diarrheic kids have actively screened for the presence of coronavirus as an etiologic agent. Either coronavirus was not found at all (Muñoz et al. 1996) or it was present at a low prevalence, almost always in mixed infections with other likely causative agents, notably cryptosporidia or enterotoxigenic *E. coli* (Nagy et al. 1983; Ozmen et al. 2006). These findings suggest that coronavirus is a possible but unlikely contributor to the neonatal disease complex in kids.

Adenoviruses are not commonly associated with diarrhea in kids. Adenoviruses were identified in diarrheic goats in Hungary (Nagy et al. 1983). They also have been isolated from the intestine of two goats in Nigeria that died of peste des petits ruminants (PPR) (Gibbs et al. 1977) as well as from goats in Senegal during PPR outbreaks (Nguyen et al. 1988). Because PPR is a major, known cause of diarrhea, it is difficult to ascribe significance to the adenovirus. Also, a new serotype of adenovirus was isolated from a three-week-old kid with diarrhea and respiratory disease in California (Lehmkuhl et al. 2001). It was one of about fifty kids from a 900-doe herd showing similar signs.

Yersinia spp., *Giardia*, and *Campylobacter jejuni* were confirmed as causes of diarrhea in New Zealand (Vickers 1986). *Campylobacter jejuni* has also been isolated from diarrheic feces of kids in Nigeria (Adetosoye and Adeniran 1987) and Canada (Prescott and Bruin-Mosch 1981). Again, the role of this organism remains equivocal because, in the Canadian study, *C. jejuni* was also isolated from the feces of normal goats.

Infection with the flagellated protozoa *Giardia duodenalis* (syn. *G. intestinalis*, *G. lamblia*) has been reported from most continents and has been identified in all the common agricultural animals, but its role in disease remains controversial (Radostits et al. 2007). Cysts of *G. duodenalis* are frequently found in the feces of healthy animals, and when present in diarrheic animals, they are often present with other potential etiologic agents,

so attribution of pathogenicity remains equivocal. This reflects the situation in goats as well. Several prevalence studies have been reported. In Spain, 19.8% of adult goats were infected in one survey and 33% in another (Castro-Hermida et al. 2007a, 2007b). In pregnant does, shedding of cysts in feces increased seven to ten times in the three weeks around kidding time (Castro-Hermida et al. 2005). In France, goats on 100% of twenty farms shed *G. duodenalis* cysts and on-farm prevalence ranged from 10% to 80%, with an overall rate of 38%. Prevalence was highest in kids six to eight months of age (Castro-Hermida et al. 2005a). In Romania, 16% to 18% of adult goats were infected in both pasture and housed environments, while 10% to 50% of kids were infected, with pastured kids having higher prevalence than intensively reared kids (Suteu et al. 1987).

Experimental infection of goats has been reported, indicating that *G. duodenalis* is capable of producing enteric disease by itself, though only three of eight challenged kids developed loose stool, depression, and decreased appetite (Koudela and Vítovec 1998). In reports of naturally occurring infection associated with diarrheal disease, *G. duodenalis* is usually identified in association with other potential etiologic agents such as *Cryptosporidium parvum* (Sutherland 1982; Sutherland and Clarkson 1984; Ozmen et al. 2006) or coccidia and trichostrongyles (Suteu et al. 1987). It is reasonable to consider *G. duodenalis* as a pathogen when found in kids with diarrhea, but additional potential causes should be investigated and the presence of the organism in adults does not necessarily mean that the organism will cause problems in kids. When *Giardia* is present in herds, however, managers and veterinarians must be cognizant of the fact that the organism has zoonotic potential as a cause of diarrhea in humans.

Caprine herpesvirus infection has been associated with diarrhea in kids. Herpesvirus infection was first recognized in California in 1972 in association with a severe generalized infection of one- to two-week-old French Alpine kids, causing increased morbidity and mortality rates (Saito 1974). A similar outbreak of disease characterized by fever and ulcerative enteritis with high mortality in kids was recorded in dairy goats in Switzerland in 1978 (Mettler et al. 1979). Affected kids show signs of weakness, dyspnea, cyanosis, abdominal pain, diarrhea, nasal discharge, and oral erosions. Not all signs are present in all individual kids. The disease has a fatal course of one to four days. Necrosis and ulceration of the digestive tract, especially the cecum and colon, are prominent necropsy findings. More detailed information on other manifestations of herpesvirus infection in goats is found in Chapter 12 and elsewhere in this text.

These limited studies suggest that the conventional wisdom about the etiologic basis of infectious diarrhea

in young goat kids, largely extrapolated from experience with calves and lambs, bears additional examination. Enterotoxigenic *E. coli* may be involved less often than is generally assumed. Veterinarians working up diarrhea outbreaks in kids should specifically seek to establish the presence and characteristics of ETEC but should also be looking to identify other likely bacterial, viral, protozoal, and/or non-infectious causes of diarrhea in young goats. *Cryptosporidium parvum* appears to be a more significant cause of diarrhea in the first week of age, with rotaviruses also playing a potentially important role. Multiple agents may be present and their contributory importance and possible interactions need to be further clarified. More local diagnostic surveys should be undertaken wherever goats are raised because appropriate recommendations for treatment and control may depend on more accurate knowledge of causative agents.

Infectious agents may not always be involved in diarrhea of young kids. Many cases may be nutritionally based and difficult to diagnose at post mortem without adequate feeding and management history which may be difficult to obtain after the fact.

Nutritional causes of diarrhea in young kids are often associated with husbandry and feeding practices. Problems identified include overfeeding of milk, using poor quality milk replacers, suddenly changing the feeding routine, and switching to cow milk replacers. Incorrect mixing and dispensing of milk replacer by a malfunctioning automatic feeder has been reported as a cause of kid diarrhea (Lane 1987). These situations may produce noninfectious diarrhea, or predispose to the proliferation of pathogenic bacteria in the abomasum, rumen, or intestine.

When kids reach one month of age, the common causes of diarrhea are better established. Coccidiosis is likely the most common and helminthiasis the second most common prevailing identifiable cause of diarrhea in weaned, growing kids worldwide. Other well-known causes of diarrhea in older kids also include enterotoxemia caused by *Clostridium perfringens* type D, salmonellosis, yersiniosis, peste des petits ruminants, and indigestion associated with the transition to solid feeds. These are either more sporadic or more geographically restricted than coccidiosis and helminthiasis.

Pathogenesis

Diarrhea, as a pathophysiologic process, results in dehydration, acidosis, and electrolyte depletion, and in neonates, is also associated with hypoglycemia. These physiologic derangements, when unchecked, are often fatal. Certain agents such as *Salmonella* spp. and *Clostridium perfringens*, though primarily enteric pathogens, can cause marked, concurrent systemic effects in addition to diarrhea as a result of bacteremia

and toxemia respectively. Certain agents may produce clinical effects in multiple organ systems as exemplified by the pneumoenteritis syndrome seen in peste des petits ruminants.

Clinical Findings

In the case of diseases limited to the gastrointestinal tract such as cryptosporidiosis, enteropathogenic colibacillosis, and the enteric viruses, diarrhea is the predominant clinical sign. The character of diarrheic feces in kids can vary considerably from pasty white to loose, yellowish green, to watery brown and it is inadvisable to ascribe too much diagnostic significance to the color or consistency of feces in a given case, especially because mixed etiologies are possible. Streaking of feces with blood may also be seen with a variety of causative agents. Regardless of cause, there may be some degree of abdominal discomfort, possible abdominal distension, and probable loss of appetite in association with diarrhea. Giardiasis has been reported to assume a chronic form in kids and lambs lasting several weeks with gassy, watery brown feces (Ozmen et al. 2006).

If diarrhea is prolonged or severe, then dehydration ensues. Dehydrated animals become depressed, the mouth is dry, and they gradually lose the sucking reflex. They grow progressively weaker until they are unable to stand. Loss of body fluid produces hypovolemia and poor peripheral circulation. Extremities feel cold, the eyeballs become sunken, and the body temperature may become subnormal. Electrolyte and acid-base imbalances resulting from diarrhea may lead to neurologic disturbances including hyperesthesia and opisthotonus or terminal convulsions. Loss of bicarbonate in the diarrheic feces and a build up of L-lactate due to the poor peripheral perfusion associated with dehydration combine to produce a severe metabolic acidosis in diarrheic, dehydrated kids, which is life threatening.

Clinical Pathology and Necropsy

Measurement of packed cell volume, total plasma protein, serum sodium, potassium, bicarbonate, blood glucose, and blood gases are useful in determining the severity of electrolyte deficits, acidosis, and hypoglycemia in neonatal diarrhea cases. In the field, however, useful estimates of these deficits can also be gauged based on the severity of clinical dehydration. In general, diarrheic kids have a hyperkalemic, metabolic acidosis with a high serum anion gap.

Submission of diarrheic feces to a diagnostic laboratory for etiologic evaluation is encouraged. At the very minimum, samples from kids younger than three weeks of age should be evaluated for cryptosporidia, enterotoxigenic and enteropathogenic *E. coli*, *Salmonella*, rotavirus, and coronavirus. In kids older than

three weeks of age, additional evaluations should include coccidiosis, giardiasis, enterotoxemia, and yersiniosis. Samples should be collected within twelve to twenty-four hours of the onset of diarrhea, because the viruses may be rapidly cleared from the gut. A volume of 5 to 10 cc of fresh, diarrheic feces should be submitted under refrigeration. If such volumes are unavailable and rectal swabs are used, they should be shipped to the lab in a suitable bacterial transport medium. Also, fresh fecal smears prepared on glass slides can be valuable in the diagnosis of cryptosporidiosis and enteric viruses by acid-fast staining and fluorescent antibody testing, respectively. Survival of cryptosporidial oocysts in fresh feces is poor. While viruses can be identified in fresh feces by electron microscopy, such equipment is not always available. Many virulence factors associated with the various types of *E. coli* can be identified using molecular techniques such as gene probes and multiplex PCR to help characterize isolates from neonatal diarrhea cases. These techniques have been reviewed (DebRoy and Maddox 2001).

At necropsy, a loop of bowel can be ligated and removed and submitted to the lab unopened under refrigeration. Formalinized tissues from major organs and various portions of the gastrointestinal tract should also be submitted for histopathologic evaluation. Gross lesions may be found at necropsy in the case of coccidiosis, salmonellosis, yersiniosis, enterotoxemia, and some forms of gastrointestinal nematodiasis, and these lesions are discussed under each of these disease headings elsewhere in the chapter. The remainder of the causes of diarrhea in young kids may produce little or no gross abnormalities beyond some gaseous distension of the bowel and slight hyperemia. Histological evaluation can be helpful in some of these cases and immunohistochemistry is now also available for identification of some enteric pathogens, for example *Cryptosporidium* and *Giardia*.

Diagnosis

Definitive diagnosis of the causes of diarrhea in young kids may require exhaustive and costly bacteriologic, virologic, and parasitologic testing in the diagnostic laboratory. A list of likely causes of diarrhea in young kids based on age is given in Table 10.3 to serve as a general diagnostic guideline.

Treatment

Many of the common causes of diarrhea are self-limiting, and the major goals of therapy are to keep the kid physiologically intact while the diarrhea runs its course. Implementation of this strategy includes moving the kid to a warm, dry place to maintain proper body temperature and providing appropriate fluid therapy to counter dehydration, electrolyte depletion, hypoglycemia, and acidosis. Oral or parenteral therapy can be used depending on the severity of disease. Oral fluids can be used in kids up to 7% dehydration, but they should receive intravenous fluids with bicarbonate supplementation if dehydration level exceeds 8%. Many commercial preparations are manufactured for oral rehydration therapy in diarrheic animals and are increasingly available worldwide. Effective oral rehydration preparations should contain sodium chloride, potassium chloride, sodium bicarbonate, glucose, and glycine. The basic intravenous fluids should contain equal volumes of isotonic saline, isotonic sodium bicarbonate, and isotonic dextrose, but additional amounts of isotonic bicarbonate (1.3%) likely need to be given to correct the bicarbonate deficit associated with severe diarrhea. Additional details on the management of parenteral therapy in diarrheic neonates is available elsewhere (Radostits et al. 2007).

The feeding of milk or milk replacer products should be approached cautiously during the acute phase of diarrhea. Because there likely will be some derangement of digestive function, lactose in milk-based feeds may remain undigested in the gut and promote a hyperosmotic diarrhea on top of the existing enteritis. Alternating oral electrolyte solutions with small feedings of milk is a reasonable approach. The use of commercial, lactose-free milk products or the addition of lactase to goat milk before feeding to kids may also be useful. Kids should be brought back on milk gradually as diarrhea improves. In diarrhea that lasts for more than several days, it is necessary to feed milk products to avoid starvation. The strategy then becomes to decrease the volume fed per feeding and to increase the number of feedings. In this manner, the residual digestive capacity of the gut may not be overwhelmed.

A variety of oral antidiarrheal medications and intestinal protectants such as bismuth subsalicylate or kaolin/pectin have been used in kids. They may be helpful, but no efficacy trials have ever been reported in goats. Similarly, oral yogurt or lyophilized *lactobacillus* cultures are given empirically to restore a more normal gut flora.

Whenever possible, antibiotic therapy for diarrhea should be based on culture and sensitivity tests. When bacterial causes of diarrhea are strongly suspected and sensitivity testing is not possible, then broad-spectrum oral or parenteral antibiotic therapy such as trimethoprim/sulfa may be indicated. More details on specific antibiotic choices are given in the separate discussions of each bacterial disease elsewhere in this chapter. Antibiotics are also indicated prophylactically in scouring kids to protect against secondary bacterial pneumonias that are common in debilitated kids. Antibiotics are sometimes used indiscriminately by goat owners in lieu of diagnostic veterinary services, and client education is an important part of managing diarrhea outbreaks.

Control

Regardless of the etiologic cause, one of the most effective means of controlling the spread of diarrhea in kid populations in the face of an outbreak is to immediately and strictly isolate affected kids at the first sign of diarrhea. When possible, other exposed kids should be moved to a clean pen or at least temporarily removed from diarrhea-contaminated pens to permit disinfection. In the case of viral enteritides and cryptosporidiosis, where effective therapeutic agents may not be available, the use of isolation and sanitation as control measures becomes critical.

As with other species, diarrhea in kids is likely to be more common in intensive rearing operations. In these situations, kids should be born in clean, draft-free quarters and not allowed to become chilled. They should receive adequate colostrum as early in life as possible, at least before six hours of age. Colostrum banks may be helpful in ensuring an adequate supply of colostrum. Outbreaks of diarrhea often occur at the end of the kidding season, indicating that there is a progressive build up of pathogens over time and that better sanitation is needed in kidding areas, kid housing areas, and feeding equipment.

Vaccination of the doe in the four to six weeks before kidding may improve the concentration and specificity of protective antibodies available in the colostrum. Vaccination of the dam with *Clostridium perfringens* types C and D is already justified. Bovine K99+ *E. coli* vaccines have been demonstrated to produce increased K99 specific antibody in doe serum and colostrum (Contrepois and Guillimin 1984). More recently, a subunit vaccine for pigs containing K88 and K99 pilus antigens reduced diarrhea in a herd when does were vaccinated and kids consumed their colostrum (Kritas et al. 2003). The economic justification for using such vaccines depends on confirmation that enterotoxigenic E. coli are involved in diarrheal outbreaks on the farm or in the veterinarian's practice area. It is also unknown if bovine rotavirus and coronavirus vaccines are effective in the control of diarrhea in young goats. In endemic areas, vaccination of goats for peste des petits ruminants is justified.

Kids should be housed separately or in small groups of approximately equal age. Bedding should be clean and dry. Regardless of feeding system, all utensils and equipment should be cleaned and disinfected between feedings. In *ad libitum* feeding systems, a small amount of formalin has been added to milk to inhibit bacterial overgrowth in the milk and the kids' gastrointestinal tract. Kids should be offered access to hay soon after birth and a grain ration offered by week two to initiate good rumen development and a normal flora, and to avoid subsequent weaning shock. When possible, kid pens should be organized so feed can be fed in trays or buckets outside the pen to avoid fecal contamination of feedstuffs.

Liver and Pancreas

Several common goat diseases principally involve the liver and may produce a considerable amount of economic loss (Sriraman et al. 1982). The most important hepatic diseases are fluke infestations and pregnancy toxemia. Pregnancy toxemia is discussed in Chapter 19. Copper toxicity, which produces hemolytic anemia and toxic hepatitis, is discussed in Chapter 7. All other liver diseases are discussed in this chapter. Pancreatic disease in goats is limited to pancreatic fluke infestations that are most often subclinical in nature.

BACKGROUND INFORMATION OF CLINICAL IMPORTANCE

Anatomy and Physiology

Liver

The caprine liver comprises four distinct lobes: the right, left, quadrate, and caudate. It is located in the dorsal two-thirds of the right anterior abdomen, in contact with the diaphragm and the abdominal wall from the seventh to last rib (Figure 11.1). Dorsally, the liver is covered by the lung as far caudally as the ninth rib space, but the liver is percussible or accessible for biopsy between the ventral lung border and the costochondral junctions in the seventh through ninth rib spaces. The gallbladder extends below the ventral border of the liver.

Structural variation has been reported in the biliary apparatus of the goat. The cystic duct from the gallbladder enters the right hepatic duct in about half of goats examined, while in the other half, it enters at the junction of the left and right hepatic ducts so that the common bile duct is not preceded by a common hepatic duct (Robinson and Dunphy 1962). The distribution of the various branches of the hepatic veins of the goat has also been identified as distinct from the arrangement traditionally described for all ruminants (Brikas and Tsiamitas 1980).

Pancreas

The pancreas is located in close association with the portal vein in the craniodorsal abdomen to the right of the midline. It is composed of a larger right lobe, extending along the descending duodenum, and a smaller left lobe (Lukens 1938; Naranjo et al. 1986). The pancreatic duct enters the common bile duct
Figure 11.1. Location of the liver in the abdomen of the goat and relationship to other visceral structures. 1, thirteenth rib; 2, descending colon; 3, pancreas, right lobe; 4, right kidney; 5, descending part of duodenum; 6, distal loop of ascending colon; 7, cecum; 8 to 10, proximal loop of ascending colon (8, middle gyrus; 9, dorsal gyrus; 10, ventral gyrus); 11, liver; 12, cranial part of duodenum; 13, costal arch; 14, gallbladder; 15, abomasum; 16, ovary and uterine tube; 17, spiral loop of colon; 18, jejunum. (Reproduced with permission from Popesko P.: Atlas of Topographical Anatomy of Domestic Animals, new revised English edition, Vydavatelstvo Priroda, Bratislava, 2008, www.priroda. sk.)

(Robinson and Dunphy 1961). Histologically, the structure of the goat pancreas is similar to that of other domestic ruminants (Reddy and Eliot 1985; Lone et al. 1989).

Clinical Pathology

Enzymology

Hepatic parenchymal disease that causes a disruption of hepatocytes can lead to measurably increased serum levels of a number of intracellular hepatic enzymes in goats. Information about normal serum levels of these enzymes and their variation in goats due to age, breed, and sex is given in Table 11.1.

Increases in aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) are not liver-specific, and also result from muscle cell damage as discussed in Chapter 4. Basal levels of sorbitol dehydrogenase (SDH) in goat liver and serum are much higher than those reported for cattle and sheep.

It is advised that alanine aminotransferase (ALT), formerly serum glutamic pyruvic transaminase (SGPT), commonly used as an indicator of hepatic disease in dogs and cats, not be used in the evaluation of liver disease in ruminants because the livers of cattle and sheep contain low levels of ALT (Cornelius 1980). This is also true in goats. Changes in serum ALT concentrations are highly variable and unpredictable in response to hepatic injury (Hanifa Moursi et al. 1979; Abu Damir et al. 1982; Jones and Shah 1982; Clark et al. 1984; Shimizu et al. 1986; El Dirdiri et al. 1987).

Concentrations of liver-specific enzymes are generally higher in acute liver disease than chronic liver disease and may be within normal limits in the later stages of prolonged hepatic disease, so careful interpretation of laboratory values in conjunction with clinical findings is essential.

Biliary stasis or obstruction can occur concurrently or independently of parenchymal damage, and different enzymes are used to evaluate cholestasis, namely,

Table 11.1. Some normal values reported for liver-associated enzymes and other blood parameters associated with liver disease.

Enzyme	Unit	Goat description (number of animals)	Mean ± S.D.	Range	Reference
Alanine aminotransferase (ALT, SGPT)	IU/l	General values		24.0–83.0	Kaneko 1980
	IU/l	Adult, lactating F, Saanen and Alpine (79)	18.7 ± 3.1	12.5–24.9	Ridoux et al. 1981
	IU/l	Adult, lactating F, Saanen only (25)	20 ± 3.6		Ridoux et al. 1981
	IU/l	Adult, lactating F, Alpine only (54)	18.1 ± 2.7		Ridoux et al. 1981
Albumin	g/dl	General values		2.7–3.9	Kaneko 1980
	g/dl	General values		2.3–3.6	Kahn 2005
Alkaline phosphatase (AP)	IU/l	General values	219 ± 76	93–387	Kaneko 1980
	IU/l	Adult, lactating F, Saanen and Alpine (63)	184 ± 120	0.0–424	Ridoux et al. 1981
Ammonia	mmol/l	Adult Nubian goats (11)		40.2–43.7	Ali and Abu Samra 1987
Arginase	IU/l	0.5 to 2.5 yr, F, breed not stated (<28)	13.21	0.0–23	Adam et al. 1974
	IU/l	0.5 to 2.5 yr, M, breed not stated (<28)	14.87	0.0–20	Adam et al. 1974
Aspartate aminotransferase (AST, SGOT)	IU/l	General values		167.0–513.0	Kaneko 1980
	IU/l	4-month-old adult MC, F, Saanen—feral (5)	70 ± 13		Kramer and Carthew 1985
	IU/l	All ages, M, MC, F, pygmy (53)	32.3 ± 10.1		Castro et al. 1977
	IU/l	Adult, lactating F, Saanen and Alpine (80)	43.6 ± 9.9	23.8–63.4	Ridoux et al. 1981
	IU/l	Adult, lactating F, Saanen only (25)	51.7 ± 8.7		Ridoux et al. 1981
	IU/l	Adult, lactating F, Alpine only (55)	39.8 ± 8		Ridoux et al. 1981
Bilirubin, Total	mg/dl	General values		0.0–0.1	Kaneko 1980
	mg/dl	4–6 yr, F, pygmy (7)	0.2 ± 0.05		Castro et al. 1977
	mg/dl	2–3 yr, F, pygmy (17)	0.4 ± 0.1		Castro et al. 1977
	mg/dl	1–2 yr, F, pygmy (7)	0.8 ± 0.3		Castro et al. 1977
	mg/dl	<1 yr, F, pygmy (10)	0.5 ± 0.1		Castro et al. 1977

alkaline phosphatase (AP) and gamma glutamyl transferase (GGT). Increases in serum AP or GGT are associated with irritation or destruction of biliary epithelium and can occur in obstructive conditions of the biliary system, such as fascioliasis. While serum elevations of GGT are essentially liver-specific, AP occurs in other tissues, especially bone, and serum concentrations may be elevated in young, growing animals because of normal osteoblastic activity or secondary to pathologic conditions of bone unrelated to biliary disease, as discussed in Chapter 4. Thus, serum GGT is the preferred test for assessment of biliary integrity in goats. While the goat kidney contains high levels of GGT, the enzyme is passed in the urine in association with renal damage and does not enter the blood.

Total bilirubin concentration in the serum of normal goats is generally reported to be in the range of 0.0 to 0.1 mg/dl (Kaneko 1980). Higher bilirubin concentrations in the range of 0.2 to 0.8, however, have been reported in normal pygmy goats, with values varying with both age and sex (Castro et al. 1977). As in cattle and sheep, circulating bilirubin levels increase only modestly in the face of severe, generalized hepatic disease (Sen et al. 1976). The most dramatic increases in serum or plasma bilirubin in the goat are due to hemolytic crises rather than liver dysfunction (Wasfi and Adam 1976).

Serum bile acids can be a useful indicator of liver dysfunction and may be a more reliable indicator of liver disease than either circulating bilirubin levels or

transaminase activities (Kaneko 1980). Because the liver is responsible for the uptake, conjugation, and secretion of bile acids, there is a decreased secretion of bile acids into bile with liver dysfunction and an associated increase in blood concentrations. However, to date there has been little reported use of bile acids for diagnostic purposes in goats. Serum bile acid concentrations have been reported for normal goats before, during, and after fasting, with no fasting effect on serum bile acid concentrations noted (Rudolph et al. 2000).

Serum cholesterol levels have been used as an indicator of liver dysfunction in various species, but there are few reports in goats on variation of serum cholesterol levels in disease. Serum cholesterol levels in goats have been reported in relation to various physiological and nutritional states including pregnancy, lactation, fasting, and diet, but the results of similar studies are sometimes contradictory, so it appears that more assessment is needed before serum cholesterol levels will be a useful diagnostic tool in goat medicine.

Liver Function Tests

Galactose elimination, a liver function test used in humans, is not appropriate in goats due to a high percentage of galactose loss in the urine (Treacher 1972). Sulfobromophthalein (Bromsulphalein, BSP) clearance is used to evaluate liver function in ruminants and other species. A delay in the clearance of this dye from the blood by the liver suggests functional impairment or decreased flow of bile. Focal liver diseases, such as abscesses, do not interfere with BSP clearance. Prolongation of clearance time in the goat is most often seen with generalized hepatic lipidosis (fatty liver) secondary to pregnancy toxemia, with chronic, toxic hepatitis, or with biliary obstruction. The T1/2 for BSP clearance in normal goats was reported as 2.13 ± 0.19 minutes (Sen et al. 1976). It increased to 4.04 ± 0.24 minutes subsequent to a single dose of carbon tetrachloride, to 16.5 minutes after repeated doses of carbon tetrachloride, and to more than 34 minutes after bile duct ligation.

In another study, Lal et al. (1991) used percent retention of BSP rather than BSP clearance to assess liver function. Normal goats had a mean % retention time of 4.2 ± 0.34 at ten minutes after intravenous injection of BSP dye at a dose of 5 mg/kg bw. Twelve hours after the induction of ruminal acidosis by feeding of wheat, % retention of BSP in those goats increased to 15 ± 1.08.

Other Laboratory Tests

The liver is the primary site of albumin production, and hepatic insufficiency leads to hypoalbuminemia. Normal serum albumin levels in the goat are reported in the range of 2.7 to 3.9 g/dl (Kaneko 1980). Hepatic

dysfunction can also cause hypoglycemia. Normal blood glucose levels in the goat are reported in the range of 50 to 75 mg/dl (Kaneko 1980). When goats are in negative energy balance, such as occurs in pregnancy toxemia or lactational ketosis, the liver produces increased ketone bodies that are detectable in serum, milk, or urine. Blood ammonia levels may be elevated in goats with generalized liver disease, particularly when neurologic signs are present, but it is not a consistently reported finding. In a case of hepatic encephalopathy associated with paratuberculosis in a goat, blood ammonia concentration was reported at 230 μmol/l compared to a value of 27 μmol/l in a healthy control goat (Rubin et al. 1999), while in a case of hepatoencephalopathy associated with portocaval shunt in a goat, plasma ammonia concentration reached 599 μg/dl (352 μmol/l) with a normal reference value range given as 25.5 to 109 μg/dl (15 to 64 μmol/l) (Humann-Ziehank et al. 2001).

Beyond the identification of ketone bodies in urine, interpretation of urinalysis in goats for diagnosing liver disease has received little attention. Normal goat urine does not contain bilirubin, so presumably, evidence of conjugated bilirubin in the urine may indicate obstructive liver disease or severe hemolytic disease. The absence of urobilinogen would suggest complete biliary obstruction, while increases in urobilinogen could represent active hepatocellular disease.

Diagnostic Procedures

Biopsy

Liver biopsy can be an aid in the diagnosis of suspected hepatic disease, particularly in cases of chronic liver disease when clinical findings suggest hepatic involvement but clinical chemistry results are equivocal. A prolonged BSP clearance time may also be justification for liver biopsy to determine the basis of impaired function. In focal hepatic disease, the liver biopsy may be misleading because a circumscribed lesion may be missed altogether.

Access to the liver for obtaining a biopsy sample is limited in the goat, and when possible, ultrasound needle guidance is desirable. Unguided liver biopsies should be performed cautiously, using a transthoracic approach. Tranquilization of excitable individuals may be helpful. With the animal standing, the preferred site for introduction of the biopsy instrument is the right ninth intercostal space (Fetcher 1983). Entry should be dorsal to a line drawn from the point of the elbow to the craniodorsal angle of the paralumbar fossa. Entering at the eighth intercostal space can cause a puncture of the caudal lung lobe, while use of the tenth space may put the biopsy instrument behind the caudal edge of the liver. The correct site should be surgically prepared and a local anesthetic applied. The biopsy

instrument must traverse the caudal thorax and penetrate the diaphragm before entering the liver. The instrument should be directed anteriorly after passing through the intercostal muscle to avoid puncture of the gallbladder, especially if the animal has been anorexic and the gallbladder is distended. It should not be necessary to introduce the biopsy instrument to a depth more than 3 to 4 cm because the transthoracic space in this area is less than 2 cm and the liver thickness is approximately 4 to 5 cm.

Ultrasound

Ultrasonography can be helpful in identifying uncommon mass lesions in the liver such as abscesses, hydatid cysts, and rarely neoplasms. It has also been reported to be useful in the diagnosis of fatty liver in goats, with affected livers showing multiple hyperechoic foci of fatty infiltration distributed throughout an isoechoic liver parenchyma (Gonenci et al. 2003). When available, ultrasonography can be particularly helpful in performing accurate liver biopsies.

Cholecystography

Intravenous cholecystography has been performed successfully in goats using 20 ml of intravenous contrast material (biligrafin). In normal goats, the gallbladder can be visualized thirty to sixty minutes after injecting contrast media. It is located between the caudal border of the eighth rib and the cranial border of the twelfth rib, 6 to 8 cm below the vertebral column. In goats with liver disease, visualization may be delayed and the position of the gallbladder may shift subject to hepatomegaly (Singh et al. 1990).

DIAGNOSIS OF HEPATIC DISEASE BY PRESENTING SIGN

Abdominal Pain

Pressure on the liver capsule from parenchymal swelling such as occurs in acute diffuse hepatitis or trauma to the capsule itself can cause liver-associated pain. If severe, the animal may adopt a guarded, tucked-up stance with an arched back and be reluctant to move. This, of course, can also occur as a result of nonhepatic causes of abdominal pain, so pain must be localized to the liver by palpation over the right anterior ventrolateral aspect of the abdomen and the last few ribs. The most commonly reported causes of hepatic pain in goats are the acute forms of liver fluke disease and acute toxic hepatitis.

Anemia

Liver-associated causes of anemia are limited to the parasitic diseases, chronic copper toxicity, and some experimentally induced plant poisonings. In acute liver fluke disease, the cause of anemia is severe hemorrhage into the peritoneal cavity associated with large numbers of larvae penetrating the liver capsule. In chronic fascioliasis, the anemia is caused by mechanical trauma and feeding activity of adult *Fasciola* spp. within the biliary tree resulting in continuous blood loss. Anemia is accompanied by hypoproteinemia in these chronic cases.

Anorexia

Loss of appetite is a consistent finding in diffuse liver disease but is nonspecific.

Ascites and/or Edema

Hypoproteinemia is a common outcome of chronic liver disease and the most common clinical manifestation of liver-related hypoproteinemia is intermandibular edema, often seen in chronic liver fluke disease. However, nonhepatic causes of hypoproteinemia, most notably gastrointestinal helminthiasis, also produce the same sign.

Generalized ascites as a result of caprine liver disease is uncommon. One exception is a disease known as "waterpens" or "water belly" seen in goats and sheep in South Africa grazing the plant *Galenia africana* (kraalbos). At necropsy, there is severe ascites and evidence of liver and cardiac disease. It is unclear if ascites is caused by a primary cardiac or primary hepatic abnormality (van der Lugt et al. 1988). Experimental challenge studies with toxic plant extracts indicate that the hepatic lesions precede the cardiac lesions in the development of the condition (van der Lugt et al. 1992).

In Texas, consumption of the range plant *Sartwellia flaveriae* by Angora goats leads to marked ascites, abdominal distension, and weight loss associated with hepatic cirrhosis (Mathews 1940). Although a rare occurrence, bile duct carcinoma has also been reported as a cause of ascites in a goat in India (Chauhan and Singh 1969).

Bleeding Tendency

Coagulopathies are uncommon in goats and are rarely associated with liver problems. Only three reported instances of prolonged clotting time in goats have been associated with hepatic disease (Bassir and Bababunmi 1972; Saad et al. 1972; Jones and Shah 1982).

Diarrhea and Constipation

Diarrhea can occur in chronic fascioliasis. Diarrhea occurs in hepatotoxic plant poisonings, but concurrent enteritis also may be responsible for the diarrhea. Constipation is characteristic of *Lantana* poisoning in goats and other ruminants.

Alternating diarrhea and constipation have been associated with liver disease in large animals due to

decreases in bile salt excretion and reflex intestinal activity associated with liver distension. This pattern is not well documented in goats with hepatitis.

Jaundice

Hyperbilirubinemia caused by obstructive biliary conditions is rare in goats. Jaundice is most likely to result from hemolytic anemia and primarily involves increases in indirect unconjugated bilirubin. Table 7.6 in Chapter 7 lists the hemolytic causes of jaundice. Chronic copper poisoning produces both liver damage and hemolytic anemia with resultant jaundice, but the condition is rare in goats, which are much more tolerant of copper than sheep. The plant *Acanthospermum hispidum*, common in the Sudan, also produces both hepatic necrosis and hemolytic anemia in goats (Ali and Adam 1978).

No cases have been reported of complete, extrahepatic biliary obstruction in goats. Nonhemolytic jaundice may occur in Rift Valley fever and Wesselsbron disease in Africa, and has been reported sporadically in goats in association with other diverse causes including aflatoxicosis (Wanasinghe 1974), suspect halothane toxicity (O'Brien et al. 1986), sawfly larvae poisoning (Thamsborg et al. 1987), hepatic fibrosarcoma (Higgins et al. 1985), and consumption of the plants sacahuiste *(Nolina texana)* in Texas (Mathews 1940a) and signal grass *(Brachiaria decumbens)* in Malaysia and Nigeria (Mazni et al. 1985; Opasina 1985). In general, the occurrence of jaundice in caprine liver disease carries an unfavorable prognosis.

Neurologic Signs

Altered states of mentation and other neurologic signs are often seen in goats with diffuse liver disease and are associated with disruptions in normal liver metabolism. The pathogenesis of this hepatoencephalopathy is not completely understood, but is presumed to be multi-factorial. Prevailing theories include: ammonia acting as a neurotoxin possibly in synergy with other toxins, alteration in monoamine neurotransmitters as a result of altered aromatic amino acid metabolism, imbalances in the amino acid neurotransmitters glutamate and γ-aminobutyric acid, and/or increased cerebral concentrations of an endogenous benzodiazepine-like substance (Maddison 1992). There is general consensus that ammonia plays a key role, especially since therapeutic interventions that decrease blood and CSF ammonia levels usually mitigate the neurologic signs associated with hepatic encephalopathy (Katayama 2004).

Clinical presentations associated with hepatoencephalopathy range from signs of hypoexcitablity including depression, head pressing, generalized weakness, ataxia, and coma, to signs of hyperexcitability such as hyperesthesia, muscle tremors, and convulsions.

While all the causes of diffuse liver disease in goats have the potential to produce neurologic signs, the most common causes are pregnancy toxemia and toxic hepatitis. The known causes of toxic hepatitis in goats are discussed later in this chapter.

Nonhepatic causes of neurologic signs are numerous in goats and must be differentiated from hepatoencephalopathy. Primary neurologic diseases are discussed in Chapter 5.

Photodermatitis

Hepatic or secondary photosensitization occurs in goats. Signs of photosensitization are varied and include uneasiness and pruritus with much scratching and rubbing activity, severe dermatitis with erythema, extensive subcutaneous edema, and eventual ulceration and sloughing of skin. Ophthalmia with excessive lacrimation, photophobia, and corneal cloudiness may also occur. The dermatitis and edema are particularly evident on the head and ears. In some outbreaks, jaundice is seen in conjunction with signs of photodermatitis. Secondary blindness, pyoderma, loss of body condition, and occasional deaths are possible sequelae. Light-colored animals are more severely affected.

Photosensitization associated with hepatotoxicity has been reported in goats consuming a variety of plants around the world, including sacahuiste weed *(Nolina texana)* (Mathews 1940a), green oats *(Avena sativa)* and wheat (Schmidt 1931), lechuguilla *(Agave lecheguilla)* (Mathews 1937), and kleingrass *(Panicum coloratum)* (Bailey 1986) in the United States; signal grass *(Brachiaria decumbens)* in Malaysia and Nigeria (Mazni et al. 1985; Opasina 1985); caltrop *(Tribulus terrestris)* in South Africa (Kellerman et al. 1980); and caltrop, boobiala tree *(Myoporum tetrandrum)*, and Ellangowan poison bush *(M. deserti)* in Australia (Allen et al. 1978; Glastonbury and Boal 1985; Jacob and Peet 1987). Additional details are given in the discussion of toxic hepatitis at the end of this chapter. Primary, nonhepatic photodermatitis also occurs in goats and must be differentiated from the hepatic form. It is discussed in Chapter 2.

Weight Loss

Chronic liver fluke disease is important in the differential diagnosis for wasting in goats. Weight loss may be the only sign associated with liver abscesses. It is one of many signs associated with a wide range of hepatotoxic plants that cause prolonged hepatic insufficiency.

Yawning

Occasional yawning in goats is normal. Repeated yawning may suggest liver disease in goats as in other species, although the causal relationship is not clear.

Goats with pregnancy toxemia or other causes of hepatic lipidosis are most likely to exhibit repeated yawning.

SPECIFIC DISEASES OF THE LIVER

VIRAL DISEASES

Rift Valley Fever

This arthropod-borne virus disease of ruminants, camels, and humans is thus far limited to Africa and the Arabian peninsula. The disease is characterized by acute, severe hepatic necrosis with abortion in pregnant dams and high mortality in neonatal animals. Goats are generally considered to be less susceptible than cattle or sheep, but there is a high variability between breeds.

Etiology

The causative agent is an enveloped, single-stranded RNA phlebovirus in the *Bunyaviridae* family. The virus is very stable near neutral pH in blood or serum and also in aerosol. It is killed by 2% sodium orthophenylphenate and 4% sodium carbonate disinfectants. There is only a single serotype of the infective agent, though differences in pathogenicity have been noted between isolates (Swanepoel et al. 1986). Phylogenetic analysis of the virus indicates two distinct lineages for the RVF virus—one Egyptian and the other sub-Saharan (Sall et al. 1997). However, there are two distinct groupings within the sub-Saharan viruses, one West African and the other central and southern African, now including the viruses from the Arabian peninsula.

Epidemiology

Rift Valley fever (RVF) was first identified in Kenya's Rift Valley in 1930, although there are earlier descriptions of what could well have been RVF. The disease was historically limited to East and Central sub-Saharan Africa and was first recognized in southern Africa in the 1950s. However, later outbreaks in Egypt, Senegal, and Mauritania indicated its potential for further spread (Ksiazek et al. 1989; Lancelot et al. 1989). It is now known to occur throughout Africa, including the island of Madagascar. In 2000, the disease was confirmed for the first time outside of Africa, on the Arabian peninsula in Yemen and Saudi Arabia, and it affected large numbers of livestock and humans, with more than 120 human deaths (Al-Afaleq et al. 2003; Anyamba et al. 2006).

The RVF virus is transmitted to susceptible hosts during feeding by infected mosquitoes in the genera *Aedes, Culex, Mansonia, Eretmapodites*, *Coquillettidia*, and *Anopheles*, and possibly by other insects. The *Aedes* mosquitoes are capable of transovarial transmission of the virus, and their eggs can survive desiccation well,

thus sustaining infection even for decades. Viremic ruminants and humans can also contribute to the spread and amplification of infection. Direct transmission from infected animals to people can occur by aerosols of blood at the time of slaughter as well as by ingestion of blood and milk.

Epizootics often follow periods of heavy rainfall; the rain facilitates the hatching of previously laid, dormant, infected mosquito eggs resulting in sudden increases in infected *Aedes* mosquito populations. These initiate infection which is then amplified markedly by *Culex* and other species of mosquitoes whose population increases lag somewhat behind those of the *Aedes* mosquitoes.

Two additional factors that contribute to epizootics are heavy winds that blow infected insects into previously uninfected areas and transport of infected livestock into such areas. Places with extensive irrigation networks or standing water, warm climate, suitable arthropod populations, and susceptible ruminant and human populations are most prone to epizootic occurrences (Wittmann 1989). An RVF epizootic which affected the contiguous areas of the Northeastern province of Kenya, the south of Somalia, and southern Ethiopia in 1997–1998 is estimated to have affected more than a half million small ruminants and sickened 89,000 people, leading to possibly 450 human deaths in Kenya alone. A similar, severe RVF outbreak occurred in Kenya and Tanzania in late 2006 through early 2007 and spread later in the year into Sudan.

It is now well documented that RVF epizootics in the Horn of Africa are associated with the El Nino-Southern Oscillation (ENSO) phenomenon. These warm ENSO events are known to increase precipitation in portions of East Africa. Retrospective studies on data from 1950 through 1998 demonstrated that an analytical model which included measurements of southern oscillation indices, equatorial sea surface temperatures in the Pacific and Indian Oceans, and satellite derived vegetation indices in East Africa would have accurately predicted 100% of the RVF epizootics that occurred during that forty-eight-year period (Linthicum et al. 1999). Such predictive epidemiological tools can be extremely useful for instituting timely and effective disease control programs.

Pathogenesis

After infection, there is a viremia with fever and leukopenia. Despite the destruction of liver cells by rapidly multiplying virus, localization of virus in tissues does not occur to any great extent, and blood always contains the highest levels of virus. A carrier state does not develop in ruminants. Lesions are limited to the liver and are characterized by focal hepatic necrosis. Experimental infections in goats have been described (Easterday et al. 1962).

Clinical Findings

The incubation period is as short as twelve hours in kids and as long as forty-eight hours in adult goats. Adult animals are always less severely affected than young stock. In epizootics involving goats, the predominant effects are abortion in pregnant does and death in kids younger than one week of age. Many infections in non-gravid individuals are subclinical.

While peracute death with no prodromal signs is most likely in neonatal kids, some young kids may show fever up to 108.0°F (42.2°C), accompanied by listlessness and inappetence. Death may occur within the next several days.

The acute form of the disease is more likely in older kids and some adults, though it is seen less frequently than in sheep. In addition to fever and depression, variable signs may include icterus, vomiting, hemorrhagic diarrhea, unsteady gait, catarrhal stomatitis, and skin necrosis on the udder or scrotum, with death in one to four days.

Except for abortion in pregnant does, most affected adult goats are likely to show only subacute disease, with fever in the range of 104°F to 106.2°F (40°C to 41.2°C), dullness, and inappetence for one to three days. Mortality rates are low in adult goats. Breeds of imported goats are more likely to show overt signs of disease than indigenous breeds.

Clinical Pathology and Necropsy

Leukopenia is common in the early stages of disease. Virus isolation in cell culture is possible from blood of live, febrile goats; or liver, spleen, and brain of fatal cases; and organs of aborted fetuses. When immediate submission to the laboratory is not possible, samples should be frozen at –94°F (–70°C). Alternatively, immunofluorescence can be used to identify RVF virus antigen on impression smears of liver, spleen, and brain. Other techniques available for detection of viral antigen include agar gel immunodiffusion (AGID), complement fixation, and reverse transcriptase polymerase chain reaction (RT-PCR)(OIE 2004).

After outbreaks, seroconversion can be documented using indirect enzyme-linked immunoabsorbent assay or other serologic methods in serum samples taken three weeks apart. An IgM capture ELISA can diagnose RVF on a single blood sample taken early in infection. Other tests that can be used to assess seroconversion in paired samples are virus neutralization, hemagglutination inhibition, and complement fixation (OIE 2004).

At necropsy, the liver may be friable and appear moderately enlarged, soft, and pale with focal areas of subcapsular hemorrhage. On cut section, 1 to 2 mm gray-yellow necrotic foci are distributed throughout the parenchyma. Other possible findings include visceral and serosal hemorrhage, icterus, hemorrhagic gastritis, and enteritis. Similar lesions may be seen in aborted fetuses.

Histologically, the liver lesion is one of focal centrilobular or midzonal necrosis of small groups of hepatocytes. As lesions progress, they may become confluent and involve a large portion of the lobule. Eosinophilic, intranuclear inclusion bodies surrounded by marginated chromatin are common in degenerating hepatocytes in advanced lesions.

Diagnosis

Definitive diagnosis is by virus isolation or the demonstration of virus genome and by confirmation of seroconversion in affected goats. In those parts of Africa where both diseases occur, RVF must be differentiated from Wesselsbron disease, a liver disease that is also described in this chapter. In sheep, bluetongue is considered in the differential diagnosis but bluetongue is almost always asymptomatic in indigenous goats. When people handling livestock complain of influenza-like illness during epizootics of animal disease, the diagnoses of Rift Valley fever or Wesselsbron disease should be pursued vigorously.

Treatment

The antiviral drug ribivarin is the drug of choice for bunyavirus infections in humans, but no recommendations for use in animals are made. The intravenous or intraperitoneal administration of 10 to 30 ml of serum from convalescent sheep to one- to three-day-old lambs reduced mortality, even when lambs were already showing signs of illness (Bennett et al. 1965).

Control

In endemic areas, an attenuated live vaccine, prepared from the mouse-brain-adapted Smithburn strain, is available. The vaccine is recommended for use in cattle, sheep, and goats, but should not be used in pregnant animals, because viremia, abortion, fetal death, and fetal anomalies occur, especially in sheep. Immunity lasts at least two years and is generally considered to be lifelong.

Vaccination should not be undertaken during an epizootic of RVF. If deemed necessary, then needles must be used on a single animal only, and then replaced, because needle passage of the disease during periods of active transmission is quite likely and can further spread the disease and extend the duration of the outbreak.

Formalin-inactivated vaccines are available for use in nonendemic areas but they are less effective, especially in cattle. Work is ongoing in the development of newer live vaccines with less objectionable side effects.

Mosquito control is problematic but there are some indications that insecticidal fogging and the use of *Bacillus thuringensis* might have potential for control in the face of an epidemic. Movement of animals out of known mosquito breeding areas after heavy rainfall, for example into cooler highland areas, might reduce the incidence of disease. During epizootic outbreaks, movement of nonvaccinated animals should be restricted.

In recent years, the use of historic and real-time climate data and vegetation indices obtained by satellite imaging have allowed for the reliable prediction of RVF epizootics two to five months in advance of the first clinical cases (Linthicum et al. 1999; Anyamba et al. 2002). In 2006, the Food and Agriculture Organization of the United Nations (FAO), through its Emergency Prevention System (EMPRES), was able to accurately predict the RVF epidemic in Kenya and Tanzania about two months before it occurred (FAO 2006). It has now been demonstrated during the 2006–2007 Kenyan epidemic that participatory disease surveillance techniques are capable of providing strong support to systems based on satellite imaging for predicting the emergence of epidemic RVF in Kenya (Jost 2007). These are very useful tools for allowing the implementation of disease response plans, including vaccination, before the onset of disease.

Most human cases can be related to direct contact with blood or tissues of infected animals, or inhalation of aerosols associated with such tissues. While the disease in humans is usually inapparent or produces transient flu-like symptoms, in a subset of patients, the disease can be fatal following signs of hemorrhage, encephalitis, and/or severe hepatic disease. Retinal damage and visual impairment is a common sequel to acute human infection. Veterinarians should take suitable precautions against infection when performing examinations or necropsies and advise against slaughter and consumption of meat from suspected cases (Davies 2006). Consumption of raw milk in areas undergoing an active outbreak is unwise. Vaccination with a killed vaccine should also be considered by people such as veterinarians and laboratory workers with a high risk of exposure.

Wesselsbron Disease

This mosquito-borne virus disease of domestic livestock is enzootic in south, central, and west Africa. Largely asymptomatic in adults, it primarily causes abortion and neonatal mortality. It is important in the differential diagnosis of Rift Valley fever. It occasionally infects humans.

Etiology and Epidemiology

The causative agent is an enveloped, single-stranded RNA, group B flavivirus in the *Togaviridae* family. The disease was first identified in the Wesselsbron district of the Orange Free State in South Africa in 1955. *Aedes caballus* and *A. circumluteolus* mosquitoes are the primary disease transmitters, but contact and aerosol transmission have also been reported (Barnard 1986).

Cattle, sheep, and goats are principally affected, but the mammalian host range is wide and includes humans. There is serological evidence of infection throughout southern, central, and western Africa but disease incidence is low. Epizootic outbreaks occur in South Africa in association with heavy rainfall, which favor increased vector mosquito activity. Cattle may be a natural reservoir of the disease. The virus is isolated from some wild rodents and birds, including ostriches, but their role as reservoirs is debatable.

Pathogenesis

Infection is followed after a short incubation period by viremia with fever. The virus shows a predilection for the liver, and even when clinical disease is not observed, focal necrosis of the liver occurs, as demonstrated in experimental infection of adult goats (Coetzer and Theodoridis 1982). Kids are more severely affected than adults (Theodoridis and Coetzer 1980). Increased levels of antibody are detectable within three weeks of infection.

Clinical Findings

In epizootics of Wesselsbron disease, clinical signs in adults are usually limited to abortion in pregnant does and ewes, with nonpregnant females and males showing no clinical effects. Kids and lambs, especially if less than four weeks of age, can die suddenly or soon after showing some weakness, loss of appetite, increased respiratory rate, icterus, and fever up to 105.8°F (41°C). Lamb mortality as high as 30% has been documented.

Clinical Pathology and Necropsy.

When laboratory support is available, intracerebral inoculation of infant mice with liver or brain of affected kids and subsequent identification of the virus by serum neutralization should be attempted. Alternately, immunohistochemical staining of formalin-fixed liver specimens using polyclonal antibody against Wesselsbron virus also has been reported in diagnosis of field cases and experimental infections (van der Lugt et al. 1995). In lieu of virus or antigen identification, seroconversion can be documented using the hemagglutination inhibition (HI) assay in acute and convalescent serum samples taken three weeks apart. An antibody detection ELISA has also been developed. It is reported to be more sensitive than hemagglutination inhibition and less cross reactive to other flaviviruses (Williams et al. 1997), but to date, the HI test is still routinely used.

At necropsy, the liver may be slightly swollen and yellow to orange brown in color. In some animals, slight hydropericardium and ascites, lymphadenopathy, splenomegaly, serosal hemorrhage, and jaundice may be seen. Histologically, the liver lesions are characterized by small, focal areas of necrosis and a pronounced, nodular Kupffer cell reaction (Coetzer and Theodoridis 1982). Eosinophilic intranuclear inclusions are sometimes seen. Lymphoid tissues may show pyknotic lymphocytes and lymphoid hyperplasia. Neutrophilic infiltration of the red pulp of the spleen may occur. Myocardial necrosis has been noted in some goats.

Diagnosis

Wesselsbron disease and Rift Valley fever present a similar clinical picture in goats. It is important to make a specific etiologic diagnosis because the zoonotic implications of Rift Valley fever are much more profound. Virus isolation is the ideal method. Intraperitoneal inoculation of suckling or weaned mice or hamsters leads to death of the lab animals in three to four days when RVF virus is present in the inoculum, but not in the case of Wesselsbron disease virus. Serology and histopathology can also be helpful in differentiating the two diseases.

Treatment and Control

There is no treatment for this virus disease. An attenuated live virus vaccine produced in South Africa is in use in enzootic areas. Pregnant animals and those younger than six months of age should not be vaccinated because the vaccine itself can cause abortion or illness in young stock. It is recommended that flocks be vaccinated in the spring three to six weeks before mating because disease usually occurs in late summer and autumn. Vaccine should not be used in the face of an outbreak. Immunity, which develops three weeks after vaccination, is considered to be lifelong. Removing animals to high ground after heavy rains in anticipation of increased mosquito activity in low, wet areas may reduce the risk of disease.

BACTERIAL DISEASES

Bacteria are an uncommon cause of clinical liver disease in goats. Infectious necrotic hepatitis, or black disease caused by *Clostridium novyi*, is uncommon in goats as compared to sheep. The disease is discussed later in the chapter in the section on fascioliasis, which predisposes to its occurrence. In this section, liver abscesses, which tend to be subclinical but can cause economic wastage due to liver condemnations, are discussed.

Liver Abscesses

The syndrome of liver abscesses secondary to rumenitis that is well documented in feedlot cattle on high energy rations has not been reported in goats thus far, even though there is increased interest in raising goats for meat under intensive or semi-intensive conditions. Sporadic cases of subclinical liver abscesses, however, do occur in goats and cause economic loss through liver condemnation at slaughter.

Etiology

A variety of organisms have been reported from caprine liver abscesses. *Corynebacterium pseudotuberculosis* is most common. *Arcanobacterium pyogenes* and *Escherichia coli* are also common. Other sporadic isolates include *Proteus* spp., *Mannheimia haemolytica, Staphylococcus epidermidis, S. aureus, Rhodococcus equi, Erysipelothrix rhusiopathiae,* and the yeast *Candida krusei* (Whitford and Jones 1974; Eamens et al. 1988; Panebianco and Santagada 1989; Santa Rosa et al. 1989). The common isolate from bovine liver abscesses, *Fusobacterium necrophorum*, is not reported from the goat.

Epidemiology and Pathogenesis

No particular management, feed, or breed factors have been identified in the development of caprine liver abscesses. Reports of caprine liver abscess have come from Brazil (Santa Rosa et al. 1989), Botswana (Diteko et al. 1988), and Australia (Carrigan et al. 1988). In the Brazilian study, 2.5% of a necropsy study population showed liver abscesses. A greater proportion of adult goats was affected than young. Concurrent disease problems were always found, including caseous lymphadenitis, bronchopneumonia, rumen abscesses, peritonitis, and omphalophlebitis, among others. The association with concurrent infections suggests that liver abscesses probably occur from lymphatic or hematogenous spread from other loci of infection, but spread by parasite migrations through the liver is another possible cause.

Das and Misra (1992) induced ruminal acidosis in goats by feeding high levels of rice and demonstrated that serum concentrations of the liver enzymes AST, ALT, and GDH increased twenty-four hours following induction of rumen acidosis. They concluded that as in other species, ruminal acidosis can disrupt ruminal epithelial integrity and lead to entry of bacteria and fungi into the portal circulation, predisposing to the development of liver abscesses. This suggests that efforts to feed concentrates to meat goats under intensive conditions could lead to increased occurrence of liver abscesses.

Clinical Findings

There is one case reported from Trinidad in which an approximately two-year-old Anglo Nubian doe with chronic weight loss was found to have a liver abscess caused by *Rhodococcus equi* as the principal necropsy finding (Ojo et al. 1993). In all other reports

Table 11.2. Helminth parasites of the liver, pancreas, and related blood vessels.*

Scientific name	Common names	Location in goat	Geographic distribution	Clinical effects
Fasciola hepatica	Common liver fluke	Liver parenchyma, bile ducts	Worldwide	Acute death; marked anemia, edema, emaciation
Fasciola gigantica	Giant liver fluke	Liver parenchyma bile ducts	Africa, Asia	Acute death; marked anemia, edema, emaciation
Fascioloides magna	Giant liver fluke; large American liver fluke	Liver parenchyma	North America	Acute death
Dicrocoelium dendriticum	Lesser liver fluke; lancet fluke	Bile ducts	Europe, Asia, North America	Marked anemia, edema, emaciation
Eurytrema pancreaticum	Pancreatic fluke	Pancreatic ducts, bile ducts, duodenum	Eastern Asia, Brazil	Ill thrift
Stilesia hepatica	Liver tapeworm	Biliary ducts	Africa	Nonpathogenic; liver condemnation
Thysanosoma actinoides	Fringed tapeworm	Bile ducts, also small intestine	Western United States, South America	Nonpathogenic; liver condemnation

*For schistosomes of the liver and related vessels see Chapter 8, Table 8.3.

to date, liver abscess in goats is either a subclinical finding or only one of several disease findings that could account for weight loss.

Clinical Pathology and Necropsy

Though not specifically reported in goats, elevation of liver-specific enzyme concentrations in the serum resulting from destruction of hepatocytes by expanding abscesses might occur. Abscesses may be detectable by ultrasonographic study of the liver but would need to be differentiated from metacestode cysts. At necropsy, abscesses may be single or multiple, measure up to 5 cm in diameter, and contain purulent or caseous material.

Treatment and Control

There are no specific treatment or control recommendations. Appropriate therapy of concurrent disease problems may lead to some improvement in affected individuals. Efforts to control caseous lymphadenitis and omphalophlebitis in goats may be instrumental in reducing the frequency of liver abscesses. If concentrates are fed to meat goats, they should be introduced gradually into the forage-based diet and not provided in excessive amounts. The inclusion of antacids or buffers such as sodium bicarbonate in the ration is also indicated to reduce the risk of ruminal acidosis which could lead to liver abscesses.

PARASITIC DISEASES

In addition to the parasitic diseases of the liver discussed below, the liver may be the site of various *Schis-*

tosoma spp. infections which can produce disease as discussed in Chapter 8. (See Table 8.3.) A summary of parasites affecting the liver, pancreas, and related blood vessels of goats is given in Table 11.2.

Stilesia and *Thysanosoma* Tapeworm Infections

The goat is a definitive host for the tapeworm, *Stilesia hepatica*, which occurs extensively throughout Africa and Asia. The adult tapeworm may be found in the bile duct in large numbers. Adult *Stilesia hepatica* measure 20 to 50 cm long and 3 mm wide. The life cycle probably involves oribatid mites as an intermediate host. Eggs are passed in the feces of the goat.

This tapeworm is considered nonpathogenic in the living animal. However, large numbers of adult tapeworms may induce sufficient bile duct thickening that affected livers are condemned during meat inspection. In one study in Zimbabwe, 18.75% of communal goats had their livers condemned at slaughter and 72.9% of these condemnations were due to *Stilesia hepatica* (Chambers 1990). Praziquantel orally at 15 mg/kg is effective in eliminating *S. hepatica* in sheep but there are no reports on its use in goats for *Stilesia* infections.

The goat is infrequently infected with *Thysanosoma actinoides*, the fringed tapeworm of North and South America that is commonly found in the bile ducts, pancreatic ducts, and small intestine of sheep, cattle, and deer. Clinical disease in goats caused by this tapeworm infection is poorly documented.

Echinococcosis or Hydatid Disease

Clinical hydatid disease is uncommon in goats, but hydatid cysts in liver and other tissues at slaughter are widespread and cause condemnations and economic loss.

The adult tapeworm, *Echinococcus granulosus*, is found in the intestine of carnivores, particularly dogs. Eggs are passed in the feces and are ingested by goats, other ungulates, or humans. In these intermediate hosts, the ingested eggs release oncospheres that enter intestinal venules or lacteals and migrate via the circulation to liver or lung. The metacestode stage, known as the hydatid cyst, develops in these organs over a period of several months. Brood capsules containing protoscolices develop within some cysts. Occasionally cysts rupture and the released protoscolices produce additional daughter cysts within the intermediate host. When dogs eat viscera containing protoscolices, these evaginate and mature to adults in the intestine in about seven weeks, completing the life cycle.

Echinococcus granulosus occurs essentially worldwide. However, there are noted areas of so-called hyperendemicity where the disease occurs frequently and represents a public health concern. These areas include much of northern and eastern Africa, the Mediterranean region, Eastern Europe, Central Asia, parts of China, and the cone of South America (Lightowlers 2002). The disease also occurs in eastern Australia and the western United States, where sheep are common. Infections are likely to occur in those places where ruminant livestock and domestic and wild canids commingle.

Newer studies of genome patterns indicate that there are numerous distinct strains of *E. granulosis*. The so-called sheep strain (G1) and the so-called camel strain (G6) affect goats (Schantz 2006). The prevalence of disease is increased when carnivore populations are high and no efforts are made to segregate domestic and wild carnivores from livestock or their grazing areas. The feeding of ruminant offal to dogs also enhances completion of the life cycle. Increases in prevalence of hydatid disease in livestock occur after rainy periods, presumably because the rain widely disseminates eggs in feces on grazing land or in water supplies.

Prevalence data of hydatid disease in goats is available from abattoir and post mortem surveys around the world. The prevalence range in endemic regions is 0.26% to 6.5% (Pandey 1971; Rahman et al. 1975; Naus 1982; Al-Yaman et al. 1985; Lorenzini and Ruggieri 1987). Hydatid cysts are most common in the liver, lung, and spleen, but may be found in other organs at slaughter or necropsy. In some places, lung cysts are more common than liver cysts in goats. More information on hydatid cysts in goat lung is given in Chapter 9.

Hydatid cysts may average 5 to 10 cm in diameter and contain a yellowish, serum-like fluid and may have a granular inner wall containing multiple brood capsules. Hydatid "sand," which is an accumulation of detached brood capsules, may be seen in the cyst fluid. Hydatid cysts should be differentiated from *Cysticercus tenuicollis* cysts as discussed below. Cysts containing nymphs of the canid nasal parasite, *Linguatula serrata*, also have been found in the liver, lungs, and mesenteric lymph nodes of goats in Bangladesh (Rahman et al. 1980).

In the last twenty years ELISA and immunoblot assays have been developed to diagnose Echinococcosis in livestock, but due to a high number of false-negative and false-positive results, these assays remain unsuitable for surveillance of echinococcal infections (Moro and Schantz 2006). Various imaging techniques can be used to identify hydatid cysts, including ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI).

There is no practical or economical treatment for hydatid cysts in ruminants. Control efforts involve disruption of the carnivore/ruminant life cycle. The principal efforts should be directed at eliminating the feeding of livestock offal to dogs, encouraging burial of livestock carcasses or viscera, and using routine anthelmintic therapy in dogs to reduce adult tapeworm populations. There has been notable progress in the development of effective vaccines for controlling hydatid cysts. Though not yet commercially available, a recombinant DNA vaccine based on the oncospheric protein EG95 has been shown to be effective in protecting cattle, sheep, and goats against hydatid disease with immunity lasting for at least one year (Dalton and Mulcahy 2001; Lightowlers 2002).

Echinococcosis is a serious zoonotic disease. Humans are infected by ingestion of tapeworm eggs shed by canids. International efforts to reduce hydatidosis, especially with regard to its zoonotic potential, have been reviewed (Moro and Schantz 2006).

Cysticercosis

Etiology

Adult *Taenia hydatigena* tapeworms are found in the intestine of dogs, coyotes, wolves, and other carnivores. The eggs are passed in the feces and ingested by goats, sheep, and other domestic and wild ruminants. Eggs hatch in the small intestine of the intermediate hosts and enter the blood. Upon reaching the liver, the embryos leave the portal vasculature and migrate through the hepatic parenchyma to the peritoneal cavity, causing distinct hemorrhagic tracts in the liver. The metacestode, which is the developmental phase

Figure 11.2. Cysticercus metacestode (*Cysticercus tenuicollis*) of the canid tapeworm, *Taenia hydatigena*, attached to the mesentery of a goat. (Courtesy of Dr. Jaroslaw Kaba, Faculty of Veterinary Medicine, Warsaw University of Life Sciences, Warsaw, Poland.)

that occurs in ruminants, is a bladderworm called *Cysticercus tenuicollis*. It matures over a period of five to eight weeks, and is found attached to the mesentery, omentum, and serosal surface of abdominal organs (Figure 11.2). Occasionally, migration out of the liver is not achieved and the cysticercus is found in the liver itself. Aberrant migrations sometimes occur with cysticercus found in the lungs or other organs.

Epidemiology

Factors that promote the infection of goats with *Cysticercus tenuicollis* from contact with canids are similar to those described above for echinoccocosis. Cysticercosis occurs worldwide. Reported prevalence in slaughtered goats around the world ranges from 0.2% in Australia to 23.3% in Nigeria (Rahman et al. 1975; McKenzie et al. 1979; Akinboade and Ajiboye 1983; Sanyal and Sinha 1983).

Pathogenesis

The migration of embryos of *T. hydatigena* in the liver produces parenchymal damage and the creation of blood-filled tracts. When many embryos are migrating, acute, fatal hepatic insufficiency may occur in goats (Everett and de Gruchy 1982). Less severe migrations of embryos may still lead to liver condemnations in otherwise healthy animals, as the blood-filled tracts become fibrotic over time. Occasionally, peritonitis is associated with migration out of the liver and into the peritoneal cavity. The mature cysts in the mesentery, omentum, or liver usually do not produce any clinical disease.

Clinical Findings

Acute cysticercosis may produce signs of depression, weakness, anorexia, and possibly collapse and death caused by hepatic insufficiency. Signs consistent with pneumonia, peritonitis, and/or anemia can occur as a result of aberrant migration in the lungs and abdominal viscera with resulting hemorrhage. Fever may be recorded if peritonitis occurs. Signs usually occur between seven and twenty days after exposure (Pathak and Guar 1981). Chronic cysticercosis is usually asymptomatic.

Clinical Pathology and Necropsy

Experimentally, goats infected with eggs of *T. hydatigena* showed marked elevations of ornithine carbamyltransferase (OCT) and AST ten days after infection, but this is not specific for cysticercosis (Pathak and Gaur 1981a). Indirect hemagglutination and complement absorption tests have been used in the diagnosis of caprine cysticercosis (Varma et al. 1973, 1974). Radiography or ultrasonography can be useful in identifying hepatic or peritoneal cysts. In human medicine, CT and MRI are also used to identify cysts, and these techniques could be applicable to veterinary medicine as well.

At necropsy, *C. tenuicollis* cysts may be present in the liver, but are common in the mesentery, omentum, and serosal surface of peritoneal viscera. Increased volumes of serofibrinous fluid may be present in the peritoneal cavity. Mature cysticerci have a smooth inner surface and contain only a single invaginated scolex, in contrast to hydatid cysts.

Acute cysticercosis is recognized by the presence of tubular, red, blood-filled tracts 2 to 4 mm in diameter in the liver, as shown in Figure 11.3. More chronic lesions may appear white as leukocytes fill the tracts and fibrosis occurs.

Treatment

Praziquantel, at a single, oral dose of 60 mg/kg, was reported as 93% to 100% effective in removing *C. tenuicollis* from sheep and goats in China (Li and Li 1986).

Control

Control measures involve disruption of the carnivore/ruminant life cycle as described above for echinococcosis. As with echinococcosis, there has been a considerable effort to develop effective recombinant protein vaccines to control cysticercosis, with good progress reported for vaccines against *T. ovis* but not yet specifically *T. hydatigenea* (Lightowlers et al. 2000)

Fascioliasis

Fascioliasis is the most common liver fluke disease of goats worldwide. In certain regions, chronic fascio-

Figure 11.3. Blood-filled tracts in the liver due to migration of embryos of *Taenia hydatigena*. (From Everett and de Gruchy 1982).

liasis represents a major constraint on goat production.

Etiology

There are two *Fasciola* species that infect goats. *F. hepatica* is smaller, with an adult length of 18 to 32 mm and a width of 7 to 14 mm. *F. gigantica* is longer, with an adult length of 24 to 76 mm and a width of 5 to 13 mm.

Fasciola spp. have an indirect life cycle, with water snails of the superfamily *Lymnaeidae* acting as the intermediate host. More than fifteen species of these snails serve as hosts for *F. hepatica* worldwide, and at least thirteen for *F. gigantica*, with some overlap. When *Fasciola* are introduced into new areas by importation of livestock, local species of *Lymnaeidae* may serve as suitable, adaptive, intermediate hosts. Infected snails introduced into a new area may also act as the source of new infections.

Adult flukes reside within the biliary tract of definitive hosts such as goats and lay eggs that are passed via the bile duct to the feces. Egg production is substantial, with a mean of 303,000 eggs found in the gallbladders of infected, slaughtered goats (Jimenez-Albarran and Guevara-Pozo 1977). Eggs passed in feces hatch within ten to twelve days, releasing miracidia that invade intermediate host snails. Eggs hatch optimally at a temperature of 79°F (26°C), while temperatures must be at least 50°F (10°C) for miracidia to survive, invade snails, and develop further. Within the

snail, the miracidium undergoes subsequent multiplications through sporocyst, rediae, daughter rediae, and cercariae stages. The average time from infection of snails to shedding of cercariae is five to eight weeks but can be as short as twenty-one days or prolonged as much as ten months under adverse conditions.

When cercariae are shed by snails, they swim to a nearby plant, attach to herbage, encyst, and become infective metacercariae that are then ingested by grazing vertebrate hosts. The ingested metacercariae excyst, penetrate the intestinal wall, and migrate through the abdominal cavity to the liver. They then penetrate the liver capsule and migrate through the liver parenchyma to the bile ducts, where they mature. They reach the bile ducts about six to seven weeks after infection. Maturation within the bile ducts to egg-laying adults requires an additional two to four weeks. Adult flukes may remain in situ for months to years.

Occasionally, flukes are found in aberrant organ locations such as kidney and lungs, caused by inaccurate migration out of the intestine (Charan and Iyer 1972; Haroun et al. 1989).

Epidemiology

Fascioliasis occurs principally in domestic ruminants, but other nonruminant livestock, numerous wild mammals, and marsupials also can be infected and may serve as reservoir hosts. Humans can contract fascioliasis from ingesting fresh plants contaminated with metacercariae.

The distribution of *F. hepatica* is cosmopolitan, and reports of fascioliasis in goats come from around the world (Rafyi and Eslami 1971; Jimenez-Albarran and Guevara-Pozo 1977; Chevis 1980; Quittet 1980; Vasquez-Vasquez 1980; El Moukdad 1981; Leathers et al. 1982; Bendezu et al. 1983; Anwar and Chaudhri 1984; Fernandes and Hamann 1985; Liakos 1985; Thompson 1986; Campano 1987; Wang et al. 1987; Molan and Saeed 1988). Prevalence varies considerably. No liver flukes were identified in an abattoir study in Queensland, Australia (McKenzie et al. 1979). Approximately 4% of sheep and goat livers were infected in a Mexican study (Vasquez-Vasquez 1980), while as many as 79% of sheep and goat livers inspected in Pakistan had *F. hepatica* (Anwar and Chaudhri 1984).

The distribution of *F. gigantica* is more limited, primarily to the tropical regions of Asia and Africa, and the Middle East. Caprine infection with *F. gigantica* has been reported from all these regions (Fabiyi 1970; Rafyi and Eslami 1971; Charan and Iyer 1972; Tager-Kagan, 1978; Assoku 1981; El Moukdad 1981; Nooruddin et al. 1987). In a year-long Indian abattoir survey, 14.7% of goat livers were infected with *F. gigantica* and 22.3% of potentially marketable liver was condemned (Pachauri et al. 1988).

Besides a suitable snail host, the key element that regulates the occurrence of fascioliasis is a suitable combination of moisture and temperature that allows persistent surface wetness on pasture for the snail and the free-living stages of the parasite to thrive. The relationship of infection rate to weather conditions is sufficiently well known that meteorological calculation of increased fascioliasis risk is done to determine the need for timing of prophylaxis (Soulsby 1982). These forecasting techniques were first applied in Europe but are now being applied elsewhere, including North America (Malone and Zukowski 1992), South America (Fuentes et al. 1999), and Africa (Yilma and Malone 1998).

Low-lying, poorly drained, persistently marshy, or swampy areas in warm climates grazed by ruminants are ideal for completion of the life cycle of *Fasciola* spp. Water sources, however, do not need to be permanent. Intermittent flooding of fields by overflow of streams or frequent irrigation can facilitate infection because snails can burrow into mud and survive temporary dry periods. Irrigation canals and ditches can be an important point of infection for goats and sheep in dry regions where fresh herbage and water may only be available at certain periods of the year along the snail-infested irrigation channels.

In temperate regions, infection of snails typically peaks in late spring and early summer, leading to peak pasture contamination with infective metacercariae in late summer and early fall. Peak incidence of clinical disease in ruminants is then seen in late fall and winter. Where winters are not extremely cold or excessively dry, some snails and eggs survive winter and recommence development in early spring so that a less significant cycle of infection with metacercariae occurs on pastures in late spring and early summer as well. In tropical regions, metacercariae can be present all year long, and there is no well-defined season for clinical outbreaks in ruminants. Grazing is not a prerequisite for infection if stabled animals are fed fresh green herbage contaminated with metacercariae. Feeding fresh cut grass to penned goats is a typical husbandry practice in much of Asia.

Goats, like sheep, do not develop as strong an immunity to *Fasciola* infection as cattle, and remain largely susceptible to re-infection. However, some immunity does develop as evidenced by reduced size and numbers of flukes recovered from repeated challenge infections (Reddington et al. 1986; El Sanhouri et al. 1987; Haroun et al. 1989).

Pathogenesis

There is little or no damage produced during migration of metacercariae through the intestinal wall or the peritoneal cavity. The potential for damage begins when metacercariae penetrate the liver capsule and begin migration through the parenchyma. When large numbers invade simultaneously, as may happen in the early fall, a traumatic hepatitis ensues and is recognized clinically as acute fascioliasis. When moderate numbers invade over an extended period of time, then subacute fascioliasis can occur. One thousand infective metacercariae can produce fatal acute fascioliasis in goats and 200 can produce severe subacute fascioliasis. *Fasciola gigantica* is more pathogenic to goats than *F. hepatica*, and goats may be more susceptible to *F. gigantica* than sheep (Ogunrinade 1984).

In acute fascioliasis, there is marked disruption of liver parenchyma with extensive hemorrhage. The liver capsule may rupture, leading to severe intra-abdominal bleeding and death. Even without fatal hemorrhage, animals may die within a few days as a result of hepatic insufficiency from parenchymal damage. In the subacute form, invading metacercariae still produce migratory tracts, hemorrhage, and necrosis within the liver and lead to a more prolonged clinical picture of hepatic insufficiency. Extensive fibrosis occurs in the liver during subsequent attempts at healing.

Acute fascioliasis is not commonly seen in goats and the reason is not clear. It may be related to feeding behavior because goats are not intensive grazers, and may not ingest sufficient numbers of metacercariae in short periods to produce severe acute reactions.

Chronic fascioliasis occurs after arrival and maturation of flukes in the bile ducts. Persistence of adult flukes in the biliary tree results in hyperplastic cholangitis with ongoing loss of plasma proteins caused by increased permeability of the biliary mucosa. Feeding activity and movement of flukes within the biliary tree produces chronic blood loss. Under natural circumstances of exposure, individual animals may simultaneously experience acute, subacute, and chronic fascioliasis.

In sheep, infectious necrotic hepatitis, or black disease, is a common complication of fascioliasis. In these cases, *Clostridium novyi* organisms already present in the liver suddenly proliferate in the anaerobic environment of necrotic tissue created by migrating fluke larvae. The release of toxins by proliferating bacteria produces an acute, fatal toxemia. The prevalence of this disease in goats is poorly documented, but it is considered to be a serious potential risk in areas of Australia and New Zealand where goat populations are expanding into traditional sheep-raising areas (Pauling 1986). In Australia, black disease has been documented in Angora goats. It occurs seasonally between February and June in well-conditioned goats between nine months and four years of age. It is presumed that goats are less frequently affected than sheep because of their browsing habits. The prevalence in goats increases when they are forced to graze in wet

areas during drought because *C. novyi* is a soil-borne organism (King 1980). Black disease was also confirmed in goats in the Sudan, where eighteen normal appearing animals in a herd of 435 were found dead overnight. At necrospy, all the goats were heavily infested with *F. gigantica* and the presence of *C. novyi* Type B was established (Hamid et al. 1991). Where there is concern of the risk of black disease, goats can be vaccinated against *C. novyi*, which is included in many of the commercially available, multivalent, clostridial vaccines.

Clinical Findings

Acute fascioliasis, though uncommon, may present as sudden death or as progressive weakness, depression, anorexia, and pallor lasting as long as three days and resulting in death. Before death, pain may be elicited by deep palpation over the liver. Subacute fascioliasis may show similar signs for as long as several weeks. Black disease usually presents as sudden death with no other signs except some possible frothing at the mouth and nostrils.

Chronic fascioliasis is the most common presentation. The history may include a period of depression, poor appetite, lethargy, and weight loss for one month or longer. In prolonged cases, some animals have diarrhea. There may also be a complaint of decreased milk production in milking does. Physical findings include poor body condition, rough hair coat, pale mucous membranes, and tachycardia. Intermandibular edema, or bottle jaw, frequently occurs in long-standing cases and is highly suggestive of chronic fascioliasis.

Clinical Pathology and Necropsy

Acute fascioliasis is most often diagnosed at necropsy. In subacute disease, the hemogram may document normochromic anemia, eosinophilia, and possibly neutrophilia. Hypoalbuminemia and increases in serum concentration of liver-related enzymes may be noted in the chemistry profile.

Normocytic or macrocytic anemia, hemoglobinemia, hypoalbuminemia, and eosinophilia can be expected in chronic fascioliasis. Total protein may be in the normal range as a result of accompanying hypergammaglobulinemia. Increases in liver-specific enzymes in the blood occur less reliably in chronic fascioliasis, although increases in GDH and OCT have been reported to occur even when flukes are present only in the biliary tree (Treacher et al. 1974).

In chronic fascioliasis, fluke eggs can be found in the feces of goats. Sedimentation methods for fecal examination are preferred to flotation methods. Eggs are yellow colored, ovoid, and operculated at one end. Eggs of *F. gigantica* are slightly larger than eggs of *F. hepatica*. Where rumen flukes occur, their eggs must be differentiated from those of liver flukes.

Because acute fascioliasis occurs during the prepatent period of infection, detection of ova in feces is not a useful aid for identification of early infections with *F. hepatica* or *F. gigantica*. This inability to detect prepatent infections has spurred a good deal of research in the area of serodiagnosis over the last two decades. The main focus has been to isolate and characterize parasite antigens suitable for use in serodiagnostic tests such as ELISA to detect anti-fasciola antibodies in infected animals. One category has been the so-called excretory-secretory antigens of *Fasciola* spp., including cathepsins. These antigens have been derived directly from flukes and purified, or more recently, obtained through use of recombinant DNA technology. ELISA assays using such antigens have been able to detect circulating IgG against *F. hepatica* and F. *gigantica* as early as one week post infection (Paz-Silva et al. 2005), but more commonly three to seven weeks post infection (Cornelissen et al. 2001, Mezo et al. 2003, Yadav et al. 2005).

However, there are still some constraints with serodiagnostic tests. Though it is becoming less common as antigen purification techniques improve, cross reactivity still may occur with other helminths sharing similar antigens, notably paramphistomes. Also, detectable antibodies persist even after effective treatment of fascioliasis, making interpretation of test results difficult. A commercial ELISA test kit for identifying prepatent fascioliasis in cattle and sheep is currently available in Europe and Australia.

Necropsy in acute fascioliasis demonstrates a swollen, traumatized, friable liver with multiple perforations of the capsule and subcapsular hemorrhage. Fibrin tags may be present on the liver surface and blood accumulated in the peritoneal cavity. Migrating flukes are not easily seen on cut surface of the liver parenchyma, but may be visualized by shaking a piece of liver in a pan of water and looking for the larvae to settle out at the bottom.

When black disease complicates acute fascioliasis, signs of clostridial toxemia may be evident. These include blackening of the subcutaneous blood vessels observed as the skin is reflected, serosanguinous pericardial and peritoneal effusions, and patchy areas of liver necrosis with reddish borders. These reddened edges are likely sites for isolation of *Clostridium novyi*.

In chronic fascioliasis the carcass is emaciated, subcutaneous edema may be present, and organs are pale. The liver may be cirrhotic and irregularly nodular and the capsule opaque in areas. On cut surfaces, there is extensive fibrosis of the parenchyma. Bile ducts are thickened and fibrosed, but mineralization is uncommon. Upwards of one hundred adult flukes may be found in the cystic biliary ducts and gallbladder. They may be expressed by squeezing on cut sections of liver.

Flukes have also been found in the pancreatic duct of goats at necropsy (Leathers et al. 1982).

Diagnosis

Acute fascioliasis is one of many potential causes of sudden death in goats, as discussed in Chapter 16. Definitive diagnosis is by necropsy. Chronic fascioliasis is most easily confused with gastrointestinal nematodiasis, and, in practice, concurrent nematode and trematode infections are common in goats. Schistosomosis, as discussed in Chapter 8, can also present similarly to chronic fascioliasis. When chronic weight loss is the major complaint or presenting sign, a wide variety of other diseases needs to be considered, as discussed in Chapter 15.

Treatment

The choice of therapy largely depends on the stage of infection requiring treatment (Boray 1985). Carbon tetrachloride, hexachloroethane, bromsalans, oxyclo-

zanide, niclofolan, and albendazole are only effective on mature flukes, ten weeks of age or older. Nitroxynil and clioxanide are moderately effective in flukes from eight to nine weeks of age and highly effective against mature flukes. Brotianide and rafoxanide are most effective against flukes eight weeks and older but only have 50% to 90% effectiveness against flukes six to seven weeks of age. Clorsulon is effective against all flukes two weeks of age and older. Triclabendazole and diamphenethide are effective against flukes from one day of age through maturity. This information is summarized in Table 11.3.

Other considerations in drug selection include safety, cost, regulatory concerns, and lactation and pregnancy status. The earliest available treatments, namely, carbon tetrachloride and hexachloroethane, are themselves hepatotoxic and can cause mortality in goats. These products may still be available in some developing countries where liver flukes exist. Though inexpensive, the use of these products should be discouraged. Brom-

Table 11.3. Summary of information on flukicides used in goats.

Flukicide	Class of drug	Reported doses (mg/kg bw)	Effective against			Withholding times (days)	
			Immature flukes 1–6 weeks old	Immature flukes 6–10 weeks old	Adult flukes >10 weeks	Meat	Milk
Triclabendazole	Bezimidizole	*5–15 PO*	+	+	+	28	X
Diamphenethide	Aromatic amine	*150 PO*	+	+	±	7	X
Clorsulon	Sulfonamide	*7 PO*	±	+	+	8	4
Closantel	Salicylanilide	*10–20 PO*	–	±	+	28–42	X
Rafoxanide	Salicylanilide	*7.5 PO*	–	±	+	28	X
Brotianide	Salicylanilide	7.5 PO	–	±	+	21	X
Clioxanide	Salicylanilide	20	–	±	+	?	?
Nitroxynil	Substituted phenol	*15 SQ*	–	±	+	30–60	X
Albendazole	Benzimidazole	*7.5–15 PO*	–	–	+	14	3
Niclofolan	Substituted phenol	*0.8 SQ, 2–4 PO*	–	–	+	?	?
Oxyclozanide	Salicylanilide	*15 PO*	–	–	+	28	X
Bromsalans	Salicylanilide	20	–	–	+	?	?
Bromophenophos	Organophosphate	*16.5 PO*	–	–	+	21	7
Hexachloroethane	Chlorinated Hydrocarbon	200–300	–	–	+	?	?
Carbon tetrachloride	Chlorinated Hydrocarbon	80 PO	–	–	+	?	?

Doses in bold italic are reported in the literature specifically for goats. Other doses are those reported for sheep because goat-specific information was not found in the literature. Similarly, very little goat-specific information is available for meat and milk withholding times following use of these flukicides. Times given are for cattle and/or sheep and come from European and Australian reports. They are to be used as general guidelines. Regulatory authorities should be contacted in individual countries to determine if there is goat-specific information available on the use and withholding times for these products. X = not suitable for use in lactating animals; – = not effective; ± = variably effective, tending to be more effective at the older range of the category; + = effective; PO = orally, SQ = subcutaneously; ? = no information found.

salans, which are substituted salicylanilides, can be toxic when combined with benzimidazoles, and should be used cautiously in goats. Diamphenethide is expensive and may be cost prohibitive for widespread use in commercial flocks. Only albendazole and clorsulon are available for treatment of fascioliasis in the United States and neither one is specifically approved for use in goats. The use of flukicides in lactating goats is problematic. Few products are specifically approved for use in lactating animals of any species, and withholding times for the same products may vary between countries. As a rule of thumb, if flukicides are used which are approved for other lactating species but not goats, then milk should be discarded for at least the time recommended for the other species, or for seven days, whichever is longer.

Specific doses for goats are established for a number of flukicides for use against *F. hepatica*. Albendazole orally at 15 mg/kg was 95.9% effective against adult flukes and produced no signs of toxicity, even when given at 75 mg/kg (Foreyt 1988). In France, it is marketed for goats at a dose of 7.5 mg/kg orally. Diamphenethide given orally at 150 mg/kg removed 87.5% of juvenile and adult flukes. Treated animals included pregnant does and no adverse reactions were observed (Wang et al. 1987). In another goat study, the drug was 84% effective against one-week-old larvae and 97% effective against three-week-old larvae (Hughes et al. 1974).

Oral triclabendazole completely eliminated ova shedding in chronically infected goats at a dose of 5 mg/kg (Wolff et al. 1983). It is commercially marketed in drench or bolus form in some countries for oral use in goats at a dose of 10 mg/kg. In sheep, it has been shown that the lower dose kills flukes only as young as two weeks of age, whereas the higher dose is effective on flukes as young as one day of age.

Niclofolan was 90% effective against *F. hepatica* when given subcutaneously at a dose of 0.8 mg/kg in goats, with no adverse effects (Girardi et al. 1979). In China, it is used in goats at 2 to 4 mg/kg given orally (Weng 1983). Closantel effectively eliminated *F. hepatica* in goats at an orally administered dose of 10 mg/kg (Lee et al. 1996) but a dose of 20 mg/kg was required for 100% elimination of *F. gigantica* (Yadav et al. 1995).

Rafoxanide was reported to be 100% effective against *F. hepatica* in goats at a dose of 7.5 mg/kg orally (Campos Ruelas et al. 1976). Nitroxynil was 89% effective against six-week-old larvae at a subcutaneous dose of 15 mg/kg (Hughes et al. 1973). Closantel, rafoxanide, and nitroxynil are also effective against *Haemonchus contortus* in goats.

Clorsulon given to goats orally at a dose of 7 mg/kg reduced fluke numbers and fecal egg counts by 98% (Sundlof et al. 1991). Oral bromophenophos at 16.5 mg/ kg eliminated all adult *F. gigantica* in goats but was only 50% effective against immature forms. Doubling the dose had little additional effect (Qadir 1979, 1981).

In many regions of the world where goats are kept, access to veterinary products may be limited and local treatments are employed. In a controlled study in Sudan, oral administration of extracts from either the local shrub *Albizia anthelmintica* or the local tree *Balanites aegyptiaca* showed reduction in liver fluke counts relative to untreated controls of 95.5% and 93.2%, respectively (Koko et al. 2000).

In most cases, drugs and dosages effective against *F. hepatica* are effective against *F. gigantica*. Acute and subacute fascioliasis are best treated with either diamphenethide or triclabendazole. All animals at risk should be treated whether they are showing signs at the time of first diagnosis or not. The prognoses in acute and subacute fascioliasis are poor.

The prospects are much better in treating chronic fascioliasis. Any of the drugs effective against mature flukes can be used in these cases. However, if drugs not effective against immature forms are used, then animals should be retreated at an interval appropriate for that drug to eliminate subsequently maturing larvae. Early response to treatment can be demonstrated by eliminating ova shedding. It may take one month or longer for erythrocyte and protein parameters to return to normal in treated goats.

In the last twenty years, parasite resistance to anthelmintics has emerged as a major challenge to treatment and control of parasitic diseases. The problem of resistance has been most pronounced in relation to treatment of gastrointestinal nematode parasites and is discussed further in Chapter 10. However, there have also been reports of anthelmintic resistance in liver flukes. The main problem, reported from a number of countries, is with triclabendazole, but failures of treatment with closantel have also been reported from Australia.

Because triclabendazole is effective against flukes at all stages of development, it has become the most widely used drug for fascioliasis and this has contributed to the development of resistance. Resistance may first be recognized as a failure for the drug to kill the youngest stages of the fluke. This may be manifested as the reappearance of fluke eggs in the feces sooner after treatment than normally expected. Gradually, as resistance grows stronger, more mature flukes survive treatment as well (Abbot et al. 2004).

There are no *in vitro* tests for evaluating resistance to flukicides (Coles et al. 2006). When resistance is suspected, other flukicides should be used. Because most other flukicides are not effective against young flukes, the treatment may need to be at a more frequent interval than when using triclabendazole.

Abbot et al. (2004) discourage the use of combination fluke and worm products because they can lead to off target selection for resistance to broad-spectrum anthelmintics in nematodes, or fasciolicide resistance in *F. hepatica*. However, in the case of closantel-benzimidazole combinations, there may actually be synergistic activity that can enhance their activity against resistant *F. hepatica* (and *H. contortus*) and slow the emergence of resistance to either class of compound.

Control

The objective of control is to limit fluke burdens in grazing animals. This is accomplished mainly by strategic use of flukicides and by keeping grazing animals out of environments likely to contain infective metacercariae from associated snail populations. Snail control is another tool, but may be difficult to achieve.

Pasture contamination by metacercariae is a dynamic process largely dependent on weather conditions. When calculated, the meteorological index can be helpful in determining the amount of tactical control necessary to avoid clinical disease and production loss on a seasonal basis (Urquhart et al. 1988). At the minimum, in temperate regions or arid zones, flukicide treatments should be administered strategically once in the early spring before turnout to pasture using an adult flukicide. Goats should be retreated in the autumn to kill developing and adult flukes picked up over the grazing season. An anthelmintic that kills immature and mature flukes should be used.

In tropical settings, particularly when year-round grazing occurs, treatment every eight to ten weeks with triclabendazole or diamphenethide may be indicated. This facilitates destruction of all ages of immature flukes within the prepatent period to eliminate egg production while controlling both acute and chronic fascioliasis in the goat. Egg production can also be controlled by using rafoxanide or closantel at five- or six-week intervals, but the risk of acute fascioliasis is still high because immature larvae are not killed. Such intensive control measures are effective in reducing pasture burdens and may not have to be repeated in subsequent years. When goats are part of mixed grazing systems, all potential hosts need to be treated simultaneously. When flukicides are used frequently, the potential for anthelmintic resistance should be monitored by fecal examinations for fluke eggs.

Limiting access of goats to snail populations is an adjunct to the use of flukicides. High-risk areas such as low-lying, marshy portions of grazing land, drainage ditches, irrigation channels, or stagnant ponds should be identified and drained or fenced off when possible. Cutting back vegetation at the edges of standing water makes the environment less amenable to snails. High-risk situations should also be identified such as intensified grazing by animals near water after drought or at the end of the grazing season when forage is in short supply. Housed goats should not be offered freshly cut herbage likely to be contaminated with metacercariae.

When mild winters and warm, moist summers promote high snail populations, the application of molluscicides to snail habitat could be considered. Copper sulfate in solutions of 1:100,000 to 1:5,000,000 or as a powder at 10 to 35 kg/hectare is effective in destruction of snails and their eggs (Soulsby 1982). Applications in spring kill overwintered snails and applications in summer and fall kill newly developed snails. Goats are less susceptible to copper toxicity than sheep, but caution should still be taken in turning goats out on copper-treated pastures before a dilution by rain has occurred. There are environmental concerns related to the use of molluscicides which may be toxic to fish and other species. Check local regulations before use. Biological control strategies using ducks and competitive non-host snail populations have also been applied for snail control with some success.

Fascioloidosis

Fascioloides magna, also known as the large American liver fluke, is a more important cause of morbidity in goats than fascioliasis in certain parts of North America and Europe.

Etiology and Pathogenesis

Adult *Fascioloides magna* are larger than *F. hepatica* and *F. gigantica*. The length is 23 to 100 mm and the width 11 to 26 mm. They are ovoid and pink-colored. Eggs are not found in goat feces for reasons described below.

This fluke has an indirect life cycle. The intermediate hosts are snails of various genera including *Fossaria, Galba (Lymnaea), Pseudosuccinia*, and *Stagnicola*. These snails tolerate a wider range of habitat, temperature, and moisture conditions than the snail hosts of *Fasciola* spp. The normal definitive hosts are members of the family Cervidae, including various deer, elk, and moose. Abnormal hosts include the large Bovidae such as bison, yak and cattle, as well as goats and sheep.

The adult fluke resides in the bile ducts of definitive hosts and lays eggs that are passed to the outside in the feces. Eggs hatch after four weeks and miracidia invade the intermediate host snails. Development to cercariae takes an additional seven to eight weeks. Voided cercariae encyst on vegetation. These encysted metacercariae are quite resistant to desiccation. When consumed by definitive hosts such as deer, the metacercariae penetrate the intestine, migrate through the peritoneal cavity, invade the liver, migrate through the parenchyma, and finally form encapsulated cysts.

These cysts communicate with the biliary tree so that mature flukes can pass eggs out through the bile. The prepatent period is thirty to thirty-two weeks.

In cattle, a similar pattern is followed except that cysts rarely communicate with the biliary tree. Eggs, then, are not passed and the life cycle is not completed. Adult flukes reach maturity in thirty-two to forty-four weeks and the cysts become thick-walled and fibrotic.

In goats and sheep, migrating larvae rarely form cysts. Instead, they continue to wander aimlessly through the liver parenchyma, causing considerable damage and hepatic dysfunction. Peritonitis and hemorrhage into the abdominal cavity can also contribute to disease severity. Even a single wandering fluke can be potentially fatal to goats. Clinical disease usually occurs three to six months after exposure (Foreyt and Leathers 1980). Ova are rarely if ever passed in the feces of infected goats so microscopic examination of feces does not aid in the diagnosis.

Epidemiology

Fascioloides magna is native to North America and is concentrated particularly in the Great Lakes region, the Gulf coast, and the Rocky Mountains and Pacific Northwest, including western Canada. The parasite was introduced into Europe with game deer and has become well established, particularly in Eastern Europe, including Italy, Germany, Austria, Slovenia, the Czech Republic, Slovakia, and Hungary.

Goats become infected with *F. magna* when they feed in areas also inhabited by deer or elk (wapiti) and intermediate host snails. Though the risk is increased when these areas are marshy, the requirement for standing water is not as strict as for fascioliasis. In the Great Lakes region, small ruminants become infected in late August or September and clinical disease is usually seen in January and February.

Clinical Findings

The most frequent presentation is sudden death. There are no descriptions of subacute disease in goats. In sheep, animals so affected show depression, pallor, weakness, anorexia, and abdominal pain that is accentuated by palpation over the liver.

Clinical Pathology and Necropsy

Animals seen before death may have increases in serum concentrations of liver-related enzymes. Necropsy reveals extensive liver damage characterized by necrosis and numerous hemorrhagic tracts throughout the liver parenchyma (Figure 11.4). These tracts are characteristically black in color due to accumulation of black iron porphyrin pigment. The pigment may also be seen in mesenteric nodes. Though rare, cysts containing live or dead flukes may be found in the livers of goats (Olsen 1949).
Figure 11.4. *Fascioloides magna* **fluke and cross section of a necrotic goat liver through which it migrated. (Courtesy Dr. M.C. Smith.)**

Diagnosis

Diagnosis is based on a history of sudden death and characteristic lesions in the liver at necropsy. Differential diagnosis must include acute fascioliasis, cysticercosis, toxic hepatitis, and in younger animals, haemonchosis and coccidiosis. Other causes of sudden death are reviewed in Chapter 16.

Treatment

Treatment is difficult because clinical disease is caused by immature flukes that can induce serious or fatal illness when present even in small numbers. This means that useful drugs must approach 100% efficacy against immature flukes. Albendazole administered orally to goats at 15 mg/kg was reported to be 99% effective against flukes eight weeks of age or older (Foreyt and Foreyt 1980). The use of albendazole during the first months of pregnancy may carry some risk to the fetus.

Other flukicides have not been evaluated specifically for *F. magna* infection in goats. Closantel was 95% to 98% effective in sheep at a dose of 15 mg/kg orally or 7.5 mg/kg intramuscularly (Stromberg et al. 1985). Clorsulon was not effective against immature *F. magna* in sheep at a single oral dose of 15 mg/kg (Conboy et al. 1988), but was 92% effective against eight-week-old larvae in sheep at a dose of 21 mg/kg (Foreyt 1988a). Oral rafoxanide at 15 mg/kg has been reported to be effective in red deer (Rajsky et al. 2002). No products are approved for use against *F. magna* in the United States.

Control

Control of fascioloidiasis is complicated by the need to control wild animal definitive hosts and an ecologically diverse, intermediate host snail population. In

endemic areas where cases have occurred, intensive management without pasturing should be considered for dairy goats. This is obviously difficult for extensively managed fiber-producing goats. Avoidance of marshy pastures and attempts to fence off deer may be helpful. When exposure cannot be controlled, reduction of fluke loads in goats can be undertaken. In northern climes, prophylactic treatment with albendazole is administered after the first killing frost and repeated one month later to help reduce clinical losses.

Lancet Fluke Infection

Dicrocoelium dendriticum, the lancet fluke, generally produces a chronic form of liver fluke disease in goats that is less severe than that produced by *Fasciola* spp. It has a cosmopolitan distribution.

Etiology

Dicrocoelium dendriticum is a small liver fluke measuring 6 to 10 mm in length and 1.5 to 2.5 mm in width. It has an indirect life cycle involving two intermediate hosts: terrestrial snails and ants. Forty species of snails from nine families may serve as primary intermediate hosts but all secondary host ant species are of the subfamily Formicinae (Boray 1985). Goats, sheep, and cattle are the common definitive hosts, but other livestock species and wild mammals and humans can be infected.

Adult flukes reside in the bile ducts and excrete eggs to the outside in feces. Eggs are ingested by snails where they develop into cercariae. Cercariae are expelled by snails in slime balls and are ingested by ants. Infectious metacercariae develop in the ants and are neuropathogenic, causing ants to remain paralyzed on herbage during peak times of livestock grazing. Infected ants are ingested by grazing livestock and the young flukes excyst from metacercariae in the small intestine of the definitive host. In contrast with the *Fasciolidae*, these immature flukes do not migrate through the peritoneal cavity and liver parenchyma. Instead, they enter the hepatic biliary system directly through the common bile duct via the small intestinal lumen. The prepatent period for *D. dendriticum* is eight to twelve weeks.

Epidemiology

Dicrocoelium dendriticum infection is common in North America, Europe, Asia, North Africa, and the Middle East. Prevalence in goat populations is reported as high as 45% in endemic areas (Manas-Almendros et al. 1978). It is less common in South America and is not found in Australia, New Zealand, and much of Africa. *Dicrocoelium hospes*, a cattle fluke of West and East Africa, has been reported in goats in Niger and Nigeria (Tager-Kagan 1979; Schillhorn van Veen et al. 1980).

Numerous habitats are potentially contaminated with *D. dendriticum* because snail hosts are numerous, terrestrial ant populations are widespread, and many wild mammals serve as reservoir hosts. Grazing areas near forests are particularly high-risk sites. The fluke eggs are also resistant to desiccation and freezing. Hibernating ants can maintain metacercarial infections so that grazing stock are at risk from the beginning of spring grazing.

Pathogenesis

These flukes are less pathogenic than the *Fascioloidae* because they do not migrate through liver parenchyma. *Dicrocoelium dendriticum* infection, which may involve thousands of flukes per goat, can cause progressive inflammation of the entire biliary tree and potentially lead to fibrosis, biliary cirrhosis, and hepatic insufficiency.

Clinical Findings

Dicrocoelium dendriticum may be a subclinical infection or produce a disease syndrome similar to chronic fascioliasis. Affected goats have a history of weight loss. They appear thin and depressed and may show signs of anemia and hypoproteinemia, including pallor and intermandibular edema.

Clinical Pathology and Necropsy

Identification of lancet fluke eggs in the feces of goats is the most reliable means of diagnosis. The dark brown, operculated eggs are much smaller than those of *F. hepatica* or *F. gigantica* and can be found by both fecal flotation and sedimentation methods. *Dicrocoelium dendriticum* infection may produce elevated serum levels of GGT and AP caused by biliary inflammation. Anemia and hypoproteinemia are evidenced in the hemogram.

At necropsy, adult lancet flukes are found in the bile ducts. In early cases there is thickening of the biliary ducts. In severe, chronic infections, biliary fibrosis, cirrhosis, and scarring of the liver surface may be noted. The comparative liver pathology of *D. dendriticum* and *F. hepatica* in goats has been described (Rahko 1972).

A paramphistome parasite of the bile duct of buffalo and cattle in Asia, *Gigantocotyle explanatum*, sometimes is found in the bile duct of goats (Upadhyay et al. 1986). It should be differentiated from *D. dendriticum*, which has a similar appearance.

Diagnosis

Lancet fluke disease must be differentiated from chronic fascioliasis, gastrointestinal helminthiasis, paratuberculosis, and other causes of chronic wasting, as discussed in Chapter 15.

Treatment

In France, albendazole is marketed for use against the lancet fluke at 15 mg/kg orally with a precaution against use during the first three months of pregnancy. Thiophanate is marketed at 50 mg/kg orally with a milk withdrawal time of three days. Diamphenethide at 220 to 330 mg/kg orally is highly effective, with no toxic side effects noted (Devillard and Villemin 1976). Drugs reported to have an efficacy of 90% or greater in sheep include thiabendazole at 200 mg/kg, fenbendazole at 100 mg/kg, praziquantel at 50 mg/kg, and netobimin at 20 mg/kg (Boray 1985; Sanz et al. 1987). Note that some of these doses exceed the routine doses used in helminthiasis. Brotianide was found to be ineffective in goats at oral doses as high as 22.5 mg/kg (Shahlapour et al. 1986).

Control

Control measures are complicated by the existence of two intermediate hosts, and strategic anthelmintic therapy may be the only practical control method. In endemic areas in temperate regions, goats should be treated in the autumn to reduce adult fluke burdens before the winter feeding season begins. In tropical and subtropical areas, year-round, repetitive treatments timed within the prepatent period of the flukes reduce fluke burdens and pasture contamination.

Pancreatic Flukes

Eurytrema spp., or pancreatic flukes, produce mostly subclinical infections in goats. The presence of *Eurytrema* eggs in feces may confuse the diagnosis of the more clinically important lancet fluke, *D. dendriticum*.

Eurytrema pancreaticum is widely distributed throughout Asia and also in Brazil. The fluke has a similar life cycle to *D. dendriticum* with different snails serving as primary intermediate hosts, and grasshoppers instead of ants serving as secondary intermediate hosts. The definitive hosts are goats, sheep, cattle, buffalo, and humans. The young flukes ascend the pancreatic duct, but occasionally mature in the bile duct or duodenum. This fluke is wider and spinier than *D. dendriticum.* The prepatent period is eleven to fifteen weeks. Other species of *Eurytrema* reported from goats include *E. cladorchis* in China and Nepal (Chongti and Tongmin 1980; Mahato 1987) and *E. coelomaticum* from Taiwan and Brazil (Shien et al. 1978; Fernandes and Hamann 1985).

Pancreatic fluke infestations are usually subclinical but heavy infections may contribute to emaciation. A case of sudden death in a cachexic adult goat in Nepal was caused by rupture of the gastroepiploic vein that contained *E. cladorchis* (Mahato 1987).

At necropsy, pancreatic flukes may be found in the duodenum and bile ducts, but most commonly in the pancreatic ducts. These ducts may show catarrhal inflammation and thickening and the pancreas itself may show focal areas of atrophy and fibrosis. The severity of lesions increases with the number of flukes present (Shien et al. 1979).

Praziquantel given two consecutive days at 20 mg/kg orally is effective against *Eurytrema* spp. in goats (Kono et al. 1986). Triclabendazole (Kono et al. 1986), niclofolan (Weng 1983), and nitroxynil (Suh 1983) are not effective.

NUTRITIONAL AND METABOLIC DISEASES

White Liver Disease

White liver disease, a manifestation of cobalt deficiency known for some time in sheep, has been reported in goats only in New Zealand and Oman, though it may be under-diagnosed in other regions where cobalt deficient soils occur. It is characterized by progressive emaciation and hepatic lipodystrophy that gives the liver a grayish appearance at necropsy.

Etiology and Pathogenesis

Cobalt deficiency in ruminants is a well-known condition associated with grazing of cobalt deficient soils. It results in chronic wasting with anemia and hypoproteinemia. However, the specific manifestation of white liver disease apparently occurs only in sheep and goats.

Cobalt is used in the rumen by microflora to produce cyanocobalamin, or vitamin B_{12}, which serves as a coenzyme to methylmalonyl-CoA mutase in the citric acid cycle facilitating the conversion of propionic acid to glucose via succinate in the liver. When small ruminants are cobalt deficient or are fed high carbohydrate diets that exceed the capacity of the liver to convert propionate to succinate, these animals may accumulate methylmalonyl-CoA or methylmalonic acid in the tissues and convert it to branched chain fatty acids that accumulate in hepatocytes. This conversion to branched chain fatty acids does not occur in cattle or deer and white liver disease as a manifestation of cobalt deficiency is not observed in these species (Black et al. 1988).

Epidemiology

Cobalt deficiency in livestock associated with cobalt deficient soils has been reported from New Zealand, Australia, Europe, and northeastern North America. Ovine white liver disease has been specifically reported from New Zealand, Australia, Brazil, the UK, Holland, Switzerland, and Norway. For a long time, caprine white liver disease had been reported only from New Zealand (Pearson, 1987; Black et al. 1988) but more recently the disease also was confirmed in goats in Oman (Johnson et al. 1999). It is reasonable to assume

that the disease occurs in goats where it is found in sheep but may be overlooked because clinically, the disease can mimic gastrointestinal helminthiasis.

Reported cases of white liver disease from New Zealand involve young Angora or Angora-cross goats between four and eighteen months of age, but mostly between four and six months of age. Grass pastures appear to be more conducive to deficiency in goats than legume pastures, and lush pasture may also predispose to the condition. The diagnosis in Oman derived from slaughterhouse samples of goat livers that showed hepatic lipidosis and low cobalt concentrations. The management of these goats while alive was unreported.

Clinical Findings

The principal complaint in cobalt deficiency is chronic ill thrift. Affected goats are thin, weak, and listless, with decreased appetite, pale mucous membranes, and submandibular edema. Diarrhea may be seen. White liver disease in sheep is associated with photosensitization, but this has not yet been reported in goats.

Clinical Pathology and Necropsy

A macrocytic, normochromic anemia and hypoalbuminemia are common findings. The cases of caprine white liver disease reported from New Zealand were confirmed on the basis of serum vitamin B_{12} levels antemortem or liver levels at necropsy using normal values established for sheep. Adequate serum levels are reported as more than 400 pmol/l and adequate liver levels as more than 200 nmol/kg. In Oman, confirmation was based on analysis of liver cobalt concentrations, which in affected goats were 0.08 ± 0.02 ppm dry matter as compared to 0.53 ± 0.11 ppm dry matter in livers of normal control goats. Standard reference values for liver cobalt in normal goats are not reported. In cattle and sheep the normal range is 0.15 to 0.20 ppm dry matter and 0.02 to 0.06 ppm dry matter in cobalt deficient animals (Johnson et al. 1999).

Necropsy findings include an emaciated carcass and a pale-colored liver. Histologically, there is widespread fatty change in the liver with many hepatocytes containing single, large fat globules in the cytoplasm, mild to moderate bile duct proliferation, portal fibroplasia, and sinusoidal accumulations of macrophages containing periodic acid-Schiff (PAS)-positive ceroid material.

Diagnosis

All causes of prolonged weight loss must be considered in the diagnosis, as discussed in Chapter 15. Because young goats often have gastrointestinal helminthiasis that appears clinically similar, cobalt deficiency as a concurrent or underlying condition should not be neglected, even when evidence of helminthiasis is found on fecal flotation or necropsy.

Treatment

For young stock, intramuscular injection of vitamin B_{12} at a weekly dose of 100 μg, or for adults, 300 μg has been used to ameliorate signs of white liver disease in affected herds. Also, sheep respond to daily oral supplementation of cobalt at 1 mg/head/day (or 7 mg/head/week) given until there is noticeable improvement.

Control

Deficient pastures may be top-dressed with cobalt as cobalt sulfate at a rate of 350 g/ha annually, but animals should be supplemented nutritionally in the short term, because pasture uptake is not immediate. When pasture treatment is not possible, cobalt should be supplemented in the diet. For sheep the recommendation is 0.1 mg/head/day. Commercially available cobalt pellets given orally to sheep provide continuous release of cobalt for as long as three years, as long as they remain in the rumen (Kimberling 1988). They are of particular value in extensive grazing systems where pasture top-dressing of cobalt or regular feed supplementation is impractical.

TOXICOLOGIC DISEASES

Numerous drugs, chemicals, plants, and fungal mycotoxins have been reported to cause toxic hepatitis specifically in goats. Recognition of toxic hepatitis and identification of the specific cause can be a difficult challenge to the practitioner, requiring careful history taking, thorough environmental examination, complete physical examination, and often, laboratory support. The following discussion is divided into two parts. The first is a general discussion of the salient features of toxic hepatitis in goats. This is followed by brief descriptions of the specific known causes of the condition.

General Features of Toxic Hepatitis

Diffuse destruction of liver parenchyma from various chemicals and drugs occurs sporadically in goats. Predisposing factors include overdosage of drugs, inappropriate uses of drugs, idiosyncratic reactions, unsuspected exposures, and predispositions to toxicity.

Patterns of poisoning by plants are variable. In some cases, goats are offered poisonous plants unknowingly in the form of garden cuttings. Occasionally, poisonous plants are incorporated into hay, but not usually at concentrations capable of producing widespread toxicity. In grazing situations, the potential toxicity of plants may be altered by weather conditions or the occurrence of fungal parasites on plants that enhance toxicity. Many poisonous plants are unpalatable to goats

under normal circumstances and will not be eaten readily. However, when drought or overgrazing occurs, goats may be compelled to eat toxic plants, and in fact, may be more likely to eat them than sheep and cattle due to their inherently diverse feeding behavior.

The development of hepatotoxicity is related to the dose of toxin, the action of the toxin, the duration of exposure, and the ability of the goat to detoxify the toxic agent. Drugs and chemicals tend to produce acute toxicity after a single exposure, while most plant poisonings involve long-term feeding or grazing of the offending plant. With some plants, chronic disease develops gradually, while with others, the plant toxicity is cumulative, and there is an extended period of normality before acute disease occurs.

Biotransformation of toxic compounds to inactive metabolites occurs primarily in the liver and involves microsomal enzyme systems, particularly mixed function oxidases, and the hemoprotein cytochrome P-450. Marked differences in various detoxifying activities occur among the ruminant livestock species (Patterson and Roberts 1970; Dalvi et al. 1987). Hepatic microsomal protein content of goats is equivalent to that of cattle but significantly less than in sheep. The content of cytochrome P-450 is equivalent to cattle but significantly more than in sheep, and goats have a significantly higher level of activity for the drug-metabolizing enzyme benzphetamine *N*-demethylase than either cattle or sheep. These findings suggest a basis for understanding the known variation in susceptibility to some toxic agents in goats, sheep, and cattle, and serve as a caution against presuming equivalent toxicities in goats for various xenobiotics based on their effects in sheep or cattle (Al-Qarawi and Ali 2003; Szotáková et al. 2004; Dacasto et al. 2005). Age can be a factor in biotransformation capacity as well. Livers of newborn goats exhibited very low activities of drug-metabolizing enzymes relative to six-week-old and adult goats (Eltom et al. 1993).

In general terms, hepatotoxins manifest their toxicity by one or more of the following mechanisms: centrilobular necrosis, midzonal necrosis, periportal necrosis, cholestasis, biliary hyperplasia, or venous occlusion. Acute, often fatal hepatic insufficiency can result when the initial toxic effects are severe. In less severe or in chronic poisonings, lesions of ongoing hepatic necrosis are mixed with evidence of attempts to heal, mainly characterized by fibrosis, leading over the long term to cirrhosis. Many of the hepatotoxic agents, particularly plants, exert toxic effects in other organs as well, particularly the kidney, lung, and the alimentary tract when toxins are ingested.

The clinical findings in toxic hepatitis of goats vary with the cause. In general, depression and anorexia are the most consistent findings. Signs of hepatoencephalopathy, including weakness, ataxia, head pressing, torticollis, coma, and convulsions are common. Evidence of liver pain, characterized by an arched back and resistance to liver palpation, are common in acute toxicities. Jaundice is a less common finding than might be expected. Signs of photodermatitis may be observed in some plant poisonings. Because many hepatotoxic agents affect other organs as well, many clinical signs may be noted that are not hepatic in origin. Common findings in this category include dyspnea, diarrhea, and signs of renal failure.

In acute toxicity, serum levels of liver-associated enzymes are elevated. Liver specific enzymes should be measured, because some toxic agents also damage muscle, causing increases in AST. Elevations of total bilirubin are not consistent in acute caprine hepatotoxicity. When elevations are observed, assessment of erythrocyte parameters is indicated to determine if concurrent hemolysis is occurring.

Evaluation of liver function by BSP clearance and characterization of lesions by biopsy are helpful in confirming the presence of toxic hepatitis in poisonings over the long term because levels of liver-specific enzymes in the serum may not be pronounced in chronic disease. Anemia, hypoproteinemia, and hypoalbuminemia are common in chronic liver disease, but are by no means specific for hepatic dysfunction. When neurologic signs are observed, elevated blood ammonia levels are helpful in distinguishing hepatoencephalopathy from primary neurologic disease.

At necropsy, in acute toxic hepatitis, the liver is swollen with rounded edges. On cut surface the lobular pattern of the parenchyma is accentuated by the presence of centrilobular necrosis and vascular congestion. When jaundice is present, organs and body fat appear yellow. Edema, and less often, ascites may be seen when hypoproteinemia has had an opportunity to develop or when there is concurrent congestive heart failure. In many instances, the toxicity of hepatotoxic agents is not limited to the liver and multiple organ involvement is common. Gastroenteritis is common with ingested toxins and kidney lesions are frequent, presumably resulting from the toxin-filtering and concentrating action of the kidney. The rumen content should be examined for evidence of hepatotoxic plants.

Definitive diagnosis of toxicity can be difficult. Success depends on careful history taking to identify all possible exposures to toxins and environmental examination to determine the presence of chemicals or plants unrecognized by the animal caretaker. Although toxic principles of many poisonous plants are identifiable by laboratory methods, these methods are often expensive and not widely available for diagnostic use. Identifying the plant itself in the rumen content or feed or on grazing lands may be sufficient to make a presumptive diagnosis. The ability to

identify fragments of toxic plants in rumen content is a valuable skill.

Specific treatments for toxic hepatitis are limited. Animals should be removed from risk of additional exposure when possible. In known, acute, oral toxicities, administering activated charcoal at a dose of 500 g for an adult goat may inhibit additional uptake of toxin from the gut. In individual, valuable animals, rumenotomy might be attempted early in the course of disease to remove ingesta that may contain toxins. Supportive care includes fluids supplemented with glucose to counter dehydration and likely hypoglycemia, feeding low protein diets to suppress additional hyperammonemia, and controlling seizures. When photosensitization is present, animals should be kept out of direct sun, given corticosteroids to ameliorate the photodermatitis, and placed on antibiotics to prevent secondary pyodermas. In many cases of toxic hepatitis, animals that recover from acute disease may never return to full health or production potential due to permanent liver damage. The prognosis, therefore, should always be guarded.

Controlling toxic hepatitis depends on identifying the toxic agent and preventing additional exposure. This includes accurate dosing of medications such as ivermectin, substituting newer drugs for carbon tetrachloride in the treatment of liver flukes, restricting grazing of goats to avoid toxic plants, avoiding overgrazing, providing supplemental feed during periods of drought, and recognizing periods of enhanced toxicity in certain plants. Obviously, accomplishing many of these goals is problematic. Additional recognition of environmental agents toxic to goats, particularly plants, and increased understanding of the patterns of occurrence of poisonings will lead to more specific recommendations for control.

Chemical and Drug-related Causes of Toxic Hepatitis

Carbon Tetrachloride

Carbon tetrachloride administered as a flukicide can be hepatotoxic, even at the recommended dose of 1 ml/10 kg bw (Jones and Shah 1982). Overdosing can lead to acute death from respiratory arrest or a more prolonged three- to seven-day course involving hepatic and renal insufficiency. The sensitivity of goats to carbon tetrachloride toxicity was increased when animals were first treated with the chlorinated hydrocarbon insecticide dieldrin (Abdelsalam et al. 1982).

Hexachloroethane

Idiosyncratic reactions to routinely used drugs may occur as reported in the case of Jamunapari goats in India given standard doses of hexachloroethane for treatment of liver flukes (Vihan 1987). Early signs of toxicity included rumen atony, bloat, diarrhea, and dyspnea, followed by depression, staggering gait, muscle spasms, and convulsions. Necropsy lesions included hepatic necrosis, renal tubular degeneration, pulmonary edema, desquamation of forestomach mucosa, and generalized hemorrhage. Such reactions have also been reported in cattle and sheep.

Halothane

Though no longer in common use in the United States, halothane gas anesthesia was used commonly in goats without incident. Nevertheless, there are two separate reports of presumed halothane toxicity producing massive hepatic necrosis with clinical signs of hepatoencephalopathy in the days immediately after anesthesia (Fetcher 1985; O'Brien et al. 1986). Although the exact mechanism remains unclear, it was postulated that a combination of prolonged anesthesia, hypoxia, and hypotension led to reductive rather than oxidative metabolism of halothane in the liver, resulting in production of hepatotoxic rather than inert metabolites. In a subsequent study, careful monitoring of clinical enzymology in goats under halothane anesthesia for no more than two hours and histologic examination of liver samples one and two months later did not indicate any evidence of liver damage or dysfunction (McEwen et al. 2000).

Iron

Iron toxicity, caused by extralabel administration of an equine hematinic product to cattle, was reproduced experimentally in goats given the same product (Ruhr et al. 1983). The product was formulated for intravenous use, but given intramuscularly at approximately five times the recommended horse dosage. Signs included respiratory distress, weakness, jaundice, recumbency, and convulsions. There was severe hepatic necrosis at necropsy.

Ivermectin

Ivermectin, given subcutaneously at twenty-five times the recommended dose (5 mg/kg versus 0.2 mg/kg), produced acute collapse, hyperexcitability, and death, or a three- to four-day course of anorexia, weakness, recumbency, apparent blindness, coma, and death in Nubian goats. The principal post mortem lesion was a multifocal, nonsuppurative, necrotizing hepatitis (Ali and Abu Samra 1987). In another study, East African goats were given eight times the recommended dose and showed no adverse effects except for some immediate, transient irritation at the subcutaneous injection site (Njanja et al. 1985).

Copper

Chronic copper toxicity has been documented in young goats fed calf milk replacers containing copper

(Belford and Raven 1986; Humphries et al. 1987). Chronic copper toxicity can cause hemolytic anemia as well as liver damage, though recently there has been a documented occurrence of chronic copper toxicosis in a dairy goat herd that showed no icterus or other signs of anemia (Cornish et al. 2007). Copper toxicity is discussed in more detail in Chapter 7.

Plants Causing Toxic Hepatitis

Caltrop

Geeldikkop, a hepatogenous photosensitization disease associated with grazing of *Tribulus terrestris*, or caltrop, a nutritious annual herb, causes severe economic loss in goat and sheep operations in South Africa (Kellerman et al. 1980). The condition has also been reported from Australia (Glastonbury and Boal 1985; Jacob and Peet 1987), Iran (Amjadi 1977), Argentina (Tapia et al. 1994), and California (McDonough et al. 1994). The plant, also known as puncture vine, yellow vine, and goathead, is found in warm, temperate, and tropical regions throughout the world. The disease is seasonal; the plant becomes toxic when wilted in hot, dry weather after summer rains. The hepatotoxicity and photosensitization are believed to be caused by steroidal saponins contained in the plant (Kellerman et al. 1991). Their toxic effect is enhanced when the plant is wilted. It has also been proposed that the presence of sporidesmin, a mycotoxin of *Pithomyces chartarum*, a fungus that grows on caltrops under the weather conditions described, may enhance the toxic effects of the steroidal saponins of *T. terrestris*. The clinical and pathological effects of experimental poisoning of goats with *T. terrestris* have been described (Aslani et al. 2004).

Sacahuiste

Sacahuiste *(Nolina texana)* poisoning occurs in Texas and other portions of the southwestern United States only during a brief, three-week period in spring when this common range plant is bearing buds, blooms, or ripe fruit, because the leaves are not toxic. The period of blooming often coincides with a period of feed scarcity on rangeland, so consumption by goats, sheep, and cattle is likely. Clinical signs include anorexia, depression, jaundice, dark yellow urine, purplish discoloration of the hoof, and photosensitization. The latter is more likely when green feed is available because sacahuiste blooms contain little chlorophyll (Mathews 1940a).

Lechuguilla

Agave lecheguilla, or lechuguilla, is another important cause of caprine hepatogenous photosensitization in Texas, New Mexico, and northern Mexico during drought conditions, especially in the spring. The disease is known locally as "goat fever" or "swellhead." The plant is believed to contain two photosensitizing toxins, one of which is a saponin. Signs include depression, loss of appetite, jaundice, yellow ocular and nasal discharge, photosensitization with swelling of the face and ears, and coma. Morbidity and mortality rates of 5% to 30% can occur (Mathews 1937).

Spurge

Poisoning by the spurge, *Phyllanthus abnormis*, occurs only in Texas in areas of sandy soil during drought periods when livestock eat young green plants. The toxin is degraded by drying. Goats are less susceptible than cattle, but can develop signs of listlessness, anorexia, unthriftiness, and diarrhea. There is severe fatty degeneration of the liver at necropsy (Mathews 1945).

Lantana

Lantana camara, which contains hepatotoxic lantadenes, is an important cause of poisoning in cattle and sheep in Australia, India, Mexico, and the United States. The shrub occurs commonly in many tropical and subtropical regions of the world and it may be consumed in large amounts during periods of drought. The toxic syndrome is characterized by photosensitization, jaundice, rumen atony, and constipation. At necropsy, the carcass is icteric, the liver swollen and dark brown to black in color, and the gall bladder is distended. Enlarged kidneys and congested lungs may also be noted. Lantana poisoning with characteristic photosensitization has been reported to occur in goats in coastal eastern Australia (Seawright 1984). A naturally occurring case in a Boer kid was reported from South Africa in which there was icterus, dehydration, and constipation but no photosensitization (Ide and Tutt 1998). Attempts to reproduce the disease experimentally in goats caused hepatotoxicity with jaundice and some deaths, but no photosensitization in one study (Lin et al. 1985) and no clinical signs at all except loss of appetite in another (Lal and Kalra 1960). More recently an experimental challenge in India produced both jaundice and photosensitization (Ali et al. 1995). Additional documentation and description of field outbreaks in goats would be useful.

Pyrrolizidine alkaloid toxicity

In contrast with cattle and horses, but similarly to sheep, goats are relatively resistant to pyrrolizidine alkaloid toxicosis commonly associated with ingestion of *Senecio* spp., *Crotalaria* spp., and *Heliotropium* spp. of plants. This resistance is not absolute, but dose-dependent. Experimentally, signs and lesions typical of pyrrolizidine alkaloid toxicity were produced in goats by prolonged feeding of tansy ragwort *(S. jacobaea)* at total

doses of 125% to 400% of bw, compared with lethal doses in horses and cattle of 5% to 20% of bw (Goeger et al. 1982). Experimental challenge of goats with *Crotalaria saltiana* (Barri et al. 1984) and *Heliotropium ovalifolium* (Abu Damir et al. 1982) have also been reported. While toxicity was produced in both cases, hepatic lesions consistent with pyrrolizidine alkaloid toxicity, namely megalocytosis, biliary hyperplasia, portal fibrosis, and veno-occlusive disease, were absent or scarce. The toxic effects in goats challenged with these plants were presumed to be caused by toxic constituents other than pyrrolizidine alkaloids.

It is unlikely that under normal grazing conditions, goats would eat sufficient amounts of *Senecio* during the period of availability of the plant to produce severe, fatal, clinical disease. However, some hepatotoxicity can occur with chronic consumption and may impair growth and production. The use of goats and sheep to clear *Senecio longilobus* and *S. spartoides* from Texas rangeland to make it safe for cattle has been recommended (Dollahite 1972).

Even though goats may not become ill from long-term consumption of plants containing pyrrolizidine alkaloids, these hepatotoxins can be passed into the milk. Rats fed milk from goats receiving a ration containing 25% tansy ragwort developed liver lesions characteristic of pyrrolizidine alkaloid toxicosis, though calves did not (Goeger et al. 1982a). Human poisoning by such a mechanism of relay toxicity from goat milk has not been reported.

Miscellaneous Plant Poisonings

A large body of research on plant poisonings in goats comes from the Sudan. The plants have been evaluated because they are commonly suspected to be involved in natural outbreaks of livestock poisoning, often under drought conditions. Plants found in the Sudan that were demonstrated experimentally to be hepatotoxic to goats include *Heliotropium ovalifolium* (Abu Damir et al. 1982), *Crotalaria saltiana* (Barri et al. 1984), *Acanthospermum hispidum* (Ali and Adam 1978), *Jatropha aceroides, J. glauca, Solanum dubium, Lagenaria siceraria, Citrullus colocynthis* (Barri et al. 1983), *Aristolochia bracteata, Cadaba rotundifolia* (El Dirdiri et al. 1987), *Ipomoea carnea* (Abu Damir et al. 1987), *Indigofera hochstetteri* (Suliman et al. 1983), *Capparis tomentosa* (Ahmed and Adam 1980), and *Tephrosia apollinea* (Suliman et al. 1982).

In Brazil, extracts of the fruit of *Sessea brasiliensis* caused anorexia, incoordination, hyperexcitability, opisthotonos and death in goats within twenty-eight to ninety-two hours. Centrilobular necrosis and fatty degeneration of the liver were observed at necropsy. *Vernonia mollissima*, another Brazilian plant toxic to sheep and cattle, produced depression, staggering gait, recumbency with paddling, and death within fifty-five

hours when fed to goats. Hepatic necrosis and renal damage were the predominant necropsy findings (Dobereiner et al. 1987).

In New Zealand, *Vestia foetida* (Solanaceae) was reported to have caused severe periacinar necrosis and fatty change in the liver. Two young goats were observed consuming the plant. Following consumption the goats had clinical signs of mydriasis, loss of menace response, ataxia, muscle fasciculations, recumbency, and malodorous breath indicative of the crushed leaves of the plant. One responded to treatment with diazepam and vitamins and the other died. Necropsy revealed the liver lesions as well as fatty nephrosis (McKeough et al. 2005).

Hepatotoxicity has been observed in goats and cattle in Western Australia eating the leaves of *Myoporum* spp., including the Boobialla tree and Ellangowan poison bush. The toxic principle is a furanoid sesquiterpene essential oil that produces midzonal and centrilobular necrosis of the liver (Allen et al. 1978). Clinical signs include photosensitization, hemorrhage, dyspnea, and death.

Other sporadic causes of hepatogenous photosensitization reported in goats include kleingrass (*Panicum* spp.) in the United States (Smith 1981) and signal grass *(Brachiaria decumbens)* in Nigeria (Opasina 1985) and Malaysia (Mazni et al. 1985).

The indolizidine alkaloids present in *Oxytropis* species can cause liver damage with vacuolation of liver observed histologically (Li et al. 2005). The clinical effects of *Oxytropis* spp. consumption are discussed in more detail in Chapter 5 relative to locoism.

Fungal and Mycotoxic Causes of Toxic Hepatitis

In South Africa, hepatotoxicity with photosensitization has been caused by a mycotoxin of the fungus *Drechslera campanulata* found growing on green oats (*Avena sativa*) grazed by Boer goats. Clinical signs developed within eight days of the onset of grazing and included photodermatitis with edema of the head, diarrhea, and a 3.5% mortality rate (Schneider et al. 1985).

Aflatoxicosis has been reported in Sri Lanka in young goats receiving a concentrate supplement containing coconut meal contaminated with *Aspergillus flavus*. Clinical cases were observed over a seven-month period and mortality rate was high. Jaundice was the most prominent sign, accompanied by lethargy, anorexia, a serous nasal discharge, and hypothermia terminally after a course of five to seven days. The livers were firm, congested, and fibrosed, and the gallbladder distended with tarry bile. There was biliary hyperplasia and periportal fibrosis microscopically. Similar findings have been reproduced experimentally in goats (Samarajeewa et al. 1975; Miller et al. 1984). Decreased milk production has been demonstrated in

aflatoxicosis and is correlated with the dosage of aflatoxin fed to goats (Hassan et al. 1985).

"Hard yellow liver" or hepatic fatty cirrhosis is a sporadic disease of grazing goats, sheep, cattle, and deer in west and south Texas causing chronic weight loss, neurologic signs, and terminal hepatic coma. At necropsy there is hepatic lipidosis and cirrhosis (Bailey 1985). The definitive cause is unknown. It was hypothesized that a mycotoxin, roridin A, extracted from *Phomopsis* fungus growing on grasses in endemic regions was responsible for the disease (Samples et al. 1984). However, administration of purified roridin A to sheep for sixty days failed to produce liver lesions typical of the disease (Thormahlen et al. 1994), and the etiology remains unclear. The epizootiologic and clinical features of the condition have been reviewed (Helman et al. 1993).

The hepatic form of lupinosis, a mycotoxicosis associated with *Diaporthe toxica* (formerly *Phomopsis leptostromiformis)* fungus on lupine plants, is an important disease of cattle and sheep in Europe, South Africa, and Australia. It has been produced experimentally in goats, but natural occurrence is poorly documented (Marasas 1974).

NEOPLASTIC DISEASES

Hepatic neoplasms are rare in goats. Two cases of hepatocellular carcinoma have been reported. One was an incidental finding from a four-year-old Angora goat detected during meat inspection (Rousseaux 1984). The other was in a ten-year-old Nubian male presenting in a thin and moribund state. This goat had a pheochromocytoma and a leiomyoma in addition to the hepatocellular carcinoma, and attribution of clinical signs to the liver tumor would be difficult (Lairmore et al. 1987). A case of primary hepatic fibrosarcoma has been reported in a Toggenburg goat (Higgins et al. 1985). Two cases of bile duct carcinoma have also been reported in goats, with metastases to the lungs (Chauhan and Singh 1969; Paikne 1970). One case presented with weight loss and ascites, the other was an incidental finding at slaughter. Two additional cases of malignant cholangiocarcinoma in goats without metastases have been reported (Rodriguez et al. 1996; Domínguez et al. 2001) as well as one benign cholangioma identified in a healthy-appearing goat during slaughter inspection (Puette and Hafner 1995). Lymphosarcoma has been identified in both diffuse and nodular forms in the livers of affected goats at necropsy (Craig et al. 1986).

DIABETES MELLITUS

There is one report of diabetes mellitus in a pygmy goat secondary to a hyperplastic pars distalis of the pituitary gland. It was hypothesized that the abnormal pituitary was excreting excessive amounts of growth hormone which led to permanent stimulation of the insulin-producing islet cells of the pancreas, resulting in their exhaustion and degeneration and the associated clinical manifestation of diabetes mellitus. The affected goat showed chronic, pronounced weight loss, polydipsia, polyuria, hyperglycemia, glucosuria, and ketonuria. Fasting insulin concentration was 5.5 µIU/ml as compared to a normal level of 45 ± 9 µIU/ml in healthy goats (Lutz et al. 1994).

There is one other report of diabetes mellitus in a goat of unknown cause (Akdoğan Kaymaz et al. 2001). Otherwise, the disease is considered rare in this species, though diabetes mellitus has been induced in goats experimentally using alloxan (Schwalm 1975; Prasad et al. 1985; Kaul and Prasad 1990) or streptozotocin (Cheema et al. 2000; Rubina Mushtaq and Cheema 2001).

Urinary System

OVERVIEW OF CONDITIONS AFFECTING THE CAPRINE URINARY SYSTEM

Clinical disease of the urinary system is uncommon in goats, with the exception of obstructive urolithiasis. This condition occurs frequently in males, especially castrated males. Urolithiasis is discussed in detail later in the chapter.

Subclinical and Clinical Conditions of the Kidney

Despite the low prevalence of clinical renal disease, pathologic lesions of the kidneys are not unusual in normal goats at slaughter. In an Indian study, 71% of all kidneys examined showed histologic abnormality, even when the kidneys were grossly normal. Nephrosis was the most common descriptive finding (Sankarappa and Rao 1982). In contrast, gross morphologic changes have been found in only 1.5% to 3% of kidneys examined at slaughter (Khanna and Iyer 1971; Tomar 1984; Babu and Paliwal 1988). Interstitial nephritis of unknown etiology is the most common histologic lesion in these kidneys, followed by nephrocalcinosis. The most common gross abnormalities are congenital polycystic kidneys and white spots on the kidney surface. White spots are sometimes caused by leptospirosis infection (Kharole and Rao 1968; Khanna and

Iyer 1971), and in one case, by *Encephalitozoon (Nosema) cuniculi*, a protozoal parasite uncommon in goats (Khanna and Iyer 1971a).

Spontaneous glomerulonephritis occurs in goats, but is rarely recognized clinically. The glomerular lesion contains heavy deposition of immunoglobulin G and complement but the antibody is not directed against basement membrane. The inciting cause of the immune mediated lesion is not known (Lerner et al. 1968). Glomerulonephritis has also been reported as an incidental necropsy finding in goats with a primary diagnosis of mycoplasma pneumonia.

A subclinical condition known first as symmetrical cortical siderosis and later as "cloisonné kidney" has been observed in goats in Iraq (Zahawi 1957) and India (Kharole 1967) and in castrated male Angora goats in Texas (Light 1960; Thompson et al. 1961; Grossman and Altman 1969). The kidney cortices are diffusely pigmented dark brown to black with the pigmentation stopping abruptly at the corticomedullary junction. The pigmentation is associated with thickening of the basement membranes of those portions of the proximal convoluted tubules present in the renal cortex. The lesion is frequently associated with renal hemosiderosis and the affected basement membranes stain variably for iron. While a number of explanations for the

etiology of this subclinical condition have been offered, the actual cause remains unknown (Hatipoglu and Erer 2001).

Pyelonephritis is infrequently reported in goats and may be caused by organisms other than *Corynebacterium renale*, such as *Arcanobacterium pyogenes* (Gajendragad et al. 1983). The relatively low prevalence of post partum uterine infections in goats as compared with cattle may in part account for the lower prevalence of this ascending kidney infection in goats.

The kidneys have filtering and excretory functions. As a result, toxins may concentrate in the kidneys, causing toxic nephropathy. A diverse group of metals, chemicals, plants, fungi, and drugs have been reported to produce renal lesions in the goat, either experimentally or in spontaneous cases. Despite this extensive documentation there is scant information on the antemortem effects of various toxins on renal function, clinicopathologic abnormalities, and relevant clinical signs.

The metals reported to cause toxic nephropathy include arsenic (Biswas et al. 2000), cadmium (Bose et al. 2001), copper (Humphries et al. 1987; Belford et al. 1989), iron (Ruhr et al. 1983), lead (Gouda et al. 1985), mercury (Pathak and Bhowmik 1998), and selenium (Hosseinion et al. 1972; Qin et al. 1994). Chemicals include aldrin (Singh et al. 1985), chlorpyrifos compounds (Mohamed et al. 1990), diesel fuel (Toofanian et al. 1979), ethylene glycol (Boermans et al. 1988), fenvalerate (Mohamed and Adam 1990), hexachloroethane (Vihan 1987), kerosene (Aslani et al, 2000) sevin (Wahbi et al. 1987), and uranyl nitrate (Dash and Joshi 1989).

Plants causing toxic nephropathy in goats include *Acanthospermum hispidum* (Ali and Adam 1978), *Agave lechequilla* (Mathews 1937), *Amaranthus* spp. (Gonzalez 1983), *Aristolochia bracteata* (El Dirdiri et al. 1987), *Azadirachta indica* (Ali 1987), *Cadaba rotundifolia* (El Dirdiri et al. 1987), *Capparis tomentosa* (Ahmed and Adam 1980), *Cestrum taurantiacum* (Mugera and Nderito 1968), *Citrullus colocynthis* (Barri et al. 1983), *Crotalaria saltiana* (Barri et al. 1984), *Gutierrezia microcephala* (Mathews 1936), *Heliotropium ovalifolium* (Abu Damir et al. 1982), *Indigofera hochstetteri* (Suliman et al. 1983), *Ipomoea carnea* (Abu Damir et al. 1987), *Jatrophia* spp. (Barri et al. 1983), *Lagenaria siceraria* (Barri et al. 1983), *Lantana camara* (Ide and Tutt 1998), *Narthecium ossifragum* (Flåøyen et al. 1997), *Nolina texana* (Mathews 1940), *Palicourea aenofusca* (Dobereiner et al. 1987), *Pennisetum clandestinum* (Peet et al. 1990), *Pieris japonica* (Visser et al. 1988), *Senecio jacobaea* (Goeger et al. 1982), *Solanum dubium* (Barri et al. 1983), *Tephrosia apollinea* (Suliman et al. 1982), *Tribulus terrestris* (Jacob and Peet 1987), and *Vestia foetida* (McKeough et al. 2005).

Fungi causing nephropathy include *Drechslera campanulata* (Schneider et al. 1985) and *Aspergillus flavus* (Samarajeewa et al. 1975). *Aspergillus* and *Penicillium* fungi are frequent feed contaminants. Experimentally it was shown that ochratoxin, a metabolite of some species of these fungi, produced marked nephrotoxicity, especially in the proximal convoluted tubules when administered intravenously (Maryamma and Krishnan Nair 1990). Ingestion of sawfly larvae also produced renal lesions in goats (Thamsborg et al. 1987).

Halothane (O'Brien et al. 1987), imidocarb diproprionate (Corrier and Adams 1976), and furazolidone (Ali et al. 1984) are drugs documented to have caused lesions in the caprine kidney. The aminoglycosides are known to be nephrotoxic in various animals when used at high doses for prolonged periods of time, or if there are underlying conditions predisposing to renal damage such as dehydration. Gentamicin was shown to produce subclinical nephrotoxicity in goats, as evidenced by decreased urine specific gravity, proteinuria, presence of granular epithelial casts in urine, and increased urine alkaline phosphatase when the drug was given intramuscularly at a dose of 35 mg/kg bw divided in two daily doses for ten days (Kumar and Pandey 1994).

Several infectious diseases that affect primarily other organ systems also may produce renal lesions and severe kidney dysfunction. They are discussed in detail elsewhere in this book. Cowdriosis, or heartwater, discussed further in Chapter 8, produces renal ischemia that leads to tubular nephrosis (Prozesky and Du Plessis 1985). Chronic trypanosomosis, discussed further in Chapter 7, can produce mononuclear infiltrates and amyloid deposits in goat kidneys (Bungener and Mehlitz 1976). Leptospirosis, discussed in Chapters 7 and 13, may cause interstitial nephritis.

Renal failure can occur as a result of massive hemolysis or muscle necrosis because hemoglobin or myoglobin accumulates in the renal tubules. Therefore, parenteral fluid administration to promote diuresis is an important aspect of therapy for the hemolytic anemias and for nutritional muscular dystrophy. Pregnancy toxemia, a nutritional/metabolic disease, can produce fatty infiltration of the kidney proximal tubular epithelium (Tontis and Zwahlen 1987).

Conditions of the Urinary System Distal to the Kidney

Pathologic conditions of the ureters and bladder are infrequent in goats, including cystitis, a comparatively common disease in cows. There are two reports of multiple leiomyomas in the bladder wall seen at necropsy. No clinical signs attributable to the tumors were reported (Jackson 1936; Lairmore et al. 1987). There are two additional reports of leiomyoma of the urinary bladder in goats as well as a transitional cell papilloma of the urinary bladder identified during abattoir inspections (Timurkaan et al. 2001; Raoofi et al. 2007).

The principal condition affecting the urethra is obstructive urolithiasis in male goats. Ulcerative posthitis affecting the preputial opening and causing dysuria is more common in sheep but also occurs in bucks and especially wethers. It is discussed in detail in this chapter.

Malformations of the urethra also occur and are most commonly reported in newborn and young kids that present with dysuria. Abnormalities may include atresia, hypospadias, diverticulum, and/or dilatation of the urethra, usually at or near the prepuce (Karras et al. 1992, Klc et al. 2005). These abnormalities are often associated with the intersex condition in goats. Vaginitis in does and balanoposthitis in bucks are caused by herpesvirus infection and are spread venereally as discussed in this chapter. *Mycoplasma* infections are also associated with vaginitis.

BACKGROUND INFORMATION OF CLINICAL IMPORTANCE

Anatomy

The comparative anatomy of the ruminant urinary tracts has been reported (Nickel et al. 1973; Sisson 1975; Barone 1978). The paired kidneys of the goat are smooth, elliptically bean-shaped, and located retroperitoneally in the abdomen. They are normally surrounded by perirenal fat, more abundantly so on the left. In the adult, they each weigh 100 to 160 g and are 6 to 7 cm in length. The location of the right kidney is fixed in the dorsal abdomen, occurring at the level of vertebrae T_{13} to L_3. The left kidney is located more caudally at L_4 to L_5 with its lateral aspect in contact with the dorsal sac of the rumen. It is frequently pushed to the right of the abdominal midline by a full rumen.

The right ureter follows the vena cava dorsal to the left kidney. The left ureter begins to the right of the median plane, courses ventral to the right ureter, and then crosses back to the left to enter the bladder. The ureters pass obliquely through the bladder wall and enter the dorsum of the bladder in the trigone region. The ureteral openings are 1 to 1.5 cm apart. The urinary bladder is ovoid and extends into the abdominal cavity when full. It lies ventral to the uterus in the doe. Cystocentesis is difficult, even when the bladder is full, because of the depth of the caudal abdomen.

The penis is fibroelastic in character as in other ruminants and similarly possesses a sigmoid flexure. Paired retractor penis muscles run laterally to the penis and attach proximal to the sigmoid flexure. The action of these muscles makes exteriorization of the penis from the prepuce for clinical examination difficult.

As is the case in sheep, the pars spongiosa of the penile urethra extends well beyond the glans penis for a length of approximately 2.5 cm, forming a vermiform

Figure 12.1. Urethral process of the buck extending beyond the glans penis. (Reproduced by permission of Dr. C.S.F. Williams.)

appendage with erectile capacity known as the urethral process (Ghoshal and Bal 1976) (Figure 12.1). While the urethral process in sheep is attached to the left side of the glans, it is median in position in the goat. The process is folded back inside the prepuce when the penis is flaccid but becomes rigid and extended when the penis is erect. During ejaculation, the process rotates spirally and is believed to spray semen on the external uterine orifice or possibly even enter the external os of the cervix. At birth, the urethral process is adhered to the preputial mucosa and gradually separates under the influence of testosterone.

Urinary calculi are commonly trapped in the urethral process, causing obstruction of urine flow. This is particularly true in castrated males, where the urethral diameter may be reduced and the urethral process remains adhered to the preputial mucosa because of loss of the developmental effects of testosterone. The urethral process is commonly removed as part of the medicosurgical management of obstructive urolithiasis to restore urine flow. There is no evidence that removal of the urethral process impairs fertility in goats.

Male goats possess a urethral recess projecting caudodorsally from the spongy portion of the urethra in the region of the ischial arch (Figure 12.2). The paired bulbourethral glands empty their secretions into this recess, which is 0.5 cm deep. In earlier descriptions, the urethral recess was referred to as the urethral diverticulum (Hinkle et al. 1978; Garrett 1987). This structure assumes clinical importance in attempts to catheterize the urethra retrograde to the bladder during clinical management of obstructive urolithiasis. As the catheter moves dorsally up the urethra in the perineal region and begins to arch cranially over the pubis, the tip invariably becomes lodged in the urethral recess and will not pass to the bladder. Ignorance of the presence of the recess may lead to forceful manipulation of
Figure 12.2. Urethral recess (arrow) of the buck at the ischial arch. (Reproduced by permission of Dr. C.S.F. Williams).

the catheter to reach the bladder. This can cause tearing of the urethral recess with subsequent accumulation of urine in perineal tissues or trauma, scarring, and contracture of the urethra.

In contrast to the male urethra, the female urethra is short and straight, with an average adult length of 5 to 6 cm. The external urethral opening is on the floor of the vestibule approximately 2 to 3 cm inside the vulva. There is a suburethral diverticulum approximately 0.5 cm deep just inside the external urethral orifice, ventral to the urethra, which must be avoided for successful catheterization of the bladder. The doe has no vestibular glands.

Physiology

As in other species, the kidney serves multiple functions, including water and electrolyte balance, nutrient conservation, maintenance of normal blood pH levels, and regulation of nitrogenous wastes. The kidney also has endocrine functions. It responds to antidiuretic hormone (ADH) for control of water balance, aldosterone for sodium and potassium regulation, and parathyroid hormone to increase excretion of phosphorus. It also produces erythropoietin for stimulation of erythropoiesis, participates in the activation of vitamin D, and produces renin in response to decreased renal perfusion to activate angiotensin. Limited physiologic data reported for the goat is provided in Table 12.1.

The excretion of inulin, creatinine, sodium sulfanilate (SS), and phenolsulfonphthalein (PSP) have been evaluated to assess caprine renal function (Brown et al. 1990). Creatinine clearance was determined not to be a reliable measure of glomerular filtration rate (GFR) in goats, primarily because of the existence of a tubular secretory mechanism for creatinine excretion in this species. Clearance of SS exceeds inulin clearance because of the existence of a secretory mechanism for SS in the proximal portion of the nephron. In addition, SS may be eliminated by routes other than the kidney in the goat. The clearance of PSP also exceeds inulin clearance, presumably because of excretion of PSP both by glomerular filtration and tubular secretion.

Even though SS and PSP clearance from plasma are not exact measurements of GFR, the use of these tests to assess renal function is attractive in that urine samples are not required to interpret results. This is important in goats because collecting urine by catheterization can be problematic, especially in males.

Maturation of the caprine kidney may affect functional studies. The efficiency of renal function is relatively low in the newborn kid but reaches adult capacity by two weeks of age, as indicated by increases in GFR and clearance of *p*-aminohippurate (Friis 1983). Tubular function increases more than glomerular function postnatally.

Goats show marked adaptation to conditions of poor nutrient availability and lack of water. Desert breeds such as the black Bedouin goat have a superior ability to conserve urea under adverse dietary conditions. In comparative studies with Swiss Saanen goats, both breeds could significantly increase the tubular reabsorption of urea when fed low-protein diets, but the Bedouin goat possessed a superior capacity to reduce GFR, thus lowering the amount of urea filtered by the kidney (Silanikove 1984). Urea thus conserved is available to the rumen microflora for protein anabolism.

Table 12.1. Physiologic parameters of caprine renal function.

Parameter	Type of goat	Special conditions	Unit of measurement	Reported value	Reference
Aldosterone in plasma	Adult Bedouin	Normal hydration	ng%	5.5 ± 4.3	Wittenberg et al. 1986
	Adult Bedouin	Water deprived	ng%	13.9 ± 2.3	Wittenberg et al. 1986
Clearance of creatinine	Young adult, mixed breed	Normal, conscious	ml/mn/kg bw	1.97 ± 0.09	Brown et al. 1990
Clearance of inulin	Young adult, mixed breed	Normal, conscious	ml/mn/kg bw	2.26 ± 0.08	Brown et al. 1990
Clearance of phenolsulphonphthalein	Young adult, mixed breed	Normal, conscious	ml/mn/kg bw	6.88 ± 0.39	Brown et al. 1990
Clearance of sodium sulfanilate	Young adult, mixed breed	Normal, conscious	ml/mn/kg bw	3.71 ± 0.39	Brown et al. 1990
Effective renal plasma flow (ERPF)	General	—	ml/mn/M^2	493	Fletcher et al. 1964
	Adult Bedouin	Fully hydrated	ml/mn	344 ± 146	Wittenberg et al. 1986
Filtration fraction	General	—	—	0.18	Fletcher et al. 1964
Glomerular filtration rate (GFR)	General	—	ml/mn/m^2	86	Fletcher et al. 1964
	Not specified	1–3 days of age	ml/mn/kg bw	2.1 ± 0.6	Friis 1983
	Not specified	14–20 days of age	ml/mn/kg bw	3.3 ± 0.2	Friis 1983
	Not specified	69–78 days of age	ml/mn/kg bw	2.8 ± 0.5	Friis 1983
	Adult Bedouin	Normal diet	l/day/kg bw	4.85 ± 0.3	Silanikove 1984
	Adult Bedouin	low-protein diet	l/day/kg bw	2.26 ± 0.1	Silanikove 1984
	Adult Bedouin	Fully hydrated	ml/mn	76 ± 29	Wittenberg et al. 1986
	Adult Saanen	Normal diet	l/day/kg bw	6.61 ± 0.4	Silanikove 1984
	Adult Saanen	Low-protein diet	l/day/kg bw	4.14 ± 0.3	Silanikove 1984
Maximum tubular reabsorption rate (T$_{max}$)	General	—	mg/mn/M^2	248	Fletcher et al. 1964
Urine chloride	Adult Saanen	Normal diet	mEq/l	209 ± 55	Silanikove 1984
	Adult Saanen	Low-protein diet	mEq/l	366 ± 37	Silanikove 1984
Urine creatinine	General	—	mg/kg/day	10	Brooks et al. 1984
Urine flow	General	—	ml/day/kg bw	10–40	Brooks et al. 1984
	Adult Bedouin	Normal diet	ml/day/kg bw	16.7 ± 3.7	Silanikove 1984
	Adult Bedouin	Low-protein diet	ml/day/kg bw	2.4 ± 0.07	Silanikove 1984
	Adult Bedouin	Fully hydrated	ml/mn	0.74 ± 0.4	Wittenberg et al. 1986
	Adult Saanen	Normal diet	ml/day/kg bw	26.3 ± 5.9	Silanikove 1984
	Adult Saanen	Low-protein diet	ml/day/kg bw	4.8 ± 0.26	Silanikove 1984
Urine osmolality	Adult Saanen	Normal diet	mOsm/kg	1745 ± 183	Silanikove 1984

Urine urea	General	—	mg/kg/day	230	Brooks et al. 1984
	Adult Saanen	Normal diet	mM/l	968 ± 84	Silanikove 1984
	Adult Saanen	Low-protein diet	mM/l	241 ± 39	Silanikove 1984

Typically, desert goats may go without water for two to four days. When offered water, they can consume as much as 40% of their dehydrated bw at one time. The rumen and kidneys work in concert to conserve water so consumed. Five hours after drinking, more than 80% of water taken in remains in the rumen. Effective renal blood flow, GFR, and urine output drop markedly, and urine flow remains below levels recorded in dehydrated goats, even four hours after drinking. At the same time, urine sodium concentration drops to half of that observed in dehydrated goats. There is a concomitant drop in urine potassium and chloride concentrations. Thus, the rumen acts as a water reservoir that is protected by renal conservation of sodium, chloride, and water (Choshniak et al. 1984; Wittenberg et al. 1986; Shaham et al. 1994).

Cold exposure causes goats to reduce their water intake. In lactating goats, there appears to be no compensatory reaction by the kidney, and circulating ADH levels remain similar to those of goats in a thermoneutral environment. The net result is a decrease in milk production as a method of water conservation (Thomson et al. 1980). When goats are exposed to heat stress and/or deprived of water, circulating ADH levels increase and the kidney actively participates in water conservation (Olsson and Dahlborn 1989; Mengistu et al. 2007). In one study, excretion of ADH in the urine increased eight-fold after forty-eight hours of dehydration (Lishajko and Andersson 1975).

Diagnostic Methods and Clinical Pathology

Examination of the Penis

Clinical management of obstructive urolithiasis requires examination of the penis. This can be difficult for several reasons. Cases often involve a young, castrated male with a small, poorly developed penis and residual adhesions between the penis and prepuce, making it difficult to manually extend the penis from the sheath. Obstructed goats are often in pain and resist manipulation. Sedation can assist in examination but must be used cautiously when animals are severely uremic.

A common approach to examination is to sit the animal on its rump, which pushes the penis forward in the sheath. The penis is then grasped just behind the sigmoid flexure and pushed forward until the glans and free portion of the penis breach the preputial orifice. The free portion of the penis is then wrapped securely, but carefully, with a length of gauze to pull the penis farther forward and immobilize it. Use of the gauze helps to resist the opposing action of the retractor penis muscles. Successful examination in this manner usually requires at least one assistant, especially if partial catheterization is to be attempted. This

technique can also be applied with the goat in lateral recumbency. In this case, the goat may be easier to restrain, but it may be more difficult to achieve extension of the penis.

An alternative method for exteriorizing the penis is to position the goat on its back with an assistant pulling both the animal's hind limbs forward as close to its ears as possible. This straightens the penis and controls kicking. The technique works better with intact male goats than with wethers, where the penis may be adhered to the prepuce (Pieterse 1994).

In cattle and sheep, the internal pudendal nerve block, though sometimes considered difficult to perform, is used for anesthesia of the penis and relaxation of the retractor penis muscle to facilitate clinical manipulation (Hofmeyr 1987). While the internal pudendal nerve also controls the retractor penis muscle in goats, the nerve block may not produce the desired effect, because the preputial muscles are under separate neurologic control and their persistent contraction may still inhibit protrusion of the penis (Prakash and Kumar 1983). Alternatively, epidural anesthesia administered at the lumbosacral junction can be used to facilitate examination, but the concomitant loss of locomotor function may complicate patient management.

Chemical restraint and tranquilization are useful adjuncts to examination. Diazepam given intravenously at a total dose of 5 to 15 mg provides patient relaxation and lowers resistance to manipulation. Xylazine at a dose of 0.05 mg/kg bw intravenously provides similar effects. Xylazine should be used with caution in obstructed goats. The drug elevates blood glucose, thereby promoting diuresis. Increased urine production is undesirable if the obstruction is not successfully relieved. Acepromazine maleate at 0.1 mg/kg intravenously may promote relaxation of the retractor penis muscle but the results are variable and the potential for phimosis exists. Propryonylpromazine at a dose of 1 mg/kg intramuscularly facilitates protrusion of the penis of goats in lateral recumbency, but spontaneous protrusion from the sheath did not occur (Schöntag 1984).

Once the penis has been exteriorized, partial catheterization of the urethra may be attempted when indicated. This is made easier by amputation of the urethral process, but passage through the sigmoid flexure is still problematic. The urethral recess at the level of the ischial arch makes introduction of the catheter into the bladder practically impossible. These constraints should be recognized to avoid unnecessary effort and trauma. Retractor penis myotomy performed at the median raphe 5 cm ventral to the anus may allow maximal straightening of the penis to assist in getting the catheter past the sigmoid flexure. Normal penis function was reported after reapposition of the muscles and healing (Shokry and Al-Saadi 1980).

Urine Collection

In cattle and sheep, urination can be induced by manual stimulation of the prepuce (male cattle) or skin in the perineal region (cows) or by holding off the nostrils (sheep). None of these techniques is effective in goats. Male goats may urinate frequently during the breeding season as part of mating behavior but patience is a virtue when waiting for a urine sample from a doe. Goats often urinate immediately after rising from extended recumbency, so the sampler should be prepared with a urine cup at appropriate moments. Introducing the goat to a new pen or stall may promote urination but this is unreliable. If able, bucks often urinate after release from restraint for examination.

Catheterization of the female for urine collection is simpler than in the male so long as the suburethral diverticulum at the external urethral orifice is avoided. A 12 French catheter can be used in an adult doe. Experience in other species suggests that administration of bethanecol, a parasympathomimetic drug, at a dose of 75 mcg/kg subcutaneously may stimulate urination in goats and not alter the composition of the urine.

For continuous collection of urine, pediatric urine bags have been sutured to the perineal region of female goats and a harness constructed to hold the collected urine (Mount 1984).

Clinical Chemistry and Urinalysis

Normal blood urea nitrogen (BUN) levels are in the range of 10 to 28 mg/dl, normal creatinine levels from 0.9 to 1.8 mg/dl, and normal uric acid levels from 0.33 to 1 mg/dl. Breed, sex, and age variations in these normal parameters have not been identified in goats.

Measurement of gamma glutamyl transferase (GGT) in urine is being used in other species as an indicator of renal damage in the proximal tubular epithelium. There is one report of its application in goats. In a study on the nephrotoxic effects of the plant *Narthecium ossifragum* on goats in Norway, normal, control goats had a mean urine GGT concentration of 18.8 U/l with a range of 10 to 25 U/l and a urine alkaline phosphatase concentration of 11.8 U/l, with a range of 5 to 19 U/l (Wisløff et al. 2003).

General values for urinalysis in the goat are given in Table 12.2. Breed, sex, and age variations are not reported for urinalysis in normal goats. However, urine osmolarity has been demonstrated to progressively decrease in advancing pregnancy in goats and increase again with the onset of lactation (Olsson et al. 1982).

Imaging Techniques

Plain survey radiographs are usually of little value as aids in diagnosing urinary tract conditions in goats,

Table 12.2. Normal caprine urinalysis values.

Parameter	Normal value
Color	Pale yellow
Turbidity	Clear
Specific gravity	1–1.05
pH level	Alkaline (7.2–8)
Glucose	Negative
Ketones	Negative
Bilirubin	Negative
Occult blood	Negative
Protein	Negative to trace
Sediment (observed per high-powered field)	
Red blood cells	<5
White blood cells	<5
Epithelial cells	Occasional
Fat droplets	Rare
Crystals	Rare
Casts	Occasional hyaline
Sperm	Variable
Gamma glutamyl transferase (U/l)	18.8 (10–25)
Alkaline phosphatase (U/l)	11.8 (5–19)

but may occasionally reveal cystic calculi (Figure 12.3). Contrast studies are often more helpful. Intravenous pyelography in the goat has been described (Cegarra and Lewis 1977). Sedation with xylazine facilitates the procedure. Ideally, goats should be fasted for forty-eight hours to reduce rumen size, but this can be detrimental to sick goats. Sodium iothalamate is given at a dose of 2 ml/kg intravenously in goats up to 28 kg, while in heavier goats the calculated dose is reduced to 75%. The kidneys are opacified within twenty seconds of injection and the entire urinary tract opacified within fifteen minutes. The technique is helpful in identifying congenital renal abnormalities and the presence and extent of uroliths, especially in the bladder.

Cystourethrography in the goat has also been described, requiring catheterization of the bladder under fluoroscopic guidance. The technique has proven useful for establishing the presence and character of cystic calculi (van Weeren et al 1987). A triple contrast cystography technique, with the addition of pneumoperitoneum, has also been described for use in the goat and is recommended for detailed evaluation of the mucosal surface of the bladder (Tayal et al. 1984).

In a review of twenty-six cases of obstructive urolithiasis, including twenty goats, positive normograde cystourethrography through a tube cystostomy catheter offered the best visualization of the lower urinary tract structures for assessing and subsequently

Figure 12.3. Multiple urinary calculi present in a goat urinary bladder as seen by plain radiography. This is an unusually diagnostic film. Contrast studies are often required to identify cystic calculi. (Courtesy of the Cummings School of Veterinary Medicine at Tufts University.)

managing the obstructive lesion (Palmer et al. 1998). In that same review, survey radiographs obtained in twenty-three patients with obstructive urolithiasis were diagnostic for urinary calculi in only one animal.

In recent years, ultrasonography has proven to be a rapid, useful technique in the diagnosis of urinary tract disease. Cystic calculi are readily identifiable by ultrasound and the technique is more reliable than survey radiography (Figure 12.4). A recent, illustrated discussion of ultrasound techniques used for examination of the urinary tract in small animals is very applicable to the goat (Widmer et al. 2004).

Kidney Biopsy

Percutaneous biopsy of the right kidney can be accomplished in some goats. The right kidney is readily palpable in the abdomen of thin goats in the anterior portion of the right paralumbar fossa just medial to the last rib. It can be captured manually, retracted caudally, and held in a fixed position in the right paralumbar fossa during the biopsy procedure. A Vim-Silverman needle is used for the procedure. A series of 300 right kidney biopsies was performed in this manner in thin Angora goats, with bleeding complications noted in fewer than 1% of the goats. This procedure would be more difficult in larger, well-fleshed goats. In dogs, it is reported that kidney biopsies obtained with lapar-
Figure 12.4. Urinary calculi (arrow at top of picture) in a goat urinary bladder as seen by ultrasound. (Courtesy of the Cummings School of Veterinary Medicine at Tufts University.)

ascopy are of higher quality than those obtained with ultrasound guidance in terms of the number of intact glomeruli in the biopsy specimen (Rawlings et al. 2003).

DIAGNOSIS OF URINARY TRACT DISEASE BY PRESENTING SIGN

Abdominal Distension

Rupture of the urinary bladder with passage of urine into the abdominal cavity secondary to obstructive urolithiasis is the most common cause of abdominal distension related to the urinary system. In rare cases, the ureter may rupture instead of or in addition to the bladder. Either condition is more likely observed in males than females. The contour of abdominal distension is bilateral and ventral. A similar "pot bellied" appearance may be seen in normal pygmy goats, obstructions of the forestomachs, gastrointestinal parasitism, infectious peritonitis, and reproductive conditions leading to distension of the uterus.

There is one case report of congenital polycystic disease affecting the kidneys and liver of a one-month-old pygmy goat. The animal presented with a history of progressive abdominal distension from birth and subsequently, hematuria (Newman et al. 2000). Congenital polycystic disease in goats is extremely rare; there is only one other case report in a Nubian kid (Krotec et al. 1996).

Subcutaneous Swelling

Rupture of the urethra secondary to obstructive urolithiasis leads to subcutaneous pooling of urine in either the perineal or preputial region. Leakage of urine into the perineal region can also result from trauma to the urethra at the urethral recess from careless or forceful attempts at bladder catheterization.

Focal swelling on the ventral aspect of the prepuce also is seen in cases of congenital urethral diverticulum in young males. This infrequent lesion consists of single or multiple outpocketings of the penile urethra, sometimes in association with a bipartite or split scrotum. Urine is not free in the subcutis, but does pool in the diverticulum. Contrast urethrography can be used to confirm the diagnosis and successful surgical correction of the defect has been reported (Gahlot et al. 1982; Fuller et al. 1992).

Hypospadias, a more extreme form of congenital urethral defect, is seen in young phenotypically male goats (Eaton 1943). These animals may be genetically female intersexes, as discussed in Chapter 13. In hypospadias, the urethra remains open on the ventral surface of the penis and is visible externally on the preputial midline. Urine may seep constantly from the opening. Phenotypically male goats showing this condition are probably infertile. In ulcerative posthitis, preputial swelling may result from accumulation of urine in the preputial space because inflammation and scabbing of the preputial orifice do not permit extension of the penis or passage of urine.

Balanoposthitis can occur in venereal caprine herpesvirus infection, causing edematous swelling of the prepuce in bucks.

Hypoproteinemia from any cause may cause subcutaneous ventral edema. The prepuce may be involved in this swelling.

Abnormal Appearing Vulva and Vagina

Hyperemia and swelling occur normally during estrus, and a clear to cloudy mucous discharge may be observed. The normal discharge of late estrus is white and tenacious and full of neutrophils. It is easily misinterpreted as pus by the inexperienced observer.

The intersex condition is common in goats and much variation in the structure of the external genitalia can be observed in affected female phenotypes. A bulbous or projecting vulva and an enlarged or protruding clitoris are indicative of the intersex condition. Additional internal abnormalities in the genitourinary organs may accompany these external signs.

Caprine herpes vulvovaginitis produces vulvar edema and erythema and a cloudy to gray or yellow vulvar discharge, in addition to vesicular lesions and erosions as discussed later in this chapter.

Granular vulvovaginitis can result from *Mycoplasma* spp. infections as discussed further in Chapter 13. Ulcerative vulvitis with purulent vulvar discharge caused by *Arcanobacterium pyogenes* and *Staphylococcus* spp. also occurs in goats.

Abnormal Appearance of Urine or Abnormal Urinalysis

Normal urine is clear and pale to dark yellow. Cloudy urine suggests inflammation associated with pyelonephritis, cystitis, or possibly vulvovaginitis. When inflammation is severe, the urine may also contain visible clumps of inflammatory cells and debris.

Pink to red urine usually indicates either hematuria or hemoglobinuria, though phenothiazine-based drugs can also turn the urine pink. Hematuria can occur in association with obstructive urolithiasis, pyelonephritis, cystitis, or, as in a case known to the author, by an infiltrative carcinoma at the neck of the urinary bladder. It has also been reported in goats with nephritis caused by consumption of broomweed *(Gutierrezia microcephala)* during drought in the southwestern United States (Mathews 1936). Bloody urine may also be found in the bladder in goats dead of anthrax. There is a case report of two kid goats with red urine from excessive water consumption leading to hypotonicity, hemolysis, and hemoglobinuria (Middleton et al. 1997).

Additional causes of hemoglobinuria secondary to hemolytic anemia are discussed in Chapter 7.

Brown urine results from myoglobinuria. In goats this may be seen in nutritional muscular dystrophy and in certain plant poisonings resulting in muscle necrosis. Brownish yellow urine can occur with bilirubinuria. Causes of bilirubinuria are poorly documented in goats.

Proteinuria caused by proteins other than myoglobin and hemoglobin does not alter the color of urine, but often accompanies inflammatory conditions of the urogenital tract. Post partum does may also have protein in the urine as a contaminant from normal discharge of lochia. Bacterial endotoxemia can result in proteinuria.

Persistent, elevated proteinuria, in conjunction with prolonged weight loss, is a hallmark of renal amyloidosis, which is the deposition of fibrillar amyloid protein in the kidney, mainly in the glomeruli. The condition is not common in small ruminants, but when it occurs, it is most likely associated with the AA form of amyloid which derives from serum amyloid A (SAA), an acute phase protein involved in cholesterol transport but also as a chemoattractant in the inflammatory process. Chronic inflammation leads to increased concentrations of SAA and the cleavage of certain isoforms of SAA, the fragments of which tend to form fibrillar aggregates (amyloid) that are deposited systemically, but mainly in the kidney, liver, and spleen (Ménusa et al. 2003). In goats, amyloidoisis has been most frequently seen in hyperimmunized animals that are used for commercial antibody production and thereby subjected to chronic stimulation of the immune system (Gezon et al. 1988). In addition, sporadic cases of amyloidosis involving the kidney and/or liver have been reported in relation to other chronic diseases of goats, including caseous lymphadenitis (Tham and Bunn 1992), caprine arthritis encephalitis (Crawford et al. 1980), contagious agalactia (Ménusa et al. 2003), and chronic arthritis presumably due to *Erysipelothrix rhusiopathiae* (Wessels 2003).

Marked ketonuria may be seen in pregnant does and is virtually diagnostic for pregnancy toxemia in the nonlactating, pregnant doe. It can also occur in lactational ketosis.

Glucosuria is recorded in enterotoxemia caused by *Clostridium perfringens* type D. Glucose may occur in the urine of goats stressed by other serious disease problems, including convulsions from any cause. Iatrogenic causes of glucosuria include xylazine and parenterally administered dextrose. Goats on aspirin therapy or those grazing *Salix* spp. may have false positive glucose tests caused by salicylates in urine (Wilkinson 1969).

Crystalluria can be observed in conjunction with or before clinical obstructive urolithiasis, or after consumption of ethylene glycol or plants high in oxalates.

Casts in the urine reflect tubular damage in the kidney, usually because of poor renal perfusion, toxins, or drugs. Increased white cells, red cells, and epithelial cells in the sediment indicate inflammation. Urine of sexually active bucks can normally contain sperm.

Anuria, Oliguria, or Polyuria

Male goats with obstructive urolithiasis may produce no urine, but dysuria is more common. Instances of anuric renal failure are poorly documented in goats. In most documented cases of toxic nephropathy, affected goats were oliguric initially and later polyuric. Oak toxicity is a common cause of nephrosis with polyuria in cattle and sheep. Goats are considered highly resistant to oak poisoning though there is one documented case in a goat herd (Katiyar 1981).

Dysuria, Pollakiuria, and Stranguria

Abnormal behavior related to urination in goats is most commonly associated with obstructive urolithiasis in males. The signs are described later in this chapter.

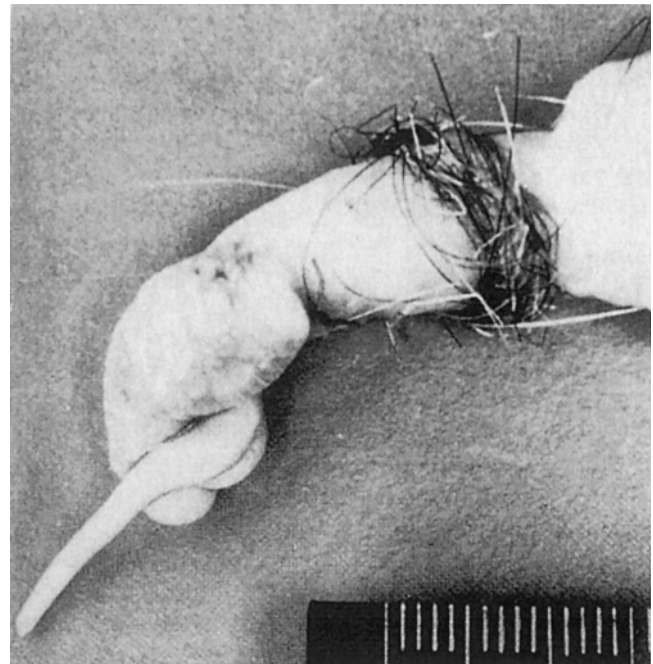
In ulcerative posthitis cases, scabbing over of the preputial orifice can also lead to dysuria in males. "Hair rings," or accumulations of loosely matted hairs encircling the penis behind the glans, have been recorded in feral goats in Australia (Figure 12.5) (Tarigan et al. 1990). These also could be associated with dysuria.


Figure 12.5. Hair ring encircling the penis of a goat. This can lead to dysuria. (From Tarigan et al. 1990.)

In females, abnormal urination occurs with cystitis and may also occur in cases of vulvovaginitis. Stranguria was observed in a doe with obstructive uropathy from trauma and adhesions of the urinary tract secondary to dystocia (Morin and Badertscher 1990). Pollakiuria, or frequent urination, can be associated with hydrometra in does and has also been reported in a case of uterine enlargement due to neoplasia (Pfister et al. 2007).

Malignant enzootic dysuria has been reported in grazing goats, sheep, and especially cattle in Morocco. The condition is considered to be most likely caused by consumption of leaves, buds, or acorns of *Quercus suber*, the cork tree, common in the Mediterranean countries. In addition to dysuria, affected animals show poor body condition, hypothermia, muzzle lesions, purulent nasal discharge, and recurring keratitis and conjunctivitis. Death can occur in two to four weeks, but more prolonged cases also occur (Mahin and Chadli 1982).

Uremia

Uremia is a systemic, toxic condition associated with the failure to remove the products of protein metabolism from the body via the urinary tract. The origins of uremia can be pre-renal, renal, or post renal. Elevated concentrations of urea nitrogen in the blood or plasma are the main laboratory indicator of uremia, also referred to as azotemia. Pre-renal uremia is associated mainly with dehydration or poor renal perfusion which may result from a variety of causes unrelated to the urinary system.

In cattle, very high levels of BUN can occur in the absence of primary renal disease (Divers et al 1982). Therefore, marked azotemia must be interpreted cautiously. Experimental evidence suggests that this is also true in goats. Induction of pyloric stenosis by ligation resulted in serum urea levels of 353 mg/dl with no evidence of impaired renal function. The increase correlated with a decrease in effective renal blood flow (Jorna 1978).

Uremia of renal origin is associated with decreased renal function or outright kidney failure. Naturally occurring, clinical cases in goats are not widely documented or reported, though they undoubtedly occur. Experiments involving partial or total nephrectomy in goats provide indications of the clinical manifestations of uremia of renal origin in the species.

Experimentally, five of nine goats subjected to subtotal nephrectomy survived for fifty-two weeks without clinical signs, while four died within eight days. All goats with total bilateral nephrectomy were terminally ill within eight days. Clinical signs included decreased appetite, rumen atony, depression, weakness, excess salivation, wiry pulse and jerky respiration, subnormal temperature, recumbency, convulsions, and coma. The degree of azotemia was not measured (Vyas et al. 1978).

Hypocalcemia, hyperphosphatemia, and hypermagnesemia have been recorded in toxic nephrosis in the goat. Hyperkalemia is not a consistent finding. In experimental lead poisoning, hypokalemia was observed along with hypocalcemia and hyperphosphatemia (Gouda et al. 1985). There is one reported case of renal (uremic) encephalopathy in a two-year-old male goat in which spongiform lesions of the brain were observed. The cause of the underlying nephrosis was not determined but the brain lesions were considered to be secondary to the uremia (Radi et al. 2005).

In goats, most reported clinical cases of uremia are post renal in origin and are associated with obstructive urolithiasis. The condition is discussed in more detail later in the chapter.

SPECIFIC DISEASES OF THE URINARY SYSTEM

INFECTIOUS DISEASES

Caprine Herpesvirus Vulvovaginitis and Balanoposthitis

In the goat, an alphaherpesvirus, caprine herpesvirus-1 (CpHV-1), has been identified as the cause of a venereally transmitted vulvovaginitis and balanoposthitis. The same agent has been implicated in epizootics of fatal viremia involving kids one-to two-weeks of age and abortion in does. It has also been isolated in conjunction with *Mannheimia* (*Pasteurella) haemolytica* from an outbreak of severe pneumonia of goats. CpHV-1 infection should be viewed as an emerging disease of growing importance in goats, especially in Mediterranean countries. The respiratory form, the viremic kid form, and the abortion form are discussed further in Chapters 9, 10, and 13, respectively.

Etiology

CpHV-1 is an icosahedral, double-stranded, linear DNA virus measuring 135 nm in diameter. It is sensitive to lipid solvents and trypsin and is inactivated at a pH value of 3 and at a temperature of 122°F (50°C). It can be cultivated on a variety of cell culture types and is cytopathic (Berrios and McKercher 1975). The biological and physicochemical properties of the virus have been described (Engels et al. 1983).

In early reports of disease, CpHV-1 was sometimes referred to as bovine herpesvirus type 6 but it is now recognized as a distinct entity, CpHV-1. Still, CpHV-1 belongs to an important group of alphaherpesviruses pathogenic to ruminants and closely related to each other. This group includes bovine herpesvirus-1 (BoHV-1), the cause of infectious bovine rhinotracheitis and infectious pustular vulvovaginitis in cattle, bovine herpesvirus-5 (BoHV-5), which causes bovine

encephalitis, bubaline herpesvirus-1, associated with subclinical genital infections in water buffalo, cervid herpesvirus-1, which causes an ocular syndrome in red deer, cervid herpesvirus-2, associated with subclinical genital infections in reindeer, and elk herpesvirus-1, associated with subclinical genital infections in elk.

The relatedness of these viruses has practical significance relative to disease diagnosis and control. Cross-species infections occur, though rarely. This has been investigated under experimental conditions, as reviewed by Thiry et al. (2006). Because of the antigenic similarity of these alphaherpesviruses, most serologic tests of antibody detection cannot distinguish reliably among them, as discussed further below in the clinical pathology section. Also, if multiple infections occur, recombination between these related viruses is theoretically possible, though it has not yet been confirmed between CpHV-1 and BoHV-1 (Meurens et al. 2004). Of greatest concern is that goats and other ruminants may serve as reservoirs for BoHV-1, and thereby confound national and international efforts to eradicate infectious bovine rhinotracheitis in cattle. This underscores the need for diagnostic tests that can reliably discriminate among the alphaherpesviruses. The molecular and epidemiological relationships of the alphaherpesviruses have been recently reviewed (Thiry et al. 2006).

Goats have been experimentally infected with BoHV-1, resulting in mild clinical signs, high levels of BoHV-1 excretion for several days during primary infection, an antibody response, and establishment of latent infection in the trigeminal ganglia of the challenged goats (Six et al. 2001). These latent infections could be reactivated by treatment of the goats with high doses of dexamethasone.

Conversely, calves experimentally challenged with CpHV-1 also became infected. They did not manifest any clinical signs but they did excrete CpHV-1 virus and produce an antibody response. Latent infection in the trigeminal ganglia was established as demonstrated by PCR, but could not be reactivated (Six et al. 2001).

Naturally occurring infections of goats with BoHV-1 have also been reported. In 1972, it was reported that the virus was isolated from nasal and ocular swabs from two goats in Maryland with fever and signs of respiratory disease (Mohanty et al. 1972). The BoHV-1 virus was also isolated from four goats in Washington state, one with clinical signs of vulvovaginitis, two with pneumonia, and one with a wart-like lesion. All these goats had commingled with cattle. The isolates were found to be more closely related to bovine vaccine strains of BoHV-1 than to CpHV-1 on the basis of restriction endonuclease analysis (Whetstone and Evermann 1988).

Recently, a gammaherpesvirus, known as caprine herpesvirus-2, was isolated from goats and characterized (Li et al. 2001). It has been shown to cause malignant catarrhal fever in whitetail deer (*Odocoileus virginianus*)(Li et al. 2003). In a more recent report, a putative case of malignant catarrhal fever in a pygmy goat was described (Twomey et al. 2006). The goat, which was kept with sheep, had a multisystemic necrotizing vasculitis and the gammaherpesvirus, ovine herpesvirus-2 (OvHV-2), was identified in the goat's tissues by PCR. The gammaherpesviruses are biologically distinct from the alphaherpesviruses and are not considered further here.

Epidemiology

The isolation and identification of CpHV-1 in association with naturally occurring disease was first reported from California in 1974 in cases of severe systemic infection of goat kids (Saito et al. 1974). Vulvovaginitis caused by CpHV-1 was first observed in Saanen does in New Zealand in 1981 and then in Australia in 1986 (Horner et al. 1982; Grewal and Wells 1986). Posthitis in males was identified in New Zealand in 1982, in Australia in 1984 (Tarigan et al. 1987), and more recently in bucks in California from herds experiencing abortions due to CpHV-1 (Uzal et al. 2004). Typical of herpesviruses, CpHV-1 infection demonstrates latency and recrudescence. In one New Zealand goat herd, the genital form of the disease was reported to reoccur a year after the first outbreak (Horner 1982).

Transmission of the genital disease is presumed to be venereal, but bucks need not be infected or have active lesions to spread the disease from infected to noninfected does mechanically. Increases in clinical prevalence or seroconversion can occur after the onset of the breeding season, suggesting either venereal transmission of new infections or recrudescence of latent infections secondary to stress associated with estrus and/or breeding activity. Clinical signs of vulvovaginitis in does have been reported to appear within eleven days of introduction of teaser bucks (Horner et al. 1982).

There is growing evidence of widespread CpHV-1 infection in world goat populations. Serologic evidence of CpHV-1 infection has been reported from Norway, northern Ireland, Spain, Italy, Turkey, Greece, and Syria (Kao et al. 1985; Thiry et al. 2006). In Greece, neutralizing antibodies were identified in 52.6% of 795 goats from various locations in the country (Koptopoulos et al. 1988). The Mediterranean region in general has a high seroprevalence of CpHV-1 infection in goats. As of 2006, CpHV-1 infection had not yet been identified in Belgium or the UK (Thiry et al. 2006). The infection recently has been identified in France (Thiry et al. 2008)

Pathogenesis

Genital infections in goats have been established experimentally by intranasal and intravaginal inoculation, but the pathogenesis appears to vary with the route of introduction. With intranasal challenge, virus first replicates locally, producing epithelial lesions in the nasal cavity. This is followed by viremia, as evidenced by the presence of virus in the buffy coat, and then infection of the genital tract, where virus produces characteristic lesions in the external genitalia and is shed in high titer (Tempesta et al. 1999). The viremia associated with intranasal inoculation has also been demonstrated experimentally by recovery of virus or its detection by PCR assay from the dead fetuses of pregnant does (Tempesta et al. 2004). Case reports of natural infections indicate that abortion in does due to CpHV-1 as well as the fatal syndrome observed in one- to two-week old kids are also the result of viremia, as aborted fetuses (Williams et al. 1997; Chénier et al. 2004; Uzal et al. 2004) and dead kids (Roperto et al. 2000) demonstrate the presence of CpHV-1 virus or viral DNA in multiple organs.

When goats were experimentally infected intravaginally, successful infection was manifested by genital lesions and recovery of virus from vaginal swabs for five to seven days post infection. However, no virus was identified from ocular, nasal, or rectal swabs or buffy coat, suggesting that genital infections can be established without an associated viremia (Tempesta et al. 2000).

As is characteristic of herpesviruses in other species, CpHV-1 results in latent infections with the capacity for recrudescence. The presence of virus in the sacral ganglia of latently infected goats has been confirmed by PCR assay (Tempesta et al. 1999a). Experimentally, recrudescence with viral shedding has been induced by repeated administration of high doses of dexamethasone over several days (Buonavoglia et al. 1996). In natural infections, recrudescence occurs in infected does in association with estrus, but primarily in does with low neutralizing antibody titers (Tempesta et al. 1998, 2005). Because recrudescence is associated with viral shedding, this suggests that the condition could spread rapidly through goat herds during the breeding season.

CpHV-1 was isolated from the lungs of goats in a naturally occurring outbreak of severe, fatal pneumonia in New Zealand in 1986. However, *Mannheimia (Pasteurella) haemolytica* was isolated from affected lungs in addition to CpHV-1 (Buddle et al. 1990). Experimental follow-up challenge studies were undertaken to clarify the etiologic role of CpHV-1 in these cases. Challenge with CpHV-1 alone did not produce pneumonia, while challenge with *M. haemolytica* alone or *M. haemolytica* with CpHV-1 did (Buddle et al. 1990a). CpHV-1 readily proliferated in the upper respiratory tract and lungs of the challenged goats, but its role in the pathogenesis of pneumonia remains unclear.

Clinical Findings

All goats of breeding age are susceptible to the genital form of disease. Clinical cases occur most frequently in epidemic form shortly after the onset of the breeding season. This reflects the presumption that hormonal changes associated with the onset of estrus trigger recrudescence of virus shedding in latently infected does, which may then be spread to susceptible does by breeding bucks.

The initial signs of vulvovaginitis in does are vulvar edema and hyperemia with possibly a slight amount of blood-stained discharge. No systemic signs of disease are observed. Over the next several days, a more copious yellow to gray discharge may develop, and multiple, focal, shallow erosions appear on the vulvar and vaginal mucosa. These erosions may be covered with yellow to red-brown necrotic scabs. The vulva is painful to the touch and dysuria is possible though not often reported. Lesions usually heal spontaneously within two weeks. Reproductive performance and conception rates are not affected, though animals that experienced the disease may have subsequent recurrences of lesions due to recrudescence of latent infections, usually at the next breeding season. Males used in breeding may or may not show lesions. When present, lesions consist of penile hyperemia and focal, punctate, epithelial erosions on the penis, and more frequently, the prepuce (Figure 12.6). A preputial discharge may also be present.

Clinical Pathology and Necropsy

The virus can be isolated from vaginal or preputial swabs of acute lesions for confirmation of CpHV-1 infection. Rising titers to CpHV-1 can be detected in both clinical and subclinical infections immediately after an outbreak of vulvovaginitis and balanoposthitis. Acute and convalescent serum sampling should be initiated early in the course of disease, because titers may begin to decline again by three weeks after onset of disease. Serum neutralization titers in infected goats range from 1:4 to greater than 1:256.

While a rise in titer using serum neutralization or ELISA techniques is certainly indicative of CpHV-1 infection, definitive diagnosis of CpHV-1 infection cannot be made by serologic methods because of the common cross reactivity of the alphaherpesviruses and the fact that cross-species infection can also occur, particularly with regard to BoHV-1. A blocking ELISA based on the B glycoprotein of BoHV-1 has been reported to be a good screening test for tentative identification of CpHV-1 in goat herds (Keuser et al. 2004).
Figure 12.6. Erosive lesions of the penis (arrows) in balanoposthitis caused by caprine herpesvirus. (From Tarigan et al. 1987.)

Confirmation can be achieved by following up with double seroneutralization tests using BoHV-1 and CpHV-1 antigens and finding higher titers to the CpHV-1 antigen (Thiry et al. 2008).

Definitive diagnosis depends on virus isolation with precise characterization of the virus or detection of CpHV-1 viral DNA in tissues by appropriate means. Current techniques used for detection or characterization of the CpHV-1 virus include restriction endonuclease analysis (REA), real-time polymerase chain reaction (RT-PCR) (Elia et al. 2008), and an immunofluorescence assay able to differentiate five related alphaherpesviruses in infected cells (Thiry et al. 2006).

Necropsy diagnosis of the genital form of CpHV-1 infection is rarely required or undertaken. However, necropsy is most valuable in the diagnosis of other forms of the disease, notably abortion and death of kids one to two weeks of age. Virus isolation and viral DNA identification techniques should be conducted on tissues of aborted fetuses and dead kids.

Diagnosis

Normal estrus produces some degree of hyperemia and edema of the vulva and should not be confused with the early signs of CpHV-1 infection. Granular vulvovaginitis caused by various *Mycoplasma* spp. must be differentiated from CpHV-1 infection. Granular vulvovaginitis is reported most often from India and Nigeria (Singh et al. 1975; Singh and Rajya 1977;

Tiwana et al. 1984; Chima et al. 1986). The condition is discussed more in Chapter 13. An ulcerative vulvitis with copious purulent vaginal discharge has been reported in Nigerian goats. *Arcanobacterium pyogenes* and *Staphylococcus* spp. were isolated (Ihemelandu 1972).

Treatment

There is no practical, specific treatment for CpHV-1 infection. However, there is a recent report of the use of the human antiviral drug cidofovir in goats. The drug, administered intravaginally, inhibited onset of local vaginal lesions in does and reduced viral shedding (Tempesta et al. 2007). Does and bucks with the genital form usually heal spontaneously within two weeks, though recurrent lesions are possible. Risk of secondary bacterial infections may be controlled by administration of prophylactic antibiotics.

Control

Efforts to eradicate genital CpHV-1 infection from infected flocks have been proposed based on the assumption that the disease is venereally transmitted. The evidence for this was that kids born to seropositive does and left to nurse on them did not acquire infection by passage through the birth canal, nursing, or close contact. Therefore, it was proposed that gradual elimination of infection from known infected flocks could be achieved according to the following recommendations (Horner 1988): Kids should be separated from older animals before they become sexually active and maintained as a separate group. Only seronegative bucks or teasers should be used for mating in this separate kid group. Buck kids tested before four months of age may have maternal antibody present and should be retested at a later age. At the same time, the mature, source herd should be serotested regularly and positive animals culled at detection. No new animals should be introduced into the herd that have not first been found seronegative.

Since those recommendations were made, it has been demonstrated, at least experimentally, that goats infected with CpHV-1 by the intranasal route can develop vulvovaginitis and shed virus from the genital tract (Tempesta et al. 1999). A better understanding of the transmission of CpHV-1 under field conditions is required to develop updated recommendations for management interventions to control CpHV-1 in infected herds.

Currently, there are no commercial vaccines available for controlling CpHV-1 infection. However, some experimental efforts have been reported that show promise. A β-propiolactone inactivated CpHV-1 vaccine given either subcutaneously or intravaginally protected does from clinical signs of vulvovaginitis when they were subsequently challenged intravagi-

nally with CpHV-1 (Tempesta et al. 2001; Camero et al. 2007). A commercially available, live, attenuated, glycoprotein E-negative, BoHV-1 virus vaccine has been reported to be safe for use in goats and demonstrated partial efficacy against subsequent challenge with CpHV-1 (Thiry et al. 2006a). Additional evaluation of the vaccine against CpHV-1 is ongoing.

Ulcerative Posthitis

Though principally a disease of sheep, this infectious, inflammatory condition of the prepuce and penis is sometimes seen in castrated male goats as well. The condition is also known as enzootic posthitis, sheath rot, or pizzle rot.

Etiology and Pathogenesis

The disease is associated with the Gram-positive, diphtheroid bacterium *Corynebacterium renale*, which is capable of hydrolyzing urea. The organism is present in the prepuce of infected animals and is believed to be transmitted venereally or by insects. However, presence of the organism in the sheath alone is not sufficient to produce clinical disease. The feeding of a high protein diet increases urine urea content and thereby provides a substrate for the production of large quantities of ammonia by *C. renale.* The ammonia is believed to irritate the preputial mucosa and skin around the preputial orifice. The condition is more common in wethers than in intact males, probably because of the hypoplastic nature of the penis in castrated males. In wethers, the preputial and penile mucosa do not completely separate and urination frequently occurs without exteriorization of the penis from the prepuce. This promotes urine pooling in the preputial space and allows more complete degradation of urea by *C. renale.* Another contributing factor may be excessive hair or wool at the preputial orifice, causing the area to remain moist with urine and allowing prolonged bacterial activity on urea substrate.

Epizootiology

The disease in goats has been reported only from the United States, though the potential for it to occur elsewhere exists, because it is seen in sheep in Australia, the United Kingdom, and Spain (Loste et al. 2005). While the disease is known to be venereally transmitted by rams to ewes in some flocks, there are no reports of the condition affecting does.

The principal report of posthitis in goats comes from south central Texas where Angora wethers may be kept to advanced ages for mohair production (Shelton and Livingston 1975). The condition was observed in a large flock of wethers on rangeland containing guajillo *(Acacia angustissima).* Guajillo, a leguminous shrub, has a protein content in the range of 22% to 27% and is readily consumed by goats. Morbid-ity was estimated at 10% and no mortality was directly attributable to the problem.

The author has observed ulcerative posthitis in wethers in a different context. Affected goats were castrated males of dairy breeds kept to advanced age for the purpose of commercial antibody production. These animals were maintained on a commercial dairy ration containing 16% protein. Morbidity was low and the condition was not severe, but obvious swelling and inflammation were evident around the preputial orifice.

Clinical Findings

The condition may be mild to severe. In the mild form, signs are limited to a swelling of the prepuce readily noted in short-haired dairy wethers or detected in long-haired Angora wethers at shearing time. In severe cases, swelling and inflammation interfere with normal urination and signs of straining are present. These animals may kick at the abdomen, show a stiff gait or an arched back, and may lie down and rise repeatedly. Examination of the ventral abdomen reveals scabs or ulcers on the skin dorsal to and surrounding the prepuce and preputial orifice. The orifice itself may be distorted, reduced in diameter, or completely scabbed over. The sheath may be filled with urine, and exudate may be expressed by applying pressure to the prepuce. Fistulous tracts may be present. The preputial cavity and the penis may show severe ulceration and possibly maggot infestation. Animals with complete occlusion of the preputial orifice may die of uremia.

Clinical Pathology and Necropsy

Swabs of the preputial cavity should allow isolation of *C. renale.* Animals with extensive ulceration inside the prepuce and on the penis may die. Necropsy demonstrates extensive exudation within the preputial cavity and ulcers and scar tissue on the mucosa. The urethral process may be necrotic and ulcers present on the glans penis.

Diagnosis

On rare occasions, goats may show scabby lesions of contagious ecthyma on the prepuce, but similar lesions also likely would be found elsewhere on the face and body. Ulcerative dermatosis, a similar viral disease of sheep, is not reported in goats. Obstructive disease of the gastrointestinal tract and obstructive urolithiasis must be considered in the differential diagnosis of goats with signs of straining or abdominal discomfort.

Treatment

Affected animals should be separated from the herd or flock and the high protein component of their

diet withdrawn. Clipping hair from around the preputial area may improve the rate of healing. Reestablishing patency of the urethral orifice is the first therapeutic goal in animals unable to urinate. Lesions should be debrided and topical treatment begun. *C. renale* is usually sensitive to penicillins, ampicillins, and cephalosporins. As these antibiotics are excreted in urine, systemic treatment will also provide local therapy. Intramammary infusion tubes designed for mastitis treatment are convenient vehicles for administering these antibiotics into the preputial cavity, though care should be taken not to transmit infection to unaffected herd mates. Repeated daily treatment with ophthalmic ointment containing bacitracin, neomycin, and prednisolone applied topically to the prepuce has also been reported to be effective as an ancillary treatment in sheep (Loste et al. 2005). In severe exudative cases, opening the prepuce surgically with a scissors along the ventrum is indicated for salvage. Except in the most severe cases, the prognosis for recovery is good.

Control

Dietary protein should be limited to a level consistent with the nutritional requirement of the animals. This may be problematic under range conditions. Preputial hair should be kept clipped to reduce urine accumulation. Animals with external lesions identified at shearing time should be treated topically with antiseptics or antibiotics to control lesions and reduce spread in the flock. Implantation of wethers with 70 to 100 mg of testosterone at three-month intervals has been effective in controlling ulcerative posthitis, but this method has not been evaluated in goats (Kimberling 1988). Castration using the so-called short scrotum technique has also been suggested because it renders wethers infertile but allows the urethra and penis to mature under the influence of testosterone. In this technique, both testes are pushed up into the inguinal canal or inguinal region and a rubber ring is applied around the neck of the scrotum below the testes. There are animal welfare concerns associated with the use of this technique (Molony et al. 2002).

NUTRITIONAL AND METABOLIC DISEASES

Obstructive Urolithiasis

In goats, clinical obstructive urolithiasis is most frequently seen in young, castrated males and the calculi are usually comprised of phosphate salts, especially calcium phosphate (apatite) and magnesium ammonium phosphate (struvite). Goats kept as pets are at high risk for developing the condition due primarily to the feeding of excessive grain in the diet. The case management and treatment options of goats kept as pets may differ considerably from those for goats kept as livestock.

Etiology and Pathogenesis

Obstructive urolithiasis is the inability to normally void urine because of obstruction of the urinary outflow tract by calculi. The formation of urinary calculi results from the interaction of numerous physiological, nutritional, and management-related factors. The tendency for urinary calculi to become lodged in the urethra derives from anatomic factors and castration practices in male ruminants. Factors predisposing to urinary calculi formation in livestock have been well reviewed (Radostits et al. 2007).

The urine is a highly saturated solution of mineral solutes. Under normal circumstances, these solutes usually remain in solution. However, numerous factors can predispose to precipitation of minerals from urine leading to calculi formation. These include increased urine concentration from decreased water intake or increased insensible water loss, urine stasis, increases in urine pH that favor precipitation of phosphate calculi, increased mineral concentration in the urine related to diet composition, and decreases in the concentration of protective colloids in the urine that ordinarily inhibit precipitation by transforming the urine into a stable gel.

Calculus composition frequently reflects diet. Silicate calculi are common where grass and cereal hays are the main dietary constituents, particularly in arid regions. Forages high in oxalates promote oxalate calculi, with certain plants such as *Halogeton* contributing significantly to the problem. Subterranean clover is high in calcium and extensive grazing may lead to calcium carbonate stones. Grain rations, or concentrates, are commonly high in phosphorus and relatively low in calcium. This imbalance promotes the formation of phosphate calculi, as frequently seen in feedlot steers and wethers on fattening diets. The calculogenic potential of such diets is increased when the concentrate is also high in magnesium.

In goats, several relationships of diet to calculus formation have been observed in the field or confirmed experimentally. Obstructive urolithiasis caused by magnesium ammonium phosphate (struvite) calculi was observed in Brazilian goats fed a concentrate ration of three parts corn to one part cottonseed meal (Unanian et al. 1982) and in Australian Angora goats fed a pelleted feedlot fattening ration with a calcium-to-phosphorus ratio of 1:15 (Bellenger et al. 1981). Goats fed rations containing magnesium in excess of 0.6% developed struvite crystals or calculi even when the calcium-to-phosphorus ratio was properly balanced (James and Chandran 1975; James and Mukundan 1978). Experimentally, phosphate calculi were consistently produced in goats fed a ground corn and soybean

meal ration supplemented with 3.5% K_2HPO_4 (Sato and Omori 1977).

There are additional factors in the actual formation of calculi. A nidus may be necessary for calculus formation to occur. Desquamated epithelial cells in the urinary bladder are commonly considered to function as a nidus. Factors which may contribute to increased desquamation of epithelial cells include vitamin A deficiency and infections of the urinary tract. A role for vitamin A deficiency in obstructive urolithiasis has been specifically confirmed in goats (Schmidt 1941). Desquamated epithelium in sufficient quantity may obstruct the urethra, even without the formation of mineral calculi. Infections can alter urine pH, which may promote precipitation of mineral salts.

Once calculus formation is initiated, growth occurs by the process of concretion. Increased mucoproteins in the urine serve as a matrix and favor concretion. The feeding of high concentrate rations, particularly in pelleted form, promotes an increase in urine mucoproteins.

Obstruction is not a necessary result of calculus formation, but is predisposed by anatomic factors. Obstructive urolithiasis is rarely seen in female ruminants despite the fact that calculi can and do form. The short, straight urethra allows calculi to pass easily with the urine. In contrast, the long, convoluted course of the urethra through the sigmoid flexure of the penis, ending in the small urethral process, provides ample opportunity for even small calculi to become lodged in the male urethra. This tendency is aggravated by early castration of male ruminants that results in penile hypoplasia with attendant reduction in urethral bore size, and failure of the maturing urethral process to separate completely from its distal attachment to the preputial mucosa. The effect of castration on reduced urethral diameter has been documented in goats (Kumar et al. 1982). Exogenous estrogens either in the diet or from growth-promoting implants can also lead to reduced urethral diameter by promoting swelling of the surrounding accessory sex glands in the pelvic region.

When complete obstruction of the urethra occurs, forceful attempts to urinate produce little or no voided urine. Animals so affected soon become azotemic because of decreased renal function, secondary hydro-ureter, and hydronephrosis.

Unless the obstruction is relieved spontaneously or by intervention, the urinary bladder or the urethra will eventually rupture. In the former case, abdominal distension may result as urine fills the peritoneal cavity. In the latter case, urine fills the subcutaneous space in the perineal or preputial region depending on the site of urethral rupture. At this point, the uremic process accelerates and, without veterinary intervention, the animal ultimately dies.

Epidemiology

Obstructive urolithiasis is a well recognized, highly prevalent, and costly disease of fattening steers and sheep wethers maintained in feedlot conditions and fed high concentrate rations. Goats are rarely managed in similar intensified fattening situations, and therefore the disease is far less prevalent in the caprine species, though growing interest in commercial goat meat production could alter this situation.

In the United States and Europe, most affected goats are young males, often castrated, and frequently maintained as pets (Craig et al. 1987; van Weeren et al. 1987a). A retrospective study of thirty-eight cases of caprine obstructive urolithiasis seen at Tufts University in Massachusetts showed twenty-four affected goats to be castrated males and fourteen to be intact males, with no female cases seen. The average age of affected goats was twenty-seven months, with a range of two months to twelve years. Many of these goats were obese, and virtually all were on high grain diets providing energy in excess of their metabolic needs as inactive pets. There was an increased prevalence in summer and winter, times when dehydration is more likely to occur. Phosphatic calculi (struvite and apatite) were most common and occurred in the form of either sand or sediment. Calcium carbonate calculi were less frequently identified, larger, and more likely to occur as stones. More recent case reviews from a number of veterinary teaching hospitals or referral centers report similar findings, with young, castrated male goats representing the most common signalment for obstructive urolithiasis, and virtually no cases involving females (Ewoldt et al. 2006; George et al. 2007). Pet goats are increasingly represented in these case populations, at least in the United States.

In Texas, obstructive urolithiasis is recognized as a potential problem in young Angora males being raised for sale as replacement breeding stock. To promote growth and condition in time for sale before the breeding season, these animals are fed a pelleted ration comprised of sorghum or corn, cottonseed hulls, and alfalfa. The diet is recognized as highly calculogenic and obstructive urolithiasis is avoided by appropriate adjustment of the calcium-to-phosphorus ratio and addition of salt and urinary acidifiers.

In Brazil, urolithiasis occurs sporadically in the Northeast region when goats are managed intensively and fed corn and cottonseed concentrates (Unanian and Silva 1987). In Queensland, Australia, Angora goats were most commonly reported to experience obstructive urolithiasis because of greater access to grain and formulated feedstuffs (Manning and Blaney 1986). Urolithiasis in goats occurs elsewhere in the world but contributing factors are not always evident or reported.

Clinical Findings

In the first phase of obstruction, male goats show restlessness and anxiety. Tail twitching is an early sign. There may be excessive vocalizing and animals strain frequently and forcefully to urinate, often stretching their bodies out to full length with a dip to the back, followed by arching. Marked abdominal press may produce some degree of rectal prolapse. Inexperienced owners may assume that the animals are constipated and medicate goats inappropriately rather than seeking veterinary attention. Palpation of the urethra on the median raphe in the perineal region reveals distension and pulsation during straining. Drops of bloody urine and/or crystals may be seen attached to preputial hairs. Animals with partial obstruction may be able to void small intermittent streams of urine, but show discomfort.

Careful examination of the urethra should be undertaken in an attempt to locate the site of obstruction. Visualization of the urethral process may reveal calculi at this common site of blockage (Figure 12.7). Deep palpation of the urethra along the prepuce and perineum may indicate pain or swelling at more proximal sites of obstruction such as the sigmoid flexure.

When the obstruction goes uncorrected, rupture of the bladder or urethra usually results within twenty-four to forty-eight hours. Rupture relieves pressure and may produce alleviation of discomfort and anxiety so that the animal resumes a more normal attitude, at least until the signs of uremia supervene. Inexperienced owners may interpret this as a resolution of the problem rather than a progression of the problem, and thereby delay seeking veterinary attention. If it is the urethra that ruptures, then subcutaneous filling of the preputial or perineal region becomes noticeable. In rupture of the urinary bladder, bilateral, ventral abdominal distension develops, but progresses more slowly and may be more difficult to detect, especially in obese goats or pygmy goats that already have distended appearing abdomens.
Ensuing uremia causes affected goats to become anorexic, weak, and depressed. Advanced cases often present in a moribund state and the condition is fatal if left untreated. The entire clinical course is usually two to five days.

Clinical Pathology, Radiology, and Necropsy

The most consistently reported abnormality of clinical chemistry in goats with obstructive urolithiasis is azotemia. This is reflected in the chemistry profile as high levels of blood urea nitrogen and serum creatinine. These levels may climb even higher if rupture of the bladder or urethra occurs. Levels of BUN in affected goats have been reported in the range of 11.7 to 47.5 mmol/l (70 to 285 mg/dl) (van Weeren et al. 1987). Recently, a summary of biochemical abnormalities in 107 goats with uroliths was reported (George et al. 2007). Compared to control goats, goats with urolithiasis had higher mean BUN, creatinine, total CO_2, glucose, and potassium concentrations, and lower phosphorus concentrations. Hypochloremic metabolic alkalosis was the most common acid-base disorder. Rupture of the bladder or urethra was associated with an increased prevalence of hyperkalemia and hyponatremia. Hypophosphatemia was an unexpected finding in this series of cases, because among the domestic species, with the exception of horses, hyperphosphatemia is usually associated with postrenal obstruction or ruptured bladder.

Urine sediment should be examined whenever a urine sample can be obtained. Marked crystalluria supports the diagnosis of obstructive urolithiasis. Aspiration of subcutaneous or peritoneal fluid can be helpful, though confirming that the fluid is urine can be problematic. It has been reported that urine can accumulate in the abdomen, even in the absence of bladder rupture, presumably due to passage of urine through an intact but compromised bladder wall under intense pressure (Ewoldt et al. 2006). Some obstructed goats develop hydronephrosis or leak urine around the kidney. A urea nitrogen or creatinine level equal to or greater than that of blood suggests that the abdominal fluid is urine. An odor of urine may be helpful in field diagnosis.

Figure 12.7. A common site of urethral obstruction with calculi is at the urethral process. The lesion pictured is highly unusual in that the obstruction at the urethral process is a lead shotgun pellet rather than mineral calculi as is usually the case. (From Blackwell and Dale 1983.)

Plain radiographs only rarely reveal cystic or urethral calculi and their use in cases of obstructive urolithiasis is not considered to be cost-effective, whereas contrast studies can be very effective both as diagnostic aids and in case management. In one retrospective study involving twenty-one goats with urolithiasis, the most useful imaging technique was normograde contrast cystourethrography performed through a tube cystostomy catheter placed as part of the surgical treatment for the cases involved (Palmer et al. 1998). Plain radiographs and excretory urethrography offered little diagnostic assistance in those cases. Ultrasonography also provides a rapid, noninvasive, and safe means of assessing the extent and location of calculi.

At necropsy, careful dissection of the urinary tract reveals the presence of calculi, urethral trauma (Figure 12.8), and bladder or urethral rupture. Calculi may be present in the bladder or renal pelvis as an incidental finding in goats dying of causes other than obstructive urolithiasis, and their presence suggests the need for reviewing nutritional management in the source herd. Calculi obtained during case management or at necropsy should be submitted for chemical analysis.

Diagnosis

Diagnosis is based on the characteristic signalment, history, and clinical signs of obstructive urolithiasis. During the early stages, when straining is present, gastrointestinal obstructions should be considered. When stranguria is recognized, cystitis and ulcerative posthitis must be ruled out. When the bladder or urethra has ruptured and signs of uremia predominate, other causes of profound depression and weakness must be considered, especially hepatoencephalopathy and enterotoxemia. Confirmation of the presence of urine in the abdomen or subcutaneously quickly narrows the diagnosis.

Treatment

The approach to treatment depends on the stage of the disease, the nature and extent of calculi present, the intended long-term use of the animal, and frequently, financial constraints. When conservative treatment does not alleviate the condition and surgical intervention becomes necessary, a guarded prognosis should be given for successful long-term outcome. This is particularly true for intact breeding bucks and goats maintained as pets.

MEDICAL MANAGEMENT. If cases are seen before rupture of the bladder or urethra occurs, conservative management can be attempted. If calculi are lodged in the urethral process, the process can be amputated to reestablish patency. When sandy material or sludge is present in the urethral process, it sometimes can be successfully milked out without removing the process itself. Such efforts require exteriorization of the penis from the sheath. This can be facilitated by the cooperation of a capable assistant as described earlier in the chapter for examination of the penis and by tranquilization of the animal, using diazepam, at a dose range of 0.1 to 0.5 mg/kg intravenously or acepromazine (0.05 to 0.1 mg/kg intravenously). Alternatively, for better analgesia and relaxation of the retractor penis muscle, lumbosacral epidural anesthesia can be

Figure 12.8. Necrosis, inflammation, and hemorrhage of the penile urethra at the site of an obstructive calculi in a young wether viewed at necropsy. (Courtesy of the Cummings School of Veterinary Medicine at Tufts University.)

employed, using 2% lidocaine at a dose of 0.1 to 0.2 ml/ kg bw administered into the epidural space at the lumbosacral junction. The maximum dose of lidocaine should not exceed 15 ml (Van Metre et al. 1996).

Amputation of the urethral process should be viewed as a short-term, temporary solution or as a salvage operation, because the likelihood of recurrence of obstructive urolithiasis is high after removal of the urethral process. This is exemplified in one retrospective study from North Carolina, where, in fourteen of sixteen cases (87.5%), urethral process amputation with medical therapy either did not relieve the obstruction or provided relief of less than thirty-six hours (Haven et al. 1992).

If calculi are lodged proximal to the urethral process, attempts can be made to pass a catheter far enough into the urethra to permit infusions of sterile saline in attempts to distend the urethra and dislodge the offending calculi (urohydropulsion). This procedure is frequently unsuccessful and often traumatic, and may result in urethral rupture or stricture, especially if attempts to force the catheter past the urethral diverticulum are made. Recently the use of urethroscopy in association with laser lithotripsy has been reported to fracture and clear calculi from the distal urethra in three goats for which urohydropulsion was not successful (Halland et al. 2002).

When urohydropulsion fails, tranquilizers and antispasmodics may help to promote urethral relaxation and facilitate natural expulsion of the calculus by the pressure of attempted urination. Diazepam, at a dose range of 0.1 to 0.5 mg/kg intravenously, acepromazine (0.1 mg/kg intravenously), or aminopromazine (2 mg/ kg intramuscularly) each have been used for this purpose, with variable results. Xylazine hydrochloride should not be used in these cases because its hyperglycemic effect promotes diuresis, and increases in urine production are problematic in a goat with urinary tract obstruction.

SURGICAL MANAGEMENT. When conservative treatment fails, then some sort of surgical intervention, or euthanasia, becomes necessary. Detailed descriptions of the surgical procedures discussed here are beyond the scope of this book and are available in current veterinary surgery texts (Tibary and Van Metre 2004) as well as on the Internet in the "hot topics" section of the Website of the American Association of Small Ruminant Practitioners (www.aasrp.org). The surgical procedures discussed here include perineal urethrostomy, penile amputation, ischial urethrostomy, ischial urethrotomy, surgical tube cystostomy, and marsupialization of the bladder. Prepubic urethrostomy, used in feline practice as a salvage technique for obstructive disease of the pelvic urethra, is also sometimes used in goats with favorable results, but is not discussed further here (Stone et al. 1997).

Before any surgery is attempted, particularly if general anesthesia will be involved, the patient should be evaluated for hydration status, uremia, and electrolyte imbalances, and these should be addressed through appropriate fluid therapy. Because goats with obstructive urolithiasis tend to be hyperkalemic, hypochloremic, and hyponatremic, sterile physiologic saline solution is a good empirical choice of intravenous fluid if laboratory assessment is not available (Van Metre et al. 1996). With regard to evaluating the suitability of cases for surgery and the associated prognosis, it has been reported that an intact urethral process, the absence of fluid in the abdomen, and serum potassium concentrations less than 5.2 mEq/L at admission were all associated with greater survival following surgical tube cystostomy (Ewoldt et al. 2006).

It should be noted that bladder rupture in and of itself does not necessarily require surgery. If urine outflow can be established by conservative means, the bladder defect, which often seals with fibrin or by adhesions, may heal spontaneously. This is more true of rents in the dorsal bladder wall than the ventral wall.

If the bladder has ruptured, urine should be drained from the abdomen via abdominocentesis to slow the uremic process if surgery is delayed. This should not be accomplished too abruptly, because it could predispose to hypovolemic shock when blood which was displaced by the fluid pressure of uroperitoneum returns to the visceral vasculature from the general circulation. If the urethra has ruptured, multiple, small stab incisions can be made in the skin over the areas of urine accumulation to allow drainage.

When the decision is made that surgery is required for satisfactory case management, then the surgical approach selected depends to a great extent on the intended use of the animal and the estimated overall cost of the surgery, hospitalization, and aftercare. Clear and careful client communication is critical in these cases, because uncomplicated, fully satisfactory recoveries cannot be guaranteed and misunderstandings or false expectations about the ultimate outcome can lead to poor veterinarian-client relations, especially when pet goats or breeding bucks are involved.

For commercial wethers or intact males destined for slaughter, two relatively simple and low cost salvage procedures are commonly in use—perineal urethrostomy and penile amputation. When performing perineal urethrostomy, a site as low on the perineum as possible should be selected for the incision for two reasons. First, it reduces the extent of subsequent urine scald. Second, the procedure is prone to failure due to stricture of the surgically created urethral opening. If that occurs, the surgery can be repeated at a site higher on the perineum to extend the salvage period for the animal. Additional salvage procedures which have

been used in goats or sheep include ischial urethrostomy and ischial urethrotomy. Ischial urethrostomy offers an advantage over perineal urethrostomy in that the pelvic urethra is exteriorized instead of the penile urethra. The wider bore of the pelvic urethra reduces the likelihood of stricture at the stoma site.

For breeding bucks, surgical tube cystostomy has emerged as the preferred surgical approach for retaining breeding capacity (Van Metre and Fubini 2006). In this procedure, a paramedian abdominal approach is made and the bladder exteriorized so that a cystostomy can be performed to remove calculi from the bladder, and to place an indwelling balloon type (Foley) catheter which is exteriorized through a second stab incision and sutured in place (Figure 12.9). Ruptures of the bladder can also be repaired during this procedure if required. Antibiotic treatment should be initiated prior to surgery and continued for one week after the cystostomy catheter is finally removed, because cystitis is a potential complication of this procedure.

Recently, in a report on the outcomes of fifty goats and thirteen sheep treated for obstructive urolithiasis with surgical tube cystostomy, forty-eight of sixty-three cases (76%) were discharged from the hospital with normal urethral urination. At six-month follow up, thirty-four cases could be located and twenty-two (65%) of these had no recurrence of urethral obstruction. While some animals were lost to long-term follow up, at twelve months up to seventy-two months after discharge, eighteen of twenty animals (90%) identified as still alive had no recurrence of urethral obstruction (Ewoldt et al. 2006).
Figure 12.9. View of the abdomen of a goat following surgical tube cystostomy for treatment of obstructive urolithiasis. Note the Foley catheter secured to the skin distal to its emergence from the urinary bladder through a paramedian stab incision. The primary cystostomy incision is lateral to the prepuce. (Photo courtesy of Dr. Peter Rakestraw.)

Early reports of surgical tube cystostomy often included antegrade flushing of the urethra as part of the surgical procedure, but more recently, flushing has been seen as potentially traumatic, contributing to prolonged surgical time and unnecessary. In the report of Ewoldt et al. (2006), calculi present in the bladder were removed, but no urethral flushing was done. Reestablishment of urethral patency was allowed to occur spontaneously after surgery.

In such cases, the indwelling catheter is left open after surgery to allow urine outflow. Then, beginning on the fourth day after surgery, the catheter is periodically occluded to determine if the animal is able to pass urine through the urethra. If the animal continues to display stranguria or failure to urinate, then the catheter is reopened to allow urine outflow and occluded again periodically until the patient can urinate freely. Once that occurs, the catheter is left in place for an additional three days and then removed, allowing the cystostomy site to heal on its own. Rakestraw et al. (1995) reported that the mean time until animals could urinate freely following surgery was eleven and a half days, with a mean time of fourteen and a half days until the cystostomy tube was removed. The principle behind this approach is that diversion of urine outflow through the catheter avoids repeated trauma to the urethra caused by straining, and thereby allows the urethra to relax and heal, with a strong likelihood that calculi present in the distal urethra will ultimately dissolve or dislodge spontaneously.

Of course a successful outcome is not guaranteed in these cases. Obstruction of the catheter itself with clotted blood, calculi, or sludge can occur. Therefore, it is suggested that larger bore catheters, 18 to 24 or larger French, be used (Van Metre and Fubini 2006). In addition, catheters have been reported to malfunction, with the balloon not retaining its inflation. This has been associated with catheters that have been reused after autoclaving and it is therefore recommended that for tube cystostomy, only new catheters be used. Animals may also chew on catheters and dislodge or damage them, so application of Elizabethan restraint collars is indicated post surgically.

Even when the animal recovers successfully from the procedure, maintenance of reproduction in breeding bucks is not assured as evidenced by the reported case of erection failure associated with vascular occlusion of the corpus cavernosum penis in a goat three months after surgical tube cystostomy. The vascular lesion was believed to be associated with trauma from the inciting urethral obstruction and not the surgical procedure (Todhunter et al. 1996). Nevertheless the ultimate goal of retaining breeding function was not realized.

Anti-inflammatory drugs post surgically should be used to facilitate urethral healing. Flunixin meglumine

at a dose of 1.1 mg/kg bw BID intravenously for three to five days and then 0.5 mg/kg SID IM for an additional three to five days has been reported. Acepromazine can be given to promote relaxation of the urethra post surgically. A low dose of 0.02 mg/kg bw given subcutaneously two or three times a day has been used (Ewoldt et al. 2006).

Efforts to dissolve existing calculi have also been employed to improve outcomes. In one case, irrigation of the bladder through the cystostomy catheter with the chemolytic solution hemiacidrin was reported for dissolution of calculi (Streeter et al. 2002). Hemiacidrin is an acidic solution of citric acid, magnesium carbonate, and glucono-delta-lactone used effectively for dissolution of calcium phosphate and magnesium ammonium phosphate uroliths in human medicine. In the case of the goat, 30 ml of hemiacidrin was infused into the bladder via the cystostomy catheter and then the catheter was occluded for thirty minutes, after which the infusion was allowed to drain out. This was repeated four times a day for three days and appeared to be effective in dissolving existing calculi based on ultrasound evaluation. Because the report only involved one case, additional assessment on the use of hemiacidrin as an adjunct to cystostomy for treatment of caprine urolithiasis is needed.

Acetic acid solution is also used for daily infusion into the bladder through the cystostomy tube post surgically (Tibary and Van Metre 2004). One drop of glacial acetic acid in 500 ml of nonbuffered sterile saline produces a solution in the desired pH range of 4.5 to 5.5, 60–150 ml of which can be infused and left for one to two hours before draining (Van Metre et al. 1996a). The pH should be checked before use.

Cystostomy combined with antegrade and retrograde flushing of the urethra but without tube placement was also reported to offer good results (Haven et al. 1993) but the procedure has some disadvantages, including the risk of urethral rupture during flushing, the need for an assistant to accomplish retrograde urethral flushing, and a potentially prolonged surgical time, since it can sometimes take two to three hours of repetitive flushing to fully clear the urethra of obstruction (Van Metre et al. 1996a). The technique has largely been displaced by surgical tube cystostomy.

Ultrasound-guided percutaneous tube cystostomy has been assessed as a surgical treatment option and found to be unsatisfactory. In a series of ten cases, all required a second surgery, five because of tube displacement from the bladder, four because of persistent or recurrent obstructive urolithiasis, and one because of subsequent urethral rupture (Fortier et al. 2004). While surgical tube cystostomy takes longer and is more costly than percutaneous tube cystostomy, the long-term outcome is much better.

Another alternative surgical procedure for breeding animals is urethrotomy in those cases in which a discrete single stone can be located by palpation or imaging studies and can be accessed and removed via an incision through the urethra. Success depends in large part on the accuracy of determining that only a single calculus is involved. Urethral stricture at the surgery site is a serious potential complication.

For pet goats, surgical tube cystostomy or marsupialization of the bladder are considered satisfactory surgical approaches. The former is likely to produce a more desirable outcome, but the latter is cheaper, a consideration for many owners. In one study of surgically managed obstructive urolithiasis cases, goats with bladder marsupialization had a median duration of hospitalization less than one-fourth the duration of goats with surgical tube cystostomy and at two-thirds the cost (Fortier et al. 2004) The main objection to marsupialization is that the permanent stoma on the ventral abdomen is associated with chronic urine scald which requires regular attention by the owner, including clipping the hair around the site, washing, and applying petroleum jelly or other salves. Surgical placement of the stoma as far forward on the ventral abdomen as is possible without causing undue tension or strain on the bladder itself helps to obviate this problem.

Other complications of marsupialization may include prolapse of the urinary bladder mucosa, stricture of the stoma, and possibly cystitis. In one report of nineteen cases of obstructive urolithiasis corrected by bladder marsupialization, eighteen of nineteen goats survived the procedure. At follow up between one and fifty-nine months after surgery, one animal had developed cystitis and one had a closure of the stoma due to fibrosis. While all the surviving goats had urine scald associated with the stoma site, fifteen of seventeen owners were satisfied with the procedure and its outcome. The two dissatisfied owners cited odor and urine scald as their objections (May et al. 1998). In that study, the median hospitalization time associated with the procedure was four days (range one to ten days) as compared to a mean hospitalization time of fourteen ± ten days in a report on a case series of sixty-three small ruminants treated by tube cystostomy (Ewoldt et al. 2006).

Before the techniques of surgical tube cystostomy and bladder marsupialization were refined and successfully applied in goats, perineal urethrostomy was often the intervention used for managing obstructive urolithiasis in pet goats. However, with the advent of these improved procedures, perineal urethrostomy should not be recommended for goats kept as pets due to the likelihood of recurrence, associated expense of additional corrective procedures, and owner dissatisfaction.

If owners insist on this salvage procedure for financial reasons, it should be made clear that long-term prospects for return to normalcy are poor because strictures of the urethra at the urethrostomy site are common. In a study from the Netherlands on perineal urethrostomy in twenty-eight goats and sheep, ten died or were euthanized in the immediate post surgical period. Of the eighteen that left the hospital, only eight had no additional problems on extended follow-up. Most of the others re-obstructed and were destroyed or required second or even third operations (van Weeren et al 1987a). Even when patency is maintained after urethrostomy, persistent problems with urine scalding on the perineum and hind limbs often make the outcome undesirable to owners.

Regardless of the type of surgical management selected, certain considerations of post surgical management apply. Animals need to be monitored for abnormalities associated with uremia and treated with appropriate fluid and electrolytes as needed. Antibiotic therapy is indicated to prevent cystitis or ascending infection. Procaine penicillin G at 22,000 IU/kg intramuscularly BID, or ampicillin at 15 mg/kg TID subcutaneously have been used effectively. In the case of surgical tube cystostomy, continuation of antibiotic therapy for one week after removal of the tube is recommended.

In bladder marsupialization, antibiotics should be given for one week post surgery. While there may be an inclination to keep the animals on antibiotics for prolonged periods because the bladder is open to contamination through the stoma, this is not recommended. One reason is that the occurrence of cystitis is facilitated by urine stasis and there is no stasis when the urine can passage continuously from the bladder stoma. Second, prolonged antibiotic use may promote selection of highly resistant bacteria so that if cystitis does occur, treatment options will be limited. As such, infections that occur in marsupialized animals should be treated as they occur, preferably with antibiotic selection guided by culture and sensitivity. Marsupialized animals should be housed in clean, dry quarters when returned home.

Whenever possible, calculi removed at time of surgery or by conservative treatment should be submitted to a suitable laboratory for structural analysis. This permits appropriate dietary and management recommendations to be made for preventing new calculi on the basis of their composition.

Control

Prevention of obstructive urolithiasis depends primarily on inhibiting the formation of calculi through ion aggregation in the urine. There are three main points of control to achieve this goal: increasing urine output, acidifying the urine, and reducing the presence of calculogenic solutes in the urine. Each will be discussed separately but in practice, they are combined to successfully control the disease.

INCREASING URINE OUTPUT. The solutes in concentrated urine are more likely to precipitate and form uroliths than the solutes in dilute urine, so efforts to increase water intake and promote diuresis are critically important. Access to a clean, reliable, and adequate water supply must be assured. Goats can be particularly finicky about drinking water that is contaminated with feces, feed, or other foreign materials, so care in placement and cleanliness of waterers is important. Goats are also very hierarchical and some dominant animals may keep others away from waterers, so adequate space at the water source is also a consideration. Heating water supplies in the winter and shading then in the summer may also promote consumption. For pet goats, owners may try adding flavored, sugared drink powders to encourage water consumption.

A key intervention to stimulate water consumption and to dilute the urine is the feeding of increased salt in the ration. Sodium chloride should be fed at a rate of 3% to 5% of the total dry matter intake, which can be estimated at about 2% of bodyweight, so that a 40-kg wether would eat about 0.8 kg dry matter and require between 24 and 40 g of sodium chloride per day. Goats may be unwilling to consume this level of salt reliably if offered free choice or in a lick, so if necessary, it should be incorporated directly into the ration. One approach is to put the salt into solution and spray it onto the hay.

ACIDIFY URINE. Ruminant urine is normally alkaline and the alkaline pH favors the formation of calculi. Acidification of urine can increase the solubility of uroliths composed of magnesium ammonium phosphate (struvite), calcium phosphate (apatite), and calcium carbonate, and thereby inhibit their precipitation from the urine. There is also evidence in sheep that silicate urolith formation can be suppressed by urinary acidification (Stewart et al. 1991). Addition of anionic salts such as ammonium chloride to the ration can be helpful in this regard (Stratton-Phelps and House 2004). The daily dose can be calculated as either 0.5% to 1% of the total dry matter intake, 2% of the concentrate ration, or 200 to 300 mg/kg/bw/day. Ammonium sulfate has been used in place of ammonium chloride at a rate of 0.6% to 0.7% of the total ration. However, feeding of ammonium sulfate has been associated with cases of polioencephalomalacia in lambs (Jeffrey et al. 1994). Ammonium chloride is not very palatable to goats, so free choice feeding is not likely to be successful. It may be necessary to add the ammonium chloride to some concentrate feed to encourage consumption, remembering that concentrate feed itself is calculogenic and should be limited in the diet. Alternately, for

individual animals, it can be mixed with a sugar solution, honey, or syrup, and administered as a drench.

Urinary acidifiers are not a panacea. Under experimental conditions in Brazil, ammonium chloride given to goats on a calculogenic diet at a rate of 0.5% of the concentrate ration did not prevent the occurrence of calculi (Unanian et al. 1985). It is also possible that goats may become refractory to the urinary acidifying effects of anion supplementation and the urine pH may gradually revert to the alkaline range (Stratton-Phelps and House 2004). In addition, it has been suggested that long-term use of ammonium chloride can lead to bone resorption in goats (Vagg and Payne 1970).

Reduce Calculogenic Solutes in Urine. Dietary management is key to reducing the solutes in urine that lead to urolith formation. Dietary changes need to be linked to the particular type of urolith affecting the animal or herd.

The occurrence of phosphate calculi such as struvite is closely associated with the feeding of rations containing high levels of cereal grains which are high in phosphorous content. There is a tendency for pet goat owners to feed grain to their animals well beyond the goat's metabolic needs, which may require no more than a maintenance diet. Grain feeding to pet goats should be sharply curtailed and grass hay or oat hay should be promoted as the basis of the diet.

The feeding of pelleted rations reduces saliva production and with it, the excretion of phosphorus through the saliva and alimentary tract. As a result, phosphorus secretion via the kidney increases. Therefore, herds in which phosphate calculi are a problem should not be fed pelleted rations. Another concern relative to phosphatic calculi is the calcium-to-phosphorus ratio in the diet. Calcium inhibits phosphorus absorption from the gut, so if the ratio of calcium to phosphorus in the diet is too low, then more phosphorus is absorbed and ultimately excreted in the urine. Ideally, the calcium-to-phosphorus ratio in the diet should be in the range of 2:1 to 2.5:1.

Magnesium can also play a role in the development of phosphatic calculi. Even when the calcium-to-phosphorus ratio is in the desired range, excess magnesium in the diet can lead to the development of calcium phosphate, or apatite calculi. With the calcium-to-phosphorus ratio maintained at 2:1, magnesium content in the total ration should not exceed 0.3% on a dry matter basis.

When calculi occur in preweaned goats fed milk replacer, constituent analysis of the milk replacer is warranted. Some milk replacers have a Ca-to-P ratio of only 1:1 that may require supplementation of calcium to kids. In addition, increased magnesium content of 0.6% in milk replacer was identified as contributory to the formation of calcium apatite calculi in calves, while a magnesium content of 0.1% produced no abnormalities (Petersson et al. 1988). The calculogenic effect of high magnesium content in the ration is exacerbated by high phosphorus content, but countered by high calcium content (Kallfelz et al. 1987).

The occurrence of calcium carbonate uroliths is associated with the feeding of alfalfa or other legume hays, which are high in calcium content, or the grazing of clover pastures. Mature breeding bucks, wethers, and pet goats—the main candidates for urolithiasis—are unlikely to require calcium in their diets at the level provided by legume hays. Therefore, a high-quality grass hay should be substituted in herds with urolith problems.

Silica calculi are seen most often in extensively grazed ruminants where the range grasses contain high silicate content. Therefore, dietary management options are limited. Ensuring adequate access to water and supplemental feeding of salt may be helpful.

Some other control interventions merit consideration. Feeding animals frequently or on an *ad libitum* basis rather than only once or twice per day may be helpful. Large meals can draw extracellular fluid into the rumen, resulting in transient increases in urine concentration that can promote calculus formation. This effect is less pronounced with smaller, more frequent feedings. Ensuring adequate vitamin A in the diet is also advised.

Delaying castration may be another management tool for reducing the prevalence of obstructive urolithiasis. However, the early precocity of goats requires that castration be performed by three months of age to avoid unwanted sexual activity unless assured separation of males from females can be achieved past that age.

Oxalate Toxicity

Like other ruminants, goats are susceptible to oxalate toxicity from consumption of oxalate-containing plants or chemical compounds such as ethylene glycol that produce oxalates as metabolites. However, reports of naturally occurring disease in goats are uncommon as compared with sheep (Kimberling 1988).

Etiology and Epidemiology

Oxalate toxicity results from consuming large quantities of plants containing increased levels of sodium or potassium oxalate. Plants in the genus *Rumex*, such as sorrel and dock, and the family *Chenopodiaceae* are well known as oxalate accumulators. The most commonly involved species are *Halogeton glomeratus* (halogeton) and *Sarcobatus vermiculatus* (greasewood) found in the semiarid grazing areas of the western United

States and *Oxalis* spp. (soursob) in Australia. Numerous other plants are also recognized as containing soluble oxalates but are less frequently involved in poisoning of livestock (Osweiler et al. 1985).

In goats, clinical oxalate toxicity has been diagnosed after consumption of *Amaranthus* spp. (pigweed) in Mexico (Gonzalez 1983). In Australia, goats died after grazing almost exclusively *Pennisetum clandestinum*, or Kikuyu grass. Though it was not the primary lesion, the affected goats had nephrosis with tubular casts containing calcium oxalate crystals (Peet et al. 1990). Goats maintained as pets or on hobby farms may be at increased risk if they are fed certain garden cuttings. Rhubarb and spinach ingestion have been associated with oxalate toxicity of goats in Australia (Baxendell 1988).

In addition, oxalates may be found in some manmade chemical products or be derived from other products by metabolism in the body. Ethylene glycol poisoning, likely resulting from automotive antifreeze ingestion, has been reported in goats (Boermans et al. 1988). Excessive administration of ascorbic acid, a metabolic precursor of oxalate, was believed to be responsible for a case of oxalate nephrotoxicosis in a ten-year-old Toggenburg doe (Adair and Adams 1990). The goat received 108 g of ascorbic acid over a six-day period before the onset of azotemia.

Pathogenesis

When small quantities of oxalates are consumed by ruminants, most of the oxalates are either destroyed in the rumen or combined with free calcium and excreted in the feces. A small quantity may be directly absorbed into the blood. When large quantities are consumed, the amount of oxalate absorbed increases. When in the blood, oxalates combine with calcium ions to form calcium oxalate. This causes a decrease of serum calcium levels, sometimes as much as 50%, and leads to a clinical syndrome of neuromuscular dysfunction similar to that seen in milk fever in cattle. Because calcium oxalate is insoluble, crystal formation ensues, with crystals accumulating both in the systemic vasculature and in the renal tubules. Renal tubular damage can cause severe renal insufficiency.

Ethylene glycol, the active ingredient in engine antifreeze products, is less toxic to ruminants than monogastrics or preruminants because much of it is degraded by rumen microflora after ingestion. However, when sufficient quantities are consumed, absorption and subsequent metabolism to toxic intermediates such as oxalic acid can occur. Unmetabolized ethylene glycol can act directly on the central nervous system as a depressant. Pathophysiologic changes induced by ethylene glycol toxicity include hypocalcemia, increased serum osmolarity, acidosis, renal tubular dysfunction, and uremia, though death is not necessarily related to the degree of uremia.

Clinical Findings

Oxalate toxicity is an acute poisoning with clinical signs developing within several hours of ingestion of offending plants. Affected goats exhibit incoordination, muscular trembling, hyperexcitability, and restlessness, followed by weakness, recumbency, and torticollis. Coma ensues and death often occurs within hours of the onset of clinical signs.

In the one reported case of ethylene glycol toxicosis in a goat (Boermans et al. 1988), the affected goat initially showed polydipsia, constipation, corneal opacity, and a progressive incoordination, especially in the hind limbs. This was followed by depression and increasing salivation. On the fifth day, before death, clonic-tonic convulsions were observed accompanied by blindness, vertical nystagmus, decreased rumen motility, diarrhea, and a subnormal temperature.

Clinical Pathology and Necropsy

Hypocalcemia may be detectable in affected goats, but the degree and occurrence are variable. Hyperphosphatemia and hypermagnesemia also may occur. A moderate to severe azotemia is usually present. Urine samples may demonstrate proteinuria and crystalluria. A characteristic rectangular parallelepiped shape for calcium oxalate dihydrate crystals found in the urine of a goat have been reported (Clark et al. 1999). When oxalate toxicity is suspect, oxalate levels should be measured in suspected plants, if available.

Oxalate toxicity is most accurately diagnosed at necropsy. The rumen content should be carefully inspected for evidence of oxalate-containing plants, and oxalate concentration of the rumen content can be measured. In affected goats, the rumen oxalate content ranged from 0.5% to 1.8% (Gonzalez 1983). Inflammation and hemorrhage of the gastric and intestinal mucosa and serosa, hydrothorax, and ascites are common but nonspecific findings. The kidneys are edematous and swollen.

A characteristic but inconsistent finding is a clearly demarcated yellow to yellow-green, streaked appearance of the renal cortex on visual inspection, with the medulla remaining red-brown. Kidney oxalate content in affected goats ranged from 2.9% to 7.1%. Histologically, the renal tubules are dilated and filled with birefringent oxalate crystals. These crystals may also be found in vessel walls, especially in the rumen vasculature. Similar histologic renal lesions are observed in ethylene glycol toxicosis. Glycolic acid, a stable metabolite of ethylene glycol, can be measured in serum, urine, and ocular fluid post mortem to support the diagnosis of ethylene glycol toxicosis.

Diagnosis

Diagnosis is based on a history of exposure, clinical signs, and often oxalate crystals in the renal tubules at necropsy. In the live animal, other causes of hypocalcemia, both metabolic and nutritional, must be ruled out. When signs of excitation or convulsions occur, primary neurologic diseases must be considered. The differential diagnosis for convulsions is given in Chapter 5.

Treatment

The prognosis for recovery is guarded once clinical signs appear. Animals at risk should be removed from the offending source of oxalates and alternate food sources provided. Subcutaneous administration of 50 to 100 ml of calcium borogluconate helps to counter the potential hypocalcemia of animals at risk. Severely affected individuals may require intravenously administered calcium salts and intravenously administered fluid therapy to counter the accumulation of oxalate crystals in renal tubules and the development of severe nephrosis. Oral administration of large quantities of water may be beneficial when there are economic constraints to therapy.

In ethylene glycol toxicosis, the prognosis is poor once signs appear. If the ingestion is recognized before signs begin, oral administration of activated charcoal (0.75–2.0 g/kg bw in water) may be beneficial in detoxification. When signs are present, intravenous fluid therapy should include sodium bicarbonate to counter the severe acidosis. Calcium borogluconate is also indicated to counter hypocalcemia. Neurologic signs may be controlled with diazepam. The administration of ethanol intravenously to serve as a competitive inhibitor of ethylene glycol metabolism in the liver has been used as an effective therapy in dogs and cats but has not been reported in ruminants. The dose in dogs is 5.5 ml of 20% ethanol per kg given intravenously every four hours.

Control

Controlling oxalate toxicity involves avoiding grazing animals on range with heavy cover of oxalate-containing plants. When such grazing is necessary, supplementary feed should be provided for at least the first few days to allow time for the rumen flora to adapt to more efficient degradation of oxalates. A good calcium source such as dicalcium phosphate helps to form calcium oxalate in the alimentary tract, thereby limiting absorption of oxalate.

Oak Poisoning

Oak poisoning (*Quercus* spp.), which is caused by ingesting large quantities of young leaves, blossoms, buds, stems, or acorns, produces considerable morbidity and mortality in cattle and sheep. The toxic principle is believed to be a gallotannin and it produces a severe intestinal irritation and a characteristic nephrosis. Animals show depression, abdominal cramping, and constipation followed by bloody, mucoid feces, and they often succumb to uremia.

Goats appear highly resistant to oak toxicity, possibly because of comparatively increased levels of tannase enzymes in the rumen mucosa. It has been demonstrated *in vitro* that infusion of tannin into goat rumen fluid increases fermentation activity while it depresses activity in sheep rumen fluid (Narjisse and El Hansali 1985). Goats are routinely used to clear scrub oak from pastures to make them safe for sheep and cattle.

The only report of spontaneous oak poisoning in goats involved consumption of *Quercus floribunda* in Sikkim. Affected animals showed signs of abdominal pain and constipation followed by hemorrhagic diarrhea and death (Katiyar 1981). In experiments, clinical signs of oak poisoning typically seen in cattle were produced in goats when they were fed a diet consisting almost exclusively of fresh shin oak *(Quercus havardi)* for an extended period (Dollahite 1961). In an unrelated study, goats fed 1 kg of dry oak leaves daily for three days showed no ill effects and it was concluded that goats can browse oak with impunity. In this same study, however, oral administration of tannic acid (1 liter of a 7% solution) resulted in an acute hemolytic crisis with hemoglobinuria. A regenerative response developed seven to fourteen days later, with macrocytes and reticulocytes observed. A transient thrombocytopenia also occurred seventy-two hours after administering tannic acid (Begovic et al. 1978).

If oak poisoning is suspected in goats, the animals should be removed from the source of oak and treated with oral purgatives including mineral oil and/or magnesium sulfate. Intravenous fluid therapy may be required to correct dehydration and acidosis.

THE ADRENAL GLANDS

Anatomy

The paired adrenal glands, or suprarenal glands, are found in proximity to the kidneys. The left adrenal gland is found anterior to the cranial pole of the left kidney and the right adrenal gland is found medial to the right kidney. The glands average 2 to 3 cm in length and 1 cm in width, with the left larger than the right. The gland is composed of a capsule, a cortex, and a medulla. The zona fasciculata of the cortex is the thickest portion of the gland and is consistently thicker in females than in males (Prasad and Sinha 1981). Accessory adrenal cortical nodules occur in goats and may be located intracapsularly or extracapsularly. These represent cortical cells separated from the germinal

cortex during embryonic development (Prasad and Sinha 1980). Extracapsular nodules are usually close to the main glands.

Physiology

The endocrine and physiologic functions of the adrenal gland in the goat are essentially similar to those in other domestic ruminants, and mammals in general. Seasonal variations of corticoid levels in Angora goats have been measured. The baseline plasma level is quite variable, with range of means between 2.2 and 10.6 ng/ml. A distinct increase is noted, however, in the autumn months associated with breeding season in females. Mean autumn corticoid levels in does reach 18 ng/ml with individual measurements as high as 26 ng/ml, while the mean in males remains less than 10 ng/ml (Wentzel et al. 1979).

Pathology

Neoplasia occurs in the caprine adrenal gland. Adrenal cortical adenomas have been identified at necropsy in a high percentage of castrated male goats older than four and a half years of age. The tumor is virtually nonexistent in females and intact males. Castration is thought to predispose the goat to the tumor (Richter 1958; Altman et al. 1969). The tumor has been recognized more frequently in Angora goats than in dairy breeds, but this probably reflects that Angora wethers are more likely to be maintained for production to advanced age than castrated dairy goats. No clinical syndromes have been associated with these tumors, except for one reported case in which a six-year-old castrated Toggenburg wether was presented for udder enlargement and lactation and subsequently diagnosed with adrenal cortical adenoma post mortem. Ante mortem, the goat had increased serum concentrations of estradiol 17β, incomplete suppression of cortisol secretion by dexamethasone, and an exaggerated response to ACTH administration (Löfstedt et al. 1997).

Less common are tumors of the medulla. There is one published report of a pheochromocytoma identified in the adrenal medulla of a ten-year-old Nubian buck at necropsy. Again, no clinical signs were associated with the tumor ante mortem (Lairmore et al. 1987). The author has seen similar gross and histologic lesions at necropsy in the adrenal medullae of aged goats, but the existence of functional pheochromocytomas that secrete excessive epinephrine and produce hypertension in living goats still remains to be documented.

There is a report of presumed hereditary caprine pheochromocytoma from Finland in which the tumor was identified in a doe, its dam, and its granddam at ages 10, 13, and 15, respectively. All three goats were said to have shown repeated, sudden attacks of nervousness and anxiety (De Gritz 1997). There is also a report of two does, aged twenty years and ten years, that were presented for lactation though neither had been bred. The abnormal lactation in both does was attributed to acidophilic pituitary adenomas, but both goats also coincidentally had pheochromocytomas (Miller et al. 1997)

Histologically, evidence of adrenal cortical hyperplasia associated with stress in chronic disease has been reported in goats with chronic paratuberculosis (Rajan et al. 1980) and prolonged trypanosomosis (Mutayoba et al. 1988).

Clinical Disease

Classic types of hyperadrenocorticism (Cushing's syndrome) or hypoadrenocorticism (Addison's disease) have not been recognized in goats. Hyperadrenocorticism, however, is believed to play a role in the complex pathophysiology of a distinct form of noninfectious abortion peculiar to the Angora goat in South Africa (Wentzel et al. 1975). Affected does that abort the characteristic edematous fetuses associated with this condition show adrenal cortical hyperplasia histologically and maintain high adrenal corticosteroid levels throughout gestation, whereas normal does show a drop in corticosteroid levels in the third trimester. This condition, inherited abortion of Angoras, is discussed further in Chapter 13.

It is well recognized that as a breed, Angora goats do not handle stress as well as other goat breeds or sheep. In South Africa, death of Angora goats stressed during periods of unexpected cold weather is a major constraint on production. These stress-related deaths are associated with hypoglycemia. Van Rensburg (1971) reported that selection of Angora goats for fine mohair production was linked to selection for reduced adrenal function. This has prompted a good deal of research to determine what role the adrenal gland might play in the hypoglycemia seen in stressed and dying Angora goats.

Experimentally, Angora goats given insulin to lower their blood glucose did not, when compared to Boer goats and Merino sheep, respond with the appropriately increased cortisol production necessary for gluconeogenesis and restoration of blood sugar under stress conditions (Englebrecht et al. 2000). Furthermore, it was demonstrated in that study using adrenal cell cultures that the adrenocorticotropic hormone receptor on the adrenocortical cell membrane of Angora goats cannot adequately stimulate the cAMP signaling mechanism required for enhanced glucocorticoid production under stress. In addition, it was reported that the activity of the cytochrome P450c17 enzyme in Angora goats differed from that in Boer goats and Merino sheep and that difference may contribute to the lowered production of glucocorticoids in Angora goats (Engelbrecht and Swart 2000).

Reproductive System

It is beyond the scope of this book to consider in detail reproductive physiology, estrus synchronization, artificial insemination, embryo transfer, and other topics more closely related to herd management than to disease. These facets of caprine reproduction have been discussed in various theriogenology textbooks (Morrow 1986; Youngquist and Threlfall 2007) and elsewhere (Evans and Maxwell 1987; Kraemer 1989; Haibel 1990a; Amoah and Gelaye 1990, 1991; Chemineau et al. 1991; Ishwar and Memon 1996; Gordon 1997; Cognie 1999; Bretzlaff and Romano 2001; Rubianes and Menchaca 2003).

Instead, this chapter attempts to provide the basic information needed by the veterinary practitioner.

Guidelines for handling infertility, abortions, and obstetric problems are included. Additional illustrations of many of the conditions discussed in this chapter are available through the Drost Project on the World Wide Web (Drost 2008).

THE DOE

The female goat is called a doe in polite circles or when discussing valuable or cherished animals. A doeling is a young female, often one that has not yet kidded. The term "nanny" should be avoided when there is a chance of offending an owner by its use, although this is the standard terminology for an Angora doe in Texas.

The anatomic features of the reproductive tract of nonpregnant and pregnant goats have been reviewed by Lyngset (1968b, 1968c). The uterus is bicornual and the cervix has approximately five fibrous rings. These rings impede passage of a pipette if the doe is not in estrus. A canine vaginal speculum, caprine artificial insemination speculum, human proctoscope, or glass test tube (22 to 25 mm diameter) with a hole fire-polished in its rounded end permits visualization of the vagina and external cervical os (Haibel 1986b).

The Estrous Cycle

In temperate regions, goats are seasonally polyestrous. Cycling begins under the influence of decreasing day length. After the days begin to lengthen again in winter, cycling gradually ceases. The duration of the period when regular estrous cycles occur varies with the region, breed, and herd. Individual factors also come into play, as high-producing dairy goats are less likely to exhibit estrus shortly after parturition than are healthy animals producing little or no milk. As a rough approximation, August until March in the northern hemisphere, and particularly October until December, encompass the normal breeding season. Some animals in a herd in temperate regions may be capable of cycling year-round, and this is typical in the tropics, where the availability of forage is more important than day length. Owners who desire out-of-season breeding should select as herd replacements the offspring of animals that bred in the traditionally anestrous period.

Macroscopic and histologic changes occurring in the ovarian structures of the goat during the estrous cycle have been reported by Harrison (1948). The estrous cycle, and particularly the ovulation, of research goats (Dukelow et al. 1971) and sheep (Oldham and Lindsay 1980) have been monitored by laparoscopic methods since the early 1970s. Equipment and techniques used for laparoscopic artificial insemination of sheep (Seeger and Klatt 1980; Killen and Caffery 1982; Gourley and Riese 1990) are also suitable for goats.

Transrectal ultrasonography using a probe extender may be useful for monitoring ovarian activity in select cases, if a probe with adequate resolution (at least 7.5 MHz) is available. The ovaries can be visualized to the left and right of the bladder by slow methodical scanning. Normal mature follicles are 9 to 12 mm in diameter (Buergelt 1997). Other ultrasonographic studies in Boer goats (Padilla and Holtz 2000) and Serrana goats (Simoes et al. 2006) have documented three to five waves of follicles per cycle (reviewed by Rubianes and Menchaca 2003), with follicular diameter at ovulation typically 7 to 8 mm. Ovulation can be confirmed by disappearance of one or more large follicles and development of corpora lutea (Baril et al. 1999). A corpus luteum is less echogenic than the surrounding ovarian stroma and may have a central fluid-filled cavity (Kähn 1994). Inactive ovaries and follicles smaller than 4 mm are difficult to identify. Large, cystic follicles could conceivably be found and monitored over time, but this has not been reported.

Cycle Length

The typical length of an estrous cycle for European dairy breeds is twenty-one days. African pygmy goats are more variable (eighteen to twenty-four days). At the beginning and end of the season, cycles of irregular length, not always accompanied by overt estrus, may occur (Phillips et al. 1943; Camp et al. 1983). Short cycles of five to seven days are to be considered normal during the transition periods, especially in kids, but persist throughout the breeding season in certain populations of goats, and more importantly, in certain individual problem breeders and in some goats superovulated for embryo transfer purposes (Armstrong et al. 1983, 1987; Stubbings et al. 1986). In these does, the corpus luteum is short-lived, demonstrated by only a brief increase in progesterone. The problem can be circumvented in embryo transfer donors by administering a progestogen sponge or implant four days after breeding. Pretreatment with a progestogen (45 mg fluorogestone acetate (FGA)-impregnated sponge for seventeen days or a single injection of 5.2 mg FGA) eliminated the occurrence of short-lived corpora lutea associated with introduction of the buck to anestrous does (Chemineau 1985).

Short cycles are also common after prostaglandin-induced abortion and are associated with delayed pre-ovulatory luteinizing hormone surges of reduced magnitude (Bretzlaff et al. 1988). Elevated prostaglandin F2α levels and shortened estrous cycles have been documented in goats in Kenya infected with *Trypanosoma congolense* (Mutayoba et al. 1989). Nymphomania has been observed in mature goats after several years of a copper-deficient diet (Anke et al. 1977). Synthetic corticosteroids (dexamethasone 10 mg twice daily for

ten days) extend the cycle length by prolonging luteal function (Alan et al. 1989).

Empirical treatments for short cycles or continuous signs of estrus include gonadotropin releasing hormone (GnRH, one-fourth to one-half a bovine dose), human chorionic gonadotropin (hCG, 1,000 IU), a pregnant mare serum gonadotropin-hCG product for swine (PG600, Intervet, 2 cc) at the time of estrus, or a three-week application of exogenous progesterone (by implant, sponge, or injection as discussed below under control of estrus). In an ultrasonographic study of five goats from Japan, cystic ovaries (defined as persistence of a follicle greater than 10 mm in diameter for ten days or more in the absence of a corpus luteum) was successfully treated with GnRH followed ten days later by prostaglandin. Four of the goats became pregnant to the induced estrus (Medan et al. 2004).

Signs of Estrus

Standing estrus lasts approximately twenty-four hours in doelings but may last two to three days in mature does. It is shortened if service by a buck is permitted (Romano and Benech 1996). The estrous doe is generally easy to identify if a mature and odoriferous buck is nearby; the doe walks restlessly along the perimeter of her enclosure, searching for a way to reach the buck, or remains close to the fence (Figure 13.1). The vulva becomes somewhat swollen and the doe's tail wags vigorously. This tail wag, which can often be observed even in the absence of a buck, presumably has the function of sending pheromones from the doe's reproductive tract into the environs to attract a buck. Other signs of estrus include a plaintive voice,

Figure 13.1. This buck in rut is teasing does in estrus through the panel. Note staining of the beard and front legs where he has urinated on himself. (Courtesy Dr. M.C. Smith.)

increased frequency of urination, decreased appetite, and decreased milk yield. The doe in estrus normally stands firmly when a buck attempts to mount and may even back up to the buck. Some does, however, find some bucks (for instance, young or descented males) sexually unattractive and will not stand to be bred.

The vaginal discharge at the beginning of estrus is thin, clear, and colorless. It becomes progressively thicker and whiter toward the end of standing estrus and ovulation (Pretorius 1977). It is important to recognize this aspect of caprine physiology as normal; otherwise practitioners might mistakenly assume that animals with a cloudy white discharge full of neutrophils need antibiotic therapy. Ovulation typically occurs near the end of standing estrus and approximately twenty-four hours after a serum peak in luteinizing hormone (Greyling and van Niekerk 1990).

Vaginal cytology during the estrous cycle has been studied but appears to have limited clinical application. During estrus, superficial keratinized acidophilic cells from the stratum corneum predominate in the vaginal smear. In the case of ovulation there is a sudden influx of leukocytes. Superficial cells and leukocytes are soon replaced by basal and parabasal cells from the stratum germinativum and intermediate cells from the stratum spinosum, which predominate during the corpus luteum phase (Schmidt 1961). Histologic changes of the vaginal mucosa have also been described (Hamilton and Harrison 1951).

Control of Estrus

Although a full discussion of estrus induction and synchronization can be found in other texts, any practitioner dealing with dairy goats will want to be familiar with some of the problems and techniques involved in year-round breeding or synchronization for artificial insemination.

Breeding Season

The methods that can be used successfully vary with the physiologic state of the goat (Smith 1986b). Thus, during the regular breeding season, prostaglandin F 2 alpha (2.5 mg) or cloprostenol (62 mcg) during the luteal phase of the cycle normally induces estrus in approximately 48 hours although some researchers have seen better response with and producers commonly use double these doses (Nuti et al. 1992; Mellado et al. 1994). Even lower doses of prostaglandin F2 alpha (1.25 mg) have been documented to be effective (Bretzlaff et al. 1981). If the doe is not known to be at day five or beyond in the cycle, paired prostaglandin injections ten days apart increase the probability of response to prostaglandin by the time of the second injection.

Although not currently available in the United States, various progestogens can be placed for five to

ten days and prostaglandin given at the time of implant or pessary removal. Products that have been used this way include ear implants (3 mg norgestomet, half of a 6 mg Synchro-Mate-B implant), vaginal pessaries (45 mg fluorogestone acetate; FGA, Cronolone, Intervet or 60 mg methyl-acetoxy progesterone; MAP, Upjohn) and controlled internal drug releasers (CIDR-G with 300 mg progesterone). Melengestrol acetate (MGA) can also be fed in some countries. A typical dose is 0.125 mg/head twice a day for ten to fourteen days, followed by a prostaglandin injection. Concerns about unknown meat and milk residues plague the use of most of these products.

Transition

During the transitional period (between the anestrous and breeding seasons), response to prostaglandin alone would be erratic, but either sudden introduction of a buck or application of exogenous progestogens followed by prostaglandin should be effective in inducing cyclicity. Although not currently available in the United States, both vaginal pessaries and subcutaneous progestogen implants work well during the transition period (East and Rowe 1989). Adding gonadotropins such as human chorionic gonadotropin (hCG) combined with equine chorionic gonadotropin (eCG, previously called pregnant mare serum gonadotrophin, PMSG) (PG600, Intervet) to the regimen may be beneficial, as during the anestrous season (Rowe and East 1996).

The buck effect usually synchronizes a group of does to begin cycling within eight days (Shelton 1960; Ott et al. 1980). The buck effect also hastens the onset of puberty in doelings (Amoah and Bryant 1984). If more precise control is needed, the does could be aborted very early in pregnancy and rebred to the buck of choice. Bright security lights in the barnyard might delay the onset of cyclicity in the fall (Bretzlaff 1989).

Anestrous Season

Breeding during the anestrous season is not so easily achieved. Two injections of prostaglandin are ineffective (Greyling and Van Niekerk 1991a), because (except for goats in false pregnancy) there is no corpus luteum available for luteolysis. Some herds, including those in the tropics (Chemineau 1984), may respond to the buck effect. One study in Mexico showed that the buck effect induced ovulation in does that were not otherwise manipulated as long as the bucks used were sexually active. This state was achieved by exposing the bucks to sixteen-hour-long days for two months and then inserting two subcutaneous melatonin implants of 18 mg each when the bucks were returned to ambient day length for a further two months, before being used

as teasers (Flores et al. 2000). Based on research done with rams (Pearce and Oldham 1988), it is likely that introduction of a novel buck would be effective in inducing ovulation if does have become habituated to a resident buck by continuous contact.

Photoperiod manipulation of does is a commonly used technique in North America. Herds can be subjected to two months of artificially lengthened days (nineteen to twenty hours of light per day) or to a one- to two-hour "flash" of light beginning sixteen hours after dawn; minimum 200 lux) and then returned to a shorter day length. Cycling begins approximately six weeks later. Some herd owners find the cost of electricity prohibitive. Goats experiencing hydrometra are unlikely to respond but could be identified by ultrasound and treated in advance (see below).

Abrupt introduction of a buck (also light-treated, but held away from the does) six weeks after the end of the long days appears to improve the success rate with photoperiod treatment (BonDurant 1986; Pellicer-Rubio et al. 2007). Improved fertility out of season also seems possible with administration to the does of a melatonin implant at the end of the artificially long days (Chemineau et al. 1986, 1999; Chemineau 1989; du Preez 2001). Melatonin, a hormone normally produced by the pineal gland during hours of darkness, serves as a signal that the nights are now long. These implants are not currently available in the United States.

Finally, the various exogenous progestogen treatments discussed under breeding season can be applied for twenty-one days with good fertility on the induced estrus if equine chorionic gonadotropin (eCG, previously called PMSG) can be given two days before removal of pessary or implant. Fertility is improved if the progestogen treatment is reduced to eleven days and prostaglandin is given simultaneously with the eCG (Corteel et al. 1988). The dose of eCG needed varies with the age and milk production of the goat (400 IU for a nulliparous doeling, 750 IU for a mature doe in early lactation). A generic protocol is then to insert progestogen source on day zero, give prostaglandin and eCG on day nine, remove progestogen on day eleven, and expect estrus thirty-six to forty-eight hours later. In goat herds where eCG is not available, there has been little success with sponges and implants during the anestrous season, although some producers in the United States have successfully used the available swine hCG/eCG product (PG600, Intervet). Adding the buck effect may improve pregnancy rates (Bretzlaff et al. 1991).

PREGNANCY DIAGNOSIS

An excellent general discussion of pregnancy diagnosis has been provided by C.S.F. Williams (1986a)

Table 13.1. Pregnancy diagnosis techniques for goats.

Technique	Stage of Pregnancy	Accuracy %		Potential errors	Comment
		Pregnant	Nonpregnant		
Estrus detection	18–24 days or until term	Varies with detection method, may stand when pregnant		End of breeding season, buck not "acceptable."	Observe tail wag; use buck, testosterone-treated doe, intersex.
Serum progesterone (Thibier et al. 1982)	19–24 days	87	97	Irregular cycle, false pregnancy, early abortion.	Best used as nonpregnancy test.
Milk progesterone (Pennington et al. 1982; Dionysius 1991)	19–24 days	Varies with each kit/antiserum. 71–98	80–100	False negative unless antiserum detects 5-pregnanedione; false positive may occur during estrus (Holdsworth and Davies 1979; Bretzlaff et al. 1989).	Concentrations more variable and higher than serum progesterone (Murray and Newstead 1988).
Urinary or serum estrone sulfate (Williams 1986a; Sardjana et al. 1988a)	After 50–60 days, some possible by 30 days	About 100	About 100	Testing milk unreliable unless in full production.	Negative in false pregnancy; secretion decreases rapidly if abortion.
PSPB	After 25 days	High	High	False positive if recent fetal death.	
Ballottement	After 100 days			Goat fat or tense.	Swing entire abdomen or push in with fist.
Radiography (Barker and Cawley 1967)	After 70–90 days	About 100	About 100	Diagnosing by uterine enlargement rather than skeleton.	Hold off feed; can count fetuses.
Amplitude depth ultrasound	60 (80)–120 days			False pregnant does positive; late pregnant does may be negative.	Clip hair right side above udder.
Doppler (Lindahl 1969; Fraser et al. 1971; Ott et al. 1981)	>35 days (rectal)	95	25–75	Increased blood flow in false pregnancy.	Fetal heart two times maternal rate.
Real-time ultrasound (Buckrell 1988; Baronet and Vaillancourt 1989)	>25 days (rectal) >35 days (abdominal)	About 100	87	False pregnancy (fluid, no fetus or caruncles); late pregnancy more difficult to visualize.	Transabdominal test earlier in older does.

and updated to include B-mode ultrasonography by Matsas (2007). Table 13.1 outlines many different methods of pregnancy diagnosis and the sensitivity and specificity of the tests for which published information is available. In fact, the apparent accuracy of most of these methods varies from farm to farm, according to the prevalence of infectious abortions, nutritional deficiencies causing early embryonic loss, and hydrometra. Experience of the examiner also affects accuracy.

Diagnostic Techniques

The most accurate tests are those that measure or detect something that is only produced by a viable fetus and that is always present when the goat has reached a certain stage of pregnancy.

Hormonal Assays

Hormones that have been used as predictors of pregnancy include progesterone, estrone sulfate, placental lactogen, and pregnancy associated glycoproteins.

Progesterone, because it is produced only by the ovaries and not by the placenta, is best used as a nonpregnancy test (Dionysius 1991; Gonzalez et al. 2004), although the probability that a goat with elevated progesterone is actually pregnant is increased during the anestrous season (Fleming et al. 1990). Goats with low progesterone in serum or milk five days or more after breeding are judged to be not pregnant. The exact cut-off varies with test method, and most commercial kits have not been validated for goats. Goats with elevated progesterone at twenty-one days after breeding could be pregnant or could have a different cycle length or be pseudopregnant. One study found that using milk progesterone kits at twenty days after breeding was no more accurate for pregnancy diagnosis than using a buck to detect return to estrus at eighteen to twenty-four days (Engeland et al. 1997).

Estrogens are produced by both the ovaries and placenta, but estrone sulfate is thought to be a product of steroid conjugation by fetal or placental tissues (Refsal et al. 1991). Estrone sulfate in whole milk or whey can be used for pregnancy diagnosis (Chaplin and Holdsworth 1982; McArthur and Geary 1986), and total urinary estrogen has also been used by a commercial laboratory (B.E.T. Reproductive Laboratories, Lexington, KY), beginning at about fifty days of gestation. Occasional false negative results in the B.E.T. test are reported in pregnant does well beyond fifty days of gestation.

Placental lactogen is a hormone produced only by the placenta (Hayden et al. 1980; Byatt et al. 1992). Concentrations in plasma or milk can be assayed after sixty days to diagnose pregnancy. The hormone concentration is also correlated with the total weight of kids produced (Sardjana et al. 1988b). Commercial assays for the caprine hormone are not currently available. Several pregnancy associated glycoproteins (PAGs) are produced by chorionic binucleate cells from the placenta and have been detected as early as twenty-one days of gestation by radioimmunoassay (Gonzalez et al. 1999, 2000, 2004). No PAG is detected if a pseudopregnancy develops early, and sequential tests show a decrease in PAG concentration when one fetus in a litter dies (Zarrouk et al. 1999). Currently, an ELISA test for the closely related pregnancy-specific protein B (PSPB) is available from Bio Tracking (Moscow, ID). This is a placental hormone that has been used as an indicator of pregnancy in goats (Humblot et al. 1990), cattle, and sheep (Ruder et al. 1988). Detection of pregnancy is possible using PSPB by twenty-six days in goats. It is not known how long the test remains positive in a pseudopregnant goat when an embryo reached the stage of hormone production before dying. It is also not yet known if concentrations of placental hormones vary according to previous selection pressures on a given breed for milk or meat production.

Amplitude Depth Ultrasound

The first ultrasound machines on the market detected the interface between a fluid-filled organ (the uterus) and the abdominal viscera. These machines are still commonly used for pregnancy diagnosis in swine and are relatively inexpensive. They are very unsatisfactory for use in dairy goats because of low accuracy. Nonpregnant animals with fluid in the uterus (false pregnancy) are classified as pregnant, thus escaping detection. Also, a false-negative diagnosis is delivered if the ultrasound beam encounters fetus rather than large pockets of fluid.

Doppler

When the limitations of the amplitude depth machines were recognized, interest switched to Doppler techniques. Doppler machines permit the operator to hear the blood flow in maternal and fetal vessels. When used rectally (after thirty-five days), the external iliac vessels are first located by directing the probe laterally within the pelvic canal. When the maternal pulse rate is ascertained, the probe is advanced and directed ventrad to search for a fetal heartbeat or blood flow in the umbilical artery, at approximately twice the maternal rate. The fetal heart rate is negatively correlated with fetal age (Fraser et al. 1971). Loud whooshing sounds at the maternal rate but ventrally located indicate increased blood flow to the uterus; this should not be taken as conclusive evidence of pregnancy because it is also heard in goats with hydrometra and might be detected in does that have recently kidded (Wani et al. 1998). After forty-five days, detection of the fetal heartbeat can be accomplished transabdominally. This technique may also be used to assess fetal viability in goats with pregnancy toxemia. The equipment is more affordable than a real-time ultrasound machine.

Real-time Ultrasound

A real-time ultrasound machine eliminates worries about false positives if the diagnosis is always based on visualizing either fetus or caruncles (Haibel 1990b). False negatives are still possible if later, unrecorded matings have occurred. Administering prostaglandin, then, should generally be delayed until the doe has been rechecked, unless later breedings are absolutely impossible. Accuracy also improves with operator experience (Bretzlaff et al. 1993). Sector scanners generally have superior resolution to linear array systems and make counting fetuses easier, but the equipment is more expensive. Portable generators permit the use of real-time technology even under range conditions. With some machines, it is important not to disconnect the

probe or let the generator run out of fuel while the power is on. Smaller battery operated units are now available.

TRANSRECTAL SCANNING. Equine and bovine linear array units with 5-mHz transducers can be used rectally for early diagnosis (twenty to thirty days) or transabdominally later in pregnancy (day thirty-five and beyond) (Buckrell 1988). Withholding food and water for twelve hours improves visualization of the uterus but is usually not necessary and might lead to pregnancy toxemia (Bretzlaff et al. 1993). Taping an insemination rod or a longitudinally split section of plastic pipe to the head and cord of the transducer simplifies manipulations within the rectum. Although more expensive, a human prostate probe also works well. A small amount of lubricant is introduced into the rectum before inserting the lubricated probe. The pregnant uterus is usually located anterior and ventral to the urinary bladder. Elevating the abdomen by placing the goat across a hay bale makes transrectal diagnosis reliable even after thirty-five days (Baronet and Vaillancourt 1989). The earliest that the embryo is reliably detected by transrectal exam is twenty-five or twenty-six days after breeding (Gonzalez et al. 2004). In another small study, at least one embryo of each pregnant doe had a detectable heart beat by day twenty-three (Martinez et al. 1998).

TRANSABDOMINAL SCANNING. For transabdominal examination, does are generally scanned standing, from the right side, and clipping hair immediately lateral and dorsal to the udder improves contact between transducer and skin. Otherwise (show does, for instance), much contact gel (such as methyl-cellulose rectal lubricant), vegetable oil, or alcohol is needed to wet the hair. Examination in dorsal recumbency (in a padded trough) has been used in early research trials (Tainturier et al. 1983), but stresses the doe to an unnecessary degree.

Early in pregnancy (thirty to forty-five days), the ultrasound beam should be directed toward the pelvic inlet. Subsequently, the uterus is usually positioned against the right ventral abdominal wall (Haibel 1986a). Late in pregnancy, the 5-MHz transducer may not penetrate as far as the fetus (caruncles are visible but not well outlined by fluid) or part of a fetus may fill the screen and be overlooked unless bones or beating fetal heart (nonechogenic because of the blood in it) is noted. A 3.5-MHz transducer is preferred but not imperative in late gestation.

A sector scanner is preferred for determining fetal numbers. The best time for counting fetuses is between forty and seventy days of gestation (Lavoir and Taverne 1989; Hesselink and Taverne 1994). The number of triplet litters is underestimated before fifty days (Dawson et al. 1994).

In early pregnancy, numerous fluid-filled cross sections of uterus are visualized. This phenomenon can be explained by circumferential folds of endometrium which protrude into the lumen (Kähn 1994). If a fetus is clearly visualized, its heartbeat can be detected by twenty-five to thirty days. It has been stated that caruncles are routinely found by day thirty (Buckrell et al. 1986; Baronet and Vaillancourt 1989) or day thirty-five (Doizé et al. 1997), but others feel that day forty or fifty is a safer date if a goat is to be called open because caruncles are not visualized. This allows for variations in resolution of the machine and position of the uterus. The caruncles appear to be doughnut- or C-shaped by forty-five to fifty days (Haibel 1986a) and are outlined by fluid (Figure 13.2). There are approximately 120 to 125 caruncles in a goat's uterus, arranged in four rows in each horn (Lyngset 1968c).

FETAL AGE DETERMINATION. With practice, the size of the fetus can be used to estimate stage of gestation. In Saanens and Alpines, the crown-rump length of the fetus is approximately 40 mm at forty-five days, 100 mm at sixty days, and 250 mm at ninety days (Mialot et al. 1991). Fetal age in dairy goats also can be

Figure 13.2. Transabdominal ultrasound of a pregnant doe showing a donut-shaped caruncle clearly outlined by black uterine fluid. (Courtesy Dr. M.C. Smith.)

BPD VS. GESTATIONAL AGE OF GOATS
Figure 13.3. Correlation of biparietal diameter and fetal age. (From Haibel, G.K.: Use of ultrasonography in reproductive management of sheep and goat herds. Vet. Clin. N. Am., Food Anim. Prac., 6(3):608, 1990.)

estimated by measuring the width of the fetal head during real-time examination (Figure 13.3). Between forty and one hundred days gestation, the biparietal diameter (measured from a symmetrical, maximum width image) correlates very closely with age (Haibel 1988, Haibel et al. 1989). A similar correlation has been reported for second trimester pygmy goat fetuses (Reichle and Haibel 1991). Later in pregnancy, there is too much difference in size of the fetuses and it is no longer possible to date pregnancies accurately enough to permit safe induction of parturition based on the estimated fetal age.

Caruncular size is also quite variable and not very useful for estimating age, except early in pregnancy. The caruncles increase in size until a maximum is reached at about ninety days of gestation. Before this time the diameter of the caruncles in the uterine body as imaged transrectally can be used as a predictor of stage of pregnancy but less precision might be expected from transabdominal measurements of caruncles in random parts of the uterus (Doizé et al. 1997).

FETAL SEX DETERMINATION. Real-time ultrasound permits visualization of the genital tubercle of the developing fetus, an embryologic structure that is initially located between the hind limbs but moves forward to near the umbilicus in males and back toward the tail in females. Transrectal scanning using an adaptor to manipulate the probe gives excellent results for single kids between fifty-five and seventy-five days of gestation, but it is not always possible to visualize the genital tubercle or external genitalia in twins or triplets (Santos et al. 2007). Other authors prefer to use presence of two thin teats between the hind legs and absence of a triangular appearing scrotum in this region to diagnose a female fetus, because the tail may obscure the female genital tubercle (Burstel et al. 2002). The penis/prepuce is located immediately behind the nonechogenic, circular umbilical cord.

Other Techniques

Where Doppler or real-time ultrasound is not available and hormonal assays are prohibitively expensive,

other, less sophisticated techniques may be used. For instance, rapid field laparotomy has been used to diagnose pregnancy in goats. Hulet's rod for recto-abdominal palpation has also been used in goats, but American practitioners will probably find this technique less than satisfactory. Goats do not lie quietly on their backs for this examination, as is typical for sheep to do, and rectal lacerations and abortions may occur (Ott et al. 1981). In a relaxed doe in late pregnancy, it may be possible to palpate or ballot a fetus in the right ventral abdomen or to observe fetal movements.

A bimanual technique has been developed for detecting early pregnancy in goats and sheep (Kutty 1999). After overnight fasting of the doe, a gloved index finger is introduced into the rectum of the standing animal and used to evacuate fecal pellets and express the bladder. Then the examiner's right hand is pushed vertically in the caudal abdomen, to displace intestines forward and the uterus caudally into the pelvic canal where it can be palpated by the left index finger. Ovaries could also be trapped between the two index fingers and palpated. A fluid distension of the uterine horns is reported to be palpable at thirty and forty-five days but cannot be distinguished from hydrometra. By ninety days, retroversion of the uterus is no longer possible, but placentomes and softening of the cervix are palpable.

For the answer to the in-passing "do you think she's pregnant?" question, the sacrotuberous ligament and other ligaments near the base of the tail should be evaluated for softening. This is easiest when comparison with a nonpregnant doe is possible. In practiced hands and the second half of pregnancy, this is a free version of the urinary estrone sulfate test. Increased elasticity of the skin around the vulva and pinbones has also been used by laymen as an indicator of pregnancy (DeArmond 1990). Development of an udder, even in yearlings, should not be taken as proof of pregnancy (see inappropriate lactation syndrome, discussed in Chapter 14).

Use of Test Results

Pregnancy diagnosis is performed for a variety of reasons, depending on the management of the goat herd. It may be desirable to cull nonpregnant does after the end of a breeding season or in times of feed shortage. Verifying pregnancy before drying off a dairy doe is becoming routine. It is also very important to monitor the success of out-of-season breeding programs, because of extremely variable results and the relatively high risk of hydrometra in these does.

What one does with the results of a pregnancy test depends on one's faith in the test results. If a goat is thought to be pregnant, usually nothing is done unless mismating has occurred or nutritional resources are so short that only well-grown, pregnant goats can be fed adequately to maintain pregnancy. Animals carrying multiple fetuses might be fed more than those with singles, to decrease the risks of pregnancy toxemia in one group and obesity in the other (see Chapter 19). When the diagnosis is that of nonpregnancy, the owner may choose to restrict feed or continue milking the goat or stop staying up nights, waiting for it to kid. If rebreeding is desired, it is very likely that the use of prostaglandins to induce estrus will come under discussion. At this point, the practitioner must be very certain of his or her diagnosis of "open." Goats with negative progesterone test results twenty-one days after synchronized breeding could be given a new vaginal sponge or ear implant (de Montigny 1988), but even these techniques frequently include prostaglandin in the synchronization protocol.

FALSE PREGNANCY AND HYDROMETRA

Goats occasionally exhibit prolonged luteal function and absence of estrus even though they are not pregnant. Some of these does were bred and may have conceived at the time that the persistent corpus luteum first developed. One study summarized by Chemineau et al. (1999) documented that approximately half of the pseudopregnancies identified by ultrasonography at forty-five days post breeding were preceded by an embryo that lived long enough to produce pregnancy specific protein B. Other affected does have never even been exposed to a buck.

Historical Perspectives and Clinical Signs

Until recent years, it was very difficult to diagnose or study this phenomenon. Results of progesterone analysis (Holdsworth and Davies 1979) and amplitude-depth ultrasound were suggestive of pregnancy. The rectal Doppler examination indicated increased blood flow to the uterus. Radiographic evaluation (absence of fetal skeleton) or laparotomy was required to make the diagnosis. Owners noticed that some apparently pregnant does (no return to estrus, with or without a gradual enlargement of the abdomen) delivered fluid but no placenta or fetus. The lay term "cloud burst" has been applied to the natural termination of a false pregnancy accompanied by discharge of large volumes of fluid. When practitioners examined goats with marked abdominal distension that had not delivered at the calculated due date, hydrometra was sometimes recognized. Surgical drainage of the uterus was soon replaced by treatment with prostaglandin to induce resorption of the corpus luteum followed by voiding of the retained fluid. A few animals that had been included in various reproductive research trials spontaneously developed false pregnancy, thereby providing retrospective hormonal profiles.

Etiology

The etiology of the condition is not yet known. It seems likely that the prevalence is greater in herds trying to delay breeding of some does (for winter milk production) than in those in which all does are bred on the first estrus of the breeding season. Certain infectious diseases—trypanosomosis if controlled with trypanocidal drugs (Llewelyn et al. 1987), toxoplasmosis (Debenedetti et al. 1989), border disease (Løken 1987)—may possibly increase the prevalence of false pregnancy. Involvement of phytoestrogens in the forage has been proposed as contributing to the occurrence of false pregnancies in certain herds (Malher and Ben Younes 1987). Others have suggested that treating short cycles with human chorionic gonadotropin or gonadotropin releasing hormone may predispose the goat to development of false pregnancy (East 1983).

Prolonged luteal function and hydrometra have been recreated experimentally by immunizing goats against prostaglandin F2 alpha (Taverne et al. 1995; Kornalijnslijper et al. 1997). Fluid accumulation is first detectable between days twenty-nine and thirty-eight of the luteal phase. Prolactin does not appear to be involved in the etiology (Hesselink et al. 1995). Possible suppression of testosterone secretion has not been investigated in relation to false pregnancy. Testosterone is usually required for luteolysis in the goat (Cooke 1989). The possibility of a genetic predisposition is supported by a study in which the daughters of goats with hydrometra had a 38% frequency of hydrometra, compared with 9% of the daughters of unaffected goats (Hesselink and Elving 1996). In another study, 20% of 125 daughters of five sires developed pseudopregnancy, as compared with 0% of the 326 daughters of twelve other sires, all in the same herd (Chemineau et al. 1999).

Epidemiology

The prevalence of the condition in privately owned herds is uncertain, but this information should be easy to estimate when pregnancy diagnosis by real-time ultrasound becomes routine. In one French herd studied in 1986, the buck was introduced to 124 adult goats in early April. Ultrasound at day fifty-four revealed that ninety-two goats were pregnant but twenty-one other goats (17%), all of which had experienced a normal gestation the past year, had hydrometra (Malher and Ben Younes 1987). In another study in France (Mialot et al. 1991; Duquesnel et al. 1992), ultrasound was performed more than 5,000 times on sixty-eight farms in 1989 and on seventy-one farms in 1990, and pseudopregnancy was diagnosed in 2.1% and 2.9% of the examinations. In 10% of the herds, the prevalence was more than 5%. The condition was most commonly diagnosed in adult goats after a fall (November to December) kidding without rebreeding or after an out-of-season synchronization program that did not include prostaglandin. A Dutch study found a mean incidence of 9% with the condition being more common in older goats (Hesselink 1993a). In a German study, 143 of 2,434 dairy goats were affected, as diagnosed by ultrasound, with an average incidence of 5.78% (Wittek et al. 1997, 1998).

Diagnosis

With the development of real-time ultrasound, it has become possible to easily differentiate a false from a true pregnancy and to institute early treatment and monitor the success of therapy (Pieterse and Taverne 1986). When a goat with advanced hydrometra is scanned from either flank, large, fluid-filled compartments are seen (Figure 13.4). Thin tissue walls separate the compartments and undulate when the goat moves or succussion of the abdomen is performed. These walls represent sections of curved horn overlapping each other rather than internal trabeculae (Hesselink and Taverne 1994). Fetus and caruncles are absent. White flecks may be seen in the fluid and settle down like snow after succussion. Diagnosis of an early stage of hydrometra is more difficult. Before forty days, when caruncles may not yet be visible by ultrasound, hydrometra is difficult to distinguish from normal pregnancy because it is not always possible to visualize the fetus when scanning an early pregnancy. In these goats, and in those when the breeding date is unknown, re-evaluation several weeks later verifies the existence of hydrometra if fetus or caruncles still cannot be found.

Diagnosis can also be confirmed by laparotomy or necropsy. The volume of fluid in the uterus is quite variable, 1 to 7.2 liters in one study (Mialot et al. 1991), and 0.25 to 8.3 liters in another (Wittek et al. 1997). In the goat that spontaneously voids the fluid (mucoid discharge on tail, decreased abdominal size), the diagnosis is presumptive. Some does that correct spontaneously early in the course of a pseudopregnancy have a bloody discharge. The condition in these animals cannot be distinguished from early embryonic loss (unless the goat was not bred) without a prior ultrasound diagnosis.

Treatment and Prevention

Prostaglandin is the treatment of hydrometra as confirmed by ultrasound or of false pregnancy as suspected in an anestrous doe that cannot possibly have been exposed to a buck. Both natural (5 to 10 mg prostaglandin F2 alpha) and synthetic (125 to 250 mcg clo-

Figure 13.4. Real-time ultrasound image of hydrometra. (Courtesy Dr. M.C. Smith.)

In intensively managed herds that practice out-of-season breeding, ultrasound should be performed on all bred does before drying off (Duquesnel et al. 1992). Those that are pseudopregnant should then remain in the milking herd and be treated with prostaglandin, and their milk production will increase. Likewise, goats to be synchronized out of season should be examined by ultrasound first so that affected does that would be expected to have poor fertility at the induced estrus can be treated with prostaglandin and synchronization can be delayed until resolution of the hydrometra is achieved.

Preventing hydrometra in pet goats that will not be bred or even just preventing estrus and associated noisy behavior in these pets can be achieved by ovariectomy. The surgery is done under general anesthesia or heavy sedation and a local block (Mobini et al. 2002). The animal is placed in dorsal recumbency and each ovary is removed after ligation of the pedicle by laparoscopy or via a ventral midline incision just cranial to the udder. Temporary elevation of the rear end of the doe by 25 or 30 degrees simplifies location of the ovaries but prolonged weight of the rumen on the diaphragm is not desirable (Wolfe and Baird 1997). Exposure of the contralateral ovary is difficult from a flank incision, but this approach is preferred for unilateral ovariectomy, as for an ovarian tumor.

A case report of mucometra in a mature West African pygmy goat in Germany documented persistent accumulation of fluid in the uterus in the absence of a functional corpus luteum. This doe did not respond to prostaglandin but was successfully managed by ovariorhystectomy performed from a ventral midline incision caudal to the umbilicus (Trasch et al. 2002).

prostenol) hormones cause regression of the corpus luteum and emptying of the uterus. Repeated doses of oxytocin (50 IU twice a day for four days) also induce emptying of the uterus, and might be attempted if scanning several days after prostaglandin therapy indicates continued presence of fluid in the uterus. The rare animal that fails to respond to therapy may have segmental aplasia of the uterus or cervix (Webb 1985; Batista et al. 2006). Many goats return to estrus after treatment and can become pregnant within two months of resolution of the hydrometra (Pieterse and Taverne 1986; Duquesnel et al. 1992). Some of these develop a new pseudopregnancy the following year. Recurrence shortly after treatment has also been observed (Batista et al. 2001), but the risk of this decreases if the goat receives a second dose of prostaglandin twelve days after the initial discharge of fluid (Hesselink 1993b).

ABORTION

Abortion by one or more goats in a herd may signal an infectious disease or some other condition that could be controlled by proper management.

Diagnostic Workup for Abortions

Practitioners are often asked to determine the cause of an abortion or to offer an opinion as to the need for diagnostic testing. The owner should be instructed to keep detailed records and accurately identify each aborting animal and the stage of gestation when fetal loss occurred. In addition to crown rump length data, guidelines for estimating the gestational age of tropical breeds in Nigeria have been reported (Sivachelvan et al. 1996) and are summerized as follows.

Week	Developmental characteristic
10–11	Hairs on eyelids
13–14	Hairs on dorsum of neck and entire calvarium hard
14–15	Eyelids separable
16–17	Body sparsely covered with hair
17–20	Body densely covered with hair, teeth buds prominent
At birth	1–3 pair incisors erupted

Similar information exists for West African Dwarf goats (Osuagwuh and Aire 1986) and Norwegian goats (Lyngset 1971).

The serious risk of zoonotic disease and prompt disposal of all fetuses or placentas not submitted for diagnostic workup must be stressed. Uterine discharges are an important source of infection for others in the herd, and thus all aborting does should be isolated at once from the rest of the herd. Pregnant does should be fed from feeders to limit exposure to discharges on the ground. When abortion has occurred outside, the immediate area can be disinfected by burning (straw and diesel fuel). It is also good policy to separate pregnant females of different species because some abortion storms may cross species lines.

After consulting with the regional diagnostic laboratory, fetus, placenta, and paired sera should be collected. If it is not convenient to submit the entire fetus, fetal tissues and fluids (stomach fluid, heart blood) should be harvested for culture and serology tests and submitted along with formalin-fixed tissues (including brain) for histology (see Table 13.2). Impression smears of the cut surface of cotyledons may permit identifica-tion of infectious agents by special stains or fluorescent antibody techniques when the placenta itself is too autolysed or contaminated to easily evaluate by culture or routine histology. Exudate from the vagina may be substituted in some tests if placenta is not available. Owners should be alerted to the unsuitability of a mummified fetus for many tests, so that long drives and expenses associated with laboratory submission of a mummy can be avoided. Although not ideal, it is possible to freeze the first aborted fetus and placenta, along with serum from the dam, then await the possible development of a herd problem.

Laboratory procedures for identifying the various causes of abortion have been described in Kirkbride's manual (Kirkbride 1990).

The importance of the placenta cannot be overemphasized. Table 13.3 summarizes the placental changes that may have diagnostic value. Small white amniotic plaques of proliferating epithelial tissue are inconsistent but normal findings (Lyngset 1971). Unfortunately, many does either eat the placenta or retain it, so that this extremely important tissue is not always available. Also, grossly visible placental lesions are not invariably present.

The diagnosis in an abortion storm often is not available for several days. In fact, absence of placentas, autolysis, bacterial contamination, or submission of unrepresentative fetuses (bad luck) may result in no diagnosis being achieved. It is reasonable to begin treatment of remaining pregnant does with tetracycline in case a susceptible infectious agent is involved. One possible protocol is three subcutaneous injections of long-lasting tetracycline (Biomycin 200®, BioCeutic) at 9 mg/lb (20 mg/kg) at three-day intervals. The intramuscular route should be avoided, because it

Table 13.3. Changes observed in placentas from aborting goats.

Disease	Placental lesion
Border disease	Pinpoint grey foci of necrosis in cotyledons.
Brucellosis	No reports, placental edema, necrosis of cotyledons in sheep.
Campylobacteriosis	Placental edema, necrosis of cotyledons.
Chlamydiosis	Thickening and necrosis of cotyledonary and intercotyledonary tissue, brownish exudate.
Listeriosis	No reports in goats. Thickened necrotic leathery cotyledons (sheep).
Q fever	Intercotyledonary and cotyledonary necrosis and mineralization; exudate on surface.
Toxoplasmosis	Small opaque white foci of mineralization in cotyledons. Intercotyledonary areas normal.
Yersiniosis	White foci in cotyledons.

causes severe muscle necrosis. Obvious nutritional deficiencies should also be addressed.

Early Abortion

In the field it is often impossible to differentiate early abortions from simple failure to conceive and false pregnancy. Similarly, when more corpora lutea than embryos are found in slaughterhouse studies, the contribution of fertilization failure cannot be determined (Lyngset 1968a). One possible genetic cause of early embryonic death, the Robertsonian translocation, is discussed later in this chapter.

Veterinarians occasionally prescribe progesterone maintenance therapy for goats that have aborted repeatedly and may have inadequate hormone levels. It may be inappropriate to assist in reproducing reproductive misfits. The presence of a live fetus should also be verified (real-time ultrasound) before progesterone administration is begun. Experimentally, progesterone in oil (25 mg daily) prevented abortion in three ovariectomized goats (Meites et al. 1951).

Drug-induced Malformations

Before attachment of the blastocyst at day fifteen, the uterus contains a fluid of increased pH that accumulates high concentrations of acidic drugs administered to the dam. Even after attachment, drugs may disrupt organogenesis. Specific information related to the goat is lacking, but in general unnecessary drugs, including anthelmintics and anesthetics, should be avoided during the first thirty-five days of pregnancy. Diazepam, xylazine, and acetylpromazine are potentially deleterious drugs, whereas thiopental, thiamylal, ketamine, and the major inhalation anesthetic agents are not believed to be teratogenic (Ludders 1988). In sheep, parbendazole (at doses of 60 mg/kg), cambendazole (at 50 mg/kg), and netobimin (at 20 mg/kg) are teratogenic and cambendazole is also embryotoxic (Szabo 1989; Navarro et al. 1998). Malformations involving vital organs may lead to early loss of embryo or fetus.

Sheep and Goat Hybrids

When flocks of sheep and goats are kept together, breeding usually only occurs between members of the same species. However, if does are housed with a fertile male sheep and no buck is available, interbreeding occurs. An embryo forms but usually does not survive beyond the second month of pregnancy. Fertilization rarely occurs when a ewe is bred by a buck (Kelk et al. 1997).

The goat has sixty chromosomes, all acrocentric. The sheep has fifty-four chromosomes, six of which are metacentric while the rest are acrocentric. The hybrid embryo has fifty-seven chromosomes, three of which are metacentric (Ilbery et al. 1967). Some hybrid embryos fail to attach to the maternal caruncles. Histologically, those that attach show evidence of rejection of the trophoblastic tissue that invades the caruncles (Hancock et al. 1968; Dent et al. 1971). The embryo degenerates and is expelled. Passage of the placenta may astound an owner who had not realized that a pregnancy had been initiated. Occasionally mummification occurs and the fetus is expelled at a later date. Rejection typically occurs in the sixth week of pregnancy (or sooner, in goats carrying a hybrid embryo for the second time). Only very rarely has a hybrid fetus (documented by karyotype) survived to term (Bunch et al. 1976; Denis et al. 1988; Letshwenyo and Kedikilwe 2000; Mine et al. 2000).

Goat-lambs (or "geep") are a different, artificial phenomenon produced by manipulation and combination of a goat embryo and a sheep embryo. The resulting chimera is then implanted in a recipient sheep or goat (Fehilly et al. 1984). If the chimeric embryo is constructed in such a way that the trophectoderm and thus the chorionic epithelium arise entirely from cells of the same species as the recipient, rejection of the embryo is avoided. In chimeras prepared by the blastomere aggregation technique (Ruffing et al. 1993), placentas and binucleate cells of some fetuses surviving to term were also chimeric. The highly publicized reports of these chimeras surviving to birth and beyond inevitably have been misinterpreted by some people as evidence that a viable sheep × goat hybrid can be produced.

Toxoplasmosis

It is reasonable to suspect that infection of a doe with *Toxoplasma gondii* in early gestation might occasionally lead to early embryonic death, rather than overt abortion. Animals affected in this way might return to estrus after an irregular interval or merely be found open when parturition was expected. Early embryonic loss has been documented in experimental infections with *Toxoplasma* (Dubey 1988), but is difficult to confirm in field cases (Calamel and Giauffret 1975; Nurse and Lenghaus 1986). Some early deaths may be the result of the febrile response in the infected doe, rather than of invasion of the placenta and fetus. In a serologic study of sheep from farms where toxoplasmosis had been identified as a cause of abortion, a significantly larger proportion of barren ewes than of lambing ewes had high titers for toxoplasmosis (Johnston 1988).

Nutritional Factors

Deficiencies of several trace minerals have been associated with lowered conception rates and abortions in controlled experiments with goats. These include copper and iodine (Anke et al. 1977). Experimental selenium deficiency leads to a lowered apparent conception rate but not to early abortions (Anke et al. 1989). Conversely, prolonged selenium toxicity (caused by excess selenium in soil and therefore in feeds) has been reported to cause abortion and failure of conception in goats in India (Gupta et al. 1982).

Under adverse field conditions, such as prolonged drought, deficiencies of several nutrients (e.g., protein, magnesium, and copper) have been suspected to cause abortion, based on lowered concentrations in the blood of does aborting early in pregnancy (Unanian and Feliciano-Silva 1984), but the exact cause of the abortions remains unproven.

Studies in Angoras have suggested that simultaneous deficiencies of energy and protein (rather than just one or the other) are required for early embryonic mortality to occur (Van der Westhuysen and Roelofse 1971). Dairy does for which both energy and protein were restricted had a lower ovulation rate and increased embryonic losses when compared with goats on a control, maintenance diet. Circulating progesterone concentrations were not affected (Mani et al. 1992, 1995). A protein and mineral supplement should be offered if reproductive failure coincides with probable nutritional deprivation. Supplementation of a low protein grass diet with leguminous browse has decreased abortion losses in West African dwarf goats (Pamo et al. 2006). Other long-term feeding trials of does have suggested that energy is more critical to successful reproduction in goats than is protein (Sachdeva et al. 1973). This suggests that a supplement that does not improve the digestible nutrients in the ration may not be effective in restoring reproduction.

Prevention of Early Losses by Flushing

Flushing is the technique of increasing energy intake just before breeding to increase ovulation rate. Maintaining the improved nutrition through the first month of gestation is advised to give the embryos ample opportunity to survive this critical period. Flushing is often interpreted as feeding grain. In range or grazing animals, other management options appear to be useful to improve the nutritional balance. These include moving to a better pasture, deworming at this strategic time, or shearing (Angoras). Shearing probably stimulates an increase in feed intake until a protective layer of fleece grows back. A study by Hart et al. (1999) failed to show an increase in conception rate or litter size with increases in either energy or protein fed to Spanish meat goats.

LATE ABORTION: INFECTIOUS CAUSES

In the United States, chlamydiosis, Q fever, and toxoplasmosis appear to be the most frequently identified infectious causes of caprine abortion. Other agents may cause serious losses in individual herds. Additional literature has been reviewed by Lefèvre (1987). The zoonotic potential of most of these agents should not be forgotten.

Akabane Virus

Akabane virus has caused abortions and perinatal mortality of calves, lambs, and kids (Markusfeld and Mayer 1971; Inaba et al. 1975).

Etiology and Epidemiology

Akabane virus is an arbovirus of the bunyavirus group. The virus is arthropod-borne, by gnats and mosquitoes. The disease has been recognized in Japan, Israel, and Australia. It is exotic to the United States. Outbreaks are believed to occur when susceptible females are in early pregnancy during periods of increased vector activity. As many as 50% of kids born on some farms have been affected (Shimshony 1980).

Pathogenesis

The pregnant dam develops viremia. Akabane virus infects lambs transplacentally at thirty to thirty-six days of gestation (Parsonson et al. 1981). The critical time for infection of kids has not been determined, but is probably similar (Kurogi et al. 1977). At this early period, the virus destroys embryonic cells in the cerebral cortex. Fetal muscles undergo neurogenic atrophy, as discussed in Chapter 4. Fetal death and mummification may occur. If the fetus survives, the virus is cleared but precolostral antibodies remain as evidence of the infection.

Clinical Signs

The disease is sometimes referred to as congenital arthrogryposis-hydranencephaly syndrome. Malformations associated with Akabane virus include micrencephaly, hydrocephalus, hydranencephaly, porencephaly, arthrogryposis, and reduced muscle mass (Haughey et al. 1988). Fetuses may be stillborn or die very soon after birth. Arthrogryposis or prepartum death of the fetus may contribute to dystocia. The pregnant dam shows no overt clinical signs at the time of initial infection.

Similarity to Cache Valley Virus

A similar arthropod-borne bunyavirus, the Cache Valley virus, is endemic to parts of North America and has caused epizootics of arthrogryposis with hydrocephalus, hydranencephaly, or cerebellar dysplasia in lambs in Texas, Michigan, and Nebraska (Edwards et al. 1989; Chung et al. 1990b; de la Concha-Bermejillo 2003) and elsewhere. A high prevalence of mummified fetuses, stillbirths, and weak lambs has been observed in infected flocks and reproduced experimentally by inoculation at twenty-seven to fifty-four days of gestation (Chung et al. 1990a). Oligohydroamnion contributes to lack of fetal movement and consequent arthrogryposis. Although case reports are rare, goat fetuses are also susceptible to Cache Valley virus (Edwards et al. 2003).

Diagnosis and Control

Congenital malformations, as described above, are suggestive of Akabane or Cache Valley virus infections. Retrospectively, the first trimester of pregnancy will have occurred during a period of biting insect activity, especially mosquitoes. A warm, humid period after several years of drought results in a large population of insect vectors interacting with a naive population of small ruminants.

Virus isolation may be attempted from placenta, fetal muscle, or fetal brain, but is always unsuccessful in full term fetuses. Demonstration of precolostral or fetal serum antibodies against one of these viruses is evidence of involvement of the virus. Maternal antibodies will probably have peaked by the time parturition occurs, and merely indicate that infection of the dam has occurred (Kalmar et al. 1975). Lack of maternal antibodies rules out the agent as cause of fetal malformation. Control of Akabane disease is discussed in Chapter 4 and elsewhere (Committee on Foreign Animal Diseases 1998).

Chlamydiosis

Chlamydiosis is a well-documented cause of abortion in goats worldwide. It remains the most frequently diagnosed cause of caprine abortion in California (Moeller 2001).

Etiology

The agent responsible for chlamydiosis is *Chlamydophila abortus* (formerly *Chlamydia psittaci*) (Everett 2000), a Gram-negative, intracellular organism that contains both RNA and DNA. The infectious particles that carry the infection to other cells are called elementary bodies. Previous names for the organism include psittacosis-lymphogranuloma venereum-trachoma agent, *Miyagawanella*, and *Bedsonia*. It is not very host-specific, but strain differences are important in determining which disease syndromes occur. Arthritis, keratoconjunctivitis, and respiratory disease caused by chlamydial infections are discussed elsewhere in this text. The abortion disease in sheep and goats is commonly referred to as enzootic or virus abortion.

Epidemiology and Pathogenesis

The intestinal tract is the natural location for chlamydia (Shewen 1980). *Chlamydophila abortus* is an organism that can only replicate in an intracellular location. The organism multiplies (according to strain and host resistance) in epithelial cells of the intestinal or genital tract or conjunctiva and in cells of the reticulo-endothelial system.

Chlamydia gain access to the placenta and fetus after an episode of chlamydemia. Inflammation and necrosis caused by multiplication of the chlamydia prevent normal transfer of nutrients across the placenta, and the fetus dies and is aborted. Other animals become infected by ingestion of placenta or uterine discharges and may abort in their next pregnancy, or (if sufficient time remains for placental damage to occur, approximately forty days) in the current pregnancy (Blewett et al. 1982). Shedding in vaginal secretions has been documented to begin as early as nine days before abortion and to last as long as twelve days after abortion (Rodolakis et al. 1984). Whereas some authors believe that immune does and ewes may remain fecal shedders and sources of infection, others believe that they do not become carriers (Wilsmore et al. 1990). Research documenting that ewes shed the organism when in estrus, even when immunity is adequate to prevent subsequent abortion (Papp et al. 1994), also may be relevant for goats. Chlamydia have been isolated from the semen and genital organs of rams (Pienaar and Schutte 1975), but the possibility that bucks spread the organism during breeding has not been investigated.

Clinical Signs

Chlamydial abortion in goats typically occurs in the last two months of pregnancy and especially the last two weeks (Yalçin and Gane 1970). In an endemic situation, abortion is primarily confined to primiparous does (Faye et al. 1971; East 1983). When the agent is

first introduced into a herd, abortions occur in goats of all ages and parities (McCauley and Tieken 1968). Fetuses usually appear fresh. Sometimes infected kids are delivered at term, either stillborn or alive but weak (McCauley and Tieken 1968). The doe is usually not clinically ill, and the placenta is usually not retained (Metcalfe et al. 1968). In experimental reproduction of the disease, delivery of autolysed fetuses, retained placenta, and metritis have occurred in some does (Rodolakis et al. 1984).

Fertility is usually normal in pregnancies subsequent to the abortion, though some feel that immunity decreases after three years and chlamydial abortions may then recur.

Diagnosis

The placenta of the aborting doe is of great diagnostic importance. Lesions resemble those seen in chlamydia-induced ovine abortions (Pienaar and Schutte 1975; Appleyard et al. 1983; Rodolakis et al. 1984). Gross lesions include thickening and necrosis of cotyledons and intercotyledonary tissue. Microscopic lesions include infiltration in the hilar region with neutrophils, lymphocytes, and macrophages. Epithelial and mesenchymal necrosis occur and elementary bodies are present in epithelial cells of the chorionic villi, intercotyledonary chorium, and exudates. The bodies are basophilic (red in acid-fast stains) and measure 250 to 450 nm in diameter (Pienaar and Schutte 1975). Vasculitis is prominent, in contrast with Q fever.

Although abortion is usually the result of placental damage, histologic lesions are occasionally recognized in the fetus. Enlargement and focal necrosis of the liver have been reported in aborted kids (McCauley and Tieken 1968; Shefki 1987).

Many laboratories make a presumptive diagnosis of chlamydial infection based on demonstration of elementary bodies in impression smears or exudates. Stains used include Giemsa, Stamp, Macchiavello's, and modified Ziehl-Neelsen. A cotyledon is transected and the cut surface used to make the impression smear. If placenta is not available, impression smears of vaginal swabs, fetal umbilicus or hair coat, and fetal liver (cut surface) may yield elementary bodies (Bloxham et al. 1977). The same impression smears and swabs may be used for immunohistochemistry testing (Szeredi and Bacsadi 2002) or PCR. Fetal tissues are generally far less satisfactory than placenta for diagnosis by either special stains or immunofluorescence. Rickettsia (Q fever) have a similar appearance in stained smears (Aitken 1986).

Isolation of the organism is usually attempted in embryonated chicken eggs or cell culture. Isolation is followed by demonstration of elementary bodies and group antigen. Recently, enzyme immunoassay tests, such as those developed to detect group antigen of *Chlamydia trachomatis* infection in humans, have been used to detect *C. abortus* in ovine and caprine placental and vaginal swabs (Souriau and Rodolakis 1986; Sanderson and Andersen 1989). Vaginal swabs should be collected within three days after abortion for best results.

The complement fixation (CF) test has been used in the past for screening (Giauffret and Russo 1976). Because the antigen used is group specific, the presence of nonpathogenic intestinal strains may give false-positive tests unless diagnosis is based on an increase in titer. It is helpful to compare titers of aborting and nonaborting goats (Shefki 1987). Animals that have recently aborted because of chlamydiosis generally have a CF titer of at least 1:80. However, infected animals that do not abort may still mount a serologic response (Giauffret and Russo 1976). The CF titers generally are not protective against experimental challenge.

Skin testing has also been used in France and appears to be more sensitive than CF testing (Rodolakis et al. 1977). Cell-mediated immunity, as identified by skin testing, is probably protective (Wilsmore et al. 1986).

Treatment

If chlamydial abortion is confirmed or highly likely to be present, it is common to treat all females remaining at risk of aborting with tetracycline. Suppression of the organism may prevent additional placental damage. Also, reduced shedding of chlamydia by treated does could decrease the number of new infections and thus the number of animals developing a carrier state that will terminate with abortion in the next pregnancy. Large sheep flocks are commonly medicated with oral oxytetracycline or chlortetracycline at 400 to 500 mg per head per day. This is a reasonable approach for fiber-producing does, perhaps at a reduced dosage in view of smaller body size. In dairy herds it is more customary to treat individual nonlactating does by injection rather than to remove all lactating does from the group to be treated so that antibiotics in the feed will not cause milk contamination. Long-acting oxytetracycline preparations given at a dose of 20 mg/kg every ten to fourteen days should decrease the abortion rate during an outbreak (Rodolakis et al. 1980). Others have given the drug every three days.

Tylosin is another antibiotic that has been used in an attempt to control chlamydial abortion outbreaks. A dose of 200 mg/head per day orally in a salt/meal supplement was used with apparent success in a herd of Angoras (Eugster et al. 1977). Chlamydia are also susceptible to rifamicin and chloramphenicol, antibiotics that may be used in some countries but not in the United States.

Prevention

Prevention of chlamydiosis depends on both hygiene and vaccination. Replacement sheep and goats, even unbred kids, should not be purchased from a herd where the disease is endemic. If acquisition of specific genetics from a diseased herd is necessary, embryo transfer into disease-free recipients avoids introduction of the agent, at least in sheep (Williams et al. 1998). If chlamydial abortions occur (introduced animals or endemic infection), all aborted fetuses and placentas should be removed and destroyed if not used for diagnostic testing. Aborting females should be isolated for several weeks until vaginal discharges cease. They should not be used as foster mothers. Animals should not be fed from the ground.

Vaccination of all animals (including bucks) before breeding with a sheep chlamydial vaccine has been helpful in some herds (Polydorou 1981b; Rodolakis and Souriau 1986). Annual revaccination, or, at the very least, vaccination of each year's crop of doelings, should continue indefinitely. Vaccination helps to prevent abortion but it does not eliminate infection. Vaccine availability has been sporadic at best in the United States.

Zoonotic Potential

Chlamydophila abortus is contagious to humans. During kidding or lambing season, pregnant women assisting with parturitions may become infected with the ruminant strain and abort (Johnson et al. 1985; Hyde and Benirschke 1997; Jorgensen 1997; Pospischil et al. 2002). An influenza-like syndrome also has occurred in men assisting lambing in infected flocks (Aitken 1986). People attending normal parturitions, dystocias, or abortions should wear plastic gloves to limit exposure to uterine fluids. The same precautions apply when collecting fetuses or placentas for disposal or diagnostic evaluation. Pregnant women should avoid contact with the herd during the parturition season.

Q Fever

Query or Queensland fever is a zoonotic infection (McQuiston et al. 2002). Signs in humans vary from inapparent infections to flu-like disease, abortion, pneumonia, or heart disease. Except for abortion, clinical signs in ruminants are rare. Human cases are notifiable nationally in the United States since 1999.

Etiology

Q fever is caused by the obligate intracellular rickettsial organism *Coxiella burnetii* that develops inside phagolysosomes. It is pleomorphic (coccoid to short rod), weakly acid-fast, and variably Gram-negative. In nature, *C. burnetii* exists in Phase I, which is virulent and analogous to smooth bacteria. When cultivated in embryonated eggs or cell cultures, the organism mutates irreversibly to a less virulent Phase II form, analogous to rough bacteria (Arricau-Bouvery and Rodolakis 2005).

Epidemiology

Cattle, sheep, goats, and wildlife throughout the world may carry the organism, which is then shed heavily in placentas, birth fluids, colostrum, milk, and feces. Stresses such as overcrowding or poor nutrition probably play an important role in determining if an infected goat will abort (Crowther and Spicer 1976). Abortion outbreaks may occur in well managed naive herds if first exposed during pregnancy. Reproductive failure associated with Q fever usually does not recur in the season following the abortion storm (Berri et al. 2005). The organism is resistant to heat and drying (Arricau-Bouvery and Rodolakis 2005), with the result that animals and humans can be infected by inhaling dust (Polydorou 1981a; Dupuis et al. 1984). Grazing contaminated pastures and tick bites are other modes of transmission.

Shedding of the organism in milk can persist for three months after parturition/abortion but was not detected during the subsequent kidding season in one study (Berri et al. 2005).

Diagnosis

Because *C. burnetii* can be shed heavily at the time of normal kidding, isolation of the organism is not proof of cause of abortion (Miller et al. 1986). Q fever abortion or stillbirth occurs in late pregnancy, but only when placental damage has been severe. Pathologic changes are rarely seen in fetal tissues. Thus, examination of the placenta is necessary for diagnosis (Moeller 2001). Intercotyledonary areas of the placenta are thickened (Waldhalm et al. 1978; Palmer et al. 1983; Copeland et al. 1991) and may be mineralized (Sanford et al. 1994). Abundant exudate is usually present. There is necrosis and neutrophilic infiltration of cotyledonary and intercotyledonary epithelium. Placental vasculitis may be present (Moore et al. 1991). The organism (pleomorphic, acid-fast) is abundant in trophoblastic cells of the chorion. Placental smears that are stained with the Gimenez method show acid-fast rod-like organisms slightly larger than chlamydia. Fluorescent antibody testing, polymerase chain reaction tests (PCR), laboratory animal inoculation, and isolation in embryonated eggs are other possible diagnostic techniques. However, it is still imperative that other causes of abortion be ruled out before the diagnosis is made. Many older reports of Q fever abortion in goats only ruled out brucellosis.

Acute and convalescent sera showing an increase in titer are suggestive, but a titer increase is also observed in late pregnant carrier animals that do not abort. A CF

titer greater than or equal to 1:8 is considered positive by some, while others use a cut-off of 1:20. Other serologic tests include enzyme-linked immunoabsorbent assay and micro-agglutination. Even seronegative animals may shed the organism (Arricau-Bouvery and Rodolakis 2005). Serologic evidence of infection in goats is common. For instance, 24% of 1,054 goats and 26% of 234 herds in California were seropositive (Ruppanner et al. 1978). In an Ontario study, 20% (four of twenty) of herds had seroreactors (Lang 1988). Very high titers (>1:4,096) were observed in some goats in a Newfoundland farm experiencing an abortion storm and many human infections (Hatchette et al. 2001).

Treatment and Control

If Q fever is suspected, aborting goats and others in late pregnancy should be treated with tetracycline. Placentas and aborted fetuses should be destroyed, such as by burning. Abortion outbreaks observed after exposure to parturient goats at a fair underscore the need to isolate all aborting animals (Sanford et al. 1994).

Q fever abortion is usually prevented by providing good nutrition and management. This also limits environmental contamination. In private herds, prevention of the zoonotic infection is aided by pasteurization of milk and sanitation (including the use of gloves) at time of abortion or kidding. A tightly fitting particle mask should be worn when removing manure from the barn. The organism is resistant to many disinfectants, including 0.5% hypochlorite, 2% Roccal, 5% Lysol, and 5% formalin, for twenty-four hours but can be inactivated in thirty minutes by 70% ethyl alcohol or at least one quaternary ammonium compound (Scott and Williams 1990). Because the environment can remain infected for a long time and many other species can be carriers, test and cull strategies are not appropriate for infected goat herds.

Control in research herds, where government regulations may be aimed at protecting researchers, animal caretakers, and other staff, presents a special problem. Researchers seeking to assemble seronegative herds of goats on the basis of prepurchase serology find the task daunting and some believe that serologic tests are not useful for determining which animals are a current risk for transmission (McQuiston et al. 2002). Protocols for human protection have been suggested (Ruppaner et al. 1983; Behymer et al. 1985; Singh and Lang 1985) and individual universities may post their recommendations electronically. Human vaccination is routinely used for high-risk groups in Australia.

Vaccine development is progressing. An experimental model of Q fever reliably produces abortion when the goats are infected at ninety days gestation and shedding can be monitored by PCR (Arricau-Bouvery et al. 2003). A commercial vaccine using inactivated phase I *Coxiella* (Coxevac®, CEVA Santé Animal, France) protected against abortion and excretion in milk and vaginal discharges, while an inactivated phase II vaccine did not (Souriau et al. 2003; Arricau-Bouvery et al. 2005). Phase I vaccines are dangerous to produce, so subunit vaccines are being investigated (Arricau-Bouvery and Rodolakis 2005).

Brucellosis

In endemic regions (Corbel 1997) (Mediterranean countries, Middle East, India, China, parts of Latin America), herd infection may first be suspected because of an outbreak of human brucellosis (Malta fever). People become infected by direct contact with infected goats or sheep or by consuming contaminated dairy products.

Etiology

Brucella melitensis is the usual cause of brucellosis in goats, although *Brucella abortus* has been shown to infect goats both naturally and experimentally (Meador and Deyoe 1986). It is a small Gram-negative facultative intracellular coccobacillus.

Pathogenesis and Epidemiology

The organism is excreted in milk, urine, and feces and in fetuses, placenta, and (for two to three months after parturition) vaginal discharges. The organism enters other adult goats by way of the nasopharynx or by direct penetration of the skin (Alton et al. 1984). In resistant animals, macrophages in the nearest lymph node kill the organism, while susceptible animals are unable to control the infection and a bacteremia ensues, with infection of the placenta and udder. Kids born alive to infected does often are infected and capable of shedding the organism. Cows in contact with infected sheep or goats may become infected and shed the organism in milk (Godfroid et al. 2005).

Clinical Signs

When goats in an endemic herd are in a stressful environment and management is not adequate to control nutritional and parasitic diseases, then abortion will occur in the last two months of pregnancy or even earlier. A mid- to late-gestation abortion storm can be expected even in a well-managed herd when the disease is first introduced (Renoux 1957).

Diagnosis

Identification of brucellosis as the cause of abortion is usually made by isolating the organism from fetus, placenta, or vaginal discharges. Selective media are used. Gross placental lesions are not mentioned in reports of natural outbreaks in goats. A polymerase chain reaction test for the organism in milk has been used to detect carrier animals (Gupta et al. 2006).

Various agglutination, precipitation, and complement fixation tests are used to detect carrier goats (Alton et al. 1984; Mikolon et al. 1998). Agglutinins usually appear before precipitins and complement fixing antibodies. In chronic infections, sometimes only the CF test results remain positive (Waghela 1978). An allergic skin test can be used as a screening test to identify infected herds (Alton et al. 1984). The milk ring test gives poor results, even with the addition of cow cream, but a milk ELISA performs better (Mikolon et al. 1998). An agglutination test on whey is possible but not sensitive.

A recently developed indirect ELISA permits monitoring of bulk tank samples, though a maximum group size of fifty goats is suggested, to allow detection of one animal with low antibody concentration (Funk et al. 2005).

False positives occur in most tests for one year or longer after vaccination. Some tests give false-positive results because of cross reactions with antibodies against enterobacteria such as *Yersinia enterocolitica*, but a recently developed competitive serum ELISA avoids this problem (Portanti et al. 2006). Serologic tests are unreliable in young kids.

Control

In countries or regions where the prevalence of infection is very low, slaughtering the entire herd (both goats and sheep) is probably the control measure of choice. This was the method successfully used to eradicate the infection in the most recently reported outbreaks in the United States, in Texas in 1969 (Whiting et al. 1970) and 1999 (AVMA 2000). In other situations, a test and slaughter program is more appropriate (Polydorou 1979, 1984). This does, however, expose personnel testing the herd to a significant risk of contracting brucellosis (Stiles 1950). Testing of dogs in the flock during eradication programs and euthanasia of positive reactors has also been recommended.

Most countries affected with caprine brucellosis control the disease by vaccination, especially in kids and lambs three to six months of age. This procedure not only protects the livestock but also limits the infection of people in contact with the small ruminants. Unfortunately, compliance is often inadequate to achieve regional eradication, even after a vaccination program that lasts for many years (Blasco 1997). Whole herd vaccination during the lactation period may be required, though safety of vaccines in lactating goats and breeding bucks has not been studied. The preferred vaccine is *B. melitensis* Rev 1 (Gaumont et al. 1984; Alton 1987; OIE 2004). This live, attenuated vaccine is usually given subcutaneously, but conjunctival vaccination has also been investigated (Alton 1987). Rev 1 causes bacteremia but does not spread to nonvaccinates. The vaccine causes abortion, and thus

is to be avoided in pregnant goats or those within one month before mating. Immunity from a single dose is considered to be lifelong but is not absolute. Conjunctival vaccination still results in abortion and reduced dose vaccination (to avoid abortion) does not provide solid immunity (Blasco 1997). In an infected herd it is also important to decrease natural challenge by appropriate hygiene at kidding and milking time. Placentas and aborted fetuses should be burned or buried deeply. Communal pastures and importation of untested goats should be avoided.

Based on experimental work with both sheep and goats, treatment of particularly valuable animals could be attempted using long-acting oxytetracycline (25 mg/kg intramuscularly every other day for four weeks) combined with streptomycin (20 mg/kg intramuscularly every other day for two weeks). This protocol resulted in bacteriologic cure in thirty-six of thirty-six goats (Radwan 1992).

Campylobacteriosis

Etiology

Although both *Campylobacter fetus* subsp *fetus* (formerly *Vibrio fetus intestinalis*) and *C. jejuni* are common causes of abortion in sheep, campylobacteriosis is reported only rarely as a cause of abortion in goats in North America (Dobbs and McIntyre 1951; Anderson et al. 1983; Gough 1987; Moeller 2001). *Campylobacter jejuni* seems to be more common in goats than *C. fetus*. Zoonotic infections (especially diarrhea) may occur.

Clinical Signs and Diagnosis

In South Africa, where campylobacter abortion appears to be more common, as many as 30% of aborted kids have grossly visible liver necrosis. The placenta is often edematous, with necrosis of cotyledons (Van der Westhuysen et al. 1988; Moeller 2001). In one outbreak in the United States, five of twenty-one late-pregnant goats aborted and two of the does became systemically ill; *C. jejuni* was isolated (Anderson et al. 1983). The organism was later isolated from diarrheic feces in the same herd.

The diagnosis should not be difficult because many laboratories are accustomed to isolating the organism from fetal lamb abomasal contents (microaerophilic conditions required) or demonstrating Gram-negative curved organisms in smears. Thus, the paucity of reports probably indicates that this agent is of minor importance in goats, although of public health significance.

Control

In an undiagnosed abortion storm, administration of tetracycline might be expected to limit the losses if campylobacteriosis were involved, while

simultaneously being effective against several other agents. However, antibiotic resistance in *Campylobacter* spp. seems to be an emerging issue (Sahin et al. 2008). In a confirmed outbreak, vaccination of all pregnant does with an ovine bivalent *Campylobacter* bacterin is advisable. Fecal contamination of feed should be prevented and aborting animals should be isolated (Anderson 1986). As with other abortions, placentas and fetuses should be burned or buried deeply.

Leptospirosis

Etiology and Epidemiology

Several serovars of *Leptospira interrogans* have been shown to cause abortion in goats, but the prevalence of losses is unknown. In a California survey, the agent was identified in only one of 211 caprine abortion submissions to the state diagnostic laboratory system (Moeller 2001). Goats probably do not serve as primary reservoirs for leptospirosis, and infection probably occurs from exposure to an environment contaminated by urine of other species (Schollum and Blackmore 1981; Leon-Vizcaino et al. 1987). Goats experimentally infected with *L. interrogans* serovar Pomona, however, remained clinically healthy but shed the organism in their urine (Morse and Langham 1958).

Clinical Signs

L. interrogans serovar Grippotyphosa has caused severe clinical illness in goats in Israel. Signs included anorexia, marked jaundice, hemoglobinuria, abortion, and death of does (Van der Hoeden 1953). The systemic signs of leptospirosis are discussed in Chapter 7. Other does experienced inapparent infections, as determined by increased agglutination titers in the absence of overt disease. *L. interrogans* serovar Hardjo has been implicated as a cause of caprine abortions in several reports that do not present the supporting evidence (McSporran et al. 1985). *L. interrogans* serovar Pomona was identified as the cause of six abortion outbreaks (out of 262 studied) while serovar Sejroe and serovar Icterohaemorrhagiae were each associated with one outbreak in goat herds in Spain (Leon-Vizcaino et al. 1987). From 10% to 43% of pregnant does in these herds aborted. Several animals in one herd also showed fever, jaundice, and anemia.

Diagnosis and Control

The organism is difficult to isolate from contaminated specimens. Dark field microscopy, immunofluorescence testing, and silver stains on fetal fluids and tissues are used to confirm the diagnosis. Microscopic agglutination titers may be static or absent in infected animals (Songer and Thiermann 1988), assuming goats and cattle respond to infection with leptospires in a similar fashion. Paired sera showing an increase in titer after abortion would suggest association with leptospirosis. A single positive serum is of no diagnostic value, because many healthy goats are serologically positive. Vaccination twice a year is a logical prophylactic measure in regions where leptospirosis is prevalent in goats or other ruminants. Other measures recommended include separating animal species, controlling rodents, and maintaining a clean water supply (Lefèvre 1987).

Listeriosis

Listeria monocytogenes causes abortion, septicemia, and encephalitis in goats. The neurologic disease is discussed in Chapter 5.

Etiology and Pathogenesis

The organism is Gram-positive and is not acid-fast. Both short rods and coccoid elements appear in culture (Timoney et al. 1988). Virulent strains are hemolytic. Abortion strains are often serotype 1. The abortion form and the encephalitic form of listeriosis do not usually occur simultaneously in a herd. Experimental intravenous inoculation of the organism has caused a rapid drop in pregnancy-associated glycoprotein normally produced by trophoblastic cells in the placenta as well as a drop in serum progesterone, with abortion typically occurring in nine to eleven days (Engeland et al. 1997; Zarrouk et al. 1999).

Epidemiology

Listeria monocytogenes is a ubiquitous organism that may be found in soil, water, plant litter, ensiled forages, and the digestive tract of ruminants and humans (Timoney et al. 1988). The ability of the organism to multiply at cold temperatures in poor quality silages (pH levels greater than 5.5) is well known and undoubtedly contributes to the occurrence of listeriosis in goats fed silage. Silage feeding also appears to have immunosuppressive effects. Excretion of listeria by healthy animals seems to increase toward the end of gestation, presumably caused by hormonal immunosuppression (Løken et al. 1982; Grønstøl 1984).

Clinical Signs and Diagnosis

Abortion is typically preceded by listerial septicemia. Signs of septicemia may include fever and reduced appetite and milk production (Grønstøl 1984). Clinical signs are minimal or absent in other goats that abort (Sandbu 1956). Some goats recover quickly after aborting while others die. During and after the septicemic stage, goats often excrete listeria in feces and milk. Kids grafted onto the aborting doe may die of listerial septicemia contracted through the umbilicus or the milk (Grønstøl 1984). The diagnosis of septicemia may be confirmed by an increase in serum antibodies by an indirect hemagglutination technique (Løken et al.

1982). Culture of the organism from the fetus confirms a listerial abortion. Ribotyping of the isolate may be helpful in epidemiological investigations (Nightingale et al. 2004).

Prevention and Control

If silages are being fed, check the pH after mixing a sample with a small quantity of distilled water; the pH should be below 5.5. Soil contamination of the feed is another risk factor, and silages should not be made from fields with many molehills, nor should they be fed if the ash content exceeds 70 mg/kg DM (Low and Linklater 1985). Feeding poor quality or spoiled silages should be discontinued if possible. If no other forages are available on the farm, better feed should be purchased. Feeding adequate energy appears to protect somewhat against abortions associated with feeding goats aerobically-deteriorated silage from round bales (Hussain et al. 1996).

Vaccination with an aim of producing cellular immunity has been investigated. Theoretically, live vaccines should be more effective than killed preparations. Two doses of reduced virulence live vaccine before breeding provided significant protection against experimental challenge in pregnant goats (Fensterbank 1987). Administration of live vaccine to late pregnant goats has occasionally been followed by abortion, but this risk would not necessarily rule out vaccination of pregnant goats in the face of an outbreak (Guerrault et al. 1988).

Salmonellosis

Salmonella enterica serovar Abortusovis was first implicated as a cause of abortion in three- to four-month pregnant goats in Cyprus in 1932 (Manley 1932). Aborting goats showed no other symptoms of illness. Abortion with subsequent death of the doe has been produced experimentally by intravenous or oral inoculation during the last month of gestation. In-contact animals became infected and excreted the organism (Tadjebakhche et al. 1974). The organism also has been isolated from goat fetuses and placentas in France. The disease was believed to be transmitted orally to other goats at the time of abortion. Control recommendations made included injecting pregnant does with tetracycline and chloramphenicol and administering two doses of vaccine, followed by an annual booster (Yalçin and Gane 1970).

Specific agglutinins can be demonstrated in the sera of adults in the herd and in aborted fetuses (Mura et al. 1952). Only sheep and goats are affected by *S*. Abortusovis. Salmonellosis as an enteric disease of goats is discussed in Chapter 10. *Salmonella* Typhimurium and *S*. Dublin have both been associated with abortion (Lefèvre 1987). The endotoxin (lipopolysaccharide) produced by *S*. Typhimurium has been documented to cause prostaglandin release and luteolysis, thereby leading to abortion in pregnant goats (Fredriksson et al. 1985).

Toxoplasmosis

Etiology

The protozoan *Toxoplasma gondii* is a very important cause of abortion, mummification, stillbirth, and birth of weak young in goats as it is in sheep.

Epidemiology and pathogenesis

Cats serve as the definitive host for this parasite (Buxton 1998); they become infected by consuming uncooked meat scraps, placentas, and small rodents (Dubey 1986). Recently infected cats then shed oocysts in their feces. Oocyst shedding typically lasts from three to nineteen days, but oocysts may persist in moist and shaded soil for as long as eighteen months (Frenkel 1982).

Goats become infected by eating grass, hay, or grain contaminated by cat feces. After initial invasion of the goat's small intestine and associated lymph nodes, the *Toxoplasma* organisms spread via the bloodstream to other tissues, including muscle, brain, and liver. Here the parasite may remain encysted for months or even the life of the goat. If the goat is pregnant at the time of initial infection, *Toxoplasma* commonly invade the placenta and fetus approximately two weeks after initial infection of the doe. Fetuses infected in the first half of pregnancy are more apt to die than fetuses infected in the second half. Sometimes abortion is repeated in the next gestation (Dubey 1982), but previously infected goats are usually resistant to abortion or other clinical signs when challenged with *T. gondii* (Obendorf et al. 1990).

Diagnosis

Fetal serology is a very specific test for abortive toxoplasmosis (Munday et al. 1987). The ovine fetus (and presumably the caprine fetus) begins to develop immunocompetency at sixty to seventy days of gestation. First immunoglobin M is produced, but by ninety days immunoglobin G is being synthesized. Thus, if the fetus is infected after midgestation, it will usually produce antibody detectable by a variety of immunologic tests (Dubey 1987; Wilson et al. 1990). A modified direct agglutination test (MAT) is considered to be very sensitive and can be used on any species, including goats, because species-specific conjugates are not used (Dubey et al. 1987). The antigen for the MAT, however, is not yet marketed in the United States (as of 2007).

Heart blood or thoracic fluid can be harvested from the fetus. Fetal autolysis does not always preclude

identification of toxoplasma antibodies. Absence of antibodies in the fetus does not rule out toxoplasmosis because the fetus may have been infected too young or antibodies may have decomposed. Screening at both high and low dilutions is recommended to avoid false negatives when the antibody concentration is so high as to occupy all binding sites (prozone effect).

Serologic testing of the doe at time of abortion is useful. Absence of antibodies is considered to be conclusive evidence that toxoplasmosis was *not* the cause of abortion (Figure 13.5). An increasing titer would at least indicate recent infection, but a stable, even high titer can persist for months or even years after initial infection of the doe. Thus, a high titer in the dam is not proof of abortion caused by toxoplasmosis (Gunson et al. 1983).

Large surveys of goats in the western United States have revealed a seroprevalence of 20% or more in yearlings or older goats (Dubey and Adams 1990), while fifty-four of ninety-nine does (55%) on nine farms in or near Tennessee were positive by indirect hemag-

Figure 13.5. Aborted twin Boer kids. The upper fetus was alive at delivery while the lower fetus had been dead long enough to begin to mummify, as demonstrated by the sunken eye sockets. Although these findings were suggestive of toxoplasmosis, the dam was serologically negative, ruling out toxoplasmosis as the cause of abortion. (Courtesy Dr. M.C. Smith.)

glutination (Patton et al. 1990). In a study in Ontario, Canada, 63% of 399 sera tested positive (1:16 or greater) by the Sabin-Feldman dye test (Tizard et al. 1977). In a serological survey conducted in Turkey, 51% of 170 goats (mostly Angoras) were positive at 1:4 or more in the Sabin-Feldman dye test and 25% were positive at 1:16 or more (Weiland and Dalchow 1970). The Sabin-Feldman dye test uses intact parasites as antigen and requires maintenance of live organisms. Enzyme-linked immunoabsorbent assay tests, which are easily automated and use soluble antigens from disrupted toxoplasma organisms, have become more popular (Denmark and Chessum 1978; Buxton 1998). Other serologic tests currently used include the indirect haemagglutination test, indirect immunofluorescent antibody test, and latex agglutination test (Buxton 1998).

If the diagnosis is to be made by histology, it is very important that placenta be submitted. Small yellowish-white foci of mineralization confined to cotyledons are apparent grossly if abortion is delayed until forty-five days or more after infection. Washing the cotyledons thoroughly in isotonic saline solution makes deeper foci easier to visualize. Another useful technique is to compress the cotyledon with a glass microscope slide; the mineralized foci resist squashing. Microscopic foci of necrosis can be identified after thirty days; tachyzoites are sparse in these lesions and difficult to locate (Dubey 1988). Nonsuppurative encephalomyelitis is found more consistently than myocarditis, but even under ideal experimental conditions it is difficult to find *T. gondii* organisms in tissue sections. Very careful histologic examination or immunohistochemistry distinguishes *Toxoplasma* from the far less common *Neospora* infection (Dubey et al. 1992).

Prevention

The control of toxoplasmosis can be approached in several ways. The first is to prevent exposure of susceptible goats to the oocysts in cat feces during the period of danger, which is pregnancy. In particular, grain should be stored in covered containers and the mangers kept clean. Contamination of the hay supply (by cats living in the hay barn) has been implicated in several outbreaks (McSporran et al. 1985; Nurse and Lenghaus 1986). If possible, feed the hay off the top of the stack to the nonpregnant does and young stock. Because exclusion of all cats from a farm is very difficult, it is usually suggested to maintain a stable population of adult neutered cats; kittens younger than six months of age are far more apt to shed oocysts than are adults. A vasectomized tomcat might be helpful in keeping stray cats off the farm, but this technique has not been evaluated. Raw meat should not be fed to cats.

Exposure of doelings to a contaminated environment (buildings where feral cats live or pastures spread with manure from such buildings) before breeding to develop protective immunity might be effective (Buxton 1998). Rubbing their noses with placentas from aborted fetuses has been suggested as one way of infecting doelings (Delahaye 1987), but this is ill-advised if other causes of abortion such as chlamydiosis were active in the herd. In the milking herd this would increase the risk of acute shedding of toxoplasmosis in milk.

A live toxoplasmosis vaccine available for sheep in the UK might be effective in goats (Chartier and Mallereau 2001) but will probably never be licensed in the United States because it is infective to humans. Repeated administration of killed vaccine or vaccination with a related but nonpathogenic organism (*Hammondia*) might be effective in preventing abortion (Dubey 1981; Munday and Dubey 1988) but would certainly be expensive; such vaccines are unlikely to be marketed in the near future. Chemoprophylaxis by feeding ionophores such as monensin during pregnancy, at the normal anticoccidial rate, initially showed promise (Blewett and Trees 1987; Buxton et al. 1988). However, fatal mixing errors may occur with ionophores. Daily decoquinate at 2 mg/kg bodyweight is a safer drug to try and is licensed in the UK for controlling toxoplasmosis in sheep (Buxton 1998).

When abortions caused by toxoplasmosis are diagnosed, emphasis should be put on properly disposing fetuses and placentas, wearing protective gloves when handling these items, and properly pasteurizing milk and cooking meat. Pregnant women should be especially careful.

Miscellaneous Infections

Other infections that induce a febrile response or generalized illness may cause abortion in does. One such agent is foot and mouth disease, as described in Chapter 4. Others that lead to occasional abortions are described below.

Bluetongue

Bluetongue is an infectious, noncontagious disease of ruminants, especially sheep, caused by an orbivirus and transmitted by *Culicoides* midges. The disease occurs in North and South America, Africa, the Middle East, Asia, and recently in northern Europe. Abortion and birth of malformed lambs are common in sheep. Goats are frequently infected in endemic regions, as evidenced by serologic surveys (Lefèvre and Calvez 1986; Flanagan 1995; Ting et al. 2005), but clinical signs are rarely recorded (Van Tonder 1975). Thus, bluetongue is unlikely to be the cause of abortions in goats. See further discussion of bluetongue in Chapter 10.

Border Disease

Border disease of sheep is caused by a pestivirus serologically similar to bovine virus diarrhea (BVD) virus, and BVD strains isolated from cattle can also produce disease in small ruminants. The disease has been under diagnosed in the past because early work concentrated on neurologic and fleece changes in lambs infected in utero. As the pathogenesis of the disease became clearer, in conjunction with important discoveries relating to BVD virus, it was learned that lambs infected in utero often remain persistently infected for life. Some fail to thrive, but others are silent carriers and shedders of the virus and can introduce the disease into other flocks. Infected ewes regularly produce persistently infected lambs. Also, some strains of the virus apparently do not produce neurologic and fleece changes (Bonniwell et al. 1987).

Spontaneous border disease (tremors, no hair coat changes) has been reported only rarely in goats (Løken et al. 1982; Løken 2000). Of three goats in Norway that seroconverted during pregnancy (out of 145 experiencing gestation failure and being sampled twice), one had an apparent false pregnancy while the other two each produced a normal and a weak-born kid (Løken 1990). Additionally, an experimental contagious ecthyma vaccine contaminated with a noncytopathic pestivirus was associated with reproductive failure in 213 of 261 goats vaccinated early in pregnancy (Løken et al. 1991) but no kids with border disease were born. A BVD type 2 virus was isolated from goats in a Korean herd experiencing abortions, stillbirths, and neonatal deaths (Kim et al. 2006). Nonpregnant goats exposed on pasture to calves persistently infected with BVD seroconverted rapidly, with ten of ten positive within six weeks (Broaddus et al. 2007).

Border disease has been experimentally reproduced in goats by inoculation of tissues of affected sheep; abortions and ataxic or shaker kids have been produced (Huck 1973; Barlow et al. 1975). In another study, intramuscular inoculation of a cytopathic bovine strain of BVD virus to does approximately forty days in pregnancy resulted in partial resorption of the fetuses and presence of 1 to 1.5 liters of fluid (hydrometra) in the uterus on slaughter at four months after breeding. Kids were clinically normal when infection occurred at one hundred days (Løken 1987). In a later study comparing a border disease strain and a BVD strain, results were similar in both groups, and all goats inoculated around forty days experienced reproductive failure. At least two viable kids were produced from later inoculations that were persistently infected (Løken and Bjerkås 1991). Some aborted and weak kids had presuckle antibodies. In another study, kids that survived experimental infection during gestation were not persistently infected (Depner et al. 1991).

Placental lesions, including multiple pinpoint foci of necrosis in the cotyledons, resemble those of toxoplasmosis (Barlow et al. 1975; Løken 1987). Birthcoat changes have not been reproduced experimentally in goats (Orr and Barlow 1978).

Caprine Herpesvirus

This agent causes a generalized infection in kids and adult goats, but not in lambs or calves; it is discussed in detail in Chapter 12. A diphasic fever has been observed in adults and may contribute to the occurrence of abortion. Fetuses aborted from experimentally infected does were passed in a very autolytic state three to eight weeks after infection in one study (Berrios et al. 1975). In another study, fetal death occurred by four days after inoculation in one goat and the fetuses were harvested by cesarean section the next day while abortion occurred in the other inoculated doe on day seven without previous ultrasonographic evidence of fetal death. Virus was recovered from the fresh placentas and from one fetal lung, but maternal rather than fetal infection was believed to be the cause of fetal death (Waldvogel et al. 1981). More recently, the caprine herpesvirus has caused cross-placental infection and death of neonates in conjunction with abortion storms. Fetal infection has been confirmed by PCR in aborted fetuses (Keuser et al. 2002; Chénier et al. 2004) and neonates (Roperto et al. 2000), and foci of coagulative necrosis with intranuclear inclusion bodies may be found in numerous tissues, including the liver and thymus (Williams et al. 1997; Chénier et al. 2004; Uzal et al. 2004; McCoy et al. 2007). Viral isolation is difficult if the fetus is autolyzed (Tempesta et al. 2004). A marked increase in serologic titer of the dam to the caprine (not bovine) herpesvirus would be strongly suggestive of the diagnosis.

In one follow-up study of a meat goat herd that experienced a caprine herpesvirus abortion storm, there were no reproductive repercussions the following year. Many does that aborted rebred in the same season, and kids born from these does and from does that were infected but did not abort during the initial outbreak remained seronegative ten months later (McCoy et al. 2007).

Nairobi Sheep Disease

Nairobi sheep disease is a noncontagious tick-transmitted bunyavirus of small ruminants (Terpstra 1990). The virus has been found especially in Kenya but also in other parts of East and Central Africa. Signs are more severe in sheep than goats and include fever, hemorrhagic gastroenteritis, abortion, and increased mortality rates. Histologically, glomerulo-tubular nephritis is present (Mugera and Chema 1967). Tick control and prophylactic vaccination could be recommended but are not warranted for controlling Nairobi

sheep disease in enzootic areas, except when susceptible animals are introduced (Davies and Terpstra 2004). The disease is discussed in Chapter 10.

Peste des Petits Ruminants

Peste des petits ruminants is a morbillivirus infection of goats and sheep in Africa, the Middle East, and Asia. Signs include stomatitis, diarrhea, pneumonia, and a fever that persists for five to eight days. Pregnant animals may abort. The disease is discussed in Chapter 10.

Rift Valley Fever

Rift Valley fever is a mosquito-borne bunyavirus disease of ruminants and humans in Africa (Yedloutschnig and Walker 1986; Kasari et al. 2008) and is described in detail in Chapter 11. Abortion may come after fever and viremia in adults (Daubney et al. 1931). Goats are generally more resistant than sheep or cattle (Erasmus and Coetzer 1981) and show a lower abortion rate. Very young kids also may die. Hemorrhages and hepatic necrosis are found at necropsy. Because serious human infection also occurs, abortion samples should be collected carefully. A modified live virus vaccine produces lifelong immunity but must not be given to pregnant sheep or goats, because it produces fetal malformations, especially of the brain (Bath and de Wet 2000).

Wesselsbron Disease

Wesselsbron disease is a mosquito-borne flavivirus disease of sheep, cattle, and goats. It is restricted to sub-Saharan Africa and may cause abortion in pregnant does (Van Tonder 1975; Van der Westhuysen et al. 1988) and ewes and neonatal mortality. Seroconversion of the aborting doe can be used for diagnosis (Mushi et al. 1998). Adult nonpregnant does rarely show any signs except fever. Differentiation from Rift Valley fever is described in Chapter 11. Live virus vaccines against both of these diseases can cause abortion if given during pregnancy. A low incidence of congenital anomalies (i.e., arthrogryposis, porencephaly, hydranencephaly, cerebellar hypoplasia) is reported in sheep infected with Wesselsbron disease but apparently not documented in goats, perhaps because goats are not numerous in the areas of virus activity.

Mycoplasmosis

Numerous *Mycoplasma* species have been isolated from goats and associated with specific clinical syndromes discussed elsewhere in this text (i.e., arthritis, keratoconjunctivitis, mastitis, pneumonia). Abortions occasionally occur during outbreaks of mycoplasma-induced disease but documentation that mycoplasms caused these abortions is often lacking. For instance,

an abortion rate of 80% was reported in a pen of fifty goats during an outbreak of mastitis and arthritis caused by *M. putrefaciens* (DaMassa et al. 1987). In another outbreak, however, transplacental infection was documented by the birth of weak kids already demonstrating swollen joints from which *M. mycoides* subsp. *mycoides* was isolated (Bar-Moshe and Rapapport 1981).

Yersiniosis

Yersinia pseudotuberculosis is a zoonotic bacterium commonly carried by wild birds or rodents. Fecal-oral infection of goats can result in establishment of an enteric infection with subsequent bacteremia. Abortions and early neonatal deaths of kids have been reported (Sulochana and Sudharma 1985; Witte et al. 1985; Albert 1988). Opaque white foci were seen in cotyledons, and microscopic lesions included suppurative placentitis and suppurative pneumonia (Witte et al. 1985). Tetracycline may be useful for halting an abortion storm.

Tick-borne Fever

Anaplasma phagocytophilum (formerly *Ehrlichia*, *Cytoecetes*, *Rickettsia phagocytophila*) causes a mild to acute, noncontagious disease of sheep, goats, and cattle in the United Kingdom, Europe, Africa, and India (Baas 1986). Although the organism is considered to be a common tick-borne zoonotic agent in the United States, reports of clinical disease in goats in this country are lacking. Natural transmission requires ticks such as *Ixodes ricinus* or *Rhipicephalus haemaphysaloides*, but the disease can be spread by anything that transfers blood. Signs include fever, listlessness, decreased milk production, lameness, and abortion. Secondary infections with *Staphylococcus*, *Pasteurella*, *Listeria*, and other organisms occur commonly and may contribute to abortion.

Diagnosis is by demonstration of cytoplasmic inclusions in granulocytes and monocytes in the blood and by complement fixation tests. The inclusions are grayish-blue in Giemsa-stained blood smears, which should be made as soon after abortion as possible. The organism does not invade the fetus, and thus smears of fetal tissue are not helpful (Scott 1983). Tetracycline is used for treatment (Anika et al. 1986). Pregnant animals should not be placed on pastures heavily infested with ticks. Pasture exposure of kids may prevent later economic losses from decreased production of milking goats (Melby 1984).

Anaplasmosis

Anaplasma ovis infection in goats usually causes a subclinical, mild, febrile disease. However, Boer goats in semi-arid regions of South Africa that had to walk long distances for food aborted and aborting does had low hematocrits. Organisms were found in the red blood cells of these goats. Ten of twenty experimentally infected pregnant goats aborted or resorbed their fetuses under conditions that included driving them 800 meters twice a day (Barry and van Niekerk 1990). Goats showed respiratory distress and pulmonary edema when driven. The average peak in body temperature was 2°F (1.1°C) above pre-infection levels and the mean hematocrit dropped from 30% to 22% at the peak of parasitemia, with the lowest recorded hematocrit being 10%. Transplacental infection occurred; *A. ovis* organisms were observed in red blood cells of aborted and live born kids. Means of control of this tick-borne infection, which is usually subclinical, are yet to be determined.

Neosporosis

Neospora caninum is a protozoal parasite similar to *Toxoplasma gondii* that can cause abortion in goats. Cattle are more commonly affected. Whitetail deer may be involved in a sylvatic cycle and dogs and coyotes have been identified as definitive hosts (Gay 2006). Experimental infection of pygmy goats has produced resorption, abortion, and stillbirths (Lindsay et al. 1995). Diagnosis is by isolation from the placenta or by histology and immunohistochemistry, which distinguishes *Neospora* from *Toxoplasma* infection (Dubey et al. 1992). Lesions in the fetal brain include meningoencephalitis with necrosis, gliosis, perivascular cuffs, and protozoal tissue cysts approximately 10 µm in diameter (Dubey et al. 1996). Hydrocephalus and cerebellar atrophy were seen in this case. Diagnosis by PCR is also possible (Eleni et al. 2004). Few serologic surveys have been done, but prevalence of antibodies was only 1% to 2% in dairy goats in western France (Chartier et al. 2000).

Sarcocystosis

Sarcocystis is a genus of cyst-forming protozoa. Cysts are frequently noted as an incidental finding on histological examination of cardiac and skeletal muscle of many species. In a New Zealand study, sarcocysts with mean cross-sectional diameters of 69 × 54 microns were found in 28% of samples from diaphragms of feral goats. When muscle from goat carcasses was fed to dogs and cats, only the dogs shed sporocysts in their feces (Collins and Crawford 1978). Experimental inoculation of goats seventy-five to 105 days pregnant with 10,000 sporocysts from coyote feces and believed to be *Sarcocystis capracanis* resulted in illness and abortions. Because no *Sarcocystis* meronts were found in the placenta or fetuses, the abortions were probably an indirect result of acute sarcocystosis. Naturally occurring abortion caused by sarcocystosis has been reported once in goats (Mackie et al. 1992; Mackie and Dubey 1996).

LATE ABORTION: NONINFECTIOUS CAUSES

Although multiple late abortions suggest the presence of one or more infectious agents in the herd, nutritional, hereditary, and toxic etiologies should not be overlooked. In addition, inadequate nutrition increases the prevalence of abortion caused by infectious agents such as Q fever and others that compromise placental function.

Malnutrition, Stress, and Other Environmental Factors

Stress abortions are common in undernourished Angoras on range and are occasionally seen in other breeds in the United States. When inadequate energy or protein is fed in late gestation, kids may be aborted or stillborn or born alive but small or weak. Colostrum and milk production may be inadequate for survival of the live-born kids. If the major deficiency is one of energy, pregnancy toxemia is likely to occur in does carrying multiple fetuses. If just protein is lacking, the does may not be thin or ketotic. Reduction in the size of the thymus has been proposed to be an indication of a stress abortion.

The underlying cause in a nutritional abortion outbreak may be poor quality (grass) roughage, inadequate feeder space, or very cold weather. Young, undeveloped females should not be bred if feed conditions are unlikely to permit them to complete gestation successfully.

An epidemiologic study of twenty-two dairy goat herds in Norway revealed fetal loss in 11% of the 1,439 goats, with losses in individual herds varying from 3% to 38%. In almost all herds there was no evidence of infectious disease. Decomposed fetuses were typically expelled during the last two months of pregnancy, and mature does (at least three years old) were at greatest risk. Inadequate natural lighting in the barn, more goats per pen, and less floor space per goat were identified as possible risk factors. Progesterone and cortisol were normal before abortion but estrone sulfate was reduced, suggesting placental malfunction (Engeland et al. 1998, 1999).

Inherited Abortion of Angoras

In South Africa, where selection for fine quality mohair has been intense, a genetic habitual abortion problem has been identified in older does (Van Rensburg 1971b; Van Tonder 1975).

Pathogenesis and Clinical Signs

The newborn doe kids destined to become habitual aborters (and the buckling that carries the trait) are above average in weight and have a very fine hair coat.

As the animals mature, they produce higher-than-average mohair yields because of decreased adrenal function. The doelings show heat and conceive better in the first breeding season. The apparently desirable offspring of the first few pregnancies are kept for breeding, thus perpetuating the trait in the herd.

Habitual abortion usually does not appear until does reach four or five years of age. Animals with the greatest mohair production relative to body size tend to abort at approximately one hundred days gestation, a time when fetal growth rate increases but placental growth ceases. Adrenal malfunction is involved. Death of the fetus apparently occurs because of placental insufficiency (Van Rensburg 1971a). Luteal function is not impaired, and dead edematous fetuses may be retained for days or weeks. Stresses such as inclement weather, shearing, and dipping promote the expulsion of dead fetuses, causing an apparent abortion storm in the herd.

The older aborter develops both pituitary and adrenal hypertrophy, which are believed to be compensatory for previous adrenal insufficiency. These does have short estrous cycles and a lowered conception rate. A decreased amount of finer mohair is produced. Some of these does show other external evidence of hyperadrenalcorticism, such as muscle wasting and abdominal distension.

Prevention of Habitual Abortion

Mature does that abort or fail to conceive should be removed from the breeding flock. This policy has been shown to decrease the frequency of abortion in Angora herds (Van Heerden 1964). However, under certain nutritional and environmental conditions, progress in decreasing the flock abortion rate is minimal (Van der Westhuysen and Wentzel 1971). The previous offspring of aborters should also be culled. Breeding males in particular should be selected from older does with no history of abortion.

In addition, adequate dietary energy should be supplied for pregnancy maintenance, because both the habitual aborters and "normal" Angoras are more apt to abort if underfed. If a correct diet cannot be supplied, provision of shelter reduces the abortion rate in times of cold weather (Van der Westhuysen and Roelofse 1971). In Mexico, producers associate cold and rainy weather with abortion in dairy goats, often primiparous animals. A greatly increased maternal cortisol level has been documented to precede some of these abortions (Romero-R et al. 1998).

Vitamins and Minerals

A severe vitamin A deficiency (caused by six months on dry pasture without green grass) was implicated as the cause of thirty-two abortions in a goat herd in

Brazil (Caldas 1961). Vitamin A concentrations were undetectable in aborting does.

Selenium deficiency can be a cause of abortions and stillbirths in localities where feedstuffs are low in this mineral. Manganese, iodine, and copper deficiencies have also been shown to cause abortions and weak kids (Anke et al. 1972, 1977; Hennig et al. 1972; Singh et al. 2003). Some aborted fetuses are mummified when does are fed copper-deficient rations. If copper deficiency (or molybdenum or sulfur excess; see Chapter 19) is the cause of abortion or stillbirth in the second to fifth month of pregnancy, some kids in the flock might be expected to be born with weakness or swayback, as described in Chapter 5. Demyelination of white matter in spinal cord and brain has been observed in fetuses aborted due to copper deficiency (Moeller 2001). Liver copper concentrations should be determined to verify the diagnosis. One herd of African dwarf goats experienced 54% loss by two weeks of age until pregnant does were supplemented several times with 10 ml of a 2% solution of copper sulfate (Senf 1974). If iodine deficiency has caused stillbirths, affected kids usually have goiters. Conversely, however, goitrous kids in endemic iodine-deficient areas might be aborted in response to an additional etiologic agent (Wilson 1975).

When goats are kept for several generations under conditions of a trace element deficiency, such as manganese, there is selection for animals that are less susceptible to the deficiency (Hennig et al. 1972). This means that imported goats may show abortions and stillbirths under conditions that permit native goats to reproduce successfully.

Toxic Plants

Several toxic plants have been associated with abortion or birth defects in goats, including *Gutierrezia* spp. (broomweed) (Dollahite and Allen 1959; Dollahite et al. 1962; Gardner et al. 1999), *Astragalus lentiginosus* (Furlan et al. 2007), *Lupinus formosus* (Panter et al. 1992), *Conium maculatum* (Panter et al. 1990), *Nicotiana tabacum* (Panter et al. 1990), and *Veratrum californicum* (Binns et al. 1972) in the United States. Ponderosa pine (*Pinus ponderosa*) does not cause abortion when fed experimentally to goats (Short et al. 1992). The normally nutritious pods of the *Acacia nilotica* tree in South Africa cause abortion and methemoglobinemia when large amounts are consumed (Terblanche et al. 1967; Kellerman et al. 2005). Experimental oral administration of *Claviceps purpurea* sclerotia (ergot) has caused abortion and fetal mummification (Engeland et al. 1998). Additional plants are documented to cause congenital defects in sheep: *Astragalus* (abortions and limb defects), *Lathyrus*, and *Sophora* (limb defects) (Szabo 1989). Akabane virus and Cache Valley virus produce similar malformations.

Drugs

The pharmacokinetics of a few drugs have been studied in pregnant goats (Davis and Koritz 1983). In does pregnant 110 to 115 days, three fetuses were aborted from seven does given 4.4 mg/kg chlorpromazine intravenously. These fetuses showed histologic evidence of major liver damage. When phenylbutazone was given intravenously to six does at 33 mg/kg at the same stage of gestation, two kids had renal insufficiency and histologic kidney lesions after birth.

Anthelmintics, because of their frequent use during pregnancy, and corticosteroids have been implicated as causes of abortion.

Phenothiazine

Abortions have been observed in sheep and goats given phenothiazine as an anthelmintic in the last month of pregnancy (Osweiler et al. 1985). Photosensitization and associated bilateral keratitis may also occur and are well documented to be caused by phenothiazine.

Levamisole

Levamisole (the levo-isomer of tetramisole) is an anthelmintic that has been used extensively in goats, although it is not approved for this purpose in the United States. Word of mouth reports of abortions in goats have led to a general, conservative recommendation that the drug not be used in late pregnancy (Guss 1977). These abortions have not been reproduced experimentally. Likewise, tetramisole did not cause abortion in Angora goats (Philip and Shone 1967). More recently, a possibly genetic polymorphism in the metabolism of levamisole (mediated by hepatic P450 isozymes) has been identified (Babish et al. 1990). The greatly prolonged half-life of levamisole in some goats might contribute to occasional toxicity, or the temporal association of abortion after levamisole administration might be caused by chance alone.

Corticosteroids

Corticosteroids are sometimes administered for an anti-inflammatory effect to goats with infectious disease or with injuries. This should be avoided during the last month of pregnancy. The intentional use of drugs to induce parturition is discussed below.

INDUCED ABORTION OR PARTURITION

Induction of abortion or parturition is easily accomplished in the doe.

Indications

Management errors and eager bucks often result in the natural breeding of goats that the owner did not

wish to become pregnant. Sometimes the problem is a buckling that is left with females past puberty or that is incompletely castrated. Frequently, a mature buck gains access to does that are considered too young or have been retained for breeding at a later time or to a different buck. Unless close examination of the buckling reveals that his urethral process is still adhered to the prepuce, effectively preventing intromission, the exposed females are usually treated with prostaglandin (see below) without waiting to confirm that pregnancy has been established.

Owners or veterinarians may desire to induce parturition in goats for a variety of reasons. Disease or injury to the doe may make survival to term and completion of normal parturition unlikely. Pregnancy toxemia appears to fit in this category, but cases must be evaluated carefully. As discussed later, early pregnancy toxemia responds to medical treatment, assuming underlying causes of anorexia can be resolved. Goats with advanced pregnancy toxemia commonly die before the hormonal sequence of events culminating in induced parturition can be completed (often thirty-six to forty-eight hours in a sick doe). These animals require surgical intervention.

Fractures, arthritis, and laminitis may be easier to manage if the goat can be relieved of the weight of fetus, placenta, and associated fluids. If a disease or injury in the late pregnant doe is expected to interfere with feed consumption for several days, (induced) parturition may prevent the otherwise inevitable development of pregnancy toxemia.

Another very important indication is the convenience of predicting the time of parturition. Owners may wish to be present to offer assistance to a primiparous or aged doe. Even more commonly, disease control programs may require rapid removal of the newborn to a clean isolation area so that exposure to disease organisms that the dam might be carrying can be limited. Included here are colostral and milk-borne diseases (CAE, mycoplasmosis), fecally transmitted diseases (paratuberculosis, intestinal parasites), and other conditions that might be contracted while the newborn kid is searching for the udder (caseous lymphadenitis, demodecosis). Hormonal induction of parturition permits the scheduling of most births for daytime or even weekend hours.

Drugs Used

The normal sequence of hormonal events in the initiation of parturition has been described as beginning with an increase in fetal cortisol, which increases placental secretion of estrogen. As maternal estrogen concentrations rise, the uterus produces prostaglandin F2 alpha, which causes luteolysis and a drop in progesterone. High estrogen and low progesterone levels together permit uterine contractions to occur and labor begins (Flint et al. 1978). There is a final surge of prostaglandin in the last few hours before delivery (Umo et al. 1976).

Historically, three classes of drugs have been used to induce parturition.

Corticosteroids

Corticosteroids (e.g., dexamethasone, 20 to 25 mg) act by increasing placental estrogen synthesis. Generally, the fetus and placenta need to have reached a stage of maturity where placental C21-steroid 17alpha-hydroxylase activity can be induced (Flint et al. 1978). This is approximately the same stage of maturity required for survival of the fetus, or roughly 141 days. Younger fetuses may fail to respond, which may be desirable if fetal survival is important, or undesirable if rapid termination of pregnancy is imperative. The average time to parturition in goats receiving corticosteroids has not been well characterized, but is approximately forty-four to forty-eight hours in animals close to term. In one study in which four does received 20 mg dexamethasone ten days before their due date, the average time to delivery was fifty-five hours (Jain and Madan 1982, 1989). By comparison, methylprednisolone acetate (240 to 270 mg) on day 111 or 125 of gestation caused abortion in six days (Van Rensburg 1971b).

Estrogen

The second group of hormones to be used is estrogens (e.g., estradiol 17-beta, 16 mg). The time to parturition is similar to that for corticosteroids, but abortion of nonviable kids can be expected if treatment is attempted too early in gestation. In a study of thirty-six goats each given two doses of estradiol benzoate (15 or 25 mg on days 147 and 148), most of the does kidded on day 149, but five of the does receiving the higher dose did not conceive in the next season (Bosc et al. 1977).

Prostaglandin

Currently, the most popular means of ending pregnancy is prostaglandin. Because the goat depends on progesterone from corpora lutea to maintain pregnancy (the placenta does not produce progesterone), prostaglandins are theoretically effective at all stages of gestation past day five. Thus, if a "buck escape" occurs, all does for which breeding was not desired can be treated with 5 mg prostaglandin F2 alpha seven to ten days later. Attention must be given to adequate buck restraint when many does return to estrus simultaneously two days after prostaglandin treatment. Because the occasional doe is not aborted by this treatment, a second dose of 5 to 10 mg might be given to animals not seen to return to estrus. In a study involving does that were approximately three months

pregnant, two doses of 5 mg of prostaglandin F2 alpha twenty-four hours apart resulted in abortion between thirty-four and eighty-one hours after the first injection. Retained placenta occurred in thirty-one of forty-one does thus aborted (Memon et al. 1986b). Thus, abortion in midgestation using prostaglandin appears to take longer than induction of parturition at term. In addition to the increased risk of retained placenta, there are anecdotal reports of difficulties rebreeding in the same breeding season does thus aborted.

The owner who plans to induce parturition (as for CAE control) must faithfully record all breeding dates and prevent later reexposure to a buck. Alternatively, biparietal diameter of the fetuses can be determined by real-time ultrasound, as described above, to date the pregnancy. Injection should not be performed until day 144 of gestation or later because triplets or quadruplets may be so small as to have reduced viability (Williams 1986b). Corticosteroid pretreatment twelve to twenty-four hours in advance may hasten lung maturation and improve viability if early induction is necessary.

There is some question as to the dose of prostaglandin required. Doses of prostaglandin F2 alpha (Lutalyse, Pfizer) as small as 2.5 mg might be expected to work, but several authors have suggested that higher doses (up to 20 mg) narrow the time period when parturition is expected to occur (Bretzlaff and Ott 1983). Reported studies have involved too few goats to justify this conclusion. Many producers use 7.5 to 10 mg, given intramuscularly in the morning, with most parturitions expected the next day, twenty-nine to thirty-six hours later. If the prostaglandin is given in the evening, a similar interval to parturition results, such that the kids are delivered during the night (Romano et al. 2001). An appropriate dose of the synthetic prostaglandin cloprostenol (Estrumate, Haver) is 62.5 to 125 µg (Williams 1986b) or 150 µg (Maule Walker 1983). A Brazilian study documented that 75 µg was an adequate dose, as 100 µg did not improve the response (Santos et al. 1992). Fenprostalene has been used successfully at 0.5 mg subcutaneously, with a mean interval to kidding in eleven does of thirty-two hours (Haibel and Hull 1988).

Retained placenta and sometimes metritis have been reported after prostaglandin-induced parturition (Bosu et al. 1979; Maule Walker 1983), but are not common in the experience of other researchers (McDougall 1990; Romano et al. 2001) or owners who routinely induce parturition in their does. In one report from New Zealand, cloprostenol was administered to 360 pregnant goats. Fourteen of them died with *Clostridium chauvoei* infection and toxemia, though they did not have retained placenta. The authors recommended that clostridial vaccination be given before abortion is induced (Day and Southwell 1979).

Experimental Techniques

In herds in which exact breeding dates are not known, it may still be desirable to have parturitions occur during the day. Observation, assistance in case of dystocia, and proper identification or early removal of kids are all simplified. Other approaches might be applicable when prostaglandin cannot be used to safely modify the time of parturition. Two techniques that have been tried on sheep are controlling the time of feeding and administering a tocolytic drug to delay parturition. Thus, sheep fed once a day tend to lamb during the period from four hours before to eight hours after feeding (Gonyou and Cobb 1986). Clenbuterol (0.2 mg per ewe) delayed parturition for ten hours or more in most ewes judged to be very near to lambing (Plant and Bowler 1988), but use of this drug is forbidden in the United States. Because kidding occurs naturally during the day (Bosc et al. 1988), these techniques have received little attention in goats.

PARTURITION

The average gestation length of the goat is 150 days. There is a tendency for goats bearing triplets to kid slightly earlier (149 days) than goats with single kids (151 days) (Peaker 1978). Doe kids tended to be carried one day longer than male kids in one study (Amoah and Bryant 1983). One Mexican study of 1,468 pregnancies showed breed effects on gestation length as well as advantages to kid survival of a longer gestation, because of increased birthweight (Mellado et al. 2000). The birthweights of twins and triplets are approximately 0.91 and 0.82 of the weight of a single dairy goat kid. Parturition in the doe is termed kidding. Births are concentrated during the daylight period with a maximum at midday and early afternoon in stabled goats (Lickliter 1984/85; Bosc et al. 1988).

Normal Parturition

Signs of impending delivery include relaxation of the pelvic ligaments at the base of the tail, separation from the herd and defense of the area chosen for giving birth, increased restlessness (up and down, pawing), and low pitched vocalizations with closed mouth. For the actual delivery of the kids, the doe lies down next to a vertical surface such as a wall, fence, or feed trough (Lickliter 1984/85). The doe should be left undisturbed and in its natural surroundings, to avoid interfering with normal delivery.

Parturition is traditionally divided into three stages. First stage labor, when the cervix softens and relaxes and uterine contractions force placenta, fetus, and fluids against the cervix to help dilate it, lasts up to twelve hours in primiparous does (Bliss 1988). Multiparous does typically proceed faster. Second-stage labor, which is accompanied by straining (contraction

Figure 13.6. Postpartum doe with lochia adhering to the tail. (Courtesy Dr. M.C. Smith.)

Figure 13.7. Meconium staining of the mucus indicates fetal distress and need for intervention. (Courtesy Dr. M.C. Smith.)

of abdominal muscles), typically lasts two hours or less and is completed by expulsion of the last kid. The third stage involves expulsion of the placenta (normally within four hours) and involution of the uterus. Lochia, which should not have a foul odor, is normally discharged for as long as three weeks (Wittek and Elze 2001). Owners may choose to clip or wash the tail to prevent unsightly accumulation of lochia (Figure 13.6). Macroscopic involution of the uterus is complete in approximately four weeks (Greyling and Van Niekerk 1991b).

Evaluation for Dystocia

Most kiddings occur uneventfully and without any human assistance. In one report of records kept by breeders, 95% of does required no help (Engum and Lyngset 1970). Some does experience difficulty delivering their kids because of problems such as fetal malpresentation or oversize or failure of cervical dilation. These animals may or may not be observed to be in active labor (straining) and placenta or fetal parts may or may not be visible. Thus, the question frequently arises of whether or not the goat is in labor or in need of assistance. Certainly, if hard labor produces no kids in one-half to one hour or if placenta has been showing for that long, closer evaluation of the doe is warranted (Yankovich 1990). Yellow staining of the mucus with fetal meconium (Figure 13.7) also indicates that assistance should be provided at once. To limit discomfort

or bruising of the doe and subsequent infection of her reproductive tract, the vulva should be washed with mild soap. Examination should be made with a gloved, well-lubricated, small hand or (less traumatic) glass artificial insemination speculum. In one study of sixty normal parturitions, the fetal forelegs appeared from three to thirty-eight minutes (average twelve minutes) before delivery of the kid was completed (Lickliter 1984/85).

When the main source of concern is merely that the seemingly happy doe is overdue to kid, the calculations of due date (including the possibility of rebreeding) should be checked. Normal does undergo a softening of ligaments around the birth canal before the onset of parturition. If the sacrotuberous ligaments (extending from tailhead to tuber ischiadicum, or pinbone, bilaterally) have softened to the point of disappearing completely, then parturition usually occurs within twelve hours (Yankovich 1989). The doe should be examined carefully if nothing happens within the next twelve to sixteen hours. Progesterone in the blood also drops within twenty-four hours of parturition (Fredriksson et al. 1984). A bovine or canine CITE test

value that is low (<2.8 ng/ml) correlates with imminent parturition, while a high value (>5 ng/ml) usually means that parturition is more than a day away (Singer et al. 2004). Induction of parturition, discussed above, shortens the period when close observation is required.

Care of the Newborn Kid

In all kids, whether born naturally or assisted, or delivered by cesarean section, attention should be given to important health measures. Unless special care is given to undersized kids, they are especially susceptible to death from hypothermia and starvation (Bajhau and Kennedy 1990). How feral goats care for their kids is described in Chapter 1.

Respiration

The parturient doe normally licks the kid intensely, beginning with its head and neck. Placental membranes (if present) are torn from the head and fluid is manually removed from the nostrils and mouth if the doe does not attend to these matters. The kid can be stimulated to breathe and fluids cleared from its nose (but not lungs) by swinging it (in a location away from walls and other hard objects). The hind limbs of the kid are held firmly by one hand while the other hand and forearm support the head, neck, and shoulder area. The kid is swung in a 90-degree arc once or twice, then returned to the ground and rubbed briskly with a clean dry towel or straw. Kids that still are not breathing but that have a palpable heartbeat may be given a respiratory stimulant such as doxopram HCl (1 to 1.5 mg/kg intravenously or sublingually). A resuscitation device for lambs has been described (Weaver and Angell-James 1986) that should be equally valuable in establishing respiration in apneic kids. It consists of a mouth piece (milk inflation), one-way valve, flange, and oral tube approximately 9.5 cm long. A lung inflation rate of twenty times per minute is recommended. Owners and veterinarians alike should resist the urge to supply direct mouth-to-mouth respiration when the kid does not respond to swinging and rubbing. Many dystocias and weak kids are the result of *in utero* infection with zoonotic pathogens.

Umbilicus

The umbilical stump should be dipped in iodine. Some authors recommend 7% tincture of iodine, while others consider 2% tincture of iodine or povidone iodine to be preferable. The stronger solution has the advantage of drying the tissues, to prevent later penetration of bacteria. However, availability of 7% tincture of iodine is currently restricted in the United States because of potential misuse for methamphetamine production. Excess length should be trimmed off the cord with clean scissors and the fresh end thoroughly immersed in the iodine. Do not dip the prepuce of the male kid. Using a partially filled plastic film canister or small paper cup avoids contamination of the stock solution. In herds experiencing problems with omphalophlebitis or septicemia, repeated dipping on a daily or twice-daily basis might be advocated. A clean, dry environment is a more effective prophylactic measure.

Housing

In cold weather, careful attention should be given to drying the kid, especially the extremities. Otherwise, the tips of the ears may be lost through frostbite. Folded ears can be straightened out and splinted at this time, using portions of a Styrofoam cup or plastic hair rollers. If the doe is to raise her kid, mother and offspring should be penned together on clean bedding or at least observed closely until a pair bond is established and the kid is nursing and following well. Kids to be raised artificially should be removed to another location where they should not be in contact with kids more than two weeks older than themselves. Heat lamps, with space for the kids to get away if they become overheated, may be used with caution in cold weather. Body socks made of sweatshirt sleeves or wool socks (toe removed, holes cut for the front feet) in place of heat lamps avoid all danger of barn fires.

If kids are chilled at birth, force feeding or rewarming may be necessary for survival. The chilled kid does not suckle. Determining the rectal temperature is helpful when choosing the method of rewarming (Eales et al. 1984). If the temperature is 98°F to 100°F (36.7°C to 37.8°C), it is often adequate to tube feed warm colostrum and place the kid under a heat lamp. Colder kids can be rewarmed in a water bath or with the aid of a hair dryer or space heater aimed into a box or a dog crate. Some producers heat bath towels in the dryer, turn it off, and install the kid into the nest of towels. Continue to monitor the rectal temperature because overheating can easily occur. If the chilled kid is to be raised by its dam, the water bath technique may wash away birth fluids and thereby cause rejection by the mother. This can be avoided by placing the kid's body into a plastic bag before it goes into the water bath.

Colostrum

Nursing kids should be assisted to obtain colostrum. Plugs should be stripped out of each teat by hand and the udder secretion inspected for evidence of mastitis. The fullness of the kid's abdomen should be monitored regularly, because this, rather than time spent sucking on a teat, is what counts. Obviously, a kid with atresia of anus or colon remains distended, even after nursing ceases, but otherwise the plump kids can be assumed to be drinking well. If kids are to

be raised artificially or are too weak to suckle, the section of Chapter 19 devoted to feeding newborn kids should be consulted. Dietary deficiencies discussed in Chapter 19 (iodine, selenium, copper, vitamin E) may contribute to a herd problem with weak kids that do not suckle. Heat treatment of colostrum and milk for disease control is discussed under caprine arthritis encephalitis in Chapter 4. Failure of passive transfer of immunity is discussed in Chapter 7.

PERIPARTURIENT PROBLEMS

A variety of serious complications can interfere with normal parturition. Frequent close observation of the doe is the best insurance that difficulties will be recognized in time to save doe and kids.

Pregnancy Toxemia

Does that are carrying multiple fetuses may become anorectic and ketonuric in the last four to six weeks of gestation if feed intake does not match the metabolic needs of both the dam and the fetuses. Possible sequelae include dystocia and stillbirth or even death of the dam. A full discussion of pregnancy toxemia is included in Chapter 19. It is very important to check late pregnant goats for ketonuria if they show any signs of ill health. Treatment of the ketotic state is equally important whether the condition is primary (caused by improper nutrition) or secondary to some other disease or misadventure.

Prolapsed Vagina

Prepartum eversion of part or all of the vagina leads to discomfort and straining by the doe. This results in eversion of more tissue (Figure 13.8). Infection or laceration of the wall of the vagina and loss of the cervical seal (with subsequent entry of infection into the uterus) commonly occur. If the bladder becomes incorporated into the prolapse, kinking of the urethra impedes urination while enlargement of the bladder provokes even more straining. Causes of vaginal prolapse are not well understood in goats but might include heredity, increased intra-abdominal pressure from a large litter or indigestible roughage diet, excess estrogen in the forage, lack of exercise, or previous prolapse (Braun 2007). Unfortunately, failure of cervical dilation often leads to dystocia when labor begins after a vaginal prolapse.

The anatomy, including innervation, of the pelvic outlet of the doe has been reported in detail (Hartman 1975).

Management of Mild Prolapses

A mild prolapse is one that is visible when the doe is lying down but disappears when the animal stands up. Sometimes this condition can be handled by restraining the doe full time in such a way that her

Figure 13.8. Prepartum prolapse of the vagina. The cervix of this pygmy doe failed to dilate when she went into labor, necessitating a cesarean section. (Courtesy Dr. M.C. Smith.)

front end is lower than her hind end whenever she lies down. Possibilities include tying the doe in a corner where an excavation big enough for her frontquarters has been made in the bedding pack or confining the doe to a narrow pen such as a metabolic cage and then raising the posterior end of the platform on which she stands and sleeps.

Retainers and Trusses

A prolapse that does not correct itself when the doe stands up should be cleansed with a nonirritating soap, coated with an emollient or oily antibiotic preparation that includes a topical anesthetic, and manually replaced. If the prolapse appears to be too large to replace, lift up from below to unkink the urethra and permit emptying of the trapped bladder. Then some means must be found to keep the vagina in its normal position until parturition brings a decrease in the dimensions of the vagina and the estrogen-induced

relaxation of surrounding tissues. Parturition is usually not possible until the vagina has been replaced. A paddle-shaped plastic bearing retainer is frequently used to treat vaginal prolapses in sheep. The same device can be used in goats, but a way must be found to attach it to the doe. Where a fleece is lacking, a length of umbilical tape can be glued to the doe's hair on each side of the hindquarters, near the point of the hip, and the two ends of the retainer are then tied to these tapes. Alternatively, a loop of suture can be placed in the skin on each side for attachment of the umbilical tapes. Presence of the retainer does not prevent kidding.

A rope truss that puts external pressure on each side of the vulva is also effective in sheep and Angora goats, but it is more difficult to keep the truss properly adjusted on the slippery hair coat of other breeds of goats. Still, the truss has the distinct advantages that it does not provoke straining by the doe and introduces no danger of infection. The center of a long piece of clothesline is placed over the doe's neck. The ends are then crossed under the chest (between the front legs) and crossed again over the back. They are then passed between thigh and udder on each side, continuing up along the vulva and forward to be secured to the rope over the neck. Short pieces of rope are used to connect the two lines above and below the base of the tail and just below the vulva. Alternatively, supporting pressure can be applied to the vulva by means of a stiff rubber, leather, or aluminum rod truss of triangular shape, with loops at the two upper lateral and single ventral corners simplifying attachment to the rope harness (Babin 1981).

Vulvar Sutures

Other methods of retaining a prolapsed vagina include several deep mattress or cruciate sutures across the vulva and a buried pursestring (Rahim and Arthur 1989). The doe must be watched very carefully because the sutures prevent parturition and cause tissue infection. A less invasive technique involves bootlacing across the vulva with a soft strip of cloth or gauze, using small loops of umbilical tape that are placed in rows lateral to each side of the vulva. A single anchoring loop between vulva and anus serves to prevent the lacing from slipping ventrally. The owner can loosen the lacing and check on the progress of parturition without causing further tissue damage or discomfort to the doe.

Sacrocaudal Extradural Anesthesia

Local anesthesia is often desirable, either temporarily for placement of some sort of retaining sutures or with a longer duration to prevent continued straining and repetition of the prolapse. Sacrocaudal extradural anesthesia has been investigated for this purpose in sheep. A dose of 1.5 ml of 2% Hostacaine provided anesthesia for forty-five minutes in sheep averaging 64 kg, whereas 2 to 3 ml resulted in ataxia and inability to rise. An injection of 2 ml of 48% ethyl alcohol created anesthesia of the genital area, croup, and thigh that persisted one to two weeks but did not impair mobility. A 0.80×40 mm needle is directed cranioventrally until it touches the bony floor of the vertebral canal between the last sacral and first (moveable) caudal vertebrae. The needle is then withdrawn slightly and checked to be sure that blood cannot be aspirated. The anesthetic should flow easily if the needle is properly placed (Schwesig 1986).

Milk Fever and Uterine Inertia

Clinical signs of hypocalcemia (inappetence, unsteady gait, weakened uterine contractions, eventual recumbency) are occasionally noted in periparturient goats. Also, a mild hypocalcemia might contribute to prolongation of first stage labor. If milk fever is suspected, calcium borogluconate (60 to 100 ml of a 20% to 25% solution) can be given very slowly intravenously or subcutaneously, split into four sites. Products with phosphorus and dextrose should be avoided subcutaneously because they cause painful abscess formation. Intravenous infusion should be avoided if the animal appears to be toxic. Other explanations for the illness, such as indigestion, pregnancy toxemia, ruptured uterus or uterine artery, metritis, and mastitis, should be ruled out. Milk fever is discussed in detail in Chapter 19.

Failure of Cervical Dilation

"Ringwomb," or incomplete dilation of the cervix, is observed occasionally in goats, as in sheep. In one study in Iraq, ringwomb accounted for 24% of 136 goats presented to a referral clinic for dystocia (Majeed and Taha 1989). The etiology remains unexplained in both species. Primiparous does may be predisposed to the condition. Undoubtedly, some cases diagnosed as incomplete dilation merely represent too early intervention. Others are accompanied by pregnancy toxemia, uterine inertia, or fetal malpresentation (Rahim and Arthur 1982). Sometimes the cervix is actually closing again after failure of parturition to occur at the appropriate time. When the cervix only opens enough for a small sack of placenta to pass and the fetuses are dead or premature, it seems likely that inadequate hormonal preparation for parturition may have been involved, as with diseases involving the placenta. Toxoplasmosis is one disease that has been documented to affect hormone production by the placenta (Engeland et al. 1996).

Possible treatments include careful manual stretching of the cervix (success in two of sixteen cases) (Ghosh et al. 1992), administration of calcium and/or estrogen

and waiting a few hours, and cesarean section. Prostaglandin F2 alpha (7.5 mg intramuscularly) has been proposed as an effective treatment, as judged by delivery of kids within four hours (Majeed and Taha 1989). Cloprostenol (500 µg IM) has also been reported to be effective, though the time to delivery was reported to be thirty-nine to fifty-one hours (Ghosh et al. 1992). The possibility that the final preparturient surge of prostaglandin is absent in animals with ringwomb needs to be investigated. It is tempting to ascribe a response to prostaglandin to induction of relaxin, a glycoprotein hormone which softens the cervix in some species (Senger 2005), but relaxin has not yet been studied in the doe. If a true ringwomb is present, manual dilation can easily rupture the cervix or uterus (Engum and Lyngset 1970). Oxytocin also should be avoided. If placenta is visible and other techniques fail, surgery should not be delayed longer than a few hours.

Abnormal Fetal Presentation, Position, or Posture

Both anterior presentation (with head and forelimbs extended) and posterior presentation (with hind limbs extended) are considered to be normal in goats. However, posterior presentation has been reported in only 3% to 9% of kids, is even rarer in single kids, and appears to predispose to dystocia (Engum and Lyngset 1970). Problems occur when multiple kids become tangled in the birth canal or the head or limbs are retained. Careful attention is necessary to distinguish front feet from hind feet and to verify that traction is being applied to the extremities of only one fetus at a time. Normal deliveries and various dystocias in goats have been well illustrated in a French publication (Babin 1981).

Some breeders report increased frequency of dystocia in Pygmy goats and suggest that selection in the show ring for a very short and compact body type is to blame (Brown 1988). Apparently there is not enough room in the doe's abdomen for the kid to present itself properly. A radiographic study of dystocia in thirty West African dwarf goats in Nigeria, with no show ring selection, demonstrated that abnormal fetal posture was more common than a small maternal pelvis as a cause of dystocia (Kene 1991). Pygmy goats were overrepresented in one study of goats undergoing cesarean section in the United States (Brounts et al. 2004).

General Guidelines for Mutation and Delivery

Wild goats are said to stand with their forequarters downhill from the hindquarters to give fetuses the opportunity to rearrange themselves. This gravitational advantage should be remembered when parturition is assisted. If it is necessary to retrieve the head or a limb of a fetus in a recumbent doe, this is easiest if the dam is positioned so that the retained extremity is uppermost. Delivery is usually possible with either one forelimb or one hind limb retained. If there is adequate room for manipulations, the second limb can be properly positioned before extraction begins. If the head is out, it is sometimes possible to deliver the normal sized kid by simple traction, without retrieving either forelimb. If the uterus is contracted around the fetus subsequent to prolonged dystocia, intramuscular epinephrine (1 ml of a 1:1,000 solution to a dairy or meat breed doe) greatly facilitates safe manipulations by relaxing the uterus.

When the kid is properly positioned, it is pulled out and downward in an arc. If a dystocia occurs when head and two forefeet are presenting, the difficulty may be a simple elbow lock; pulling firmly on one limb at a time extends the elbow joint so that the tip of the nose is positioned closer to the carpus rather than directly over the hooves. It is also possible that parts of more than one fetus are represented or that a relative fetal oversize is present.

Deviation of the Head

One should never try to extract a kid in anterior presentation unless the head and neck have either been properly positioned or amputated. Rupture of the uterus is very likely to occur and may already be present before human intervention when the fetal head is retained. A lamb puller (Nasco, Fort Atkinson, WI) makes an excellent head snare. The head typically deviates to the side of the fetus but occasionally drops down between the front limbs. It is usually necessary to repel the fetus by pushing the front limbs inward or elevating the hindquarters of the doe to have space to straighten out the head. Epinephrine, as described above, may also be helpful.

Retention of Forelimbs

Sometimes the head of a kid is delivered but then progress stops because of retention of both forelimbs. Assistance should be provided at once; the neck is followed to a shoulder and then the corresponding limb is retrieved. It may be necessary to repel the head to have room for passing a hand as far as the shoulders. Care must be taken not to push the head around to one side.

If the head of a live kid with retained forelimbs passes beyond the lips of the vulva, compression of the jugular veins results in edema of the head. The head swells to the extent that repulsion becomes impossible yet there is no room to reach inside and straighten a leg. Extensive lubrication may permit delivery of a small kid in this position without additional manipulation. If the kid is dead, there should be no hesitation about amputating the head at the atlanto-occipital joint with a scalpel blade to provide more room for mutation.

Multiple Fetuses or Transverse or Malformed Fetus

When more than one kid is presented simultaneously, it is important to accurately identify the extremities in the birth canal and to trace them back to the body of the fetus. In general, it is preferable to first deliver a kid whose head is in the birth canal rather than risk creating a more difficult dystocia by repelling the head. Otherwise, a kid in posterior presentation is easier to deliver first. If a kid is transversely positioned, it should be moved (with the finger tips) into a posterior, breech position. From this point, retrieval of at least one hind limb usually permits delivery. Epinephrine to relax the uterus, as described above, may be helpful.

A schistosomus reflexus fetus (Buergelt 1997; Gutierrez et al. 1999) could cause dystocia that resembled the simultaneous presentation of twins. If correctly diagnosed by noting abdominal organs outside the fetal body, the dystocia can be relieved by a single cut with a regular fetotome.

Controlling Straining

An epidural injection of lidocaine (with or without xylazine) can be used to decrease straining, as discussed in Chapter 17. The beta-adrenergic compound clenbuterol (Ventipulmin; Boehringer, Ingelheim) is available in some countries as a tocolytic drug to temporarily cause myometrial relaxation. Initial favorable studies in cattle suggest that the drug might also be useful during correction of fetal malposition or exteriorization of the uterus during cesarean section in goats. A possible dose to try is 0.8 µg/kg intramuscularly (Menard and Diaz 1987). The use of this drug in food animals is forbidden in the United States, but epinephrine may be substituted (see above).

Relative Fetal Oversize and Fetotomy

Multiple kids are rarely too large for the birth canal unless the doe is severely stunted or has suffered some injury such as ankylosis of a fractured tail (Engum and Lyngset 1970). On the other hand, a single large kid may be too large for a small first freshener. Owners rarely have the luxury of breeding doelings to a buck of known kidding ease. Addition of lubricant to the birth canal may assist delivery of a large kid, but often the fetus is emphysematous, malformed, or too large to be extracted intact.

Fetal hydrops (anasarca, dropsy) is a specific cause of fetal oversize that warrants discussion. Massive accumulation of fluid in fetal tissues and body cavities may make extraction impossible unless incisions are first made with a finger knife to drain the fluid. Accumulation of fluid within the placenta may be so great that abnormal distension of the dam's abdomen occurs and the subsequent interference with circulation, respiration, and locomotion necessitates a cesarean section or induction of parturition to save the dam. Anasarcous kids may be cotwin to normal, viable kids, and the same doe may produce another affected kid in a subsequent gestation (Elze and Müller 1960; Walser 1963). In one herd, eleven kids with hydrops were produced, all sired by a single buck. The condition may be inherited as a simple recessive character (Ricordeau 1981). Hypothyroidism is another proposed cause (Kumar et al. 1989). Wesselsbron disease (Chapter 11) is also reported to cause hydrops, at least in sheep.

Unless the kid is alive and its value warrants the expense of a cesarean section, consideration should be given to a subcutaneous fetotomy. This procedure is relatively safe for the doe because instruments are not used in the birth canal and the fetal skin protects the friable maternal tissues. An initial skin incision is made with a scalpel just above and all the way around the carpus, and is then extended as far as possible up the medial side of the leg. The skin is then pushed proximally and the front limb is torn loose from the thorax and extracted, an easy process if the fetus is autolyzed. This procedure is repeated with the other front limb. The thorax can be compressed by sliding a hand beneath the kid's skin and manually fracturing the ribs. Rotation of the head and trunk causes the vertebral column to fall apart in the lumbar region. The hind limbs can then be pulled out. A complete subcutaneous fetotomy is rarely necessary (Engum and Lyngset 1970).

Special tools have been described for fetotomy in small ruminants. A long-handled nipper with blunt-tipped jaws bent upward has been used to amputate a front or back limb or the head. Fetal pieces are then extracted with the aid of small tongs (Deckwer 1951).

Hydrops of the Uterus

Rarely, distention of the pregnant uterus with excess amniotic or allantoic fluid occurs. Extreme abdominal distension, discomfort, and difficulty rising may be noted. Presence of caruncles and fetus on ultrasound distinguishes hydrops from hydrometra. Pregnancy toxemia (see Chapter 19) may be concomitant or incorrectly suspected. The normal allantoic fluid volume in sheep and goats has been reported to be between 0.5 and 1.5 liters, while one doe with hydrallantois had approximately 12 liters of fluid at the time of successful treatment by cesarean section (Morin et al. 1994). Hormonal induction of parturition permits slower release of the accumulated fluid but the delivery is also slow and probably requires assistance because of weakness of the myometrium (Jones and Fecteau 1995). It has been proposed that ram × doe hybrid pregnancies are predisposed to the development of hydrops of the uterus (Kelk et al. 1997).

Uterine Torsion

Torsion of the pregnant uterus is occasionally observed in goats (Wyssmann 1945) as in sheep (Smith and Ross 1985). In one report from Kerala, India, torsion was identified as the cause of dystocia in twenty-two of fifty-three goats treated by cesarean section during a five-year period (Philip et al. 1985). The condition is more likely to occur with a single fetus than with bicornual twins. The torsion may involve the vagina, but it also may involve only the cervix or body of the uterus. Thus, when a doe is in dystocia, as evidenced by ineffective straining, it may not be possible to distinguish uterine torsion from incomplete dilation of the cervix. Early cesarean section permits differentiation and correction of both of these conditions. Ultrasound examination may demonstrate marked thickening and edema of the uterine wall near the site of torsion (Wehrend et al. 2002).

If the torsion is recognized at the time of examination for dystocia, correction may be attempted by rolling the doe while weight is applied to the abdomen to prevent rotation of the fetus (Sathiamoorthy and Kathirchelvan 2005). Thus, if the torsion palpable in vagina or cervix is to the left, the doe is placed in left lateral recumbency and rolled over her back to the other side while the uterus is prevented from turning by hand pressure or a weighted plank held across the flank. Suspending the doe by her hind limbs and shaking the doe or manipulating the uterus through the body wall is an older, but sometimes successful approach to repositioning the uterus.

Cesarean Section

When pregnancy toxemia or other misadventure makes immediate termination of pregnancy desirable or when a dystocia cannot otherwise be resolved without sacrificing the life of a kid, surgical delivery of the fetuses is necessary. Ultrasound can be used to assess fetal viability, as immediate slaughter might be the economically correct decision if the fetuses are dead. Research or disease eradication programs requiring gnotobiotic kids may involve elective cesarean section. Because many goats shed the Q fever organism (*Coxiella burnetii*) in birth fluids, all people assisting with the surgery or aftercare of fetuses should wear gloves and tightly fitting masks.

Anesthesia and Surgical Approach

Either general or local anesthesia may be chosen (Benson 1986). Suitable general anesthetic agents (halothane, isoflurane) are rapidly cleared after surgery so that there is minimal respiratory depression of the kids or interference with maternal behavior. Xylazine tranquilization should be kept to a minimum or avoided altogether, unless reversal agents (yohimbine or tolazo-

line) are available. Intramuscular xylazine at 0.2 mg/kg causes hypoxemia, respiratory acidosis, uterine contractions, and decreased uterine blood flow in the pregnant goat (Sakamoto et al. 1996). Tranquilization with diazepam is preferable to xylazine. An intravenous diazepam dose of 5 mg per goat has been suggested for standing surgery (Snyder 2007). When the doe is toxic or exhausted, local anesthesia (see Chapter 17) alone is adequate. Intravenous fluid therapy should be begun on these patients before surgery commences.

The doe may be tied in right lateral recumbency, with a towel covering the eyes. A vertical incision is made halfway down the left paralumbar fossa. Care should be taken to enter the abdominal cavity rather than the perirenal retroperitoneal space. A ventral midline incision along the linea alba starting at the base of the udder and extending cranially 20 cm is an alternative that requires less suturing to close, but dorsal recumbency increases pressure on major blood vessels and the danger of regurgitation. Using a cuffed endotracheal tube and positive pressure ventilation overcome these disadvantages. A ventral abdominal paramedian approach, between the linea alba and the subcutaneous abdominal vein, is yet another option (Tibary and Van Metre 2004).

Surgical Techniques

When the abdominal cavity has been opened, the greater omentum should be retracted cranially and the abdomen explored to determine the number and location of fetuses. A gravid horn is then exposed and packed off with moistened towels. A single incision along the dorsal curvature of one horn usually permits removal of all fetuses from one site (Wallace 1982). Placentomes should be avoided. Extremities (e.g., hind feet) are grasped and the first kid is gently delivered from the abdomen. Additional kids are milked to the same incision. The umbilical cord is separated by grasping it firmly close to the kid's abdominal wall with one hand and tugging firmly with the other hand that grasps the cord several inches distally. If the cord fails to break, it should be clamped with Carmalt forceps and ligated. The placenta is only removed if it is no longer attached to caruncles. After the surgeon is sure that all fetuses have been removed, the uterus is closed with one or two layers of inverting 0 or 1 chromic catgut or synthetic absorbable sutures. After the surface of the uterus has been lavaged, closure of the abdominal incision is routine (Tibary and Van Metre 2004).

If the doe has a problem that prevents vaginal delivery on subsequent pregnancies but it is to be kept as a pet, ovariectomy should be considered before abdominal closure, as the surest way to prevent rebreeding.

Aftercare

Aftercare of kids is as described for vaginal deliveries. Ideally, an assistant should attend to the kids, because their body temperature can drop dangerously low during the time it takes to finish the surgery. If the doe is to raise the kids, she should be permitted to mother them as soon as possible. Systemic antibiotics (penicillin, ceftiofur, or tetracycline) and tetanus prophylaxis are generally administered to the dam. Oxytocin (5 units) should not be given until suturing of the uterus is completed. Research conducted in ewes suggests that oxytocin doses exceeding 3 or 4 IU intramuscularly cause a prolonged and undesirable spastic contraction of the periparturient uterus (Marnet et al. 1985), but higher (empirical) doses have been recommended in small ruminants. Analgesics such as flunixin meglumine (1.1 mg/kg intramuscularly or intravenously) may be given if needed to control postoperative pain (Vivrette 1986).

The prognosis for life and fertility of the doe is good if the surgery was elective (Brounts et al. 2004), but must be guarded if the fetus was macerated or the doe was seriously ill, as with pregnancy toxemia, before surgery.

Prolapsed Uterus

Eversion of the uterus (typically one horn) occurs occasionally, but is apparently less common when goats are loose-housed than when they are confined to individual stalls (Engum and Lyngset 1970). The prognosis is usually good, even if the prolapse has been present for twenty-four hours. The uterus should be washed with copious water and a mild disinfectant. The hindquarters are then elevated with the hind limbs spread apart. Working through a towel while replacing the uterus protects against accidental perforation. When the uterus is back through the cervix, manipulation with fingers held together is continued until the very tip of the uterine horn is replaced. An antibiotic powder is placed in the uterine cavity and oxytocin (perhaps 5 IU) is given to contract the uterus. Systemic antibiotics may be given for several days. Tetanus prophylaxis should not be neglected. Some authors recommend suturing the vulva, but this should not be necessary if replacement is complete and the doe can get up easily. A truss could be used.

If the prolapse is older than thirty-six hours or is extensively damaged, amputation of the uterus is required. A tight ligature is required, and a stay suture should be placed ahead of the ligature in case the ligature should slip during amputation and retrieval of the cut end should be required (Engum and Lyngset 1970).

Uterine Artery Rupture

Though this condition is not well described in the literature, rupture of the uterine artery occurs occasionally in the postpartum goat. It is conceivable that some does merely experience hematoma formation in the broad ligament, but a problem is usually only diagnosed if fatal hemorrhage occurs. The doe may be found dead or dying; cold skin, muscle tremors, and bloat in the hypovolemic animal may suggest hypocalcemia. Death may occur before the packed cell volume has time to fall. The author has seen goats that bled to death as long as four days post partum.

Retained Placenta and Metritis

The placenta is normally passed within three or four hours. If the placenta has not been expelled within twelve hours after delivery of the last kid, it is then considered to be retained (Franklin 1986). Retained placenta may occur in an infectious abortion (or birth of a live kid from an infected doe) caused by diseases such as toxoplasmosis (Calamel and Giauffret 1975) and chlamydiosis. Practitioners have associated a dietary deficiency of selenium with herd problems of retained placenta in goats, and recommended injectable and oral selenium supplementation for prevention (Cochran 1980). Some delay the injection until ten days before the due date, in light of label warnings against the use in pregnant animals, reasoning that kids might still be viable if treatment induced early parturition. Cesarean section is another risk factor for retained placenta (Brounts et al. 2004).

Metritis associated with retained placenta, retained kids, or trauma and infection of the uterus in the course of dystocia may lead to signs of systemic illness shortly after parturition. Fever, depression, anorexia, and a malodorous vaginal discharge are typical. The occurrence of a retained placenta may be difficult to confirm without a vaginal examination because goats commonly eat all or part of the placenta. In one study of sixty normal parturitions, the placentas were eaten by 38% of the does (Lickliter 1984/85). Transabdominal ultrasound during the first week, at least in sheep, permits identification of hyperechoic placenta in fluid in the uterine lumen, attached to hypoechoic caruncles (Hauser and Bostedt 2002). Peritoneal fluid analysis may suggest peritonitis if a severe metritis or uterine tear is present. If a vaginal examination is performed, intrauterine antibiotics are commonly administered, but manual removal of the placenta should not be attempted. Instead, oxytocin may be administered (5 IU subcutaneously or intramuscularly several times a day) and systemic antibiotics are recommended to prevent development of a life-threatening toxemia or septicemia. It is the author's personal preference to give penicillin prophylactically but to use oxytetracycline if the goat is already systemically ill. Tetanus prophylaxis should be ensured.

Postparturient or genital gas gangrene caused by infection of the uterus with clostridial organisms is

common in Angora goats in South Africa that are penned for kidding (Van Tonder 1975). Signs usually develop six to twenty-four hours after kidding. Metritis is accompanied by septicemia and death occurs in untreated animals in twelve to seventy-two hours.

Pyometra appears to be far less common in goats than is mucometra or hydrometra associated with false pregnancy (Hesselink and Taverne 1994). Previous dystocia with cervical damage may predispose to pyometra (Haibel 1986a), as does the presence of parts of a macerated fetus (Lyngset 1968d). The contents of the uterus are more uniformly echogenic when examined by real-time ultrasound than is the fluid in a hydrometra. Fetal bones are sometimes found embedded in the wall of the reproductive tract at necropsy. Treatment is with prostaglandin, systemic antibiotics, and possibly surgical emptying of the uterus.

Vulvovaginitis

Vaginal discharge (other than clear or cloudy heat mucus and lochia) or lesions of the vaginal mucosa in the absence of uterine or urinary tract disease warrant a speculum examination of the vagina. Traumatic lesions and retained vaginal pessaries should be ruled out before investigating the possibility of specific infections localized to the caudal portions of the reproductive tract. Ectopic mammary gland (see Chapter 3) should not be mistaken for inflammatory disease of the vulva.

Caprine Herpesvirus

Postbreeding genital disease (papules, vesicles, and pustules coalescing to form ulcers) associated with caprine herpesvirus-1 has been reported in does in New Zealand (Horner et al. 1982) and Australia (Grewal and Wells 1986). Lesions healed in four to six days and does developed neutralizing antibody. Vaginal lesions have also been produced by experimental infection and reactivated by estrus or corticosteroids (Tempesta et al. 2002). There is no apparent interference with fertility.

Infection can be confirmed by viral isolation from vaginal swabs or by rising serum neutralization titers. The condition is discussed in Chapter 12.

Mycoplasma

A granular vulvovaginitis has been observed in spontaneous cases and reproduced experimentally by inoculation of scarified vulvar mucosa with *Mycoplasma agalactiae* (Singh et al. 1974, 1975). Spontaneously affected goats have a mucopurulent vaginal discharge with multiple, yellowish-white, pinhead-sized elevations, especially near the clitoris. Occasionally the granules are red and ulcerated. Histologically, findings include perivascular cuffing, accumulation of lymphocytes and plasma cells in the lamina propria,

and lymphoid follicles in the vulvovaginal region. Numerous other mycoplasmas, including *M. bovigenitalium* and *Acholeplasma laidlawii*, have been isolated from Nigerian goats with clinical vulvovaginitis (Chima et al. 1986). *Acholeplasma laidlawii* is found on all mucosal membranes (Rosendal 1994) and is of questionable pathogenicity, but experimentally has been reported to cause lymphocytic vulvitis and vaginitis in goats (Gupta et al. 1990).

There is no published evidence that this condition interferes with fertility or that its occurrence or duration can be limited by treatment. To avoid additional spread, however, it seems prudent to avoid natural mating until clinical signs disappear.

Leiomyofibromatosis

A prolonged vaginal discharge (purulent or serosanguinous) has been reported from a Saanen goat with multiple firm nodular polyps in the vaginal wall. Based on histology, a diagnosis of vaginal leiomyofibromatosis was made and an association with follicular ovarian cysts was proposed (Haibel et al. 1990). One of the authors (MCS) is aware of a similar case in a goat with bilateral granulosa cell tumors. Because the diagnosis was only considered retrospectively after review of the first report, it seems likely that leiomyofibromatosis also may have been overlooked in other goats. Ovariectomy has been proposed for alleviation of the condition. This option is presumably limited to pet goats unless a unilateral ovarian disease were discovered at laparotomy.

NEOPLASIA OF THE FEMALE REPRODUCTIVE TRACT

Few tumors of the genital system have been reported in does. Select cases might be treated by ovariectomy or hysterectomy.

Ovarian Tumors

A 400 g cystic ovarian tumor histologically resembling a granulosa cell tumor was identified in an Alpine doeling that first underwent a false pregnancy with udder development and lactation and then developed masculine appearance, behavior, and odor. Metastasis to the uterus occurred. Histologically, pituitary, adrenal, and thyroid glands were normal (Dewalque 1963). Another granulosa tumor caused short estrous cycles and masculine behavior in a three-year-old Toggenburg doe (Lofstedt and Williams 1986); its removal allowed establishment of a normal pregnancy. Additional granulosa cell tumors were reported by Cooke and Merrall (1992) and Kutty and Mathew (1995). A dysgerminoma weighing 1,450 g was ballottable through the abdominal wall of an aged doe (Smith 1980). A mucinous adenocarcinoma of the ovary of a six-year-old Nubian doe was associated with

accumulation of 30 liters of ascitic fluid in the abdomen (Memon et al. 1995). Ovarian involvement with multicentric lymphosarcoma has also been reported (DiGrassie et al. 1997).

Uterine and Cervical Tumors

The most commonly observed tumor of the tubular genitalia of the doe may be the leiomyosarcoma, which grows by slow invasion and rarely metastasizes. Vaginal bleeding is a common presentation, and Saanens may be predisposed to this tumor. Seven cases were diagnosed over a twenty-year period at a diagnostic laboratory in New York, and five of these were in Saanens, including co-twins affected at twelve and thirteen years of age (Whitney et al. 2000). A seven-year-old Saanen doe with a leiomyosarcoma of the body of the uterus collapsed and died from hemorrhage when the uterus ruptured at the tumor site. The tumor had invaded the broad ligament but had not metastasized to lymph nodes, liver, or lungs (Ryan 1980).

Leiomyomas occur occasionally and may be an incidental finding at necropsy (Ramadan and ElHassan 1975). One reported leiomyoma of the uterus caused dystocia and was removed per vagina after parturition (Kaikini and Deshmukh 1977). Another leiomyoma of the cervix of a nine-year-old Toggenburg invaded the vagina and uterus; it caused a hemorrhagic discharge and severe straining and was diagnosed by vaginal examination (Cockcroft and McInnes 1998). Other reported tumors include a leiomyofibroma of the uterus in a five-year-old goat (Damodaran and Parthasarathy 1972), fibromas of the uterus and vagina and an adenoma of the vagina (Kronberger 1961), a cervical fibroma that protruded from the vulva (Gokak 1988), and a fibroid (Sastry 1959). A twelve-year-old goat in poor body condition that had not become pregnant for many years was found to have a uterine adenocarcinoma that had metastasized extensively to oviduct, ovary, lymph nodes, lung, liver, spleen, and skeletal muscle (Riedel 1964). Lymphosarcoma can also involve the uterus (Whitney et al. 2000).

THE INTERSEX

Although the older literature describes hermaphrodites (ovarian and testicular tissue both present) and pseudohermaphrodites (gonads of one sex but some morphological structures typical of the other sex), the term intersex is currently preferred and can be applied even when the exact nature of the gonads is unknown. An intersex, then, is an animal that shows both male and female characteristics.

The Polled Intersex

Within the breeds originating in western Europe (such as Saanen [Soller 1963], Alpine [Boyajean 1969], and Toggenburg [Eaton 1943]), there is a well known and much studied association between the natural absence of horns and the intersex condition. The condition also occurs in the Damascus or Shami goat (Al-Ani et al. 1998). It is likely that Nubian and Angora goats have a different inheritance of horns (Crepin 1958). The polled intersex condition is not reported in these breeds, although freemartins may occur.

Etiology

The polled condition in the European breeds is determined by an autosomal dominant gene that is the same as or very closely linked to a recessive gene causing infertility. One older theory held that this gene, where homozygous, causes expression of H-Y antigen (Wachtel et al. 1978). The H-Y gene is normally on the Y chromosome. Translocation of a subcritical portion of H-Y genes to an autosome would give rise to a recessive mode of inheritance. H-Y antigen is secreted in hormone-like fashion and binds to cells of the developing ovary (Wachtel 1980). A variable H-Y dosage would explain the extreme variability in phenotype of polled intersex goats (Shalev et al. 1980).

Polled intersex goats have been shown to be negative for SRY, the sex-determining region of the Y chromosome which is one of the major genes responsible for testicular induction (Just et al. 1994). Recently, an 11.7-kb deletion on chromosome 1 of the goat known as the PIS (polled trait related intersex syndrome) deletion has been identified as causing the polled condition (Basrur and Kochhar 2007). The deleted segment of DNA normally has regulatory effects on nearby genes for horn bud development and development of fetal ovaries. Female goats homozygous for the deletion show sex reversal because testis promoting genes in the fetal ovary become active; the intricacies of the sex determination cascade in the developing fetus are detailed by Basrur and Kochhar (2007).

Clinical Signs and Management

Affected animals are genetically female but may exhibit male, female, or mixed external characteristics (Eaton 1943). An enlarged clitoris in a doe-like animal or a decreased ano-genital distance in a more masculine individual is typical. Hypospadias may be present. The gonads (usually testes or ovotestes) may be scrotal, inguinal, or abdominal in location and are smaller than the testes of normal bucks of the same age. In one instance, the uterine tubes attached to the scrotal testes also herniated into the scrotal sac (Ramadan et al. 1991). Testosterone is commonly produced, which accounts for masculine behavior, neck development, erect hair on the neck, and odor (Hamerton 1969; Zlotnik 1973). Sperm are not produced, and thus the intersex can be used as a teaser animal. Gonadectomy is generally required if the animal is to be kept as a pet.

Unless the masculinized intersex goats are counted as females, the sex ratio in European breeds favors males rather than females (Eaton 1945; Soller et al. 1969). Polled does tend to have a larger litter size than horned does (Soller and Kempenich 1964; Constantinou et al. 1981).

Diagnosis

The anatomic variations just described are very suggestive of this condition, if the animal is naturally polled and both parents were polled. In this regard it should be remembered that some breeders disbud every kid at a very young age without paying close attention to hair swirls that would permit differentiation of polled from horned animals (Chapter 18). Thus some polled goats have been "disbudded" and recorded as horned. Likewise, a small horny scur is usually taken as evidence of previous horn removal but conceivably could represent partial growth in a heterozygous animal. If a polled doe is fertile, she is presumed to be heterozygous for the polled gene. Differentiation of a polled intersex from a freemartin requires karyotyping; the polled intersex is a chromosomal female.

Difficulties are encountered in identifying the intersex animal with normal or nearly normal (slight projection of the vulva) external genitalia. Failure to exhibit estrus, development of male odor or behavior during the breeding season, a shortened vagina on speculum examination, or smaller than normal teats may be first signs that the intersex condition is present. At the other end of the spectrum, polled genetic females with male phenotype and hypoplastic testes are difficult to identify without a karyotype until they are old enough that sperm production would be expected (Corteel et al. 1969; Soller et al. 1969). Karyotyping is available from various commercial laboratories, including the Veterinary Genetics Laboratory at the University of California, Davis.

Prevention

The occurrence of intersex goats associated with the polled condition can be avoided by insisting that one goat in each breeding pair have been born with horns and is therefore homozygous for the gene for horns (p). This ensures that no kids are born homozygous for the PIS polled gene mutation/deletion (P) and its associated recessive effects on fertility. A polled buck can be heterozygous or homozygous. A polled doe, on the other hand, must be heterozygous if she is fertile. The potential for obtaining undesirable offspring by mating polled animals is detailed in Figure 13.9.

Freemartins

A freemartin is a female rendered sterile by being co-twin to a male fetus.

Pathogenesis

In cattle, freemartinism is common because the fetal membranes from twin calves generally fuse, thereby permitting exchange of cells and hormones (testosterone and Müllerian inhibiting substance) between male and female fetuses (Padula 2005). Although multiple births are common in goats, freemartins are not. This is presumably because placental fusion does not usually occur, at least not until after differentiation of fetal gonads is completed (Basrur and Kochhar, 2007).

Diagnosis

Caprine freemartins cannot be distinguished on the basis of external or internal genitalia from polled intersexes (Basrur and Kochhar 2007). The gonads may be partially descended testes devoid of germ cells or internal testes or ovotestes. The goat may be polled or horned. A male litter mate must have been present in the uterus early in embryologic development, but might not have persisted to term (the case of the

Figure 13.9. **Results of crossing a polled doe (always heterozygous, Pp) with a homozygous (PP) or heterozygous (Pp) polled buck.**

missing womb mate). The diagnosis can be confirmed by demonstrating XX-XY blood chimerism (BonDurant et al. 1980; Ricordeau 1981; Smith and Dunn 1981; Bosu and Basrur 1984). The expense of karyotyping is usually prohibitive. Some laboratories, such as the Veterinary Genetics Laboratory at the University of California, Davis, offer freemartin testing of goats for a lower price than a karyotype, but even this may not be warranted, because clinical management of a freemartin is the same as for a polled intersex.

Other Chromosome Abnormalities

The karyotype of the domestic goat consists of sixty chromosomes; all except the small metacentric Y chromosome are acrocentric. Because the acrosomes appear similar under conventional staining techniques, identifying individual autosomes requires special staining techniques such as G-banding (Cribiu and Matejka 1987a) and R-banding (Cribiu and Matejka 1987b).

If karyotyping is done on infertile goats, very occasional animals are identified that have abnormalities other than the polled XX intersex condition or XX-XY blood chimerism of freemartins. Fusion of embryos and other genetic accidents may be proposed. Goats that are true hermaphrodites are often whole-body chimeras (Basrur and Kochhar 2007). There is a report of a single fertile Saanen × Beetal buck goat with both XY and XXY cell lines in its blood, but the mechanism by which this mosaic was created could not be determined. At least four of the buck's sixteen progeny were culled for breeding problems (Bhatia and Shanker 1992).

Robertsonian Translocation

An inherited centric fusion (Robertsonian translocation) of two acrocentric chromosomes (resulting in a chromosome number of fifty-nine instead of sixty) has been identified in a family of Saanen goats (Soller et al. 1966). Similar Robertsonian translocations involving different chromosomes have been reported in other populations of Saanen or Toggenburg goats (Popescu 1972; Cribiu and Lherm 1986; Burguete et al. 1987). In most instances, no anatomic abnormalities have been identified. In one case, two sterile bucks (with one and two polled parents) were found to have a centric fusion (Ricordeau et al. 1972a). Females carrying this chromosomal abnormality tended to produce fewer kids than did noncarrier sisters (Ricordeau 1972), which suggests increased embryonic mortality rates. Homozygotes with fifty-eight chromosomes were not reported (Ricordeau 1981), again suggesting that the trait was lethal in the homozygous state.

A translocation involving chromosomes five and fifteen in a Saanen buck in Brazil, imported from Switzerland, produced no adverse effects on fertility. Test matings showed that homozygous offspring were viable and produced in the expected frequency (Gonçalves et al. 1994).

THE BUCK

The male goat is called a buck or billy. Many dairy goat owners are offended by the term "billy," and Angora breeders are often confused by "buck" because in many parts of the United States, the ram (male sheep) is referred to as a buck.

The buck is frequently described as half of the breeding herd. Many owners find him the more difficult half to control. Because of his size and strength and his distinctive odor, the buck is often skipped when the does are dewormed, vaccinated, given selenium injections, or foot trimmed. Unless pens are massive and fences both sturdy and high, a resident buck breeds does earlier in the breeding season than desired and leaves no written records of his activities. Owners choosing to raise or purchase a buck for breeding would do well to read lay articles on the subject of buck management (Hicks 1987) before getting into this phase of goat husbandry.

Anatomy

The anatomy of the male goat's reproductive tract has been reviewed elsewhere (Smith 1986c; Garrett 1988; Constantinescu 2001). The scrotum is pendulous and in some animals it is divided to a greater or lesser extent into two sacs. There is little evidence that this trait (bipartite scrotum) is detrimental to fertility in the absence of other anatomic defects.

The testes are present in the scrotum at birth and are positioned with the longitudinal axis vertical. Approximately fifteen to twenty efferent tubules collect spermatozoa from the testis and join the head of the epididymis, which is located on the dorsolateral aspect of the testis. The body of the epididymis is caudal and slightly medial, and the tail of the epididymis, where semen is stored before ejaculation, is ventral. Blood is supplied to the testis by the testicular artery, which is precooled by its proximity to the pampiniform venous plexus in the spermatic cord. The cremaster muscles and smooth muscle in the wall of the scrotum also serve to control the testicular temperature by adjusting the position of the testis relative to the abdomen.

The deferent duct passes dorsally on the medial side of the testis and spermatic cord to the inguinal ring, then passes medial to the ureter and widens to form an ampulla before emptying into the pelvic urethra on the side of the seminal colliculus. The vesicular glands cover the dorsal aspect of the ampullae. Their excretory ducts open at the seminal colliculus, usually through common ejaculatory ducts and orifices that also serve the deferent ducts (Constantinescu 2001). The prostate gland is disseminated in the wall of the pelvic urethra and opens into its lumen by many small

ducts. A recess extends caudodorsally from the urethra where the pelvic urethra turns ventrally after leaving the pelvic canal. The bulbourethral glands open into the lumen of the urethral recess, on the fold of mucous membrane that separates the recess from the pelvic urethra.

The bulb of the penis (corpus spongiosum penis) surrounds the penile urethra and is itself covered by the bulbospongiosus muscle ventral to the anus. There are two crura of the penis that are formed by the corpus cavernosum penis surrounded by the heavy tunica albuginea and are covered by the ischiocavernosus muscle, which is important for erection. The hemodynamics of penile erection have been reported by Beckett et al. (1972a, 1972b). Paired retractor penis muscles insert ventrally on the fibroelastic penis just distal to its prominent sigmoid flexure. The penis ends with the glans penis, but the urethra continues as the urethral process, which extends 3 or 4 cm past the glans.

Physiology and Sexual Development of the Male

Breed, age, and nutrition all contribute to the onset of sexual maturity. In Boer goats, spermatogenesis was found to begin as early as eighty-four days of age, with spermatozoa present in the epididymis at 140 days of age (Skinner 1970). In another study of twenty Boer goats, puberty (as defined by presence of spermatozoa in the ejaculate) was reached at 115 to 234 days (Louw and Joubert 1964). Fast-growing, well-fed kids are able to breed sooner than starved males born at the same time. In dairy breeds in the United States, many bucklings are fertile by five months of age, but successful breeding has occurred as early as three months of age. Some other breeds, under other management conditions, mature much later (Elwishy and Elsawaf 1971).

Natural adhesions of the urethral process and glans penis to the prepuce render the immature male incapable of copulation (Figure 13.10). Under the influence of testosterone, the urethral process becomes free, beginning at its tip, and finally the penis separates from the preputial mucosa (Skalet et al. 1988). This separation never occurs in the early-castrated wether.

Serum testosterone concentrations in normal bucks in temperate climates vary with the season; the highest are in the fall breeding season. Increases in testosterone are preceded by increases in luteinizing hormone from the pituitary. Testosterone rises earlier in bucks provided with a high quality diet than in those that are underfed (Walkden-Brown et al. 1994). Mean values in yearling pygmy goats in the fall reach 15 ng/ml (Muduuli et al. 1979). In an Australian study of six Angora bucks, the mean androgen level was approximately ten times more in March (10.25 ng/ml) than in July, at the end of the breeding season (1.05 ng/ml) (Ritar 1991). There is also a diurnal pattern (Bosu and Barker 1982), although this pattern was not consistent

throughout the year in another study (Ritar 1991). In Black Bengal goats, higher testosterone concentrations have been reported in two- to three-month-old kids (7 ng/ml) than in three- to five-month-old (3 ng/ml) or mature bucks (5 ng/ml) (Georgie et al. 1985). When samples are taken for analysis, testosterone appears to be stable in the plasma or serum of bucks for at least twenty-four hours (Fahmi et al. 1985).

The buck odor, originating in part from sebaceous glands caudomedial to the horns, contributes to the breeding success of a male. The odor stimulates onset of cyclicity, demonstration of overt estrus, and receptivity in females. Bucks that were descented during disbudding may be ignored or rejected by some choosy does. The glands are testosterone responsive and the odor is most intense during the breeding season (Walkden-Brown et al. 1994).

Sexual behavior and sperm production also vary with season. In a French study, the percentage of bucks that failed to ejaculate increased to as high as 25% in the nonbreeding season, especially May to August. Testicular weight and total spermatozoa in the ejaculate also decreased out of season (Delgadillo et al. 1991). Similar seasonal variations have been seen in semen quality of dairy bucks in England (Ahmad and Noakes 1996b). Photoperiod control, alternating two months of long, sixteen-hour days with two months of short, eight-hour days, largely abolished the seasonality in sexual activity and semen characteristics (Delgadillo et al. 1991). This could be very useful for managing semen production by bucks at artificial insemination centers.

The effect of rearing conditions other than nutrition on the development of sexual activity in bucks has received little attention. In one study, twenty male goats at weaning were raised in individual pens and an additional sixteen male goats were group housed with four females of the same age that had been ovariectomized before puberty. Collection of semen with an artificial vagina was begun between seven and eight months of age. There was no difference in sexual behavior or sperm output between the two groups, but the average semen volume was significantly higher in the group-housed bucks, caused by increased seminal plasma (Orgeur et al. 1984). A "female effect," where exposure of bucks to estrous does stimulates pulsatile release of luteinizing hormone by the buck, with consequent increase in testosterone production, has also been noted (Gordon 1997).

Breeding Soundness Examination

The ability of the buck to be a successful, highly fertile breeder can never be guaranteed, but close evaluation should permit identification of problems that might interfere with fertility. This is ideally done several months before intended onset of breeding, so

a

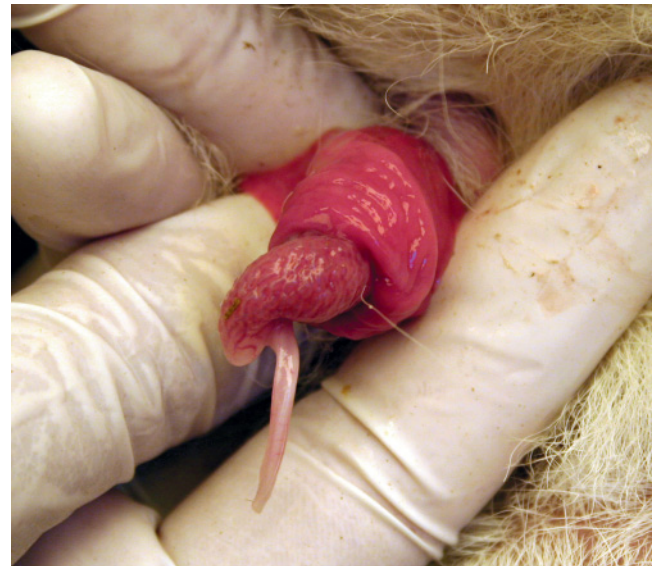
b


Figure 13.10. Normal maturation of the penis. a. The urethral process is completely adhered to the lining of the prepuce; b. separation of the urethral process and glans penis has begun, giving a striking, although normal, red cauliflower-like appearance; c. The urethral process and glans penis are completely separated from the prepuce, and intromission is now possible. (Courtesy Dr. M.C. Smith.)

c

that the buck can be treated or replaced if found to be "unsound." However, it is more difficult to evaluate libido outside the fall breeding season.

The Society for Theriogenology has developed scoring methods for evaluating the bull and ram. A formal system for the buck has not been widely used, and even the validity of those for the major species has been questioned (Ott 1987). It is inappropriate to assign points for each portion of the examination and then compare the total with an "acceptable" value. Superiority in one aspect of the evaluation does not compensate for poor performance elsewhere.

Physical Examination

The first portion of the breeding soundness examination is a thorough physical examination for general health (Ott 1978; Ott and Memon 1980; Memon et al.

2007). Body condition, color of mucous membranes, and sleekness of hair coat should be evaluated for evidence of parasitism, malnutrition, or chronic infection. Teeth, eyes, feet, and joints should be in good condition so that the buck can continue to eat well and can follow and mount the doe in estrus. The buck should be free of known genetic or possibly hereditary defects such as hernias, jaw malformations, or supernumerary teats. The presence of extra teats apparently has no relationship to the fertility of the buck (Schönherr 1956), but if the trait is passed to the next generation, the buck's offspring may be less suitable for milking. Next, the reproductive organs should be examined. This includes palpating the scrotal contents and inspecting the prepuce and penis for various abnormal conditions described in detail in later sections.

Scrotal Circumference

Although scrotal circumference or testicular diameter charts are lacking for most breeds of goats, it is reasonable to assume that, as for bulls and rams, the male with the larger testicular size at a given age is likely to produce more sperm. The risk that the goat has testicular hypoplasia or an intersex condition (polled intersex or freemartin) is also less when scrotal circumference is larger. It has been suggested that the habitual abortion trait in Angoras is associated with small testicular size (Van Heerden 1964).

Some researchers selecting sheep for accelerated lambing and year-round lambing programs believe that rams that show little seasonal (from October to April) decrease in scrotal circumference sire ewes that have less seasonal breeding tendencies (Ringwall et al. 1990). This possibility should be investigated in commercial goat herds striving for out-of-season breeding. Photoperiod effects appeared to account for a 2-cm difference in scrotal circumference in Alpine and Nubian bucks kept in environmental chambers (Nuti and McWhinney 1987).

The scrotal circumference can be measured with a specially designed metal tape (Lane Manufacturing Inc., Denver, Colorado) or with any other measuring tape or even a cord whose length can be compared with a ruler. The circumference is measured at the widest part of the scrotum with both testes held at the same level; it is important not to distract the testes by grasping the neck of the scrotum (Ott 1986; Memon et al. 2007). When bucks have similar age and body-weight, those with above average scrotal circumference may be expected to produce offspring with earlier sexual maturity and greater fertility. Older bucks are expected to have larger testes and more sperm, but do not underestimate the potential breeding capacity of a young buck.

As an approximate guideline for dairy goat breeds in the United States, bucks weighing more than 40 kg should have a scrotal circumference of at least 25 cm. Bucks of British breeds had a mean scrotal circumference of 24 cm when they reached sexual maturity at five and a half months, but the value decreased several cm in the following January and February (Ahmad and Noakes 1996a, 1996b). In another study, the scrotal circumference of mature (three- to four-year old) Nubian bucks of proven fertility was 30 to 33 cm (Skalet et al. 1988). In ten young bucks of German breeds, the scrotal circumference was 24 to 28 cm in October, when the bucks were eight months old and weighed 26 to 52 kg. Scrotal circumference decreased a median of 3 cm when poor hay was fed for two months, then increased again by February with improved nutrition (Arbeiter 1963). A study of Creole goats found that nutrition, rather than photoperiod, determined scrotal circumference in this breed as managed locally (de la Vega 2006). Likewise, Australian cashmere bucks on a high-quality diet had markedly higher scrotal circumference than bucks fed a low quality diet. In both groups the testicular weight dropped through the fall breeding season (when voluntary feed intake was low) and reached a low point early in the winter (Walkden-Brown et al. 1994). In Jordan, Damascus goats had the largest scrotal circumference in the spring, when day length was increasing, which is their normal breeding season (Al-Ghalban et al. 2004). In a young, growing buck, a sudden increase in testicular size indicates the onset of spermatogenesis (Skinner 1970; Bongso et al. 1982).

As an alternative to scrotal circumference, scrotal volume can be measured by measuring the amount of water displaced when the scrotum is immersed. In one study of six Angora bucks, the scrotal volume peaked nine weeks after day length began to shorten (Ritar 1991).

Semen Collection

Collecting and evaluating semen (Eaton and Simmons 1952; Chemineau et al. 1991; Memon et al. 2007) comprise the final portion of the breeding soundness examination. The most representative semen samples for laboratory evaluation are obtained by artificial vagina (AV) (Barker 1958; Austin et al. 1968). The technique has been described elsewhere (Refsal 1986; Memon et al. 2007). Most bucks of normal libido in the breeding season try to mount any restrained goat, though a cycling doe treated two days previously with 5 mg of prostaglandin F2 alpha or a doe or wether treated with estrogen (1 mg estradiol administered one or two days previously) may make a more willing mount. Assuming that the temperature of the AV is appropriate (104°F to 113°F; 40°C to 45°C), even untrained dairy bucks can usually be collected without difficulty. The volume of an ejaculate is typically 0.5 to 1.5 ml.

Vocalization by the buck, contraction of voluntary muscles during electroejaculation, and the more dilute semen obtained make electroejaculation less desirable than the use of an AV (Greyling and Grobbelaar 1983; Memon et al. 1986a). It also is impossible to evaluate libido during electroejaculation. This technique, however, may be the only practical way to collect semen from a range buck (O'Brien et al. 1963). One report suggested (but certainly did not prove) that a sine-wave electroejaculator resulted in collection of more sperm with less distress to the buck than a pulse-wave electroejaculator (Carter et al. 1990). The animal is initially set up on its hindquarters to extrude the penis, which can be prevented from retracting by wrapping it in gauze clamped in place with a spring paper clip.

Induction of erection and ejaculation in bucks, rams, and bulls by massage of the glans penis within the sheath has been described (Megale 1968). The animal should be standing unrestrained in a quiet environment. After the penis is extruded from the preputial orifice, ejaculation may occur spontaneously (into a funnel) or semen can be collected with an artificial vagina.

SPERM MORPHOLOGY. Morphology should be carefully evaluated. Previously, sperm abnormalities were designated to be primary if they were thought to have originated in the seminiferous epithelium (i.e., abnormal head shape, abnormal acrosome, midpiece abnormalities, strongly coiled tails) or secondary if they were thought to have occurred in the epididymis (i.e., proximal and distal cytoplasmic droplets, tailless heads, single bent tails). Newer work in bulls favors designation of the various abnormalities as major or minor (Ott 1986). It is not yet known which morphologic abnormalities are of greatest significance relative to buck fertility.

Many veterinarians mix eosin nigrosin stain with a drop of semen on a slide and quickly draw the mixture out with another slide to create a smear. Evaluation of the air-dried smear with a bright-field microscope allows differentiation of live (appearing white) sperm from dead ones (red because of uptake of eosin) as well as visualization of many morphologic defects. The use of formol saline, or glutaraldehyde fixation (without staining) and a phase contrast microscope permits detection of more abnormalities. So will greater experience with semen evaluation. It is best to count at least 200 spermatozoa per sample. The number of each type of abnormality should be recorded. If the first sample yields unsatisfactory spermatozoa, a second sample should be collected on the same day (Schönherr 1956). Repeated semen evaluations during several months may be necessary to establish an accurate prognosis. In particular, a variety of febrile diseases may be followed by poor semen quality that lasts for as long as two months.

A high prevalence of morphologic abnormalities may be associated with either sexual immaturity or degenerative changes. Arbeiter (1964) found 15% abnormal sperm in 144 ejaculates from nine healthy German bucks initially nine months old. In a two-year study of four "yearling" dairy bucks collected multiple times in fall (November) of two successive years, the percent of abnormal acrosomes and of most other sperm abnormalities was decreased the second year (Chandler et al. 1988). In one study involving Nubian bucks, 65% of sperm cells were abnormal at the onset of puberty but only 12% were abnormal by eight months of age (Skalet et al. 1988). Misshapen heads, abnormal midpieces (abaxial, double, coiled, bent, looped) and proximal droplets were common in the young bucks. By eight months of age, only the midpiece abnormalities were common. Dead sperm are more common in the semen of young bucks in spring and summer than in fall and winter (Ahmad and Noakes 1996b).

In older bucks, the season did not influence sperm abnormalities. Likewise, no seasonal effect on sperm morphology was observed in bucks of native breeds in India (Sahni and Roy 1972) although small increases in percentage of abnormal spermatozoa were noted in bucks in Greece in the nonbreeding season (Karagiannidis et al. 2000). However, it has been shown that in hot climates, bucks with a divided scrotum (each testis in a separate scrotal pouch) produce sperm with fewer morphologic abnormalities, presumably because of enhanced cooling. The average percentage of sperm abnormalities was 5.4% for six Moxotó bucks with a divided scrotum and 32.9% for four bucks with no scrotal division collected during the dry season (Nunes et al. 1983). The percentage of live sperm was decreased in the dry season compared with the rainy season, and sperm abnormalities were increased in the dry season (Silva and Nunes 1988).

Few reports are available on the influence of disease on semen quality. Detached heads, tightly coiled tails, and thickened midpieces were prominent in semen samples from an eighteen-month-old infertile LaMancha buck with testicular degeneration (Refsal et al. 1983). Detached heads and acrosomal defects were increased in goat semen after fever was induced by an injection of Freund's complete adjuvant (Yokoki and Akira 1977). Detached heads were also common (70% of the spermatozoa) in the semen of a Nubian buck with seminal vesiculitis diagnosed by histology (Ahmad et al. 1993). Semen changes associated with various infections are described in the discussion of the individual diseases.

SEMEN MOTILITY AND CONCENTRATION. Motility has received much attention in the past. Because it is very difficult to optimally maintain conditions such as temperature, it is common for normal semen (expected motility of 70% to 90%) to have very poor motility when examined under field conditions. Thus, motility is no longer considered to be an important part of the breeding soundness examination. Concentration of spermatozoa in semen of bucks collected by artificial vagina should be estimated. This can be done by hemocytometer techniques or measurement of optical density, after the instrument is calibrated for buck semen. Concentrations of 2.5 to 3 billion/ml are normal (Eaton and Simmons 1952). Concentration decreases somewhat with more frequent electroejaculation (Oyeyemi et al. 2001).

An approximation of concentration can be determined by spinning the semen for ten minutes in a microhematocrit centrifuge (Foote 1958). One

spermatocrit point represents approximately 200 × 10^6 sperm/ml (Foote, 1992). Spermatocrits of 25 to 33 in normal bucks have been observed by the author. A commercial Unopette system (Becton-Dickinson, Rutherford, NJ) can also be used to estimate sperm concentration (Memon et al. 2007). The yellow color often seen in the seminal plasma is caused by riboflavin (Mendoza et al. 1989; Ahmad and Noakes 1996b) and does not influence semen quality.

Processing Semen for Artificial Insemination

Undiluted fresh semen can be used for artificial insemination when the buck and does are on the same premises, but usually the semen is extended for short- or long-term storage. Methods of semen preservation and insemination have been described elsewhere (Corteel 1981; Haibel 1986b; Leboeuf et al. 2000; Purdy 2006; Nuti 2007). Skim milk (such as UHT milk) -based extenders are often used. High concentrations of egg yolk should not be used in an extender for unwashed semen because a lipase enzyme secreted by the bulbourethral glands (Chemineau et al. 1999) hydrolyzes egg yolk lecithins to products that are toxic to sperm. When semen is to be kept frozen for many months, washing the spermatozoa to remove most of the seminal plasma before freezing has sometimes improved fertility, especially with breeds or seasons when the original ejaculate volume was small (Corteel 1981; Corteel et al. 1984). Nonbreeding season seminal plasma is more detrimental to post-thaw motility than breeding season seminal plasma (Leboeuf et al. 2000). Photoperiod treatment (alternating two months of long days with two months of short days) alleviates adverse effects of the nonbreeding season on post-thaw semen quality (Chemineau et al. 1999).

Although fertility was low, cryopreserved epididymal sperm collected from postpubertal bucks at necropsy has been successful in producing a pregnancy (Blash et al. 2000).

TESTICULAR AND EPIDIDYMAL ABNORMALITIES

Except for changes induced by fever or malnutrition, most abnormalities are not amenable to treatment.

Procedures for Evaluating Testis and Epididymis

In addition to judging the testicular volume by scrotal circumference or the diameter of each testis by the use of calipers, the consistency of the testes should be evaluated. Normal testicular tissue should feel resilient and approximately as firm as muscle. Its ultrasonographic appearance is uniformly homogeneous with a central hyperechoic line representing the mediastinum testis. The testicular tunics and testicular capsule are also distinct hyperechoic lines, whereas fluid around the testis (hydrocele) is hypoechoic (Eilts et al. 1989). The tail of the epididymis is more heterogeneous and less echogenic than the testis (Ahmad et al. 1991). The use of ultrasonography for evaluating testicular lesions has also been described for bulls (Pechman and Eilts 1987; Powe et al. 1988).

Testicular biopsy is not routinely used in goats. In bulls, biopsy procedures have led to decreased semen quality. It is important to avoid highly vascular areas and to suture the incision in the tunica albuginea, or else hemorrhage and infarction may occur (McEntee 1990).

Testicular Atrophy or Degeneration

A common cause of testicular degeneration is debility from malnutrition or parasitism (Memon 1983). The chronically recumbent buck might also experience testicular atrophy because of impaired thermoregulation in the scrotum. Sperm granulomas (see below) cause progressive testicular degeneration. Testicular atrophy of unknown etiology but accompanied by abnormal spermatozoa appears to be common in some goat populations. The testes often are more elongated and smaller than normal. The head of the epididymis may undergo a palpable loss in lobulation (Fraser 1971). Multiple foci of calcinosis are grossly visible on cut surfaces of the testis. Histologically, granuloma formation occurs where masses of dead sperm have accumulated in collecting ducts (Fraser and Wilson 1966).

Foci of testicular necrosis or mineralization are hyperechoic during ultrasonographic examination but only the echogenicity of the near-field testis should be assessed, because of attenuation of the far-field ultrasound beam. Firm, mineralized parenchyma, detectable by ultrasound, has been observed in elderly or infertile bucks (Buckrell 1988). These changes are irreversible. Testicular neoplasia, although rare in goats, should also be detectable by ultrasonography.

Atrophy and degeneration of the seminiferous tubules have been reported in goats in the Sudan experimentally fed *Acanthospermum hispidum*, which also causes hepatic necrosis and fibrosis (Ali and Adam 1978). Likewise, the feeding of *Leucaena leucocephala* is reported to cause mild degeneration of the testes. (Rajan et al. 1991), possibly secondary to hypothyroidism. Experimental hypothyroidism in goats (achieved by feeding thiouracil) was associated with a relative decrease in the weight of the testis and epididymis, a reduction in spermatogenesis, and degenerative changes in the testis and accessory sex glands. There was loss of libido, decreased ejaculate volume, and decreased sperm concentration, motility, and viability, and an increase in abnormal spermatozoa. These changes were reversible (Sreekumaran and Rajan 1978;

Reddi and Rajan 1985, 1986). Thyroidectomy in young male goats also results in smaller than normal testes (Reineke et al. 1941). Detrimental effects of naturally occurring hypothyroidism on testicular function in adult goats have not been documented. Additional discussion of thyroid function and goiter is provided in Chapter 3.

Testicular Hypoplasia

Abnormally small testes most commonly occur with severe malnutrition (Neathery et al. 1973) or in animals that are actually intersexes (i.e., polled intersexes or freemartins). Hypoplasia is often difficult to distinguish from atrophy, but with either condition, testicular size and function should improve with proper feeding if malnutrition is responsible. Intersexes and freemartins do not produce any sperm at all, even in the breeding season, and generally are less odoriferous than normal bucks. Their testes do not undergo the increase in size that normally occurs at puberty, or else the testes may atrophy at that time.

One case of testicular hypoplasia has been reported in a horned buck with chromosomal mosaicism (XXY and XY) (Jorge and Takebayasi 1987). Two sterile polled bucks with a Robertsonian translocation were found to have normal seminiferous tubules interspersed with tubules devoid of germinal cells (Ricordeau 1972). Histologically, similar findings have been reported in polled bucks with sperm granulomas obstructing the epididymis but with normal karyotype (Corteel et al. 1969).

Bucks with severe experimental zinc deficiency compounded by reduced feed intake and control bucks with just reduced feed intake in the same trial showed normal tubules adjacent to tubules containing only spermatogonia (Neathery et al. 1973). A secondary zinc deficiency, caused by excessive fertilization of fields, resulted in atrophy of the seminiferous tubules, hyperplasia of the germinal epithelium, and thickening of the walls of blood vessels in the testes of young Black Bengal bucks (Ray et al. 1997).

Unilateral testicular hypoplasia (in males producing sperm) has been reported in two goats in India (Mathew and Raja 1978b) and in a polled Saanen XY buck in the United States (Sponenberg et al. 1983). In the Indian bucks, spermatogenesis only progressed to the formation of spermatocytes, while in the latter case, some seminiferous tubules in the affected testis were devoid of sperm cells while others were normal. Three additional bucks (horned feral animals) in Australia with unilateral hypoplasia had small seminiferous tubules lined by Sertoli cells (Tarigan et al. 1990). A unilateral segmental tubular hypoplasia in a testis of normal size but with discrete pale areas on section also has been observed in two animals in this Australian slaughterhouse survey of 1,000 bucks.

Cryptorchidism

Intersex animals, as discussed previously, may exhibit retained testes or ovotestes. The gonad may be abdominal or inguinal in location. The animals are usually genetic females or freemartins. No sperm are produced.

Failure of one testis to descend into the scrotum has been reported frequently in Angora goats. Bilateral cryptorchidism appears to be rare in this breed. The cryptorchid goat is sometimes referred to as a "ridgling."

Etiology

Cryptorchidism is hereditary in Angora goats but is not related to the polled intersex condition, which does not occur in this breed. Affected Angoras are genetic males (Skinner et al. 1972). The cryptorchid trait is recessive but controlled by a few pairs of genes (Warwick 1961). In other breeds, cryptorchidism in XY males occurs occasionally, and although less is known about the etiology, a genetic explanation is probable.

Clinical Signs and Surgical or Necropsy Findings

The testes normally descend into the scrotum by twelve to thirteen weeks of gestation (Sivalchelvan et al. 1996). Cryptorchidism is detectable at birth. If the condition is bilateral, no scrotum is present. In Texas Angoras (Lush et al. 1930) and in Indian goats of unspecified breed (Mathew and Raja 1978a), the right testis was retained, whereas in South African Angoras, the left testis was retained (Skinner et al. 1972). In one research farm in India, six of eighty-nine Tellicherry bucks born during a four-year period were unilaterally cryptorchid. In five of these the right testis was retained (Murali et al. 2005). In a slaughterhouse study in Ethiopia, twenty-two of 404 (5.5%) horned native breed bucks were cryptorchid; eighteen of these were unilateral and ten involved the right testis (Regassa et al. 2003). The unilaterally affected buck is generally fertile, although semen volume and sperm concentration are reduced. Mohair quality in cryptorchid Angoras is normal.

In the unilateral cryptorchid, the retained testis is often located near the kidney. In two Anglo-Nubian bucks in Brazil with unilateral cryptorchidism, the retained testis (one left, one right) was located at the entrance to the inguinal canal (Vinha and Humenhuk 1976). If castration is required, as for a pet animal, the location of the testis can be confirmed before surgery by ultrasound. The tunica albuginea of the retained testis is echogenic and clearly demarcates it from surrounding tissue (Kaulfuss 2006). This testis is generally smaller than the scrotal testis.

The cryptorchid testis resembles a prepuberal testis histologically. Sertoli cell degeneration has been

described in the cryptorchid testis in West African dwarf goats (Ezeasor and Singh 1987), whereas tubular degeneration and Sertoli cell hyperplasia have been reported in two cryptorchid feral goats in Australia (Tarigan et al. 1990).

Prevention

The prevalence of the condition in a flock varies with the selection pressure against it, often approximately 2% but as much as 10% in commercial herds and more than 60% when cryptorchids are intentionally bred. Breeders wishing to sell bucks realize that a unilateral cryptorchid is of little commercial value. To decrease the prevalence of the condition, cryptorchid bucks should not be used for breeding and their sires and dams should also be culled. Even stricter selection involves culling all offspring of known carriers (Warwick 1961).

Persistent Müllerian Duct Syndrome

A single male (60, XY) Nubian goat with bilateral cryptorchidism and persistent Müllerian duct syndrome has been described (Haibel and Rojko 1990). Hypoplastic testes, rudimentary epididymides, and a bicornuate uterus were present. Vesicular glands, bulbourethral glands, and penis resembled those of a normal male. Similar syndromes are seen in Miniature Schnauzers and human males and are thought to be associated with a lack of either secretion of or receptors for Müllerian inhibiting substance, normally of fetal Sertoli cell origin.

Infectious Diseases Causing Orchitis and Epididymitis

Bacterial orchitis and epididymitis are far less common in goats than in sheep. Expected clinical findings include swelling, increased heat, and pain on palpation of the testis. The semen may contain pus and the percentage of live spermatozoa drops. In one case report, transrectal ultrasonography also demonstrated changes in the echogenicity of the seminal vesicles (Santiago Moreno et al. 1996).

Coliform bacteria and *Pseudomonas* have been cultured from ejaculates of young bucks. Coliforms have caused both orchitis and epididymitis when injected into the testis (Löliger 1956, 1957). *Actinobacillus seminis* was isolated from four of forty Angora bucks examined in South Africa, but details as to clinical presentation were not supplied (Van Tonder 1975). When pathologic changes are not palpable, they might be suspected based on the presence of increased leukocytes in the semen. The major differential diagnosis is the nonsuppurative sperm granuloma originating from a malformation of the epididymis.

In one five-year-old buck, unilateral testicular enlargement progressed to five times the normal size.

The animal was inappetent and walked with a stiff, straddling gait. The affected testis was firm and fixed in the scrotum. *Staphylococcus pyogenes* was isolated from a purulent epididymitis at time of unilateral castration. Involvement of the second testis was obvious within three weeks (Jackson and White 1982). In another report, *Corynebacterium pseudotuberculosis* was associated with epididymitis and orchitis in two bucks in Brazil (Alves et al. 2004). *Burkholderia (Pseudomonas) pseudomallei* caused orchitis and peri-orchitis in a buck (Fatimah et al. 1984). The buck was inappetent and the swollen testes developed pyogranulomas. There was no response to antibiotic therapy.

Mycoplasma putrefaciens was isolated from the testes of a buck that died during a severe herd outbreak of contagious agalactia with concomitant infection with *M. agalactiae* and *M. putrefaciens*. Spermatozoa were absent in seminiferous tubules and there was calcification and loss of germinative epithelium, with only Sertoli cells remaining (Gil et al. 2003).

Brucellosis

Brucella ovis is an important cause of epididymitis and orchitis in sheep. Stamps stain can be used to demonstrate the organism in semen smears, and white blood cells and detached heads are commonly found in the semen. This organism is not recognized as a cause of natural infections in goats. Experimental infection of bucks by conjunctival or intrapreputial inoculation of this organism has led to clinical and histological epididymitis, transient infection, and serologic response (García-Carrillo et al. 1974). In a subsequent trial, the organism was isolated from the semen of one of fifteen goats (García-Carrillo et al. 1977). In another experiment, inoculation of *B. ovis* onto the preputial epithelium (two yearling goats) and nasal mucosa (two goats) led to an antibody response best detected by enzyme-linked immunoabsorbent assay but also (in three animals) by CF testing. One intranasally inoculated buck persistently shed *B. ovis* and white cells in semen. The experiment was concluded at ninety-eight days, when chronic epididymitis and seminal vesiculitis were demonstrated only in the goat that had excreted organisms (Burgess et al. 1985). Thus, if bucks engage in homosexual activity with infected rams there is some potential for transmission to occur.

Brucella melitensis occasionally causes orchitis in bucks (Dubois 1911). The Rev 1 vaccine strain has also caused orchitis in a buck kid vaccinated at five months of age (Tolari and Salvi 1980). In South Africa, where the Rev 1 *melitensis* vaccine has been used to control *Brucella ovis* in sheep, orchitis and epididymitis have developed in Angora bucks soon after vaccination (Vermeulen et al. 1988). The authors failed to create clinical disease in bucks by experimental infection

with *Brucella ovis* and concluded that bucks should not be vaccinated unless *B. ovis* has been confirmed on the farm or *B. melitensis* is causing abortions in the herd.

Trypanosomosis

Trypanosoma brucei and *T. vivax* have been associated with inflammatory and degenerative changes in the testis and epididymis of sheep and goats in Africa. After experimental infection with *T. brucei* (in rams), persistent scrotal edema and a nonsuppurative granulomatous periorchitis developed associated with tissue invasion by the parasite. Trypanosomes were readily detected in fluid from the scrotal sac. Secondary degenerative changes in the testis included atrophy and calcification of seminiferous tubules and intertubular sclerosis (Isoun and Anosa 1974; Ikede 1979). In bucks experimentally infected with *T. vivax*, organisms were not seen outside blood vessels in the testes and it was postulated that testicular degeneration occurred because of recurrent fever (Anosa and Isoun 1980). Affected animals are expected to have low fertility until some time after the infection has cleared.

Experimental infection of bucks with *Trypanosoma evansi* also caused microthrombi in testicular blood vessels, severe mononuclear cell infiltration in the epididymis and testicular interstitium, and subsequent dystrophic mineralization. The number of abnormal and dead sperm increased greatly, and bucks with clinical orchitis became aspermic (Ngeranwa et al. 1991). A later experimental infection of bucks with an equine isolate of the same organism caused scrotal edema in 20%, degeneration of spermatogonia and Sertoli cells, and infiltration of the testes with macrophages and lymphoid cells (Dargantes et al. 2005). Experimental infection of bucks with *Trypanosoma congolense*, a plasma parasite that does not invade tissue, also has caused testicular degeneration with marked shrinking of seminiferous tubules and epididymides, but the pathogenesis is unknown (Kaaya and Oduor-Okelo 1980). Trypanosomosis is described in Chapter 7.

Besnoitiosis

There is one report of a buck in Africa with masses of *Besnoitia* cysts in the wall and lumen of veins and arteries of the pampiniform plexus; parasitic cysts were also present in the epididymis and testis. Thrombosis of vessels, absence of sperm production, and extensive testicular fibrosis were believed to be caused by the parasite (Bwangamoi et al. 1989). Encrustation of the scrotum and presence of numerous *Besnoitia* cysts in the tunica vaginalis, tunica albuginea, and interstitium of the epididymis were reported from two male wild goats in Iran (Cheema and Toofanian 1979). The existence of a distinct species, *Besnoitia caprae*, has been proposed in Kenya, where cattle housed with infected goats do not develop besnoitiosis (Njenga, J.M., et al. 1993).

Sperm Granulomas

Obstruction of the head of the epididymis is a common cause of infertility in polled male (XY genotype) goats (Hamerton et al. 1969). Bucks of the Damascus breed in Jordan have higher reproductive capabilities when horned rather than polled (Al-Ghalban et al. 2004), but sperm granulomas have not been documented in this breed.

Etiology and Pathogenesis

This condition is believed to be hereditary and recessive, with incomplete penetrance (estimated in one study as 0.55) (Ricordeau et al. 1972a). An early theory that the problem was caused by excessive nutrient intake by the young buck came about because better nutrition leads to earlier puberty and thus earlier expression of the problem. Other early theories included psychological factors and abnormal thyroid function (Schönherr 1956).

The normal head of the epididymis forms from the union of approximately sixteen to nineteen efferent ductules (Hemeida et al. 1978). The direct cause of the obstruction is believed to be one or more of these ductules that end blindly (Machens 1937). The ducts become distended with inspissated sperm until rupture occurs and sperm are released into the stroma of the epididymis (Figure 13.11). A severe inflammatory reaction with lymphocytes and giant cells occurs in response to the sperm cells and eventually a granuloma forms. The granuloma may calcify. Epididymal ducts that were previously patent may become obstructed by the
Figure 13.11. Sperm granuloma in the head of the epididymis of the testis on the left, from a polled buck. (Courtesy Dr. M.C. Smith.)

granuloma (by compression or fibrosis) (Machens 1937). Back pressure eventually leads to degeneration and even mineralization of the testicular stroma (Corteel et al. 1969; Soller et al. 1969).

A partially split scrotum has been associated with increased frequency of sperm granulomas in Germany (Schönherr 1956), but appears to be a desirable trait in breeds native to very hot climates, where cooling of the testes is facilitated.

Clinical Signs and Diagnosis

Some animals are sterile from the beginning because all of the efferent ducts are affected. Others are initially fertile but become infertile if bilateral granulomas form. Normal libido persists.

By the end stage, both the firm granuloma (lentil- to egg-sized) in the head of the epididymis and the reduced size of the testis are palpable. Less commonly, granulomas form in the body or tail of the epididymis. Normal epididymis is clearly softer than normal testis (München 1951). In ultrasonographic evaluations, appearance of sperm granulomas (in a ram) has been described as fluid-filled structures within a ring of echogenic tissue (Buckrell 1988). Ultrasound examination is also useful for demonstrating testicular mineralization, the end stage of degeneration induced by back pressure.

Correction of this defect is not possible. The diagnosis can be confirmed by gross and histological examination after castration or slaughter.

Prevention

Because sperm granulomas are very strongly correlated with the homozygous polled condition, breeders can avoid the expense of raising animals that will be (or become) sterile because of this defect by culling all young bucks that are by phenotype homozygous for the polled gene. These bucks have very smooth, well-separated protuberances on the poll. Heterozygous bucks, in contrast, typically have bean-shaped protuberances that converge anteriorly and many have irregular horny bosses that become evident by three to six months of age (Ricordeau et al. 1972b). If polled bucks are kept for breeding, their potential fertility should be monitored regularly by palpation and semen evaluation.

Segmental Aplasia of the Epididymis

In a slaughterhouse study of one hundred bucks in Brazil, three were found to have segmental aplasia of the body of the epididymis. One buck was affected bilaterally. Two bucks were horned and one (Moxotó breed) was polled. The head of the epididymis was distended, the body could not be palpated, and the tail was reduced in size (Humenhuk and Vinha 1976).

Scrotal Hernia

Scrotal and inguinal hernias have not been described in goats, but are seen in sheep and generally presumed to be hereditary in that species. Clinical signs include distension of one side of the scrotum with a freely movable, fluctuant loop of intestine. If a hernia is identified in a buck and surgical correction is desired, the buck should be castrated bilaterally.

Other Scrotal Lesions

Wounds (shearing cuts, dog bites, vasectomy) involving the scrotum may result in establishment of a purulent orchitis or periorchitis. Fly strike and grass awn migration might also occur, although these conditions are better described in rams. Some breeders in Texas believe that a split scrotum increases the risk of injury to the scrotum by burrs or brambles (Drummond 1988). Other causes of scrotal dermatitis include mange (Kambarage 1992), bacterial infections, zinc deficiency, and frostbite; the reader is referred to Chapter 2.

Elastosis and fibroblastic proliferation of the intima of the testicular artery have been observed in goats, as has calcification of the wall of the testicular artery and veins (Panebianco et al. 1985). Possible effects of these vascular lesions on fertility are unclear. Varicocele does not seem to have been reported in goats.

PENILE AND PREPUTIAL ABNORMALITIES

Examination of the penis is most easily performed with the buck positioned on his rump. Tranquilization may be helpful, because goats rarely rest quietly in the sitting position. The shaft of the penis is pushed anteriorly with one hand while the prepuce is pushed posteriorly with the other hand. The young buck kid is held in a sitting position in the examiner's lap, with legs pointing away from the person, to facilitate exteriorization and examination of the penis.

Malformations

Most congenital malformations (i.e., hypospadias [Al-Ani et al. 1998], shortened penis of some intersexes) are easily detected by physical examination. Congenital diverticula in the urethra were associated with swelling of the ventral sheath and continuous dribbling of urine in eleven goat kids two to six months of age in India. Ten of these animals also had a completely divided scrotum. The animals recovered after surgical excision of the diverticula (Gahlot et al. 1982).

Maturation of the Penis

When the sexual maturity of a male is questioned (e.g., during a breeding soundness exam or when he has inadvertently gained access to females that were not to be bred), the penis should be carefully

examined. As long as the urethral process and glans penis are adhered to the prepuce, successful copulation is unlikely to occur. These adhesions, normal in the immature buck, break down with testosterone, time, and good nutrition.

Injuries

Traumatic hematoma of the penis is rare in small ruminants; a single case report describes successful surgical treatment in a buck with return to normal breeding (Bani Ismail and Ababneh 2007). The presence of a hair ring (accumulation of loosely matted hairs) around the shaft of the penis may be accompanied by irritation (Tarigan et al. 1990). Grass awns in the prepuce can also cause irritation.

Loss of the urethral process is a common shearing accident in Angoras. If the urethral process is absent but the glans penis is intact and normal, no direct adverse effect on fertility is expected (Ott 1978). In other goat breeds, a previous bout of urolithiasis is usually responsible for loss of the urethral process. Re-obstruction at a later date may endanger the buck's life or fertility. There also might be an increased risk of contamination of the semen by urine, caused by damage to sphincter muscles during obstruction. There is a single report of erection failure in a Nubian buck after urolithiasis, secondary to a vascular obstruction in the corpus cavernosum penis (Todhunter et al. 1996). Urolithiasis is discussed in Chapter 12.

Posthitis

Posthitis, the inflammatory condition of the prepuce also termed "pizzle rot," often results from overgrowth of urea-splitting bacteria in the prepuce of males consuming excessive dietary protein. Free ammonia scalds the preputial and penile mucosa. Wethers appear to be more susceptible than intact males (Shelton and Livingston 1975). This condition is discussed in Chapter 12.

Pustules and ulcers on the prepuce and penis of bucks have been ascribed to caprine herpesvirus-1, which is associated with abortion and with vulvovaginitis in does (Tarigan et al. 1987; Uzal et al. 2004). The gross appearance varies with the extent of secondary bacterial infection. Histologically, findings of acidophilic intranuclear inclusion bodies and chromatin margination in epithelial cells adjacent to the ulcers are considered highly suggestive of the herpesvirus infection (Tarigan et al. 1990). It is also reported that bucks that spread the infection to does during mating may remain free of clinical signs (Grewal and Wells 1986). This condition is discussed further in Chapter 12.

Trichomoniasis

Trichomonad protozoa have been observed in large numbers in the semen of Alpine and Saanen bucks in France and Sardinia and in Angoras in South Africa. The parasite, which is approximately the size of a sperm head, infests the sheath and urethra. Quantity and quality of ejaculates are decreased, as is libido. The infections have been treated successfully with dimetridazole (3 or 5 g, divided into three intravenous doses at twenty-four-hour intervals), but use of this drug is currently illegal in goats in the United States. Routine treatment of all bucks in the artificial insemination centers in France each summer, before the season of semen collection, has been proposed as an alternative to repeated testing of each buck (Corteel 1991). Effects of this organism on the doe have not been elucidated and recent reports of the condition are lacking.

OTHER PROBLEMS AFFECTING THE BUCK

Poor Libido

Mounting and thrusting behavior, sniffing of the anogenital region, and flehmen are well established as common behaviors of normal goat kids of both sexes before the age of one month (Sambraus 1971). Normal libido, then, although necessary for fertility, is clearly not sufficient.

In the anestrous season it may be difficult to obtain an ejaculate by artificial vagina or the buck may be very slow to serve a doe in heat. The buck may rest his head on the doe's hindquarters but fail to align himself with the longitudinal axis of the doe. Proper alignment is gradually approached as the breeding season nears (Fraser 1964). If heat detection is all that is needed, a doe or wether can be treated with testosterone propionate (100 mg every three days) until male behavior is observed. Testosterone is a controlled substance in the United States. Additionally, extralabel drug use for production purposes is not permitted.

Testosterone should not be given to the breeding buck because of its negative feedback effect on sperm production. Instead, the buck to be used out of season should be prepared in advance by a light treatment at the same time the does are exposed to a nineteen- to twenty-hour photoperiod. Daily training with a doe treated with estrogen may increase libido as the planned breeding time approaches (Van der Westhuysen et al. 1988), or else eCG (500 IU once) (Skinner and Hofmeyr 1969) or GnRH (40 μg every eight hours for four days) (Minnia et al. 1987) may be administered to the buck.

Gynecomastia

Development of mammary glands in bucks is occasionally observed (Heidrich and Renk 1967). The best description of the condition comes from the German literature.

Etiology and Pathogenesis

One documented case involved a polled one-and-a-half-year-old fertile male Fawn German goat (Deutsche bunte Edelziege) that yielded 20 ml of milk daily. The animal was determined to be a chromosomal mosaic with variable deletions of the Y chromosome (XO/XY) (Rieck et al. 1975). The authors suggested that gynecomastia might be an early sign of feminization, analogous to the XO/XY condition in humans. Another buck that yielded 250 to 300 ml of milk per day had drum sticks in 45% of neutrophil nuclei, suggesting a genetic intersex, but karyotyping was not performed (Panchadevi and Pandit 1979).

Earlier reports of gynecomastia in bucks do not include karyotype (Harms 1937; Ullner 1961; Hamori 1983). Presumably, a variety of conditions disturbing the endocrine balances in a goat (i.e., hypophyseal, testicular, or adrenal abnormalities, administration of exogenous hormones) could be accompanied by gynecomastia. For example, a six-year-old Toggenburg wether of normal (60, XY) karyotype developed gynecomastia that was traced to estradiol 17 beta production from an adrenal adenoma (Lofstedt et al. 1994). Another fertile Toggenburg buck with normal karyotype had normal plasma testosterone and estradiol concentrations but prolactin was markedly elevated (Janett et al. 1996). A fertile Nubian buck with gynecomastia associated with hyperplasia of acidophilic cells in the pituitary has also been reported (Buergelt 1997). Some case reports lack hormonal studies (Al Jassim and Khamas 1997).

In England, mammary gland development is seen in bucks from high producing lines of British Saanens (Matthews 1991). The phenomenon is usually observed in the summer and fertility is unaffected. This suggests a genetic basis and perhaps an increased production of hormones or an increased sensitivity of mammary tissue to normal hormones.

Clinical Signs

Polled intersex goats (genetic females) that have a masculine phenotype are best excluded from this discussion. Thus, if a given "male" animal has no history of being fertile, the discussion of intersexes should be consulted. Unfortunately, early writers considered gynecomastia to be just another expression of the intersex problem. In affected fertile bucks, the teats are enlarged and the mammary gland is developed to a variable, often asymmetrical, degree (Figure 13.12). There is true glandular development rather than just local fat deposition. These signs generally appear after sexual maturity is reached. Analysis of the milk has disclosed no major differences from milk of does. There appear to be seasonal variations in milk production as production is lower during the breeding season.

Figure 13.12. Gynecomastia in a five-year-old Nubian buck. Although initially fertile, severe chronic mastitis led to weight loss and testicular degeneration. (Courtesy Dr. M.C. Smith.)

Several animals that have been followed closely showed a progressive decline in libido and semen quality (Ullner 1961). At time of slaughter, mineralization of the testicular parenchyma has been identified. The authors were unable to determine if the testicular lesions preceded (and might have caused) the gynecomastia. In another study, milk secretion by four mature bucks could not be associated with reduced fertility (Schönherr 1956).

Treatment and Control

Reducing the protein and energy levels in the feed during the summer has been suggested for managing gynecomastia in bucks from high producing lines. This may reduce the risk of mastitis (Matthews 1991). Apparently the superior milk production of the daughters of these bucks discourages culling, though gynecomastia occurs in the male offspring.

No specific treatment has been suggested that might not be detrimental to fertility. Amputation of the glands may be attempted if nonresponsive mastitis (Dafalla et al. 1990) or neoplasia (Wooldridge et al. 1999) develops. Semen quality should be monitored so that the buck may be culled if infertility develops, but there is insufficient evidence at this time to justify automatic culling of the fertile animal. Researchers might choose to karyotype these animals.

Neoplasms of the Male Reproductive Tract

Reports of testicular tumors in goats are very scarce. One seminoma has been reported (Pamukcu 1954). A single case of hemangiosarcoma of the bulbourethral gland was also found in a slaughterhouse survey (Tarigan et al. 1990). Adrenal cortical adenomas are a relatively common but incidental finding in castrated

male goats. Fifteen percent of wethers examined in one study (Altman et al. 1969) and 26% of wethers in another study (Richter 1958) were affected. Most of these animals were Angoras, the breed of goats in which wethers are most commonly allowed to live to an old age. Lack of testicular negative feedback on release of pituitary gonadotrophins may be involved in the pathogenesis of these tumors. Hyperplastic adrenal cortical nodules (subcapsular, intracapsular, or extracapsular) are also common. They have been found in the head of the epididymis of intersexes (three of ten) and of polled (six of twenty-seven) and horned (one of eight) bucks (Widmaier 1959).

Arthritis and the Breeding Buck

In the United States, one of the most common reasons for a buck to come to the end of his breeding career is arthritis. Painful hips, stifles, or hocks cause a reluctance or inability to mount. The occasional very willing doe manages to get into a compatible position for breeding, but most service attempts fail. If several bucks are run together with the does, the arthritic male may interfere with and prevent breeding by another, normal buck. The lame buck also tends to lose body condition because it does not get up to eat as much as it should.

The decision regarding how to handle the arthritic buck deserves careful thought. In particular, it is important to know the etiology of the lameness. If arthritis involves one limb and is the result of a known traumatic event, then continued breeding with semen from the buck is a reasonable goal, assuming his progeny are of adequate quality. If the buck has clinical caprine arthritis encephalitis (CAE), then the breeder should consider retiring the buck from breeding. Clinical disease is more common in some families than others, suggesting an inherited susceptibility to the effects of the virus. Also, research has shown that clinical CAE is associated with certain histocompatibility antigens, again suggesting a hereditary component (Ruff and Lazary 1989). A herd with a goal of eradicating the CAE virus should not be propagating inherently disease-susceptible animals. That means that the practice of freezing as much semen as possible from a crippled buck must be questioned. Transmission of CAE infection by natural breeding appears to occur infrequently (Adams et al. 1983), although virus has been detected in the seminal fluid and non-sperm cellular fraction of semen from infected bucks (Travassos et al. 1999; Martinez-Rodriguez et al. 2005). Handmating (to decrease contact with other secretions of the infected buck) or washing and extending the semen would presumably reduce the risk of venereal transmission of CAEV.

Similarly, if the buck's lameness is caused by degenerative arthritis, in turn caused by congenitally poor conformation or anatomy, he should not be used for breeding. The veterinarian needs only to think of the increased incidence of stifle injuries in certain breeds of dogs to imagine the long-term results of indiscriminate propagation of such traits.

If the buck has no genetic faults or the owner refuses to consider these arguments as valid, then semen is collected with an artificial vagina or (less commonly) by electroejaculation. The semen can then be frozen or used fresh. Many bucks are willing to serve an AV while standing behind the doe in heat. The undiluted semen can be used to breed that doe, or semen can be diluted in heat-treated milk if several does are in estrus simultaneously. As the buck's condition worsens, an owner may choose to collect as much semen as possible for freezing, then euthanatize the buck. Custom freezers of goat semen have reported poor semen quality and freezability when semen is processed from bucks with severe CAE that have received phenylbutazone. This might be because of direct effects of the virus on testicular function, prolonged recumbency, or decreasing body condition as the disease advances rather than a toxic effect of the anti-inflammatory drugs. No detrimental effects of phenylbutazone on semen quality of artificial insemination stud bulls have been demonstrated.

Diseases Transmissible by Semen or Embryos

When it is desirable to transfer genetic material between herds or even between countries, the risks of introducing an infectious agent must be considered. Our knowledge concerning the transmission of diseases via semen is still fragmentary (Hare 1985; Philpott 1993). Agents known to be transmitted this way in small ruminants include foot and mouth disease virus, bluetongue virus, leptospires, mycoplasma, *Mycobacterium paratuberculosis* (Eppleston and Whittington 2001), and *Toxoplasma gondii* (Dubey and Sharma 1980). Probably transmitted agents include peste des petits ruminants and *Brucella melitensis*. Most infectious agents survive the freezing process. This means that a single ejaculate can potentially infect does in several herds or seasons. On the other hand, extended semen may have less than the minimum infective dose of an organism present. Also, if bucks are kept in artificial insemination centers, they can be routinely screened for many diseases.

When evaluating the risks from embryo transfer, it should be noted that infection could come from the ovum, the sperm, uterine fluids, or infection of the embryo by the dam after fertilization. In general, if embryos are deep frozen after collection, there will be time to complete laboratory tests on the donor dam and collection fluid from the donor before embryos are transported to the recipient herd. Protocols to decrease the risk of disease transfer by embryos to near zero

include requiring an intact zona pellucida and ten consecutive washings at 1:100 dilution with use of a new sterile pipette for each washing.

Almost no research with goat embryos has been reported to date. Preliminary work suggests that bluetongue virus (Chemineau et al. 1986) and caprine arthritis encephalitis virus (Wolfe et al. 1987) are not transmitted by embryos. Also, scrapie is apparently not transmitted by either artificial insemination or embryo transfer (Foote et al. 1986). However, the International Embryo Transfer Society (Givens et al. 2007; OIE 2007) still places bluetongue and scrapie in goats into category 4, indicating that either no conclusions are possible or else there is evidence for a non-negligible risk of disease transfer by embryo transfer.

SURGERY OF THE MALE REPRODUCTIVE TRACT

Preparation of Teaser Bucks

There are many situations in which the presence of a teaser animal is desirable. A teaser can be used to stimulate the onset of cyclicity at the beginning of the breeding season or in the off season (male effect). If the teaser is incapable of inseminating his does, breeding can be intentionally postponed until the second estrus, when there is an increased ovulation rate.

A teaser animal may also be more efficient than a human caretaker at eliciting or observing signs of estrus, including tail wag, buck-seeking behavior, and willingness to stand. The teaser, then, generally simplifies protocols involving superovulation, artificial insemination, or breeding to a distant buck. It can also be used to detect returns to estrus when rebreeding must be to the same distant buck or buck in a straw. One study showed a decrease in the duration of estrus and an increase in fertility to artificial insemination (from 59% to 74%) when a vasectomized buck serviced the does before AI was performed (Romano et al. 2000). Finally, the owner can be more sure of the last possible due date, as for induction of parturition, if there was no post-breeding exposure to a fertile buck.

Angora goats are reported to be inactive outside the normal breeding season, and selection and preparation of a less seasonal goat such as the Boer has been recommended for use as an early season teaser in South Africa (Van der Westhuysen et al. 1988).

Nonsurgical Teasers

There is a teaser to fit almost every situation. If a small herd has only one buck, that animal can be fitted with an apron to ensure that copulation does not occur. If no bucks are present, other animals can be substituted. One of the simplest teasers is the intersex goat. This infertile animal usually has no idea that it is a genetic female. Where year-round masculine behavior

is not desired or the expense of maintaining an otherwise nonproductive animal is too great, a temporary teaser can be created with hormones. A wether or a doe that will not be bred for several months is chosen. The animal is then given testosterone by injection to develop adequate libido. One protocol involves using 100 mg of testosterone propionate every third day (Barker and Bosu 1980; Bosu and Barker 1982). Another uses 150 mg repositol testosterone weekly, beginning three weeks before intended use and continuing until the teasing job is done for the year (Herndon 1989). Intravaginal sponges impregnated with 100 mg testosterone have also been used (Gordon 1997). Practitioners in the United States should note that testosterone is currently regulated as a schedule III drug under the Controlled Substance Act (Parkhie 1991).

Penile Translocation

The owner of a large herd may want one or more surgically prepared teasers. A penile translocation (deviation) is the surgery of choice if later breeding to the selected buck might be desirable (Barker 1977). The buck should be held off feed and water twelve hours before surgery because he will be positioned in dorsal recumbency. If surgery is done under general anesthesia, a cuffed endotracheal tube should be used. If the buck is only tranquilized and analgesia is provided with local injection of 1% lidocaine, the head should be positioned lower than the neck. The abdomen is clipped and scrubbed and a new location, above the fold of the flank and on an angle from the base of the scrotum that is 45 degrees off midline, is chosen for the preputial opening. The right flank is preferred if a right handed person is trying to collect semen from the buck with an artificial vagina at a later date. A circle of skin and cutaneous trunci muscle (4 to 5 cm in diameter, lower edge 1 cm above the fold of the flank) is removed and discarded (Ames 1988; Mobini et al. 2002). Next, a circumferential skin incision approximately the same size as that of the target hole (5 cm diameter) is made around the preputial orifice and extended along the midline, over the shaft of the penis, from the preputial incision two-thirds of the way to the base of the scrotum (Figure 13.13). The prepuce and penis are dissected free of the body wall. A reference suture is placed to mark the most cranial aspect of the skin of the prepuce (Mobini et al. 2002), and the finger of a sterile glove is slipped over the prepuce to prevent tissue contamination as the penis is pulled through a subcutaneous tunnel to the flank incision with the aid of long forceps. Finally, the prepuce is sutured into its new location with two layers of interrupted absorbable sutures, being careful to locate the reference suture dorsally. The midline incision is closed except for the most cranial aspect, which is left open for drainage (Mobini et al. 2002). Postoperative penicillin and tetanus
Figure 13.13. Location of incisions for penile deviation. —— = incision lines; ..... = line for infiltration or local anesthetic.

prophylaxis are warranted. Hot-packing or anti-inflammatory drugs may be needed for several days to control swelling at the preputial orifice. The buck thus prepared can still breed an artificial vagina. He can also breed a cooperative doe, given adequate time for maneuvering, and he should not be allowed to run loose with the does unless aproned or sterilized with a further surgery.

Vasectomy

If no additional breeding with the animal is planned, a vasectomy can be used to create a permanent teaser. Possibilities for anesthesia (see Chapter 17) include sedation and local infiltration, epidural anesthesia, or general anesthesia. The procedure is as for rams and has been well described elsewhere (Copland 1986). Briefly, the neck of the scrotum is prepared for surgery. An incision can be made anteriorly, laterally, or posteriorly, according to the surgeon's preference. It is also possible to perform a bilateral vasectomy through a single cranial midscrotal incision (Lofstedt 1982). The firm, cord-like ductus deferens is located and ligated twice and a section 2 to 3 cm long is removed between the ligatures. Both pieces of excised ductus should be examined to verify that an artery was not removed by mistake. An impression smear can be made to look for sperm in the ductus of a mature male. The center of the ductus of an immature male appears as a red dot. Under a dissecting scope, however, the lining has a stellate appearance. The tissue should be preserved in formalin in case histologic verification of the vasectomy should be required. The vaginal tunics need not be sutured; skin can be closed with absorbable or non-

absorbable suture or with wound clips. The vasectomized buck should be permanently identified (e.g., by tattoo) to prevent later confusion, and it should not be used for at least two weeks after surgery. Some authors suggest a minimum of thirty days before the animal should be used as a teaser (Mobini et al. 2001), but numbers are greatly decreased and 95% of the sperm in the ejaculate are already dead by one week (Batista et al. 2002a).

Inflammatory and degenerative changes have been reported after vasectomy. Palpable granulomas, anechogenic on ultrasound and consisting of dead sperm, develop in the firm and enlarged tail of the epididymis. Efferent ductules may rupture, causing extravasation of spermatozoa into the tissues and evoking an immune response with multinucleated giant cells (Batista et al. 2002b). Some bucks showed degeneration of seminiferous tubules by four months after vasectomy. In another report, anechoic granulomas developed in the deferent duct of six bucks and in the head of the epididymis of a seventh. Only in the latter animal, with obstruction of the epididymis occurring close to the testis, were ultrasonographic changes visible in the parenchyma of the testis by five months after vasectomy (Ahmad and Noakes 1995).

Epididymal Surgery

An alternative to vasectomy is destruction or removal of the tail of the epididymis. Tranquilization or infiltration of a local analgesic may be used, although neither is mentioned in the original descriptions. As always, tetanus prophylaxis should be ensured.

One technique involves simply incising through skin and tunics over the tail of the epididymis and then amputating it with scissors. Heat cautery or ligation of the exposed stumps of epididymal tissue is recommended to hinder recanalization (Van Rensburg et al. 1963; Shelton and Klindt 1974; Mobini et al. 2001), which otherwise frequently occurs. The skin should be sutured to avoid infection, unless the surgery was not aseptic. Another technique involves injecting a sclerosing agent such as 1 ml of 10% calcium chloride into the tail of each epididymis (Smith 1986a).

Castration

Castration is commonly performed to avoid undesirable odors and aggressive sexual behavior in male goats kept as pets and to prevent breeding by bucks deemed to be of inferior genetic quality. The flavor of the meat of males raised past puberty is also affected by castration, although in some societies, especially where meat is served with plenty of spices, the rank buck remains quite acceptable. An intact male is preferred for some religious feasts (Muslim), so producers should plan according to their intended markets.

Numerous methods of castration are covered in standard surgery and medicine textbooks (for one example, see Mobini et al. 2001). The procedure is usually performed by an experienced producer; the veterinarian is asked to castrate the maturing pet or the buck with a scrotal lesion (abscess, hernia). Tetanus prophylaxis is advised for all techniques. (See discussion in Chapter 18.) Small goats are restrained on their rumps with front and hind limbs held together on each side by an assistant. Larger (tranquilized) goats are held in a standing or laterally recumbent position.

When a goat is to be kept as a pet wether, delaying castration until puberty permits separation of urethral process and glans penis from the prepuce, thus simplifying manipulations to examine or catheterize the goat if urolithiasis develops. Delaying castration also may lead to some additional increase in diameter of the urethra (Kumar et al. 1982). In general, anyone willing to plan this far ahead to prevent deaths caused by urolithiasis should be encouraged to choose a doe kid as a pet instead. Ejaculatory behavior may be retained for months after castration of adult bucks (Hart and Jones 1975).

Surgical Castration

Young kids (less than one month old) are often castrated by producers by the knife method, without anesthesia. By the time the well-fed kid is several months old, surgical removal of the testes is the preferred technique unless environmental conditions make an open wound unacceptable. By this age the desirability of anesthesia is also evident; older bucks sometimes die very quickly after being subjected to the stress and pain of castration.

Large bucks are tranquilized lightly. Diluted (0.5% to 1%) lidocaine can be injected with a fine needle to avoid provoking as much reaction from the injections as castration itself would have engendered. One to 2 ml, depending on the size of the goat, is deposited in each of four sites: high in the cord and at the distal end of the scrotal sac bilaterally. Alternatively (and especially in larger animals), an intratesticular injection can be made, placing 2 to 10 ml of 1% local anesthetic into each side with most of this being injected into the testis and the remainder being deposited subcutaneously in the bottom of the scrotum (Hall and Clarke 1983).

A U-shaped skin incision is made over each testis or the distal third of the scrotum is cut off. Testes, still within their tunics, are expressed and removed by scraping the cords with a sterile knife or (for larger bucks) by an emasculator with a crushing blade. Caprine testicular size approaches that of a stallion, and a good, well used equine emasculator is appropriate. If such an instrument is not available, the cords of a mature buck should be transfix ligated with absorb-

able suture. An alternative technique for bloodless castration of a large buck is use of a Henderson Castrating Instrument (Stone Manufacturing, Kansas City, Missouri). This device is clamped across tunic and cord above the testis and rotated with a variable speed drill until tissue separation occurs. General anesthesia (see Chapter 17) in addition to the local anesthetic seems ideal.

If very young kids are castrated by simply pulling on the testis until the cord snaps, a finger should be placed at the inguinal ring to avoid enlarging it while traction is being applied, with subsequent risk of herniation. In warm weather, a fly repellant is needed and the kid should ideally be kept on clean grass rather than in a dirty pen or on sawdust. Hands and equipment should be disinfected between animals.

Rubber Rings and Banding

Very young kids are commonly castrated with elastrator rings, very heavy rubber rings that are first soaked in alcohol or iodine to disinfect them and then placed around the neck of the scrotum with a special applicator. The scrotal sac and whatever has been trapped within it (hopefully both testes and none of the penis) become ischemic and eventually drop off several weeks later. There is no hemorrhage and no open wound, but there is an increased risk of tetanus relative to several of the other techniques, and blowflies may be attracted to the gangrenous scrotum in hot weather (Van der Westhuysen et al. 1988). Rubber bands also evoke more prolonged signs of pain in older animals than does surgical castration (Shutt et al. 1988) but this might be attenuated by intratesticular lidocaine in advance of application. On humane grounds, it seems preferable to restrict the use of rubber rings to kids younger than three weeks of age. There is a very real danger of an incomplete castration if the operator is not careful to verify the entrapment of both testes in the scrotum below the band. While fertility is probably decreased because of the elevated temperature of a testis forced into an inguinal position, testosterone production (and thus male behavior and odor) will continue. Some unwanted pregnancies might occur if the improperly castrated male is allowed to run with females.

Special instruments have been produced to tightly stretch solid rubber tubing around the neck of the scrotum of bulls. These same devices, such as the Callicrate bander® (No-Bull Enterprises, St. Francis, Kansas) can be used to castrate mature bucks. The band is applied close to the dorsal aspect of the testes, because higher placement results in a larger skin defect when the scrotum sloughs. The animal should receive two doses of tetanus toxoid in advance. With the aid of light tranquilization, 7 to 10 ml of 1% lidocaine is infiltrated into the skin of the neck of the scrotum and

into the spermatic cords before the band is applied. The scrotum should be amputated about 1 inch (2.5 cm) distal to the band three days later and the stump sprayed with a fly repellant. This technique is especially useful for avoiding hemorrhage or when the animal must be bedded on shavings which would otherwise contaminate an open castration wound.

Burdizzo

The small Burdizzo emasculatome can be used to crush the contents of the cord above each testis (Ames 1988). Each cord in turn is held tightly against the lateral aspect of the scrotum with one hand while the instrument is applied twice on each side. The crushes are made approximately 1 to 2 cm apart, both above the testis, and should not cross the midline of the scrotum (to avoid sloughing skin) or include the penis. The testis is manipulated vigorously while the instrument is in place in an attempt to snap the cord. The kid should be evaluated one month or longer afterward to ensure that both testes have atrophied. Improper technique or a sprung instrument (as from using it to dock tails) gives the Burdizzo method a bad reputation. If castration is delayed until the testes enlarge with spermatogenesis, too much tissue will be present to be completely resorbed. The infarcted testis (often with a viable epididymis, see Figure 13.14) remains as a palpable mass in the scrotum, engendering uncertainty in the owner's mind as to the sterility of the wether.

The chief advantages of this technique are the absence of hemorrhage and open wounds and the decreased risk of tetanus. Anesthesia is usually not

Figure 13.14. Necrotic testicular parenchyma and crimp lines on the cords above the testes following Burdizzo castration. The testes were too large when the procedure was performed to be resorbed. (Courtesy Dr. M.C. Smith.)

used, except when the buckling is dehorned at the same time. A small (to avoid toxicity) quantity of lidocaine can be injected into the cords before crushing. Disadvantages include swelling or sloughing of the scrotum or survival of a testis if the clamp is not applied properly.

Similar results might be obtained using a pinhole castration technique recently described for calves (Ponvijay 2007). Under local anesthesia, the spermatic cord is forced laterally, and an 18-gauge needle is used as a guide to pass absorbable suture through the scrotum. The needle is then withdrawn, the cord forced medially, and the needle reinserted through the same holes, to permit passage of the suture to now completely encircle the cord. After ligation to constrict the cord within the neck of the scrotum, the knot is trimmed short and becomes subcutaneous.

Manipulation of the Testes into the Inguinal Ring

It has been reported that in Venezuela, producers twist each testis around the spermatic cord and push it back into the inguinal canal (Gall 1981). This takes manual dexterity and must be done at an early age. The animal is rendered sterile without risk of hemorrhage, infection, or tetanus and without the need for any specialized equipment. The more rapid growth characteristics and carcass composition of the buck kid are retained. The results of a short scrotum castration (elastrator band intentionally applied below the testes) would have similar effects on growth, although the potential for partial fertility has not been studied in bucks.

Chemical Castration

In the United States, an 88% solution of lactic acid was briefly marketed for castration of calves (Chemcast®, Bio-Ceutic Labs Inc., St. Joseph, Missouri). This product was used on lambs and kids also. A 20-gauge or smaller needle (to avoid leakage from the injection site) was inserted from above, downward into the center of each testis. A small quantity (0.3 to 0.5 ml) of solution was deposited; larger amounts leaked back and caused adhesions between testis and scrotum or draining tracts (Blackburn 1985). Although this method was praised by the manufacturer as being superior to the Burdizzo technique, verification of castration before "wethers" are allowed to run with females of breeding age should be mandatory. Other sclerosing chemicals such as cadmium chloride (200 µg/kg) (Kar 1962) have also been injected to destroy testicular tissue, without consideration of possible meat contamination. More recently, injectable zinc gluconate has been licensed for castrating dogs (Levy et al. 2008), but evaluation of efficacy in goats has not been reported.

Mammary Gland and Milk Production

ANATOMY OF THE UDDER AND MALFORMATIONS

The goat's udder is composed of two glands, called halves or sides. In the male, teats are present but the glands usually remain rudimentary.

Normal Anatomy

Each gland has a single large teat. Six to nine large milk ducts join to form the gland cistern. The gland cistern blends with the teat cistern, which ends at a single streak canal and a single teat opening (Turner 1952; Heidrich and Renk 1967). The major blood supply is provided by the external pudendal artery. Venous return is via the external pudendal vein and the subcutaneous abdominal vein. The genitofemoral nerve, which passes through the inguinal ring with the external pudendal vessels, supplies most of the udder. Some skin innervation is also supplied by the lumbar cutaneous nerves cranially and the mammary branch of the pudendal nerve caudally.

The glands are separated by a median suspensory ligament. The lateral laminae of the suspensory apparatus are lateral to the external pudendal vessels and attach to the symphysial tendon caudally and the tunica flava abdominis cranially. The mammary (superficial inguinal) lymph nodes are located deep to the lateral laminae and caudal to the external pudendal arteries (Garrett 1988; Constantinescu 2001).

The ultrasonographic anatomy of the bovine teat and udder has been well described (Trostle and O'Brien 1998) and the images supplied should be applicable to the goat udder as well. A 5-MHz rectal probe can be used but a 7.5-MHz probe gives better resolution. Isopropyl alcohol or coupling gel is applied to achieve good contact with the skin, and the teat is scanned in longitudinal and transverse planes. The gain of the machine is adjusted until the normal milk appears anechoic. Using a commercial standoff device or a saline-filled examination glove between probe and skin improves the image of superficial tissues. The

near teat wall can be used as a convenient standoff for imaging lesions of the far teat wall.

Supernumerary Teats

Small supernumerary teats, completely separate from and usually cranial to the main teats, are occasionally observed in goats. Almost 12% of Barbari goats in one study had supernumerary teats (Bhat 1988), as did 30% of West African dwarf goats in Ghana (Oppong and Gumedze 1982), while goats with supernumerary teats predominated in a population of native goats in Japan (Nozawa 1970). These teats represent remnants of the embryologic mammary line that extends to the vulva, where ectopic milk secreting tissue also may be located. The distinct supernumerary teats are commonly amputated with scissors while the doe kid is still young. Tetanus prophylaxis (such as 200 to 300 IU antitoxin) is recommended (Smith and Roguinsky 1977).

Rarely, the extra teats are of a size comparable to the normal teats, resulting in an udder divided into four equal glands (Balasurbramanian et al. 1994).

Double or Fused Teats

It is relatively common for goats, especially of breeds that have not been selected for dairy purposes, such as Pygmy and meat goats, to have double teats on one or both sides of the udder. The abnormal teats may be fused to the tip but have two orifices (including fishtail teats). Forked teats (Figure 14.1), where both ends are of similar size, and small spurs protruding from the side of larger teats are other variations. Double teats are probably inherited in a complex way (Cunningham 1931–1932).

Kids (both does and bucks) of dairy breeds should be examined at birth, and all those with teat malformations other than simple, discrete, supernumerary teats

Figure 14.1. Bilateral forked teats in a Boer kid. (Courtesy Dr. M.C. Smith.)

should be marked for culling. Breed associations vary in the importance they place on abnormal teats. The American Veterinary Medical Association has determined that removing an extra teat that would have interfered with milking is not ethical in an animal to be shown, bred, or sold (AVMA 1976). Owners who are unconcerned about the possible genetic basis for these malformations occasionally choose to cut off part of a double teat. Sometimes the wrong guess is made and the doe freshens with a small spur off a separate, larger gland that no longer has a teat orifice. Infections may also become established in the remaining gland at time of spur removal.

Weeping Teats and Teat Wall Cysts

Some goats have milk secreting tissue in the wall of the teat, especially near its base. If this tissue communicates through one or more pores in the skin to the outside, milk oozes out. The condition is noticed when the hand of the milker becomes wet. Cauterization of the opening(s) with silver nitrate sticks after each milking may solve the problem. If the glandular tissue does not communicate with the outside or to the teat cistern, a cyst may form in the wall of the teat and interfere with milking. Real-time ultrasound clearly demonstrates a fluid-filled cavity. If the cyst is large, it may need to be drained occasionally using aseptic techniques.

An extreme version of this condition, possibly hereditary, has been reported in Israel, where nineteen of 324 lactating mixed-breed goats in one herd had multiple cysts 3 to 8 mm in diameter in the wall of the teat near its base. Most of these cysts contained clear rather than milky fluid (Yeruham et al. 2005).

Blind Udder Halves

A presumably congenital abnormality has been described in a single Saanen goat in which the primary milk ducts ended blindly instead of joining the gland cistern. The mammary gland was capable of secretion, but no milk could be obtained from either teat (Turner and Berousek 1942). Absence of leukocytic infiltration in the udder tissue made a bacterial or retroviral etiology unlikely. Blind teats are common in artificially reared calves that suck on each other, and presumably scar tissue in the teat end could cause a similar problem in goats.

Poor Udder Suspension

The various suspensory ligaments of the udder should be strong and broad so that the udder is held tightly against the body with the floor of the udder above hock level (Considine and Trimberger 1978). Low-slung udders are prone to injury and are also bruised by alternately wrapping around one hind leg and then the other as the goat runs. Affected does and

their offspring should not be allowed to contribute more to the gene pool in the herd. The heritability of the medial suspensory ligament as scored by the American Dairy Goat Association linear appraisal program has been estimated at 0.33 (Wiggans and Hubbard 2001). An enlarged, pendulous udder may also be the result, rather than the cause, of mastitis (Addo et al. 1980).

Neoplasia and Fibrocystic Disease

Neoplasms of the parenchyma of the udder are rarely reported in goats. In one Indian slaughterhouse study of 2,000 female goats four years of age or older, multiple gray-white dots seen grossly in three udders were identified as intraductal carcinomas. The tumors were multicentric, with diffuse intraluminal proliferation of cells. Metastasis to the supramammary lymph node had occurred in one animal (Singh and Iyer 1972). In another study of more than 4,000 mature goats, two more multicentric intraductal carcinomas were identified (Sharma and Iyer 1974). Diffuse involvement of both glands with a mammary adenocarcinoma was observed in a seven-year-old doe that had not kidded or lactated for five years. Tumor metastases were found in the bronchial lymph node (Miller 1992). An aged Toggenburg doe with a chronic history of mastitis was found at necropsy to have a locally infiltrative adenocarcinoma in the udder and a granulosa cell tumor on one ovary, suggesting that high estrogen concentrations might be a risk factor for mammary cancer (Cooke and Merrall 1992)

Slaughterhouse studies from India report a condition termed fibrocystic disease or cystic hyperplasia (Singh and Iyer 1973; Sharma and Iyer 1974; Tripathi et al. 1989; Upadhyaya and Rao 1994). Affected goat udders are enlarged and very firm/indurated, with multiple pea- to grape-sized nodules containing straw-colored fluid. Periductal and perilobular fibrosis with mononuclear cell infiltration surrounds dilated ducts filled with proteinaceous material. A predisposition of fibrocystic disease to the development of intraductal carcinomas has been proposed (Tripathi et al. 1989). A unilateral fibroepithelial hyperplasia of the udder of a nulliparous goat has also been reported and compared to mammary fibroepithelial hyperplasia in young, sexually intact cats (Andreasen et al. 1993). Because the histologic findings in biopsies from the udders of goats with inappropriate lactation syndrome (see below) are often suggestive of neoplasia, these various syndromes may be related.

MILK PRODUCTION BY KIDS AND UNBRED GOATS

Udder development and even milk production are relatively common in unbred doelings of dairy breeds. Gynecomastia in bucks is discussed in Chapter 13.

Witch's Milk

Occasionally kids have enough udder development at birth that the glands are tense and conical. Milk sometimes can be expressed from the teats, but this is not desirable because of the risk of mastitis once the teat seal is broken. The condition occurs in other species, including human infants (Nelson 1964). It is presumed to occur in response to increased levels of hormones (estrogen, prolactin, placental lactogen) in utero. No treatment is necessary.

Inappropriate Lactation Syndrome

Unbred goats frequently develop a large "precocious" udder. In some animals, the udder enlargement is mainly because of deposition of adipose tissue. In others, milk is actually produced from one or both glands without a preceding parturition (Figure 14.2). Precocious milking may be a hereditary trait (Campbell 1961). It has been said that doelings who lactate precociously, also termed "maiden milkers," generally come from genetic stock with high production potential (Baxendell 1984a; Matthews 1999). It should be noted, however, that some intersex animals lactate (Hamerton et al. 1969).

Neither the etiologic basis nor the ideal treatment for such inappropriate lactation has been determined. Two affected does have been reported to have increased prolactin from an acidophilic pituitary adenoma (Miller et al. 1997), but this is a rare explanation for a common clinical condition. One theory is that some goats are very sensitive to either prolonged progesterone exposure from a persistent corpus luteum or to elevated prolactin levels in the spring.
Figure 14.2. Precocious udder in a doe that was never bred. The udder produced one cup of normal milk per day. (Courtesy Dr. M.C. Smith.)

A possible treatment if false pregnancy is suspected is a luteolytic dose of prostaglandin (2.5 to 5 mg prostaglandin F2 alpha), although withdrawal of progesterone by natural termination of the false pregnancy may have already occurred before the udder developed. Progesterone and estrogens should stimulate additional mammary gland development, and are therefore contra-indicated. Feeds with estrogenic action, such as moldy corn or subterranean clover, should be eliminated from the diet. Temporarily eliminating the grain ration and feeding dry hay should discourage milk production, but water deprivation is not warranted. Milking the goat is not desirable because disrupting the seal in the teat predisposes to mastitis if the goat is not milked regularly. If the udder becomes painfully engorged so that milking is necessary or if the owner has milked the goat before seeking advice, a milk culture should be taken to check for mastitis and a bovine dry period treatment infused into the udder after it has been emptied completely.

If this regimen fails to stop lactation, the goat can be milked daily for several months and dry-off can be attempted again, preferably in the fall, the season when production naturally decreases. An expensive and as of yet inadequately tested alternative is the administration of an antiprolactin drug such as bromocryptine (5 mg bromocryptine mesylate [Parlodel, Sandoz]/day for fourteen days orally). A similar empirical treatment is cabergoline, 5 µg/kg orally for four to six days (Galostop, Boerhringer) (Matthews 1999), but owners report that this treatment has not worked. Also, the bromocryptine-induced decrease in milk production is only temporary in normal goats (Forsyth and Lee 1993).

There are anecdotal reports of destroying the secretory tissue by infusing a destructive substance such as ether or 2% chlorhexidine solution (5 to 10 ml only) into the affected gland. Occasionally the precocious udder develops severe chronic mastitis or becomes so pendulous that udder amputation is advisable. In summary, milking, mating, or mastectomy seem to be the most reliable options for treating persistent maiden milkers (John Matthews, personal communication 2007).

Self-sucking

Because the simple act of trying to extract milk from a teat on a regular basis stimulates development of milk-secreting tissue, the possibility that another goat has been nursing the doeling with a developed udder or that she is a self-sucker should be investigated. The first possibility can be handled by separating the animals involved or by fitting the animal engaged in illicit sucking with a halter that holds a wooden bit in the mouth (Gall 1981). Self-sucking, on the other hand, is a difficult habit to break. Many goats like the flavor of milk and drink their own regularly when they have learned the trick. The behavior has been observed in a feral goat (O'Brien 1982) and theorized to have begun as an attempt to relieve discomfort from a turgid udder.

Treatments that have been tried with variable success include applying teat tape (as for preventing suckling in CAE control programs), painting the teats with a solution distasteful to the goat, and fitting the goat with an Elizabethan collar or a bra-like udder bag. A side brace constructed of aluminum rod is another possibility; the side extensions of a padded neck ring are taped to the forward-directed ends of a padded arch that goes over the lumbar area. A strap made of tape joins the two sides of the brace underneath the abdomen.

Hormonal Induction of Lactation

Lactation physiologists have made extensive use of goats in their study of hormonal treatments (e.g., estrogen, progesterone, prolactin, and corticosteroids) that will induce udder development and lactation in nonpregnant animals (Erb 1977). Space does not permit review of this information here. A successful protocol for inducing lactation in the field was developed in France but was not pursued because of regulatory constraints on sale of milk from treated goats. It consisted of 17β-estradiol (0.25 mg/kg bw twice daily) and progesterone (0.625 mg/kg twice daily) in alcohol, given subcutaneously for seven days. Machine milking and hydrocortisone (25 mg/goat intramuscularly twice daily for three to five days) were begun on day twenty-one after initiation of treatment (Delouis 1975) or else the hydrocortisone was given before milking began, on days eighteen, nineteen, and twenty (Lerondelle et al. 1989). Recently, the addition of reserpine as a prolactin-releasing agent has been found to be beneficial (Salama et al. 2007). The technique is useful for goats that aborted or were found to be nonpregnant after having been dried off. However, milk production will be low, subsequent reproduction may be adversely affected (Salama et al. 2007), and extralabel use of drugs for production purposes in the United States is illegal. Hormonal induction of lactation of both immature does and bucks has been used to permit early expression of recombinant proteins in the milk of transgenic goats (Cammuso et al. 2000).

SKIN DISEASES AND INJURIES OF THE UDDER

Skin diseases that are frequently localized to the udder include bacterial folliculitis and contagious ecthyma (sore mouth). Readers should refer to Chapter 2 when additional information is desired or when symptoms are more general (e.g., capripox infection, bluetongue).

Contagious Ecthyma

Parapoxvirus infection may be limited to the teats or present elsewhere on the body. In regions where capripox virus also occurs, both viruses cause similar lesions on the udder and teats of lactating goats (Okoh and Obasaju 1983).

Pathogenesis and Clinical Signs

Contagious ecthyma lesions predispose to mastitis by interfering with the function of the streak canal while simultaneously harboring many pathogenic bacteria. A kid with sore mouth lesions can pass the infection to a doe's teats during suckling. Milking equipment and bedding contaminated by other infected does are other possible sources. The lesions are proliferative and crusty. Often they are secondarily infected with staphylococci.

Treatment and Prevention

Affected goats should be milked last, and an antiseptic udder salve may be applied to keep the scabs pliable and control bacterial proliferation until self-healing occurs. The arguments for and against herd vaccination are discussed in Chapter 2. The zoonotic potential of the virus must not be forgotten.

Staphylococcal Dermatitis

Lesions of the udder caused by staphylococcal infection include folliculitis, moist dermatitis in the intramammary sulcus, and deep furuncles.

Etiology

Staphylococcus aureus is the most important cause of folliculitis and furunculosis of the teats and udder skin of goats, but other staphylococci and streptococci may be involved.

Clinical Signs and Diagnosis

Pinhead- to pea-sized pustules typically develop on the skin on the back of the udder, base of the teat, or intramammary sulcus (Figure 14.3). Lesions are usually not painful. When a deeper furuncle develops, there is a reddened, warm, and tender swollen area that develops into an abscess (Fontanelli and Caparrini 1955; Heidrich and Renk 1967).

Cultures are rarely performed unless the condition is unresponsive to conventional therapy or spreads to other parts of the goat. Important differentials include contagious ecthyma, capripox, and warts when lesions are superficial; furuncles can be differentiated from milk cysts by careful palpation and, if necessary, aspiration. Enlarged or abscessed supramammary lymph nodes are located more dorsally than furuncles.

Figure 14.3. Pustules on the skin of the udder and moist dermatitis between the udder halves caused by *Staphylococcus aureus* infection. The doe later developed gangrenous mastitis. (Courtesy Dr. M.C. Smith.)

Therapy and Prevention

Lesions should be washed with a mild disinfectant and dried with single service towels. Disinfectant ointment or spray is applied after milking. Affected animals are to be milked last, and the milker should wear gloves or wash hands to avoid spread to other goats. Furuncles can be encouraged to point with ointments containing iodine or ichthyol. The abscess is then lanced and flushed. Autogenous *Staphylococcus aureus* vaccine (two doses) has appeared to limit the course and spread of the disease in some goat herds (Heidrich and Renk 1967).

Caseous Lymphadenitis

In herds in which *Corynebacterium pseudotuberculosis* is endemic, wounds to the teats or udder permit penetration of the organism. Infection of the wound may be noted, but more commonly, the problem first becomes obvious when an abscess develops in a supramammary lymph node (Figure 14.4). This abscess may break and drain pus down the back of the udder, or additional enlarged nodes may appear in a chain that extends upward toward the vulva. Caseous lymphadenitis is discussed in detail in Chapter 3.

Dermatomycosis

Flat, slightly thickened, circular, nonpainful skin lesions on the udders of goats in Florida have been diagnosed as tinea versicolor, a dermatomycosis of humans resulting from *Melassezia furfur* (Bliss 1984). Lesions on dark skin appear depigmented, whereas on lightly pigmented skin they are lightly colored. Biopsy specimens contained basophilic, PAS (periodic acid-Schiff stain) -positive filamentous organisms and oval,

Figure 14.5. Udder warts on a Saanen doe. (Courtesy Dr. M.C. Smith.)

thick-walled cells (nicknamed "spaghetti and meatballs") in the stratum corneum. No treatment has been attempted.

Frostbite

If the teats are wet from inadequate drying after udder preparation for milking or from confinement in a wet environment, frostbite may occur when the goat is exposed to extreme cold and wind. Pendulous or edematous udders are especially vulnerable. Mildly chapped teats may be treated with protective ointments. If the full thickness of a teat is frozen, thawing in warm water 106°F to 111°F (41°C to 44°C) and protecting from refreezing are advised (Scott 1988). Sloughing of skin on the teat and secondary bacterial mastitis are to be expected. Powder teat dips are available for dipping in cold weather after milking.

Sunburn

Does with light-colored udder and teat skin are subject to sunburn when first turned out in the spring, even with cloud cover. The best means of avoiding a painful burn is to initially permit only very brief grazing, then drive the animal back into the barn. With succeeding days the exposure to sunlight is gradually

lengthened. This protocol also avoids indigestion in goats changing from dry hay to green grass. Many owners lack time, patience, or both. Their animals can be protected by application of colored teat dip or a sunscreen sold for human use. All such material must be washed off before the next milking to avoid contamination of the milk.

Saanen does that have pale pink udders at the end of the housing season often have large black spots akin to freckles on the udder after a summer on pasture. This condition is not pathological and requires no treatment.

Warts and Squamous Cell Carcinomas

Papillomas (warts) of the udder of white goats are a very serious problem, especially in areas with abundant sunshine (Moulton 1954; Ficken et al. 1983; Theilen et al. 1985).

Etiology and Epidemiology

Most attempts to demonstrate virus in these lesions have failed. Recently, papillomavirus-like sequences have been detected in wart-like lesions by DNA hybridization, even though no virions were found by electron microscopy (Manni et al. 1998). An epidemiologic survey (Ficken et al. 1983) revealed that appearance of udder warts in the herd often begins three to six months after introduction of an affected goat. Exposure to sunlight appears to be involved.

Pathogenesis and Clinical Signs

The warts are multiple and initially may be flat and scaly (Figure 14.5) or prolonged into cutaneous horns. Some flake off the teat or bleed during milking. In some animals the warts regress completely during the

nonlactation period. In other goats, the warts partially or totally regress but recur the next spring and summer (during lactation). The animals with persistent lesions may develop squamous cell carcinomas in subsequent years. The carcinomas have a flat base and often an ulcerated surface. They occasionally metastasize to the supramammary node. Much more serious is their propensity to eventually erode through the wall of the teat. This leads to mastitis and loss of the udder half, as may penetration of the streak canal by bacteria harbored in tumors located near the teat orifice. Myiasis may also occur.

Treatment and Prevention

No effective treatment is known. Neither have vaccines been of any value. The recently affected goat could be housed in the hopes that permanent regression will occur. Certain carcinomas may be surgically removed; cryosurgery has the advantage of minimizing hemorrhage. Prevention involves excluding affected goats from the herd and selecting for other breeds or at least for pigmentation of the skin of the udder in white breeds. The prevalence of udder warts in Saanens in Queensland, Australia, has been greatly decreased by selecting for tan skin on the udder (Baxendell 1984a). In South Africa, providing adequate shade for milking Saanens has prevented the development of squamous cell carcinomas (Donkin and Boyazoglu 2004).

Teat Obstruction and Stenosis

A doe at kidding may have a temporary teat obstruction caused by a plug blocking the streak canal. This material can be manually expressed from the teat, and afterward the doe milks easily. When kids are allowed to suckle the doe, it is important to remove a squirt or two of colostrum from each half of the udder. Not only does this allow inspection of the secretion for evidence of clinical mastitis, but it avoids starvation of the kid that is too weak to suck out the teat seal on its own. Even a strong kid prefers to suckle the side that yields milk for less effort. The unmilked side then becomes distended and painful, and the doe no longer permits nursing on that teat. Stripping out milk from the enlarged gland as soon as the udder is noticed to be lopsided is necessary if both glands are to remain productive in the current lactation.

If difficulty in milking persists after removal of the initial teat plug, an experienced person should evaluate the teats of the goat in question. People who are just learning to hand-milk goats may have difficulties because of lack of proper technique. If a teat sphincter is too tight for milking, it is important to determine if scar tissue from a previous injury is responsible. If no scar tissue is detected, the doe and its offspring should not be kept for breeding purposes. In such an animal

and in goats that previously milked normally, a stenotic teat opening sometimes can be corrected by removing a core of tissue with a disposable 18-gauge needle (Nigam and Tyagi 1973) after previous infusion or spraying of local anesthetic. Consideration should be given to antibiotic therapy after such manipulation because the protective keratin lining of the streak canal will undoubtedly be damaged. In large teats with scar tissue or an excessively tight sphincter, several cuts (on opposite sides, with care to avoid incising skin) with a teat bistoury may be tried; milk should drip from the teat end immediately after surgery, as some contraction is to be expected during healing.

If the udder of a multiparous doe appears to be distended but no milk reaches the teat cistern, the problem may be scar tissue at the base of the teat. This develops as the result of chewing behavior by hungry nursing kids when milk production is inadequate. The obstruction may not be recognized until the subsequent lactation. An important differential is hard udder, in which interstitial mastitis caused by the caprine arthritis encephalitis virus (see below) prevents milk from reaching the teat end.

Milkstones, lactoliths, or "peas," small, hard concretions floating in the teat cistern, may occasionally work as a ball valve and interfere with milking. An association with incomplete milkout has been proposed (Guss 1980). Stones that cannot be forcibly expressed from the teat or crushed with alligator forceps could be removed surgically.

Udder and Teat Wounds

Udders with poor suspensory ligaments or long teats can be injured during grazing activities. Barbed wire, dog attacks, and horn punctures can also tear the skin of the teats or udder. Repair of the wound follows general surgical principles but has been described in some detail by Anderson et al. (2002). After cleansing and debriding to bleeding tissue, the fascial layer of the udder or the inner teat lining (depending on the location of the wound) is closed with a fine (4-0) absorbable suture material. Nonabsorbable sutures or wound clips can be placed in the skin. The goat is given systemic antibiotics (penicillin) and the gland is infused with a bovine intramammary antibiotic product. Tetanus prophylaxis must not be neglected. Aftercare involves frequent gentle milking or drainage with a sterile teat cannula to prevent back pressure, leakage, and formation of a permanent fistula.

In fiber-producing goats, teats are occasionally cut off accidentally during shearing. Does with only one teat remaining may not be able to raise a kid under range conditions.

Teat biting is an abnormal behavior which has been observed in dairy goats at the time of estrus if the group is being reserved for later breeding. The teat

may be scratched or bruised or bitten completely off. Often the goat that is biting the teats of other animals is not identified, but sometimes it is a frustrated buck, sticking his head through a fence to a waiting doe. The use of a sexually active vasectomized buck has been recommended to prevent this problem (Coleshaw 2004).

Udder Edema

Periparturient udder edema, characterized by excessive accumulation of fluid in the interstitial spaces and pitting on digital pressure of the skin of the udder, has been reported in goats but has received little scientific attention. The goat may be uncomfortable and difficult to milk. Does kidding for the first time are frequently affected. Differential diagnosis includes mastitis, hard udder caused by caprine arthritis encephalitis, hematoma, and rupture of the prepubic tendon (Al-Ani and Vestweber 1983). Treatment with exercise, massage, and a diuretic (e.g., 50 to 100 mg furosemide, although a goat dosage has not been established) can be tried, but the edema often resolves within a few days after parturition without any treatment except milking. Vitamin D_3 has been suggested to aid resolution of udder edema by counteracting hypocalcemic effects of hypomagnesemia (Mills 1983a, 1983b). Some owners start milking a week before parturition as a means of controlling edema (Baxendell 1984b); the first milking colostrum should be heat treated and frozen for later feeding to the kids. Draining the fluid with one or more 3-cm incisions in the skin caudal to the teat has been reported to be effective and innocuous in goats (Rebesko et al. 1974), but is not presently recommended. Because the pathogenesis of udder edema remains unclear, even in cattle (Al-Ani and Vestweber 1986; Goff 2006), one can only speculate on how to prevent the condition in goats. Limiting salt before parturition is reasonable, but limiting grain, as commonly recommended, might cause pregnancy toxemia.

MASTITIS

Mastitis, or inflammation of the mammary gland, is a broad diagnosis that may be based on changes in the physical characteristics of the udder or its secretion. Mastitis usually results from an infectious agent, although consuming avocado leaves also causes marked inflammation (Craigmill et al. 1992). Several reviews of caprine mastitis have been published (Smith and Roguinsky 1977; Lewter et al. 1984; Menzies and Ramanoon 2001; Bergonier et al. 2003; Contreras et al. 2007).

DIAGNOSIS OF MASTITIS

Physical examination for changes in the milk or signs of inflammation and culture of the mammary secretion are the most commonly used techniques for identifying clinical or subclinical mastitis. Various other laboratory tests, especially those relating to cell enumeration, have been investigated as possible indicators of mastitis. Tests currently available other than culture are unsatisfactory in goats, in the author's opinion. Monthly somatic cell determinations on all herd members are valuable for keeping track of increased cell counts (and satisfying government regulations) but are rarely worth the expense regarding mastitis control.

Clinical Examination

Early indications of clinical mastitis include a decrease in milk production by one gland or a lameness on the affected side as the goat attempts to avoid contact of the hind limb with the tender half of the udder. Nursing kids may appear to be hungry, and mastitis is associated with increased kid mortality rates (Addo et al. 1980). Visual inspection of the udder from behind and from the sides may reveal asymmetry whereby the affected gland is swollen (acute) or atrophied (long-term inflammation). Predisposing teat end lesions (Kapur and Singh 1978) (wounds, contagious ecthyma, warts) also may be identified. Palpation may disclose the presence of heat, tenderness and swelling (acute), induration or atrophy (chronic mastitis), or even multiple abscesses. Regarding acute mastitis, the goat may be systemically ill, with signs of fever, anorexia, and depression. If the teat is cold and edematous or the secretion red and watery, gangrenous mastitis should be suspected. This severest clinical form is discussed in detail below.

Culture

Culture of an aseptically obtained milk sample is necessary to identify the etiologic agent of bacterial mastitis. The ideal sampling technique begins with brushing off any loose debris and discarding several streams of milk. The teats are then predipped in an approved bovine product and the predip is allowed thirty seconds of contact time before being wiped off with an individual paper towel. Finally, the teat end should be carefully disinfected with a cotton ball moistened with 70% ethyl or isopropyl alcohol before a milk sample is collected in a sterile vial (National Mastitis Council 1999). Refrigerate the samples promptly, or freeze if culture will be delayed more than forty-eight hours. Freezing results in a minimal decrease in recovery of organisms from goat milk samples (McDougall 2000; Sanchez et al. 2003). Sensitivity testing using routine techniques sometimes assists in selecting antibiotic therapy.

Some researchers require positive cultures from two consecutive milk samples from the same gland before a culture result can be interpreted as positive (Contre-

ras et al. 1997b). Two or more consecutive negative culture test results are often presumed to indicate absence of infection.

Practitioners who wish to perform in-house mastitis cultures find that most mastitis isolates grow on blood agar at 95°F to 98.6°F (35°C to 37°C) and can be identified on the basis of a few simple tests such as colony characteristics and hemolysis on blood agar, Gram stain, and catalase tests. A standard reference book that includes color photographs of culture plates is extremely helpful (National Mastitis Council 1999). A simplified flow chart for identifying common pathogens adapted from this reference is provided in Figure 14.6. An organism is catalase positive if bubbles are produced when a colony is emulsified in 3% hydrogen peroxide. The oxidase test requires special discs and should not be performed on colonies grown on selective media such as MacConkey agar (National Mastitis Council 1999).

Various multipartite culture plates are also available commercially that include selective media for Gram-negative or Gram-positive organisms, staphylococci, or streptococci. An example is the Bi-plate from the University of Minnesota Laboratory for Udder Health, St. Paul, Minnesota, which includes Factor medium (Gram-positive growth, *S. aureus* shows hemolysis) and MacConkey medium (Gram-negative growth).

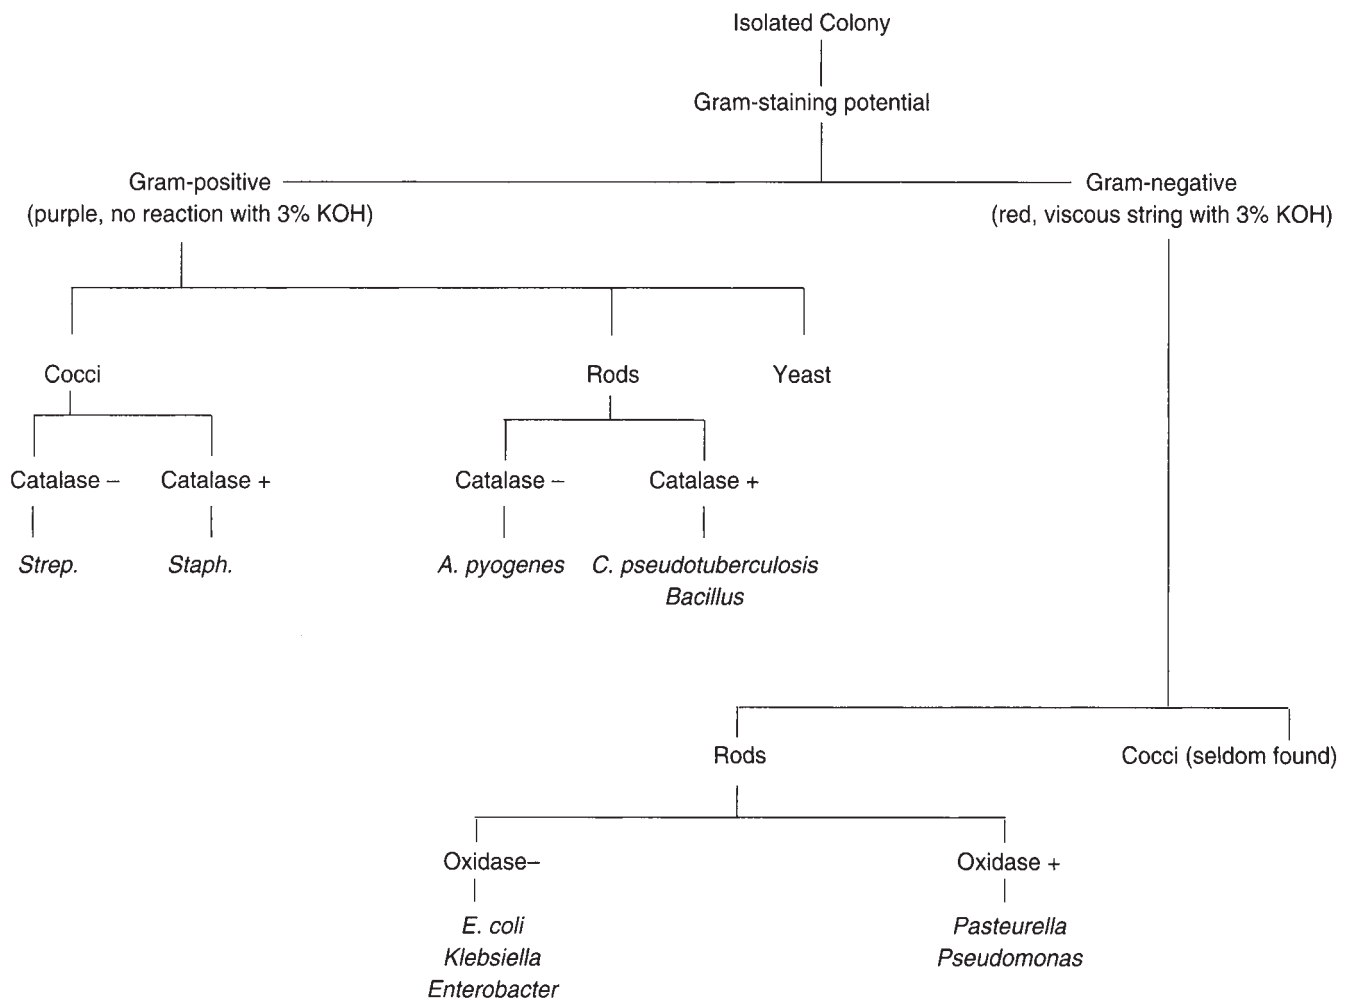
Mycoplasma are more difficult to grow in the laboratory. *Mycoplasma mycoides* subsp. *mycoides* (large colony type) grows on blood agar plates supplemented with ovine blood; "fried egg" colonies 1 mm in diameter and beta hemolysis are detectable after one week (DaMassa et al. 1983). Isolating the other species usually requires special mycoplasma medium and a moist 10% CO_2 incubator (National Mastitis Council 1999). Plates are observed under 20 to 50× magnification for seven to ten days before being termed


Figure 14.6. Flow chart for identification of bacteria causing mastitis.—represents negative test result, + represents positive test result.

negative. Most colonies have a fried egg appearance. Exact identification of an isolate is difficult, and typing is performed by only a few laboratories.

Cell Enumeration

An increase in the number of somatic cells in milk has been used as an indication of mastitis, including subclinical mastitis, in cows. Application to dairy goats of tests and regulations developed for cattle frequently has led to panic in the commercial producer who interprets "high" cell counts as evidence of a serious mastitis problem or who is threatened by the inspector with loss of a milk market. Currently the legal limit for somatic cell count (SCC) in goat milk in the United States is 1 million cells/ml. In a survey of seventy-one commercial U.S. herds in November and December, only 35% could achieve this low a count (Droke et al. 1993). A legal limit has not yet been set in the European Union (Paape et al. 2007). Numerous factors affecting cell count in goat milk have been reviewed recently (Haenlein 2002; Paape et al. 2007).

Cytoplasmic Particles and Epithelial Cells

In discussions of bovine mastitis, the number of somatic cells per ml of milk is generally assumed to correlate directly with the severity of mastitis or the degree of irritation to the mammary gland. The relationship of somatic cell count (SCC) to caprine mastitis is limited, unless tests appropriate to caprine milk are used. This is partly because goat milk differs from cow milk due to the presence of cytoplasmic particles and epithelial cells. The caprine mammary gland produces milk by a process called apocrine secretion (Wooding et al. 1970). Portions of the cytoplasm of the epithelial cells are pinched off and appear in the milk as DNA-free particles similar in size to leukocytes (Dulin et al. 1982). By contrast, ewes produce milk with approximately 10% of the number of cytoplasmic particles found in goat milk (Paape et al. 2001). Also present in variable numbers in goat milk are intact epithelial cells sloughed from acini and ducts.

Interpretation of Reports and Counting Methods

Very careful attention must be paid to the counting technique when comparing or contrasting various reports or when attempting to estimate the prevalence of mastitis in a goat herd. Another inadequacy of much of the literature is in the realm of determining mean SCC. Most older studies have not used a log transformation such as the linear score (also called somatic cell score) developed for bovine SCC where linear score = 3 + $\log_2$ (X/100) for a somatic cell count of X × 10^3 cells/ml. Somatic cell scores and equivalent SCC are: 1 = 25,000; 2 = 50,000; 3 = 100,000; 4 = 200,000; 5 = 400,000; 6 = 800,000; 7 = 1.6 million; 8 = 3.2 million/ml.

The direct microscopic somatic cell count, using a stain appropriate for goat milk, is the standard against which other counting methods should be judged.

Direct Microscopic Somatic Cell Count

The confirmatory test for somatic cell numbers in bovine milk is usually a direct microscopic examination of 0.01 ml of milk on a slide within an area of 1 cm^2. The Levovitz-Weber modification of the Newman-Lampert stain is commonly used to stain somatic cells for counting (Schalm et al. 1971). This stain is inappropriate for goat milk because staining is similar for cytoplasmic particles and cells (Dulin et al. 1982). A research technician might be able to recognize the difference between particles and cells, but over counting would be expected in a commercial laboratory.

Currently, the stain preferred for determining SCC in goat milk in the United States is the pyronin Y-methyl green stain (Dulin et al. 1982; Paape et al. 2001), often referred to simply as the green stain. Methyl green is specific for DNA and pyronin Y is specific for RNA. Chromosomes, then, stain blue-lavender while cytoplasmic particles and the cytoplasm of epithelial cells stain red. Neutrophils do not contain pyronin Y-positive material (Paape et al. 1963). Unfortunately, this staining is difficult to do and the reagents are potentially toxic to laboratory workers. Neutrophils are the predominant cell type in goat milk from both infected and uninfected glands, whereas the macrophage is the predominant cell in milk from uninfected sheep and cows (Sierra et al. 1999; Paape et al. 2001).

Leukocytes and epithelial cells in goat milk have also been differentiated by a modified Wright's stain technique (Hinckley and Williams 1981). Others have reported that many leukocytes are masked by the background in smears prepared with Wright's stain (Paape et al. 1963).

California Mastitis Test (CMT) and Teepol Test

The CMT is a simple, semiquantitative test for determining the number of nucleated cells (both neutrophils and epithelial cells) in milk (Schalm and Noorlander 1957). Equal quantities (typically 2 ml) of milk and the commercial reagent (Nasco, Inc., Fort Atkinson, WI, and others), which contains 3% alkyl arylsulfonate and bromcresol purple as a pH level indicator, are combined in the cup on a white paddle and swirled. Different scoring schemes are used in different parts of the world. As described originally, there is no change with a negative reaction, while a T (trace) reaction consists of a slight thickening of the milk. Scores of 1, 2, and 3 are given with increasing gel formation and deepening of color. A score of 3 means that a gel has formed that pulls away from the edge and collects in

Table 14.1. CMT scores on goat milk (after Schalm 1971).

CMT score	Scand. system	Samples	Neutrophil leukocytes/ml	
			Range	Median
0	1	46	0–480,000	60,000
trace	2	43	0–640,000	270,000
1	3	29	240,000–1,440,000	660,000
2	4	16	1,080,000–5,850,000	2,400,000
3	5	6	>10,000,000	—

the center of the cup. It is potentially confusing that some workers designate the same five categories as scores of 1 to 5 (Scandinavian system).

The reaction detects the presence of DNA, which is released when the detergent ruptures somatic cells. The approximate numbers of leukocytes for each score for goat milk (Schalm et al. 1971) are indicated in Table 14.1. In a Norwegian study, the total numbers of leukocytes and epithelial cells were 690, 800, 820, 1,230, and $4,520 \times 10^3$/ml for the five CMT scores from 1,966 goat milk samples (Pettersen 1981). A French study of midlactation samples that categorized any reaction greater than a trace as positive concluded that a positive CMT result had a sensitivity of 88% and a specificity of 93% for detecting SCC by Fossomatic methods greater than 750,000 cells/ml (Perrin et al. 1997). It is generally believed that scores of T or 1 (up to 1 million cells/ml) are usually no reason for concern.

In France, the equivalent to the CMT is called the Teepol test, after a European brand of neutral liquid detergent. The commercial detergent is diluted 1:10 and then used as the reagent (Lefrileux 2002). It reacts with both epithelial cells and neutrophils. Test results with goat milk have been graded and interpreted as follows (Roguinsky et al. 1971):

1. No or fine precipitation (as many as 500,000 cells/ml): normal
2. Granular precipitate (200,000 to 1 million cells): mild irritation, as by improper milking
3. Filamentous precipitate (500,000 to 2 million cells/ml): weakly pathogenic organism such as nonhemolytic staphylococcus
4. Viscous precipitate (more than 1.5 million cells/ ml): suggests presence of *Staph. aureus*

The CMT is more useful for ruling out than for diagnosing mastitis in goats (Contreras et al. 1996). In a Norwegian study of 1,161 milk samples, 331 of 422 samples with CMT values of 1 to 3 in the American system yielded no bacterial growth; 732 of 739 with a negative or trace CMT score yielded no growth (Nesbakken 1978b). High scores at the end of lactation (Maisi 1990) or in systemically ill goats with drastically reduced milk production occur in the absence of mas-

titis. A sick goat with a negative or trace CMT reaction is probably not sick because of mastitis. If there is a marked difference between the scores of two halves of a goat's udder, mastitis is very likely. The usefulness of the CMT (or any other test) for diagnosing subclinical mastitis depends on the prevalence of mastitis in a herd. In a well-managed herd, the predictive value of a positive test is unacceptably low (Hueston et al. 1986).

Wisconsin Mastitis Test (WMT)

The Wisconsin Mastitis Test uses diluted CMT reagent. It is more objective than the CMT because the viscosity of the milk-reagent mixture is estimated from the volume remaining in a special tube after draining through a standard-sized hole for fifteen seconds (Schalm et al. 1971). The WMT is considered to be DNA-specific. Results obtained using standard conversion factors for cow milk are similar to counts obtained by the Fossomatic method (Dulin et al. 1982).

That the test results accurately predict the etiologic agent of mastitis has not been adequately documented.

Fossomatic and DeLaval Cell Counters

The Fossomatic method (Foss-O-Matic, Foss Electric, Hillerod, Denmark) of determining SCC is an automated fluorescent technique that uses a dye that specifically binds to the DNA of cell nuclei. With Fossomatic equipment currently used by dairy herd improvement associations in the United States, both epithelial cells and leukocytes are counted, but counts are not confounded by cytoplasmic particles. There is good correlation between Fossomatic counts and those obtained by direct microscopic exam using the pyronin Y-methyl green stain (Droke et al. 1993).

Test temperature (104°F versus 140°F; 40°C versus 60°C), use of bronopol preservative, and sample storage time (one to four days) have little effect on SCC results (Sierra et al. 2006). Counts are slightly lower when azidiol is used as the preservative (Sanchez et al. 2005). If the Fossomatic machine is calibrated according to the manufacturer's directions using goat milk standards, the SCC is 27% lower than when cow standards are used (Zeng 1996).

The DeLaval counter (DeLaval International AB, Tumba, Sweden) is a newer device that is portable and can be used on the farm. A single-use cassette is employed for each milk sample and the technique is DNA-specific. Fluorescence of cell nuclei is detected as a digital image. There is a high correlation (95%) with cell counts obtained with the more laborious direct microscopic method using the pyronin Y-methyl green stain on goat milk (Berry and Broughan 2007). Early, mid, and late lactation goats were included in this study.

Coulter Counter

The Coulter counter enumerates particles as milk flows past an electronic eye. Because cytoplasmic particles are similar in size to leukocytes, they too are counted in goat milk. Certain counters with channels that permit categorizing cells by cell diameter may improve differentiation of mastitic from nonmastitic samples (Smith and Roguinsky 1977). Coulter counter cell counts tend to be approximately double the counts in goat milk determined by Fossomatic equipment (Poutrel and Lerondelle 1983; Lerondelle 1984).

One study involving 483 half samples from goats in Scotland found that SCC by Coulter counter is neither specific nor sensitive for diagnosing caprine mastitis. Approximately one-third of noninfected samples or those yielding coagulase-negative staphylococci gave counts more than 2 million, whereas 73% of samples yielding *Staphylococcus aureus* had SCC more than 2 million (Hunter 1984). The stage of lactation and yield were not specified for these goats. In a longitudinal study in Greece, the SCC by Coulter counter increased as lactation progressed in uninfected goats, varied with the breed of goat, and was higher is goats infected with *S. aureus* than in animals with coagulase-negative staphylococci, which in turn were higher than the count from goats with no infection (Boscos et al. 1996), demonstrating the same relationships seen by others with Fossomatic counts.

Cell Counts in the Course of a Normal Lactation

The number of cells and distribution of cell types are not constant throughout lactation. Epithelial cells are most numerous in late lactation. In a study that did not distinguish stage of lactation and did count cytoplasmic particles, epithelial cells accounted for 5.6% of the total cells plus particles (Sierra et al. 1999). Macrophages are also increased in late lactation and may have a foamy cytoplasm due to phagocytized fat globules. They are extremely difficult to differentiate from epithelial cells. In the fall, when many goats in the herd are "stressed" by estrus, the percentage of neutrophils in the milk increases (Atherton 1992) as does the overall SCC (Haenlein 2002). An association has also been proposed between herd events such as vaccination or nutritional problems leading to acidosis and increased cell counts (Lerondelle et al. 1992). Cytoplasmic particle numbers change little with stage of lactation (Dulin et al. 1983).

The proportion of polymorphonuclear cells in the milk increases as days in milk increases (Rota et al. 1993). A differential count of cells from uninfected goat milk in late lactation has revealed that approximately 80% of the cells are polymorphonuclear cells. This is due to the presence of chemotactic factors different from those found in mastitic milk (Manlongat et al. 1998). These cells may participate in the involution of the udder and protect from new infections. In one study, increased SCC was clearly linked to advancing lactation and decreased production. Goats producing less than one pound (454 g) of milk per day all had counts more than 5 million/ml (using a DNA-specific method) (Perez and Schultz 1979). Other studies have also shown SCC above 1 million/ml in uninfected goats in late lactation (Zeng and Escobar 1995). In a seasonal dairy goat herd, then, where most animals are in late lactation simultaneously, cell counts determined by whatever method often exceed regulatory standards for cow milk even with low prevalence of mastitis. It has been proposed that the regulatory threshold should be adjusted according to herd average days in milk (Haenlein 2002), but implementation might be easier if month of the year were considered instead, in regions where seasonal breeding is the norm. The cell count may also vary with time of day, as one study found higher SCC for afternoon than morning milk samples (Randy et al. 1988).

The arithmetic mean cell count by Coulter counter at drying off is approximately three times the cell count in midlactation in halves infected with nonhemolytic staphylococci or in halves with negative bacterial cultures. Thus, in noninfected halves, the Coulter counter cell count mean in one study was 1.54×10^6 cells/ml (n = 1061) in lactation versus 4.31×10^6 cells/ml (n = 617) at drying off (Lerondelle and Poutrel 1984). In another study, the sum of cytoplasmic particle count and mononuclear (epithelial) cell count exceeded 10 million/ml in several goats in very early and very late lactation, although it was not clear if they were actually free of mastitis (Hinckley 1983).

Cell Counts in Mastitis

It is very difficult to establish a threshold cell count for the diagnosis of mastitis. Many authors have attempted to do so, but their results cannot be combined because different techniques for cell enumeration were used. Marked herd differences in SCC of milk from uninfected goats have been reported in several studies. Also, the specificity of a given threshold as an indicator of mastitis is greatly decreased at or near drying off (Lerondelle and Poutrel 1984). In other words, goats with a high SCC in midlactation are more likely to be infected than are late lactation goats with elevated counts. A threshold of 1 million cells/ml has been proposed for detecting major pathogens in early and midlactation (Poutrel and Lerondelle 1983).

The presence of more than 3 million cells/ml in one or both of the first two monthly tests in lactation has been used in France to diagnose infection with *S. aureus*, with a sensitivity of 82% and a specificity of 95% (Baudry et al. 1999). In another French study of

5,905 samples from 1,060 goats in eight herds, the geometric mean cell count per ml (by Fossomatic) was 272,000 for uninfected glands, 932,000 for coagulase-negative staphylococci, and 2,443,000 for glands infected with major pathogens (Poutrel et al. 1996). In an eight-year survey of herds in Rhode Island and Connecticut, 2,911 milk samples were evaluated. Of these, 466 had SCC above the 1×10^6 threshold but were culture negative, representing 44% of all samples classified as mastitic by SCC (White and Hinckley 1999). A marked difference in the cell count (by whatever test) between halves is a very good indicator of infection in the gland with the higher cell count.

Whatever the cell counting technique and threshold used, it is also very important to realize that the prevalence of infection affects the predictive value of a positive test. Thus, using sensitivity and specificity determined in a Fossomatic study at forty days of lactation, the predictive value of an SCC above 1 million was 0.21 at an infection prevalence of 5%, 0.57 at a prevalence of 20%, and 0.84 at a prevalence of 50%. The corresponding predictive values with a 3 million threshold were 0.39, 0.76, and 0.93 (McDougall et al. 2001). One study concluded that approximately 90% of the difference in goat somatic cell counts cannot be explained by infection, and that a better test for milk quality is needed (Wilson et al. 1995).

Most (but not all) goats with subclinical *Staph. aureus* infection show an elevated cell count (Lerondelle and Poutrel 1984). The nucleated cell count in the milk from a half chronically infected with *Staphylococcus aureus* can fluctuate widely from week to week (Nesbakken 1978a). The SCC in the half infected with *Staph. aureus* is higher than the SCC of the goat's other gland if it is uninfected (Moroni et al. 2005b). A decrease from 10 million to 1 million per ml cannot be used as evidence of elimination of the infection.

Most studies show increased SCC in goats infected with coagulase-negative staphylococci as compared with noninfected herdmates, while others show no or minimal difference (Sheldrake et al. 1981; Hunter 1984; Manser 1986; Paape et al. 2001; Moroni et al. 2005d; Schaeren and Maurer 2006). In one study, the proportion of cells that were neutrophils was increased (approximately 75% compared with approximately 50%) in milk from goats with coagulase-negative staphylococci when compared with milk from goats with negative culture test results (Dulin et al. 1983). It has been proposed that strain differences in pathogenicity are responsible for variation in inflammatory response in different herds. Contreras et al. (1999) reported that *S. epidermidis* was associated with a higher SCC than other coagulase-negative staphylococci in the same herd. Hemolytic strains of coagulase-negative staphylococci induce a higher SCC response than nonhemolytic strains (Bergonier et al. 2003).

However, one recent study failed to find a difference in SCC according to species of coagulase negative staphylococci (Leitner et al. 2004b).

Infections with coliforms or other bacteria producing endotoxin can result in increased nucleated cell counts, and specifically neutrophils, in goats as in cattle. Several workers have demonstrated this by infusing endotoxin into the udder (Dhondt et al. 1977; Jarman and Caruolo 1984). Various species of *Mycoplasma* have also been associated with increased leukocyte counts in goat milk (Prasad et al. 1985).

Some researchers feel that caprine arthritis encephalitis (CAE) virus infection leads to higher cell counts in goats and accounts for part of the difference between SCC of "normal" goats and cows. French workers have noted an increase in the proportion of mononuclear cells in milk from goats with interstitial mastitis caused by CAE (Lerondelle 1988; Lerondelle et al. 1989, 1992). In one study, goats serologically positive for CAE had increased cell counts but also had more subclinical infections with staphylococci than did CAE-negative herdmates (Smith and Cutlip 1988). A similar study from Italy found significantly higher SSC and lower protein and lactose in seropositive doelings but did not determine bacteriologic status (Turin et al. 2005). A Norwegian study of 1,799 goats from sixty-six herds found increased SCC but no statistical differences in production of milk, fat, protein, or lactose in seropositive goats (Nord and Adnoy 1997). Several studies of goats free of bacterial infection have reported increased SCC in milk of CAE positive animals (Ryan et al. 1993; Sánchez et al. 2001). Some researchers have found no effect of CAE status on SCC (Luengo et al. 2004).

The feeding of avocado leaves (*Persea americana*) of the Guatemalan but not Mexican variety to goats has caused a marked drop in milk production, udder edema, grossly curdled milk, and somatic cell counts that were markedly increased (mean more than 7 million/ml; technique not reported but probably Fossomatic) (Craigmill et al. 1984, 1989). There is an apparent injury to the microcirculation of the gland followed by coagulative and lytic necrosis of acinar epithelium (Craigmill et al. 1992). Doses of 20 g fresh leaves/kg body weight cause mastitis while higher doses cause a cardiomyopathy.

Finally, some intramammary infusion products cause a marked increase in SCC; swelling and tenderness of the udder and flakes or clots in the milk occur when given to healthy goats. Oxytetracyline increased the SCC by an average of forty-two times twelve hours after infusion, erythromycin by an average of twenty-three times, and penicillin and cephapirin by six times pretreatment cell counts (Ziv 1984). In a more recent study using bovine mastitis infusion tubes available in South Africa after three consecutive milkings, a cefuroxime product caused no irritation, whereas an

ampicillin/cloxicillin product caused a significant (but unspecified) increase in SCC and the irritation caused by a cephalexin/neomycin/prednisolone treatment was less marked (Karzis et al 2007).

Cell Counts and Cheese Yield

Work with cow milk has shown a small decrease in cheese yield from milk with high SCC. It is believed that proteolytic enzymes from neutrophils break down milk solids into smaller fragments that are then lost in the whey. Lipolysis, which results in off-flavor and decreased yield, also increases, apparently caused by increased susceptibility of the milk fat to lipolysis when mastitis is present (Murphy et al. 1989). Preliminary work with goat milk has failed to show any abnormal protein composition related to increased neutrophil production (Atherton 1992). However, a goat study that compared the milk of uninfected halves with halves infected with coagulase-negative staphylococci demonstrated higher somatic cell counts, lower lactose concentration, and decreased cheese curd yield from the infected glands (Silanikove et al. 2005). Another study found that cheese yield increased in late lactation and was negatively correlated with CMT but that there was no correlation with SCC by Fossomatic (Galina et al. 1996).

Other Tests Correlated with Mastitis

Various constituents and properties of normal goat milk have been reviewed by Jenness (1980). The chloride content of goat milk is greater than in cow milk, with means in various studies ranging from 121 to 204 mg/100 ml.

Bacterial infections in the udder alter cell wall permeability and permit an increased flow of sodium and chloride into the milk. Lactose and potassium concentrations decrease (Linzell and Peaker 1972), but these substances have not been used to diagnose caprine mastitis.

Electrical Conductivity

Subclinical infections by minor pathogens that do not damage mammary epithelium may be of little or no concern to udder health or milk production. With this in mind, researchers have tried to use electrical conductivity of the milk as an indicator of the severity of a mastitis infection (Linzell and Peaker 1975; Fernando et al. 1982; Sheldrake et al. 1983; Norberg et al. 2004). A convincing increase in accuracy of detecting bovine mastitis, relative to somatic cell counting, has not been demonstrated.

Preliminary work has not shown electrical conductivity to be useful in screening for subclinical mastitis in goats. One group failed to find a correlation between SCC (Fossomatic) and electrical conductivity (Park

and Nuti 1985; Park 1991). They noted little variation between conductivity of foremilk and strippings of the same goat but demonstrated a negative correlation between electrical conductivity and butterfat percentage. Another study showed no correlation of electrical conductivity with SCC, a positive correlation with butterfat, and an increase in electrical conductivity as lactation progressed (Das and Singh 2000). Another study showed that electrical conductivity of goat milk was a poor predictor of infection status and less accurate than somatic cell count (McDougall et al. 2001).

NAGase

N-acetyl-β-D-glucosaminidase (NAGase) has received attention as a possible marker for inflammation in both bovine and caprine milk. Because this enzyme is present in the cytoplasm of epithelial cells of the mammary gland and in sloughed-off cytoplasmic particles, and because NAGase is increased in the colostrum and late lactation milk of goats free of bacterial mastitis (Maisi 1990), it suffers from the same problems relative to interpretation as do cell counting techniques.

Several studies have confirmed that NAGase is elevated in milk from halves with major pathogens and with coagulase negative staphylococci (Timms and Schultz 1985; Maisi and Riipinen 1988; Vihan 1989; Maisi and Riipinen 1991; Leitner et al. 2004a, 2004b). Increased NAGase has also been demonstrated in milk from CAE positive goats free of bacterial infection, when compared with CAE negative, bacteria negative goats (Ryan et al. 1993). The test has been reported to be less sensitive than CMT for detecting infection and there is no significant difference between NAGase levels in the infected and uninfected halves of the same goat according to one study (Maisi 1990). Others have concluded that NAGase is superior to cell counting techniques for diagnosing subclinical mastitis in goats (Vihan 1989, 1996).

INFECTIOUS CAUSES OF MASTITIS

Numerous bacterial and mycoplasmal agents have long been associated with caprine mastitis. More recently, retroviral infections have been recognized as an important cause of udder inflammation.

Retroviral Mastitis (Hard Udder)

Goat owners in the United States and Australia have been frustrated for many years by a condition known as "hard udder." More recently a milder form of the condition has been recognized in many countries.

Etiology and Epidemiology

Undoubtedly, the diagnostic characteristics of a firm udder at parturition with scanty milk flow are not specific enough to limit "hard udder" to a single etiol-

ogy. However, it has become clear since the discovery of CAE (caprine arthritis encephalitis) that the condition as a herd problem tends to disappear when CAE is eradicated from the farm (Kapture 1983). Interstitial mastitis has been recognized in two goats experimentally infected with CAE virus (Cork and Narayan 1980). A similar hard udder syndrome has been recognized in sheep infected with the closely related ovine progressive pneumonia and maedi-visna viruses (Cutlip et al. 1985; van der Molen and Houwers 1987). A recent histologic study of sixty-two agar gel immunodiffusion (AGID) positive native goats in Japan found nonsuppurative mastitis in 80% of the animals (Konishi et al. 2006). Infection is readily spread and histologic lesions created by introducing infected cells into the udder (Lerondelle et al. 1995). There is one report of another as of yet unidentified virus smaller than CAEV in the cytoplasm of inflammatory cells in the udder of a goat with typical hard udder (Post et al. 1984)

It is not clear if CAE is involved in the etiology of cystic hyperplasia of the caprine mammary gland described in the older literature from India (Singh and Iyer 1973; Sharma and Iyer 1974). Periductal and perilobular fibrosis infiltrated by lymphocytes was associated with dilated ducts in the cystic lesions. "Udder edema" accompanied by decreased milk flow is another poorly described condition that might be related to CAEV (Sedgman 1982). When true udder edema is present (as described earlier in this chapter), the skin pits on pressure.

There is a recent suggestion that the scrapie agent could be excreted in the milk of sheep with retroviral interstitial mastitis (Ligios et al. 2005). Scrapie is not common in goats (see Chapter 5), but the possibility of horizontal spread of scrapie via milk of CAE infected goats is intriguing.

Clinical Signs

When the acute form of retroviral mastitis appears at parturition, the udder is very firm, almost like a rock, but the overlying skin is loose and free of edema. Heat and erythema are also absent. Almost no milk can be obtained, even with the aid of oxytocin and warm compresses. What milk is obtained appears normal but has an elevated cell count (Lerondelle 1988). Signs of systemic illness are absent. Some affected goats come gradually to milk over a period of several weeks, which has allowed numerous medical or herbal treatments to appear to be effective. In other animals, palpable induration of the udder or udder half persists (Zwahlen et al. 1983). Supramammary lymph nodes are enlarged. Clinical signs may be less severe and cell counts lower in subsequent lactations (Le Guillou 1989; Lerondelle 1989).

Careful udder palpation reveals increased firmness in additional does that appear to be milking normally.

A Swiss study based on palpation of the udder of 1,517 animals found palpable changes (diffuse or focal induration of the parenchyma) in 23% of ELISA seropositive goats, 19% of suspicious goats, and only 7% of seronegative animals (Krieg and Peterhans 1990). Bacteriologic cultures were not undertaken.

Diagnosis

Diagnostic evaluation should include a physical examination to detect other problems such as metritis, udder edema, and teat obstructions. Udder biopsy might be performed but microscopic examination is more commonly performed at necropsy. Histological changes reported for retroviral mastitis in goats and sheep include accumulation of mononuclear cells (lymphocytes, macrophages, and plasmacytes) in the parenchyma and around ducts in the udder (Zwahlen 1983). These mononuclear cells are sometimes organized into lymphoid follicles, a histologic change that has been seen in a three-month-old doeling infected naturally with CAE and in adults (Kennedy-Stoskopf et al. 1985). These cellular infiltrations may externally compress ducts or protrude into ducts, preventing the passage of milk (Post et al. 1986). Lobular atrophy and prominent corpora amylacea are also reported in CAE-affected udders.

Bacterial and mycoplasmal cultures and herd testing for CAE are performed if the owner or veterinarian is unsure of the diagnosis. Not every animal infected with the CAE virus has detectable serum antibody, especially at parturition when circulating antibody has passed into the colostrum. Demonstration of virus by isolation or immunofluorescence testing could be attempted on milk or udder tissue from serologically negative goats. Many goats with CAE infection (including many shedding virus in their milk) do not develop a hard udder. Thus, serology is inconclusive at best. However, if the entire herd is free of evidence of the virus, the diagnosis becomes very unlikely.

Treatment and Control

No cure for the interstitial mastitis has been identified, and culling is indicated. Cortisone administered two days before expected parturition has been reported to cause regression of clinical signs in some goats (Lerondelle 1988). Control is through a CAE eradication program, as discussed in Chapter 4. Kids should be removed from the affected doe and fed virus-free colostrum and milk. Infected animals, if left in the herd, should be separated and milked last, and milk or whey should not be fed back to any goats in the herd without proper heat treatment.

Mycoplasma Mastitis

When repeated efforts to isolate bacteria from udders affected with clinical mastitis yield no growth

or only non-hemolytic staphylococci, the possibility of mycoplasmal involvement should be investigated. The simultaneous presence of mastitis with other clinical signs such as arthritis, pneumonia, or conjunctivitis also warrants consideration of mycoplasma.

Etiology

Numerous species of mycoplasma have been isolated from the milk of goats (DaMassa et al. 1992; Bergonier and Poumarat 1996), sometimes with more than one species present in the same animal (Gil et al. 1999a) or the same herd (Kinde et al. 1994). Others have been infused experimentally into goat udders to test pathogenicity. The various organisms cannot be distinguished on clinical grounds.

Mycoplasma agalactiae. Contagious agalactia of sheep and goats is a specific disease common in Mediterranean countries, much of Europe, the Middle East, and South Africa. The causative agent is classically *Mycoplasma agalactiae*, although some authors now use the term contagious agalactia for almost any mycoplasmal mastitis of small ruminants (OIE 2004; Corrales et al. 2007). As discussed in Chapter 4, *M. agalactiae*, *M. capricolum* subsp. *capricolum*, *M. putrefaciens*, and *M. mycoides* subsp. *mycoides* large colony (LC) type are recognized by the World Organization for Animal Health (OIE) as causes of contagious agalactia for regulatory purposes. *M. agalactiae* is generally considered to be exotic to the United States, although it has been isolated from goats in California (DaMassa 1983; Kinde et al. 1994). In many regions, this condition must be reported to regulatory authorities.

Septicemia occurs in infected animals, and the organism may then localize in the udder, joints, or eyes. *Mycoplasma agalactiae* is shed for months via milk, urine, feces, and ocular and nasal discharges. Infection can be by either ingestion or inhalation. The environment becomes contaminated, and infections may spread via communal browsing areas or driving routes (Dhanda et al. 1959; Corrales et al. 2007).

Mycoplasma mycoides subsp. mycoides (large colony). California goat dairies have experienced mastitis outbreaks and polyarthritis in kids due to *Mycoplasma mycoides* subsp. *mycoides* (large colony type) (East et al. 1983). Its role in respiratory disease is discussed in Chapter 9. This same organism is isolated frequently enough in Europe that recent authors classify it as one of the causes of contagious agalactia (Corrales et al. 2007). In Israel, udder inflammation and agalactia in does and conjunctivitis and polyarthritis in kids have been reported to be caused by *Mycoplasma mycoides* subsp. *mycoides* (ovine/caprine) serogroup 8 (Bar-Moshe and Rapapport 1978, 1981), which is possibly the same organism.

Mycoplasma putrefaciens. Mycoplasma putrefaciens has caused an outbreak of mastitis, agalactia, abortion, and arthritis in a large California dairy (DaMassa et al. 1987) and in Europe (Gaillard-Perrin et al 1986; Mercier et al. 2000) and the Middle East. Subclinical mastitis can occur also. Some goats infected with *M. putrefaciens* have no visible changes in the milk nor palpable inflammation or fibrosis (although milk leukocyte percentages are increased). Even when agalactia develops, fibrosis is absent (Adler et al. 1980). The organism does not seem to induce a febrile response (DaMassa et al. 1992).

Other mycoplasmas. Mycoplasma mycoides subsp. *capri* (normally a cause of pleuropneumonia) and *M. capricolum* subsp. *capricolum* have been isolated from goats with mastitis in France (Perreau 1972; Perreau and Breard 1979; Picavet et al. 1983). Intramammary inoculation of several *M. capricolum* strains produced severe mastitis (thick yellowish secretion, increased cell count, agalactia, enlargement of the supramammary nodes) in does, and pneumonia, polyarthritis, and keratoconjunctivitis in nursing kids (Taoudi et al. 1988). In India, *M. mycoides* subsp. *capri* has produced a purulent mastitis after experimental inoculation (Misri et al. 1988). *Mycoplasma capricolum* has also been isolated from California goats.

Mycoplasma arginini has produced natural cases of purulent mastitis in goats in India (Prasad et al. 1984), and the condition has been reproduced experimentally (Prasad et al. 1985). Leukocyte counts were markedly increased and agalactia developed. In contrast, Jones (1985) was unable to demonstrate pathogenicity of *M. arginini* to the goat udder. The organism is usually considered to be nonpathogenic (DaMassa et al. 1992).

Experimental inoculation of goat udders with *Acholeplasma laidlawii* has produced mastitis leading to agalactia and marked fibrosis (Singh et al. 1990). The goat udder has also been used to test other strains of mycoplasmas isolated from other species or body systems for potential pathogenicity (Pal et al. 1983; Jones 1985).

Clinical Signs

Contagious agalactia (*M. agalactiae*) often appears in a herd in the spring, soon after lactation begins. An incubation period of seven to fifty-six days has been reported. Early signs (during the septicemic stage) include inappetence, depression or malaise, and an unwillingness to follow the herd (U.S. Animal Health Assoc. 1998). A purulent mastitis and agalactia then develop. The secretion is initially watery but later turns thick or lumpy. Keratoconjunctivitis or arthritis may occur in the same goats or in kids drinking unpasteurized milk. Mortality of untreated animals can approach 20%. Some herds have animals infected with and shedding *M. agalactiae* in milk without clinical mastitis or elevation in the bulk tank somatic cell count (Corrales et al. 2004).

Clinical signs with other mycoplasma infections are variable. The classic mastitic mycoplasma milk sample is one that separates into a granular sediment and a greenish-yellow watery supernatant. The milk is said to have a putrefactive odor when *M. putrefaciens* is the cause of the mastitis. In acute, severe cases both mammary gland and supramammary lymph node are enlarged. Both halves of the udder are often but not always affected, and there is no response to treatment. Milk production ceases quickly, with does essentially agalactic in two to three days. The udder atrophies but may be completely functional after the next parturition. Some does die during the acute stage of the disease (East et al. 1983; Gil et al. 1999b). Some mycoplasmas also may be associated with respiratory disease or abortion.

Diagnosis

Mycoplasma should be suspected if blood agar cultures of milk samples from a herd outbreak of mastitis are negative. Appropriate cultures for mycoplasma (for instance on Hayflick's medium) should then be initiated. In herds with *M. mycoides* subsp. *mycoides* LC, it has been noted that most milking does are asymptomatic with normal appearance to the milk, though large numbers of mycoplasma are present. This species is somewhat unique in that it can be isolated on sheep or calf blood agar, where colonies resemble alpha-hemolytic streptococci but no bacteria are seen on Gram stain (Rosendal 1994). When contagious agalactia is suspected, other samples from septicemic animals can also be positive by culture, including ocular swabs, ear swabs, joint fluid, blood, liver, spleen, feces, and urine. As with respiratory disease, the identification of the species of mycoplasma involved in a mastitis outbreak can be hastened and simplified by using appropriate polymerase chain reaction tests (Nicholas 2002; Corrales et al. 2007). Serologic testing using ELISA can also be helpful if vaccination is not part of the control strategy (Corrales et al. 2007). Commercial ELISA kits for *M. agalactiae* are available in Europe (OIE 2004).

Histopathologic examination of the mammary gland reveals marked interstitial infiltration with mononuclear leukocytes, especially around acini and ducts. Mononuclear cells and desquamated epithelial cells are seen in ducts. Giemsa stain can be used to demonstrate the mycoplasma (Dhanda et al. 1959), but immunochemistry is more specific and preferred (Corrales et al. 2007).

Treatment

Treatment is generally ineffective. Improvement in systemic signs is usually noted with drugs generally used against mycoplasma (such as tetracycline, tylosin, erythromycin, spiramycin, lincomycin, tiamulin, florfenicol, or fluoroquinolones where legal), but the goat is apt to become an inapparent carrier (Perreau 1974; Bergonier and Poumarat 1996; Nicholas 2002). Thus, slaughter of all infected goats is recommended unless the herd is in an endemic region. Practitioners should particularly avoid infusion into the udder of preparations of tylosin or erythromycin meant for systemic administration. The irritating nature of these drugs often ensures destruction of milk secreting tissue, even if the infection can be eliminated. It has been reported that tiamulin at 10 mg/kg intramuscularly can maintain concentrations in the udder inhibitory for *M. agalactiae* for twelve hours (Ziv et al. 1983). Spectinomycin penetrates the udder poorly. In endemic herds, using an antimycoplasma treatment for all animals at dry off has been recommended (Corrales et al. 2007).

Control

Because mycoplasma mastitis is usually introduced into the herd by a carrier goat or sheep (Ruhnke et al. 1983), it is very important to investigate the health status of the herd of origin before buying or boarding an animal. Serologic tests have been undertaken in some countries with an aim of eradicating infection from herds and preventing re-introduction. The variety of species possibly involved complicates this approach. Serology using enzyme-linked immunoabsorbent assay tests for *M. agalactiae* and *M. mycoides* subsp. *mycoides* LC has shown promise for identifying individual carrier goats (Davidson et al. 1989). Culture tests of bulk tank samples appear to be a starting point in regions where the problem occurs. An outbreak of mastitis may be delayed until several months or years after introduction of carrier animals (Picavet et al. 1983). Stress, as is associated with parturition or with transport and adjustment to a new herd, appears to trigger shedding of the organism.

As with all cases of mastitis, affected animals should be milked last and hands or milking machines disinfected before milking other goats. Common udder towels should be avoided. In dairy herds undertaking an eradication program for *M. mycoides* subsp. *mycoides* LC, one approach is to cull all positive animals to slaughter based on an initial herd culture. Then colostrum is cultured from each doe at freshening. The eradication efforts are monitored by frequent culturing of tank milk from each milking string (East et al. 1983). Because feeding of raw colostrum and milk can be the source of serious joint and lung infections, a pasteurizer should be used if goat milk is to be fed to kids.

Mycoplasma agalactiae organisms are shed in urine and feces, making the environment an important source of infection to other sheep and goats. Stalls should be disinfected and litter removed. Mycoplasma are inactivated by many routine disinfectants, including sodium hypochlorite (30 ml of household bleach in

1 gallon or 4 liters of water), cresol, 1% formalin, and ionic and nonionic detergents (U.S. Animal Health Association 1998). A variety of vaccines against *M. agalactiae*, both killed and attenuated, have been evaluated. Although some provide protection from clinical disease and are thus very useful in endemic areas, carrier states may still develop (Foggie et al. 1970, 1971; Arisoy 1973; U.S. Animal Health Assoc. 1998). In regions where vaccination is routine, leaving a small population of unvaccinated sentinel animals in the herd permits monitoring of disease activity by serologic screening (Corrales et al. 2007). Goats previously inoculated with *M. putrefaciens* showed resistance to subsequent challenge for at least one year (Brooks et al. 1981), suggesting that a vaccine might also help to control this organism.

Bacterial Mastitis

Bacteria causing caprine mastitis, with a few exceptions, usually enter the udder through the teat end. Clinical cases occur most commonly in early lactation (Moroni et al. 2005c). Control is achieved by udder hygiene during and between milkings.

Organisms and Clinical Syndromes

The clinician cannot expect to identify the organism by the nature of the secretion but can often make a tentative diagnosis based on herd history (prior probability). Culturing the etiologic agent from the milk or udder tissue is necessary to identify the cause of mastitis. In turn, identifying the organism involved assists the veterinarian and owner in designing future control programs. Organisms are discussed in alphabetical order because prevalence and importance vary between herds and regions.

ARCANOBACTERIUM (ACTINOMYCES, CORYNEBACTERIUM) PYOGENES. This organism is frequently isolated from udders containing multiple abscesses (Figure 14.7). Teat or udder wounds predispose to the entry and establishment of the infection in the udder. In experimental infections, nonlactating glands are more severely affected than lactating glands (Jain and Sharma 1964). In the chronic stage, culling is advisable, although teat (Sasshofer et al. 1987) and udder amputation return the goat to systemic good health if localization in other organs has not occurred. The organism grows slowly on blood agar. Colonies are tiny at forty-eight hours but made visible by a narrow zone of clear hemolysis. The organism is a small Gram-positive rod and is catalase-negative.

BRUCELLOSIS. *Brucella melitensis* and *Br. abortus* can cause a subclinical interstitial lymphoplasmacytic mastitis (Heidrich and Renk 1967). The organism is carried by macrophages to the udder and then to the supramammary lymph node, which may be enlarged (Meador et al. 1989). The number of organisms in the

Figure 14.7. Udder abscesses in an aged doe caused by *Arcanobacterium pyogenes*. The animal was managed by udder amputation. (Courtesy Dr. M.C. Smith.)

milk and the degree of inflammation in the gland are increased by milk stasis, as when milking or nursing does not occur (Meador and Deyoe 1991). The presence of these organisms is often first suspected when brucellosis is diagnosed as a cause of abortion in the herd (see Chapter 13) or if humans consuming raw milk products develop undulant or Malta fever (Stiles 1950). Serologic testing of the goats is then undertaken, because the milk ring test is not accurate in goat milk (see Chapter 13). Sometimes a clinical mastitis occurs with palpable nodules in the udder parenchyma and flakes in the secretion (Dubois 1911). The mastitis resolves spontaneously, but the goat should be slaughtered to avoid human infections.

COLIFORMS. Coliforms, including *Escherichia coli* and *Klebsiella* spp, occasionally cause clinical mastitis in goats (Adinarayanan and Singh 1968; Lewter et al. 1984). The organisms are Gram-negative, KOH-positive, oxidase-negative rods. Colonies are large, gray or yellow, and moist. *E. coli* gives off a fecal odor.

Infection appears to be more common in periparturient does. Clinical signs in acute cases include anorexia, fever, and a yellowish or reddish watery secretion with an increased somatic cell count. The affected gland is warm, swollen, and painful. These signs have been reproduced experimentally by intramammary infusion of *E. coli* endotoxin (Dhondt et al. 1977). Occasionally signs progress to gangrene (Ameh et al. 1994).

These organisms represent "environmental" mastitis. Thus, control involves keeping sleeping areas clean and dry, drying teats thoroughly before milking, and avoiding teat-end injuries. Using post-milking teat dipping does not aid much in controlling coliform infections, because these are initiated between milkings, except when wet udders are milked.

CORYNEBACTERIUM PSEUDOTUBERCULOSIS. Though caseous lymphadenitis is very common in goats, mastitis caused by this disease is relatively rare. Infection of skin wounds on the udder may cause abscessation of the supramammary lymph node with no involvement of mammary gland tissue. Occasionally, goats develop mastitis or abscesses in the parenchyma of the udder (Addo et al. 1980; Burrell 1981; Schreuder et al. 1990). Positive catalase test results distinguish *C. pseudotuberculosis* from *A. pyogenes*.

LISTERIA. It has been suggested that *Listeria monocytogenes* can cause a subclinical interstitial mastitis, with diagnosis based on isolation of the organism from milk (Sasshofer et al. 1987). A chronic inflammatory lesion with lymphocyte infiltration, alveolar destruction, and fibrosis has been seen in the udder of sheep shedding listeria in the milk after natural or experimental infection (Tzora et al. 1999). Documentation of an inflammatory lesion in the goat udder is lacking, but listeria are commonly shed in the milk of clinically normal goats during herd outbreaks of listeriosis or immediately after parturition (Løken et al. 1982). Shedding of *L. monocytogenes* in the milk of goats correlates well with the presence of antibodies against the organism in the milk as detected by an ELISA (Bourry et al. 1997). *Listeria ivanovii* has been isolated from a mastitic goat in India (Elezebeth et al. 2007). *Listeria* are more important from a food safety perspective (Pearson and Marth 1990) than as a cause of mastitis in goats.

MANNHEIMIA. Mannheimia (*Pasteurella*) *haemolytica* has been isolated only occasionally from goat milk (Schröter 1954; Bagadi and Razig 1976; Manser 1986; Donkin and Boyazoglu 2004), although it is a well-recognized cause of mastitis (including gangrene) of sheep. In an Italian study of 720 goats over an entire lactation, it was responsible for 16% of clinical cases (Moroni et al. 2005c). In Angoras in South Africa, *M. haemolytica* is reported to be a more frequent cause of acute mastitis than *Staphylococcus aureus*, typically occurring four to six weeks after parturition and seldom being accompanied by gangrenous color changes (Van Tonder 1975). The infection is most likely acquired from suckling kids, since it is a common inhabitant of the upper respiratory tract. The organism is a Gram-negative, oxidase-positive, bipolar rod. Colonies are medium, gray, transparent, and hemolytic on blood agar plates.

MYCOBACTERIUM INFECTIONS (TUBERCULOSIS). Mycobacterium bovis, *M. tuberculosis*, and *M. avium* can all be associated with tubercular mastitis in goats (Murray et al. 1921; Davies 1947; Sasshofer et al. 1987). In regions where bovine tuberculosis is common, cows infect goats by the respiratory or alimentary routes (Heidrich and Renk 1967). The udder becomes involved during generalization of the infection to other organs such as lungs, liver, and spleen. Often, the source is infected humans.

The infection is subacute to chronic and manifests itself by slight swelling of the udder and development of firm, caseous or calcified, nodules in the parenchyma (Davies 1947; Soliman et al. 1953). Supramammary lymph node enlargement occurs. Antemortem diagnosis is by tuberculin test. Culture requires special media. Affected goats are slaughtered because of the risk they pose to human health.

PSEUDOMONAS. Like *Mannheimia*, *Pseudomonas* species are oxidase-positive, Gram-negative rods, but colonies are usually granular and dry and may be a variety of colors. The source is usually contaminated water or teat dips, old pitted inflations, or wet bedding. If the water system is contaminated, flushing with heavily chlorinated hot water (160°F; 71°C or hotter) should kill the *Pseudomonas*, which are otherwise protected by a biofilm. Cleaning directions for pipeline systems (Dairy Practices Council 2000) are applicable. Paracetic acid can also be used to flush hoses and the water system in the parlor (Yeruham et al. 2005).

In one natural outbreak, systemic signs of illness were so severe that gangrenous staphylococcal mastitis was originally suspected. Only when appropriate antibiotics (based on a sensitivity test) were administered did affected goats survive (Petgen and Martain 1977). In another herd outbreak, 18% of 450 goats were infected and 12.5% developed clinical mastitis due to *Pseudomonas aeruginosa*. These does were depressed, inappetent, and febrile and the udders were firm, swollen, and painful. Many of these animals developed gangrenous mastitis and twenty-five died while the other fifty-seven infected goats were culled because they did not respond to treatment (Yeruham et al. 2005). In some herds, prolonged infections develop and clinical signs occur periodically.

Goats have been experimentally infected, but inoculation of the udder with large numbers of *Pseudomonas aeruginosa* was required; clinical signs varied from mild mastitis to severe, hemorrhagic mastitis with terminal septicemia (Lepper and Matthews 1966).

Burkholderia (*Pseudomonas*) *pseudomallei*, the causative agent of melioidosis, is a soil saprophyte found in parts of Australia and tropical Asia. Mastitis sometimes occurs, although abscesses are most common in lymph nodes, spleen, and lungs. This may take the form of udder swelling with pus in the milk (Thomas et al. 1988; van der Lugt and Henton 1995). Abscesses in the udder that repeatedly break and drain to the outside also have been observed (Olds and Lewis 1954). The organism has been isolated from macroscopically normal goat milk. Treatment (with tetracycline) is often unsuccessful, and affected goats are usually destroyed because of public health concerns.

STAPHYLOCOCCUS AUREUS. Coagulase-positive (usually hemolytic) staphylococci are a common major pathogen of the goat's udder. In regions free of mycoplasmal mastitis, these organisms are often the most prevalent cause of clinical mastitis in dairy goats. *Staphylococcus aureus* isolates from caprine mastitis have been shown to resemble bovine mastitis strains in that most contain surface protein A (that binds to immunoglobin G) and fibronectin binding protein (involved in bacterial adherence and colonization) (Jarp et al. 1989). Most strains produce both alpha hemolysin and beta hemolysin (Roguinsky and Grandemy 1978). Colonies are large on blood agar media and usually surrounded by a zone of incomplete hemolysis or more than 2 mm of complete hemolysis (Figure 14.8). The organisms are Gram-positive cocci in pairs or clumps and are catalase-positive. Although the coagulase test is commonly used to identify *S. aureus*, *S. intermedius*, and *S. hyicus* can also be coagulase-positive (National Mastitis Council 1999) and are occasionally isolated from goat milk (Kalogridou-Vassiliadou 1991; Kyozaire et al. 2005) when full speciation is performed.
Figure 14.8. Zones of complete and partial hemolysis around colonies of *Staphylococcus aureus* growing on blood agar. (Courtesy Dr. M.C. Smith.)

The infection can be subclinical (identified by culture during herd survey), chronic (decreased production accompanied by induration and abscess formation), or acute (swollen, hot, painful half of the udder, accompanied by systemic illness). The most severe, acute form is gangrenous mastitis, which is described in detail below. These same forms have been reproduced by experimental inoculation of *S. aureus* into goat udders (Derbyshire 1958a).

As is the case with cows, the organism resides in microabscesses in chronically infected goats and infections are very difficult to cure (Derbyshire 1958b). Transmission to other goats occurs during milking. Animals that are culture positive for *S. aureus* should be culled to slaughter or milked last. In larger herds with machine milking, a "staph" unit can be identified and used to milk only *S. aureus* infected goats. If these animals are retained in the herd, they should certainly be dry treated and then should remain in the "staph string" (the group of infected goats) into the beginning of the next lactation. Intermittent shedding is common, and a single negative culture of a previously infected goat is not proof of a cure. If cultures are repeatedly negative and somatic cell counts remain low, the animal could be returned to the main herd.

Ideally, the milk of infected does should be pasteurized before it is fed to kids. Diarrhea, pneumonia, and death of nursing kids, with isolation of *S. aureus* from heart blood and abomasal and intestinal contents, have been reported (Paliwal et al. 1977).

GANGRENOUS MASTITIS. Gangrenous mastitis in goats is most frequently due to *Staphylococcus aureus* in animals lacking adequate concentrations of antitoxin against the necrotizing alpha-toxin produced by the organism. Clostridial infections have also been implicated, as have coliforms (Renk 1957, Petris 1963).

The condition usually is restricted to the period of lactation. However, sometimes gangrenous mastitis occurs during the last week of pregnancy, when it often causes loss of the fetuses and death of the doe from toxemia (Petris 1963). Affected goats have poor appetite and a transient fever. In early cases, the skin of the teat or udder floor becomes cool and edematous, and the goat appears lame. A reddish (Figure 14.9), then bluish discoloration of the skin is noted next. The secretion becomes watery and red; gas bubbles may be present and produce a squeaking sound when the teat is stripped. Death may occur within twenty-four hours. In animals that survive the acute phase, a clear line of demarcation forms on the udder and the gangrenous portions are sloughed after several days or weeks.

Histologically, there is venous thrombosis, and the initial inflammatory changes are replaced by necrosis and sloughing of epithelial cells (Derbyshire 1958b). This thrombosis is probably responsible for edema of the mammary gland and ventral abdominal wall. The

Figure 14.9. Early gangrenous mastitis with edema and erythema of the udder. *Staphylococcus aureus* was isolated from the milk and a portion of the gland sloughed. (Courtesy Dr. M.C. Smith.)

supramammary lymph node is enlarged, edematous, and hemorrhagic.

Because of its dramatic presentation and associated great economic loss, gangrenous mastitis caused by *S. aureus* is often the most prevalent form of mastitis recognized in herds free of mycoplasmal infections. In one report from Cyprus in 1961, almost 9% of 8,000 goats were affected with gangrene (Petris 1963). The average case fatality rate in this study was 40%.

COAGULASE-NEGATIVE STAPHYLOCOCCI. In many herd surveys, the most commonly isolated organisms are staphylococci other than *S. aureus*. As many as 71% of udder halves in a herd have been found to be infected (Sheldrake et al. 1981; Poutrel 1984). In a large California survey (sixteen herds, 2,522 lactating does), coagulase-negative *Staphylococcus* spp. were isolated from 17.5% of does (East et al. 1987). In four commercial herds in Australia, the prevalence was 13.3% of 896 halves tested (Ryan and Greenwood 1990). In a study in Italy that sampled 305 goats monthly throughout the lactation, 1,474 of 4,571 udder half samples cultured coagulase negative staphylococci (Moroni et al. 2005b). Numerous staphylococcal species have been identified, including *Staphylococcus epidermidis*, *S. intermedius*, *S. caprae*, and *S. hyicus* (Poutrel 1984; Maisi and Riipinen 1988; Maisi 1990; Kalogridou-Vassiliadou 1991). Many studies have been summarized by Contreras et al. (2003). Because different staphylococcal test systems often result in different species assignments, reported species prevalences in the literature may not be comparable (Burriel and Scott, 1998). These infections tend to persist throughout much of the lactation and are more common in older goats (Contreras et al. 1997b; Sanchez et al. 1999) and later lactation.

Bilateral infections are common (Moroni et al. 2005b). The organisms commonly reside on the skin or in the environment (Valle et al. 1991; National Mastitis Council 1999).

Some authors regard the coagulase-negative organisms as major pathogens (Dulin et al. 1983), while others see them as minor pathogens or incidental infections (Moroni et al. 2005d). In a study comparing milk production of the udder halves of twenty-five unilaterally infected goats (Leitner et al. 2004a), production was significantly higher (0.98 kg/milking) in the uninfected halves, as compared with the infected halves (0.69 kg/milking). Some authors define an increased cell count to be equivalent to a serious mastitis and then conclude that because some goat milk samples with an increased cell count yield the organism, it must therefore have caused serious mastitis (Hinckley et al. 1985). The economic importance of coagulase-negative staphylococci remains unclear. Generally, the practitioner should look further to explain serious illness or marked loss in production because the coagulase-negative staphylococci are unlikely to be the cause. However, a high prevalence of these bacteria may suggest suboptimal milking procedures that should be addressed (Contreras et al. 2003).

STREPTOCOCCUS AGALACTIAE. Infection with *Streptococcus agalactiae* has been reported in goats in sporadic or epizootic forms, but occurs less frequently than in cattle. Most reports are in the older literature (Heidrich and Renk 1967) or from India (Mukherjee and Das 1957), New Zealand (McDougall and Anniss 2005), or Brazil (Langoni et al. 2006). The organism does not appear to be a problem in goats in the United States (White and Hinckley 1999).

The goat is not systemically ill, but induration of the udder and loss of secretory tissue may occur. *Streptococcus agalactiae* has been associated with severe stromal proliferation and fibrosis in goat udders (Addo 1984). The lesions have been reproduced experimentally (Pattison 1951). Abscess formation does not occur. The disease is transmitted from cow to goat or goat to goat, by milk on the inflations or the hands of the milker. Introduction of the disease to the herd can be avoided by screening bulk tank milk from the herd of origin or culturing the milk of the individual purchased doe before it joins the milking herd. Most isolates are sensitive to penicillin.

Colonies are not sufficiently characteristic in blood agar cultures to permit differentiation from other streptococci (see below), because *Streptococcus agalactiae* may be accompanied by greening of the medium, beta hemolysis, or no hemolysis. *Streptococcus agalactia* does not split esculin. The CAMP test is frequently used to make a presumptive diagnosis of *Streptococcus agalactiae* (Schalm et al. 1971). Erythrocytes sensitized by beta hemolysin from a nearby streak of *Staph. aureus*

are completely hemolyzed by a factor diffusing into the agar from the *S. agalactiae*.

Other Streptococci. Streptococci other than *S. agalactiae* are occasionally the cause of sporadic cases of mastitis of environmental origin (Mallikeswaran and Padmanaban 1991). In one study that followed 720 machine milked goats over a complete lactation, 16% of the clinical cases of mastitis were ascribed to *Streptococcus* species, as compared with 74% due to *Staphylococcus aureus* (Moroni et al. 2005c). A herd outbreak of mastitis caused by *Streptococcus zooepidemicus* (twenty-eight of fifty animals with chronic mastitis) was ascribed to poor hygiene. Clinical signs included udder atrophy, induration, and abscessation (Nesbakken 1975). Outbreaks of *Streptococcus zooepidemicus* in three herds in Spain resembled contagious agalactia due to mycoplasma, including the occurrence of septic arthritis, and were controlled with an autogenous vaccine (Ruiz Santa Quiteria et al. 1991). Somatic cell counts are elevated, even in subclinically infected goats (Hall and Rycroft 2007). Provision of a clean, dry environment for the goats and assuring that the udder is clean and dry at milking should help to prevent new infections.

Streptococcal species form colonies on blood agar that are smaller than staphylococci, and the bacteria are catalase-negative. Many streptococci of environmental origin are esculin-negative (National Mastitis Council 1999).

Miscellaneous Bacterial and Fungal Organisms. It is conceivable that any pathogenic bacterium introduced into the udder might cause mastitis. For instance, isolation of the environmental organism *Serratia* is occasionally reported on herd surveys. Based on experience with cattle, antibiotic therapy is not helpful, but hygiene of the barn and teat dip should be investigated (National Mastitis Council 1999). If treatment has preceded isolation of an uncommon agent, the possibility of iatrogenic inoculation of the udder cannot be discounted. Miscellaneous organisms isolated from mastitic goat milk include *Yersinia pseudotuberculosis* (Cappucci et al. 1978; Jones 1982), *Nocardia* (Dafaalla and Gharib 1958; Bassam and Hasso 1997; Rozear et al. 1998), *Cryptococcus neoformans* (Pal and Randhawa 1976; Aljaburi and Kalra 1983), and numerous other fungi (Lepper 1964; Pal 1982; Jensen et al. 1996). Fungal mastitis has also been produced experimentally in goats using numerous *Candida* species and *Rhodotorula glutinis*. Antibiotic treatment prolonged the disease (Jand and Dhillon 1975). *Corynebacterium* spp. (Schaeren and Maurer 2006; Hall and Rycroft 2007) and yeasts (McDougall 2000) have been isolated from clinically normal goats. The isolation of *Corynebacterium bovis* from dairy cows is usually interpreted as evidence for inadequate teat dipping (National Mastitis Council 1999).

Treatment of Bacterial Mastitis

Although the owner of a valuable or pet goat expects and desires treatment for the doe with mastitis, culling of affected animals is often an economically sound alternative. Culling serves to decrease exposure of other does to contagious organisms and to increase selection pressure for genetic resistance to infection. Culling is also a logical choice when abscesses are found in the udder of a fiber-producing or meat goat during weaning or when selection for rebreeding occurs.

Lactation Treatment with Antibiotics. If treatment is elected, it should begin as soon as clinical signs are noted. Otherwise, additional destruction of milk secreting tissue may occur or the mastitis may turn gangrenous (*Staphylococcus aureus*). Lactational treatment of subclinical mastitis detected by culture or somatic cell determination usually is not economically profitable, except possibly for *Streptococcus agalactiae*, which is uncommon in goats. Milking such animals last is desirable.

Choice of Antibiotics. The range of antibiotics available for either intramammary or parenteral treatment of mastitis varies from country to country. Practitioners should evaluate the antibiotic sensitivity of isolates relative to drugs that are available, legal, and not prohibitively expensive. Because *Staphylococcus aureus* is the most frequent cause of clinical mastitis in many herds, initial treatment (in the absence of sensitivity results) should ideally be with a drug this organism is normally sensitive to; tetracycline and cephapirin are frequently effective *in vitro*. Resistance to penicillin is common, while ampicillin and amoxicillin have a broader spectrum of efficacy. Some studies have not shown beta lactamase production by goat isolates (Moroni et al. 2005a). Unless the animal is systemically ill, treatment is often limited to intramammary infusion with a full bovine tube administered two or three times at twelve- or twenty-four-hour intervals.

When extensive swelling or tissue penetration by bacteria such as *S. aureus* has occurred, parenteral administration of an antibiotic with good bio-availability for five to seven days is recommended (Ziv 1980). Because of pharmacokinetic considerations, some drugs that are administered parenterally do not achieve adequate concentrations in the udder (Ziv and Soback 1989). Gentamicin penetrates the udder poorly, and cephalosporins also do not pass readily from blood to milk. Oxytetracycline and potentiated sulfonamides are broad-spectrum and nontoxic but also have limited or variable penetration. Chloramphenicol has excellent properties for parenteral treatment of mastitis but is forbidden in many countries. Slow-release formulations (penicillin, tetracycline) are not usually effective in maintaining adequate milk concentrations.

Infusion of the udder on a prescription basis with gentamicin or trimethoprim/sulfadiazine has been recommended for confirmed coliform mastitis (Lewter et al. 1984). Research in cows suggests that gentamicin therapy does not affect severity or duration of *E. coli* mastitis, and clearance of gentamicin from kidney tissue requires many months (Erskine et al. 1991). The use of this antibiotic, then, is best avoided. Furthermore, infusion of any antibiotic solution other than a commercial mastitis tube is undesirable because of sterility, safety, and residue issues.

The antibacterial and udder penetration properties of several newer agents have been summarized by Ziv and Soback (1989). Florfenicol, enrofloxacin, norfloxacin nicotinate, tiamulin, and doxycycline afford good or excellent udder penetration after parenteral administration. The use of enrofloxacin and other fluoroquinolones in goats is expressly forbidden in the United States.

INFUSION TECHNIQUES. Most commercial bovine infusion tubes have an applicator tip that is too large to be inserted into an average goat's teat. It is currently recognized that full insertion, even in a cow, damages the lining of the streak canal. In addition, bacteria that colonize the keratin lining are forced upward into the teat cistern, thereby predisposing to new infections. Thus, even in the case of a large teat opening, the applicator tip should be inserted only far enough to prevent leakage of the product during infusion. A specially designed 3.5-mm (one-eighth-inch) syringe tip (Opti-Sert, Ft. Dodge Labs, Ft. Dodge IA) should make partial insertion easier. When the teat sphincter is too tight or the doe too uncooperative, a sterile tom cat catheter may be used to infuse the mastitis medicine into the teat. Some authors recommend treating both halves even if only one is clinically affected (Sasshofer et al. 1987).

Teat dipping with a disinfectant before and after infusion is advisable, as is cleansing of the teat end with alcohol. Owners may need instruction in the importance of clean hands (or gloves) and sanitary techniques.

ANTIBIOTIC RESIDUE AVOIDANCE. The owner or veterinarian who has treated the lactating goat with antibiotics is left with the question of when the milk will be free of antibiotic residues. In one study using commercial lactating cow infusion tubes in the United States, erythromycin, oxytetracycline, penicillin, and cephapirin were administered according to label directions to ten goats. Antibiotic residues were not detected after the labeled discard periods (thirty-six, ninety-six, sixty, and ninety-six hours, respectively) except for one goat that still had detectable penicillin after seventy-two hours (Long et al. 1984). Another study found that oxytetracycline (426 mg) was still detectable at 108 hours and cloxacillin (200 mg) at 156 hours after last treatment (Hill et al. 1984). A commercial combination product (200 mg amoxicillin trihydrate, 50 mg potassium clavulanate, and 10 mg prednisolone) labeled with a forty-eight-hour withdrawal in dairy cows required 112 hours withholding time to achieve acceptable amoxicillin concentrations in goat milk (Buswell et al. 1989). It seems prudent to at least double the recommended bovine withdrawal period when treating goats. European regulations specify a seven-day withdrawal period for extralabel intramammary treatment of lactating small ruminants (Bergonier et al. 2003).

Duration of antibiotic residues in healthy goats after intramammary treatment (thirty-five commercially available infusion products) or parenteral treatment (twenty-seven injectable products) has been reported by Ziv (1984). Ceftiofur is labeled for systemic use in goats in the United States with zero milk withdrawal but does not penetrate the udder well. Systemic oxytetracycline is expected to be cleared from goat milk as fast as or faster than cows clear the antibiotic, but a milk discard period of six days has been suggested after high or prolonged dosage (Martin-Jimenez et al. 1997). Duration of penicillin residues in goat milk is variable, especially if given by the subcutaneous route, and testing of the milk is advised (Payne et al. 2006).

As the sensitivity of assays in use increases, it can be expected that the prudent withdrawal period will lengthen. Several residue tests have been shown to detect antibiotic concentrations in goat milk below the tolerance limit set for cow milk in the United States (Zeng et al. 1998); typically no confirmatory testing is done and the producer is presumed to be guilty of supplying milk with an illegal residue. It is also important to remember that detectable concentrations of antibiotics appear in milk from the untreated half (Hill et al. 1984). Even when residue levels are too low to endanger any except the most allergic human consumers, a cultured cheese may fail because of antibiotics in the milk. Ideally, milk from treated does should be tested at a milk plant or laboratory with the most sensitive antibiotic test available; milk with positive test results should not be used for human consumption.

FALSE-POSITIVE INHIBITOR TESTS. Normal goat milk appears to have some antibacterial action. In one study, 24% of pre-antibiotic treatment milk samples from seventy-five healthy goats showed false-positive Delvotest results, and in 11% of the seventy-five animals the natural inhibitors were heat stable (140°F or 60°C for twenty minutes) (Ziv 1984). Small zones of inhibition (halos) are sometimes noted with the *Bacillus stearothermophilus* disc assay, especially late in lactation, and this naturally attracts the attention of regulatory officials (Hinckley 1991). Iron-binding protein (lactoferrin) in goat milk has been shown to be bacteriostatic for *B. stearothermophilus* (Oram and Reiter 1968). Both the

bacteriostatic effect and the lactoferrin concentration are increased in dry secretion. Rancidity (lipolysis) is also increased in late lactation, and heat treatment does not affect bacterial inhibition due to fatty acids (Hinckley 1991; Atherton 1992). The *B. stearothermophilus* test may be inappropriate for goat milk (Klima 1980). The Delvotest P® culture medium version of the *B. stearothermophilus* assay has been shown to produce false positive results when compared with the disc assay (Zeng et al. 1996). The Penzyme® test for beta lactam residues has been reported to be sensitive and specific when used on goat milk containing penicillin or cephapirin (Zeng et al. 1996). Another study using eight different test kits and milk from clinically normal goats found all kits, including Penzyme®, to be suitable for screening goat milk when performed according to the manufacturer's directions because specificity was at least 0.99 (Contreras et al. 1997a).

Incubating bovine milk samples at warm temperatures, with resulting increase in bacterial numbers and decrease in pH levels, has been shown to cause inhibitory zones in disc assays. Some of these inhibitory zones, like those caused by antibiotics, persisted after raw milk had been heated to 180°F (82.2°C) for five minutes (Kosikowski 1963). Thus, improper handling of milk samples may contribute to false-positive residue test reactions.

Non-antibiotic inhibitors in milk may have an importance that transcends regulatory considerations. Residues of disinfectant in milk or iodine originating from excessive dietary levels may interfere with bacterial acidification necessary for cultured products (Le Jaouen 1987).

Supportive Therapy for Mastitis

Frequent stripping, which serves to remove both bacteria and toxins, is beneficial. Oxytocin (5 to 10 units) and hot compresses assist in achieving milk letdown from a painful gland. Infection or starvation of kids and spread to other does are potential risks if kids are left on the doe to aid in removal of secretions from the udder.

Anti-inflammatory agents such as intravenous or oral flunixin meglumine (1 mg/kg once or twice daily) or corticosteroids (dexamethasone 0.44 mg/kg single dose) are frequently administered to animals with signs of discomfort or toxemia. In an experimental intramammary *E. coli* challenge, goats treated with anti-inflammatory agents showed some improvement in clinical signs without any adverse effects on bacterial clearance (Anderson et al. 1991). In a clinical trial, intramuscular flunixin meglumine at approximately 2.5 mg/kg once daily for two treatments resulted in more rapid resolution of clinical signs compared with control goats receiving the same intramammary antibiotic but no anti-inflammatory drug (Mavrogianni

et al. 2004). Phenylbutazone should be avoided in goats to be used for meat or milk and is explicitly forbidden in some countries. Intravenous fluids may be indicated in systemically ill animals. If the goat is still ambulatory, oral fluids, such as commercial electrolyte products, can be substituted and are less expensive. Systemic antibiotics are commonly administered when the mastitis is severe or chronic.

Treatment of Gangrenous Mastitis

When a reddish udder secretion is accompanied by blue discoloration and coolness of the udder skin, the severity of the mastitis warrants intensive therapy and, usually, a poor prognosis for return to function.

MEDICAL MANAGEMENT. In the early stages, when the affected gland is warmer than normal and painful and the secretion is blood tinged, successful medical treatment has been reported. Even when signs of gangrene were unequivocal (i.e., coolness, pitting edema, loss of skin sensation, and a watery red secretion), complete recovery was reported in 91% of eighty-one goats in the Sudan (Abu-Samra et al. 1988). Oxytetracycline systemically (5 mg/kg intravenously) and intramammary (426 mg daily) for five days was used in the Sudanese study, but cephapirin also seems to be a rational choice. The secretion was drained with a sterile teat cannula. In addition, a diuretic (40 mg furosemide) daily for five days and topical treatment of the udder with an antiseptic cream were used.

Most authors do not claim such successful results with less intensive medical treatment. For instance, in a study from Cyprus in which 9% of 8,000 goats suffered from gangrenous mastitis, in no case was there complete recovery of the udder (Petris 1963).

MASTECTOMY. Surgical removal of one half or of the entire udder is sometimes performed.

- **Indications and reservations**. Amputation of the udder can be a life-saving procedure if the goat is very toxic with gangrenous mastitis. Udder amputation avoids the unhygienic and unpleasant process of sloughing of necrotic tissue (Abu-Samra et al. 1988). Another candidate for the surgery is the goat that has chronic abscesses in the udder and is in poor body condition; udder amputation may result in a return to good health (Cable et al. 2004).

  The reason for saving the goat's life should be discussed with the owner in advance. Is it a pet or a commercial animal? Salvaging an animal for later slaughter in societies where meat from sick animals is not consumed is justification for udder amputation and also for use of inexpensive surgery techniques. Salvaging the goat for continued breeding is hard to justify unless the mastitis was clearly the result of an injury and cannot be attributed to a

decreased genetic resistance. In herds participating in a Swedish mastitis control program, goats with milk cultures that were positive for *Staphylococcus aureus* are slaughtered because of the poor prognosis for microbiologic cure and the danger to people consuming unpasteurized goat milk products. Therefore, mastitis has become relatively rare in these herds (Danielsson et al. 1980). Owners become more careful and goats are selected for genetic resistance.

- **Anesthesia.** A variety of anesthetic regimens have been used successfully. The choice depends on the previous experience of the veterinarian and the drugs and facilities available. In the United States, gas anesthesia or a ketamine/xylazine combination is commonly selected. Intravenous barbiturates and lumbosacral spinal anesthesia are other possibilities. These methods are discussed in detail in Chapter 17. Antibiotic therapy (penicillin or ceftiofur) should be begun before surgery commences and intravenous fluids should be administered during surgery.

- **Surgical techniques** (Otte 1958; Kerr and Wallace 1978; Matthews 1999; Anderson et al. 2002; Cable et al. 2004). The animal should be fasted for twenty-four hours before surgery if possible. The goat is placed in lateral recumbency with the upper hind limb pulled caudally or in dorsal recumbency, depending on whether one or both glands are to be removed. A clamp attached to the teat simplifies manipulation of the udder during surgery. After skin preparation, an elliptical incision is made around the base of the teat or udder, leaving as much skin as possible to provide for closure. Blunt dissection is used to separate the gland from the skin and, if only half is to be removed, from the median suspensory ligament. The supramammary lymph node (caudal and dorsal to the gland) should also be removed. Major vessels that need to be ligated include first the external pudendal artery at the inguinal ring (double ligate), and then the external pudendal vein, the subcutaneous abdominal vein, and the perineal vein (Figure 14.10). Dead space is closed with subcutaneous sutures and drains are placed if deemed necessary. A potential blood donor and equipment for obtaining a blood transfusion should be located before the surgery is undertaken.

- **Other alternatives to udder amputation.** Amputation of the teat under tranquilization and local anesthesia has been used in goats to improve drainage of purulent or gangrenous infections of the udder. The base of the teat is clamped and the teat is amputated in its proximal one-third, distal to the large vessels. Hemostasis is achieved with cautery or ligation after removing the clamp (Sasshofer et al. 1987).

In selected cases, when surgery is not an option, the gangrenous gland can be infused once with 60 ml of 5% to 10% formalin (normally used for fixation of pathological specimens). The formalin kills organisms and binds toxins produced by
Figure 14.10. Initial skin incision and vessels to be ligated during udder amputation. e.p.a. = external pudendal (mammary) artery; e.p.v. = external pudendal vein; s.a.v. = subcutaneous abdominal vein; p.v. = perineal vein; s.l.n. = supramammary lymph node.

either the infectious agent or the necrosis of tissue. The gland thus treated does not return to production, but the doe's life may be preserved. In cattle, both 2% chlorhexidine and 5% povidone iodine have been used to cause cessation of lactation in chronically infected glands (Smith et al. 2005); a dose of 10 ml might be appropriate for goats.

Dry-off Procedures and Dry Period Therapy

Dairy goats are commonly allowed a two- to three-month nonlactating ("dry") period before the next parturition occurs. Provision of this rest period increases milk production in the next lactation. It also permits production of colostrum for protection of neonates; colostrum from goats with a fifty-six-day dry period had an IgG concentration of 42.4 mg/ml, as compared with 5.6 mg/ml in goats not given a dry period (Caja et al. 2006). It is possible to milk a goat daily for several years with reasonable milk yield if production of kids is not desired or the doe fails to conceive.

When does are milking heavily at the time of weaning or dry-off, it is helpful to restrict feed to a poor quality roughage and (if climate permits) to limit water for several days. During this time, animals should be kept clean and dry and observed for inordinate udder swelling. In commercial dairy herds, careful infusion of a dry period mastitis preparation is recommended. Udders that become severely distended should be milked out and retreated five to seven days later. It is very important to clearly mark the animal that has been dry treated, because it is likely to try to return to the milking group if it is put into a different pen, and antibiotic residues will follow.

In one survey, 76% of udder half infections caused by major pathogens (*Staph. aureus* or streptococci) and 55% of infections caused by coagulase-negative staphylococci persisted through the dry period to the next lactation (Lerondelle and Poutrel 1984). Infusions of an appropriate long-lasting dry cow preparation (one tube per half) at the time of drying off should increase the cure rate during the dry period while simultaneously preventing some new infections during this period. In one report, approximately two-thirds of infections were eliminated in goats receiving dry treatment (Plommet 1974). A study using a cattle cephapirin benzathine product found a 79% cure rate of infections, most of which were coagulase negative staphylococci (Fox et al. 1992). In a study from New Zealand, a dry treatment licensed for goats containing 300 mg procaine penicillin, 100 mg dihydrostreptomycin, and 100 mg of nafcillin resulted in a 92% cure rate, compared with 31% cure of untreated glands. *Staphylococcus aureus* did not respond as well as other organisms. At the same time, new infections were reduced

from 9% to 2% (McDougall and Anniss 2005), although most authors have not shown an effect on new infections. A 66% to 78% cure rate was found in another study using the same antibiotics (Poutrel et al.1997) with no antibiotic residues detected seven days after parturition. Cloxacillin has also been shown to be efficacious (Paape et al. 2001). There are anecdotal reports of severe systemic reactions in goats treated with erythromycin dry cow preparations, so this drug should probably be avoided.

It has been suggested that herds with more than 30% or 40% subclinical mastitis should treat all goats at dry-off, while herds with lower infection rates should treat selectively those animals that are infected (Paape et al. 2001). In herds free of mycoplasma infection, two or more monthly cell counts greater than 2 million/ml have been shown to be indicative of *S. aureus* infection with a sensitivity of 100% and a specificity of 74%, thus aiding in the selection of goats to be dry treated (Baudry et al. 1999). Teat dipping before and after infusion and partial insertion of the tube are recommended.

Prevention of Bacterial Mastitis

Management decisions that decrease the risk of injury to the udder or teat (such as selecting for improved udder attachment) or that control skin lesions on the teats (including contagious ecthyma, staphylococcal infections, or warts; see Chapter 2) should decrease the risk of mastitis. Genetic aspects of udder conformation also affect risk of mastitis via ease of machine milking (Barillet 2007). Attention to sanitation, proper milking procedures, teat dipping, and dry period antibiotic therapy are also beneficial. Less is known regarding the value of nutritional adjustments or vaccination programs in preventing mastitis in goats.

ENVIRONMENTAL CONSIDERATIONS. Dry, clean surroundings are especially important at freshening and at dry-off. When goats are housed and fed dry hay, the dry consistency of their fecal pellets combined with their tendency to bed themselves on wasted hay usually ensures acceptable conditions. Otherwise, slatted floors or elevated sleeping platforms may help to keep conditions sanitary. Teat end injuries predispose to mastitis and thus should be prevented as much as possible (Ameh and Tari 2000).

MILKING PROCEDURES. The method of udder preparation for milking is very important in determining the incidence of new cases of mastitis in goats, as it is in cows. For example, herds in which individual towels were used to wash and dry the udder had a decreased prevalence of intramammary infections compared with herds in which common towels were used (East et al. 1987). Hands and udders should be clean and dry. Disposable nitrile gloves are recommended. Goat udders are usually cleaner than cow udders. If washing

is required, only the teats should be washed. It is better not to wash at all than to leave the udder and teats wet. Sanitizer solution for washing teats should be delivered from a hose or spray bottle, rather than from an open bucket. Animals with mastitis or with skin lesions on the teats should be milked last, with appropriate sanitation of hands between affected animals. Careful attention to unit placement to prevent liner slip and teat end impacts (causing reverse flow of milk into the udder) is important to prevent introduction of bacteria, mycoplasma, and the CAE virus into the gland during milking.

Goats should be milked gently and in quiet surroundings to encourage oxytocin release and milk letdown. The physiology of these events has been reviewed elsewhere (Martinet and Richard 1974). The biological half-life of oxytocin has been calculated to be approximately twenty-two minutes in goats (Homeida and Cooke 1984). The premilking stimulation afforded by udder washing is not necessary for goats to milk out completely. Research, then, has demonstrated no effect of udder washing on milking time or milk yield (Ricordeau and Labussière 1970). This is because the goat holds nearly 80% of its milk in the cistern rather than in the alveoli and means that the machine can be attached immediately if the teats are clean (Ohnstad 2006). The satisfied goat often ruminates while being milked. Vigorous stripping, by hand or machine, should be avoided. Overmilking of late lactation does may contribute to the risk of mastitis (East et al. 1987). Restraining goats during milking by pulling on the teats has been proposed as one reason for a high incidence of gangrenous staphylococcal mastitis in Cyprus (Petris 1963). When machine milking, it is important to use a vacuum cut-off valve before removing the teat cups, to avoid teat end impacts (Bergonier et al. 2003).

Milking should occur at regular times, but equal twelve-hour intervals are not necessary. The goat has a relatively large gland cistern for holding milk. One study found no difference in yield with milk intervals of 16:8 hours and 12:12 hours (Henderson et al. 1983). Yield is increased by milking three times a day. French workers have also investigated the effects of omitting the Sunday evening milking and have found a reduced milk yield of 4.5% if this practice is begun one month into the lactation, and only 1.2% if begun after five months. An increase in mastitis has not been noted, and on some farms the savings in labor costs more than offset the decrease in yield (Le Du 1987).

Preliminary research in France suggests that the speed of milking is under genetic control, with the goats homozygous for the recessive gene "hd" having the most rapid milk flow (Bouillon 1990). How this gene might affect the incidence of mastitis remains to be investigated.

MILKING PARLOR DESIGN. A raised platform is the most basic equipment for milking goats, and most owners of small herds use individual milking stands. When herd size justifies construction of a parlor, several different designs are satisfactory and have been described (Le Du 1987; Mottram et al. 1991). These include a side-by-side parlor with milking from behind, herringbone parlor with milking from the side, inverted herringbone with milking from the front, and tunnel parlor with milking from the side. To additionally increase throughput, the goats, stalls, and milking units can be mounted on a rotating platform.

MILKING MACHINE FUNCTION. When a commercial goat dairy installs or modifies a machine milking system, attention should be given to choosing an efficient system that milks goats under low vacuum with minimal vacuum fluctuation. Low-line systems, in which the milk line is just below the edge of the pit or elevated milking platform, are generally preferred. Vacuum levels of 11.5 to 12 inches Hg are adequate for low-line systems, but higher vacuum is needed for high-line systems. Machines available for milking goats in France are operated at comparable vacuum levels (gauge pressures) of 30 to 38 cm Hg (Darracq 1974). Yet another vacuum unit in use in the literature is the Pascal, which equals 10 dyne/cm^2 or 7.5×10^{-3} mm Hg; a kPa equals 0.75 cm Hg.

The vacuum pump should have a capacity of 30 cubic feet per minute (CFM) (ASME standard) for the pipeline system, 1.5 CFM per unit, and 3 to 4 CFM reserve air flow. Bucket milker systems require 10 CFM reserve and 1 CFM per unit (East and Birnie 1983; Spencer 1984).

Pulsation rates of 70 to 100 per minute and pulsation ratios of 50:50 to 70:30 (milk: rest) have been recommended for goats (Le Du 1987). In a study that attempted to optimize milking rate and somatic cell counts, a pulsation ratio of 60:40, a pulsation rate of 90 per minute, and a vacuum level of 45 to 52 kPa were judged to be optimal (Lu et al. 1991). Another recommendation is for a vacuum of 37 to 38 kPa, a pulsation rate of 90 to 120 per minute, and a 50:50 pulsation ratio (Ohnstad 2006).

Inflations should be replaced before they become worn and cracked. Some authors propose changing inflations on the same schedule used for cows (every 1,000 to 1,500 milkings for molded liners) (East and Birnie 1983). In Europe, allowances are apparently made for the very short milking time (one to two minutes) per goat. One producers' guide from France recommends changing inflations twice a year (Cardoen and Delahaye 1977). Because liners tend to deteriorate with time, washing, and use, they should not be used for longer than sixty days.

TEAT DIPS. Although few studies have been conducted in goats, it is generally accepted that teat dipping or

spraying with a properly mixed and uncontaminated solution is of economical benefit via prevention of bacterial mastitis (Plommet 1974; Bergonier et al. 2003; Contreras et al. 2007). One French study documented a 62% decrease in new infections in early lactation and a 41% decrease over the entire lactation when the right teat was dipped but the left teat was an undipped control (Baudry et al. 2000). Some studies have found a beneficial effect on somatic cell counts (Paape et al. 2001) while others have not (Poutrel et al. 1997). Products with evidence of efficacy for preventing mastitis in dairy cows (e.g., 0.5% iodine or 0.5% chlorhexidine) are commonly used. Nisin, a bacteriocin protein synthesized by the bacterium *Lactococcus lactis* subspecies *lactis* and long used as a food grade preservative in dairy products, has also been shown to be effective in goats (Paape et al. 2001). Recently concerns have been raised that use of teat dips increases selection for bacteria that are resistant to disinfectants, which might impact human health (Contreras et al. 2007).

In small herds, purchasing large quantities of teat dip at one time should be discouraged because settling of the product may occur and cause teat irritation. Even a newly purchased supply may cause problems because of past freezing or prolonged storage. When concentrates are used, they should be mixed with clean water; some pathogens such as *Pseudomonas* or even the common saprophyte *Serratia* can survive and even multiply in the teat dip (Van Damme 1982). Owners should also empty and sanitize the dipper after every milking. Hand pumps or aerosol sprays (e.g., chlorhexidine; Fightbac-SmithKline Animal Health Products, West Chester, Pennsylvania) help to avoid contamination of the teat dip, but the milker must take the time to ensure that the teat ends are adequately covered. Teat dipping for one week after dry off or before kidding probably is of no value.

DRY PERIOD THERAPY. Infusion of an antibiotic into the udder at time of dry-off, as discussed previously, helps to prevent new cases of mastitis in addition to curing some pre-existing infections.

VACCINATION. Staphylococcal toxoid vaccinations have been used in herds experiencing clinical mastitis caused by *Staph. aureus* (Petris 1963; Lerondelle and Poutrel 1984). An adjuvanted cell-toxoid vaccine (formolized cells and toxoid adjuvanted with aluminum hydroxide gel) has been used in studies using goats as a model for cows (Derbyshire 1960). These vaccines do not lower the prevalence of infection but do decrease severity. In contrast, a polyvalent somatic antigen vaccine did not prevent mastitis or decrease severity of clinical signs (Lepper 1967). Field experiments with sheep vaccinated twice with oil adjuvanted alpha and beta staphylococcal toxoids demonstrated a reduced rate of clinical mastitis when compared with unvacci-

nated control sheep (Plommet and Bézard 1974). Recent studies on vaccination of goats for this organism or its toxins are lacking. An attempt to increase resistance by gene therapy, causing expression of lysostaphin in the goat udder, failed because of adverse immune reactions to the molecule (Fan et al. 2004).

Although *E. coli* mastitis is relatively rare in goats and vaccination as a substitute for hygiene is not justified, goats have been proposed as a model for coliform vaccination research in cattle. A J5 vaccine moderated the clinical signs and decreased shedding in the milk after experimental challenge (Aslam et al. 1995).

NUTRITION. Although it seems reasonable that nutritional deficiencies should increase an animal's susceptibility to mastitis and other infectious diseases, few studies in goats are available. However, it has been shown that selenium deficiency is associated with reduced neutrophil function in goats (Aziz et al 1984; Aziz and Klesius 1986). Also, somatic cell count (by Fossomatic) was decreased and milk production increased in Finngoats with a high glutathione peroxidase activity when compared with goats with decreased selenium status judged by this enzyme's activity (Atroshi et al. 1985). This study did not include cultures of milk samples. In a selenium-deficient region in Spain, an injection of slow release barium selenate before mating to half of the goats in four herds was associated with a significant decrease in somatic cell counts and the incidence of clinical mastitis in the subsequent lactation of the supplemented goats. There were ten clinically affected goats out of 260 treated animals, compared with forty clinical mastitis cases in the 260 controls (Sánchez et al. 2007). Improved bactericidal activity of neutrophils in selenium-supplemented cows is believed to moderate the severity of *E. coli* mastitis in that species (Erskine et al. 1989). Vitamin E status is probably important for resistance to mastitis as well.

NONMASTITIC ALTERATIONS IN GOAT MILK

The presence of blood or unpleasant flavors in goat milk decreases the desirability of milk and cheese for human consumption. Decreased butterfat is another common but serious problem for commercial producers of fluid milk or cheese.

Bloody Milk

Sometimes goat milk is slightly pink or a red sediment collects on the bottom of the milk container in the refrigerator because of ruptured blood vessels in the udder. The skin over the udder is not cold or blue, and the goat is not systemically ill (in the absence of other disease conditions). The need to distinguish bloody milk from gangrenous mastitis often prompts performance of a milk culture. One author advises

telling the owner to call for results in five days, because by then the blood has usually disappeared from the milk (Baxendell 1984a). The irrelevancy of a coagulase-negative staph species to the condition should be discussed in advance if the owner is to obtain maximum assurance from the culture test results.

If the goat has kidded recently, the possibility of hypocalcemia could be investigated. Some veterinarians administer vitamin K or other blood coagulant therapy. The results have not been compared with the self-cure rate. The environment should be examined for sources of trauma to the udder, including high door sills and rough milkers, be they hands, machines, or butting kids.

Off-flavored Milk

Off flavors or milk taint problems must be considered in relationship to the intended use for the goat milk. In Scandinavia, the aim is to produce certain cheeses with a characteristic "goaty" flavor. To achieve this flavor, producers may feed more dry hay or store the milk for as long as forty-two hours before processing into cheese. They also can use genetic selection, as the hereditability coefficient for goat flavor in Norwegian goats has been calculated to be 0.25 (Trodahl et al. 1981). In America or Australia, where a relatively larger proportion of the milk is consumed in the fluid form, goaty flavors are only tolerated by owners who have become so accustomed to the taste as not to notice it. Otherwise, good goat milk should taste like good cow milk. Some of the possible causes for undesirable flavors in milk from the entire herd or from individual goats are outlined in the box titled "Causes of Abnormal Flavors in Goat Milk."

Causes of Abnormal Flavors in Goat Milk

Herd Problem

a) *Hygiene:* Buckets should be chemically sanitized or scalded to avoid introduction of psychrophils that multiply in refrigerated milk. Stainless steel, glass, and enamel are preferred over other materials because of ease of cleaning. Clean, well-ventilated barns avoid inhalation of ammonia and other malodorous agents.

b) *Milk Handling Procedures:* Milk should be rapidly cooled and stored in covered containers in the refrigerator. Exposure of milk or cheese to copper or iron metal, sunlight, or fluorescent light results in oxidized flavors that are variously described as "cardboardy," "metallic," or "oily." Copper tubing should be avoided in the milkhouse, especially if water pH is less than 7.0. Airborne taints may be absorbed if the milk con-

tainer is not properly sealed. Violent agitation of milk (as from air leaks in pipeline milkers) may rupture the lipid membrane around fat globules. Mixing warm raw milk with cold or pasteurized milk allows active lipase to attack damaged fat globules, which also leads to lipolysis and rancid flavors.

c) *Nutritional Considerations:*
1) Cobalt deficiency: Expect a response within a few days after providing a mineral block containing cobalt or after injecting vitamin B_{12}.
2) Vitamin B_{12} deficiency secondary to helminthiasis has been proposed as a frequent cause of tainted milk (Mews 1987).
3) Vitamin E deficiency: Without vitamin E's antioxidant effects (e.g., winter feeding), oxidized flavors may develop. Based on recommendations for cattle of daily supplementation with 1,000 to 7,000 IU of vitamin E, feeding an additional 400 IU vitamin E/day/goat for one to two weeks could be tried (Ishler and Roberts 2002).
4) Unsaturated fatty acids in milk are more susceptible to oxidation and may be limited by decreasing fat (full-fat soybeans, whole cottonseed, added fats) in the diet and by increasing the forage to concentrate ratio.
5) Inadequate dietary protein may lead to weakened fat globule membranes and thus to rancidity (Ishler and Roberts 2002).
6) Feed or weed flavors: Plants incriminated include silage, cabbage, turnip, fresh alfalfa, ragweed, goldenrod, honeysuckle, buttercups, blackberry, and grape leaves (Lovegrove 1990).
7) Garlic preparations used for possible anthelmintic effect.
8) Drugs such as anthelmintics that are secreted into milk.

d) *Buck Odor:* Housing the buck with the does usually has not caused flavor problems unless the milk is not properly handled.

Individual Goat Problem

a) *Genetic Flavor:* The reverse of the Scandinavian approach suggests selecting for does with a good flavor to their milk.

b) *Spontaneous Lipolysis:* Abnormal flavor develops under refrigeration.

c) *Ketosis.*

d) *Mastitis.*

e) *Feed Flavors:* Strong-flavored feeds should be fed after milking, not within the four hours preceding milking.

Table 14.2. Zoonotic diseases potentially transmitted by raw goat milk.

Causative agent secreted in milk	Fecal contaminants in milk
Brucellosis	Campylobacteriosis
Caseous lymphadenitis	Cryptosporidiosis
Cryptococcosis	*Escherichia coli*
Leptospirosis	Listeriosis
Listeriosis	Salmonellosis
Louping-ill	Yersiniosis
Melioidosis	
Q Fever	
Staphylococcal food poisoning	
Toxoplasmosis	
Tuberculosis	

Evaluating Off-flavored Milk

While investigating a milk flavor problem, the owner needs to determine if the flavor is present at milking or if it develops with storage. Is the milk tainted from one half (suggestive of mastitis) or from both halves of one goat? Is the milk from certain pairs of goats incompatible, such that mixing produces the problem? Are many goats involved? If the owner has not yet evaluated the flavor from each half of each goat separately, immediately after milking, the veterinarian should at least suggest pasteurization to avoid any danger of the zoonotic diseases listed in Table 14.2. If a single goat is involved and if mastitis can be ruled out, the goat can then be kept in a stall and fed only weed-free hay for several days. If the abnormal taste disappears, it was probably caused by feed. The goat is then introduced again to one feed at a time and then one pasture at a time until the source of the offending feed or weed is identified (Baxendell 1984c). See also an investigation scheme by Matthews (1999).

Milk Lipase and its Effects

Goat milk contains an intrinsic milk lipase (e.g., lipoprotein lipase, LPL) that is capable of causing enzymatic hydrolysis of milk fat and an increase in free fatty acid content of the milk. Approximately 46% of the lipoprotein lipase is to be found in the cream portion of goat milk. The enzyme is responsible for both "spontaneous lipolysis" (initiated by cooling fresh milk) and "induced lipolysis" (initiated by mechanical or thermal treatment of milk). The LPL activity is correlated with the degree of spontaneous lipolysis that occurs in the milk sample, with an r-value ranging from 0.65 to 0.80 (Chilliard et al. 1984).

There are great differences between goats in LPL activities and in milk lipolysis. In one study (Chilliard et al. 1984), the most susceptible sample released twenty-six times more free fatty acids in twenty-four hours than did the least active sample. In France, the level of lipolysis is approximately four times greater in milk collected during the summer months (midlactation) than in the winter (LeMens 1987). Evening goat milk has relatively more LPL than morning milk. Other activators and inhibitors that might be involved in the process have not yet been identified. Dairy processing plants can determine acid degree values (ADV) as an objective determination of rancidity. At least for cow milk, a soapy-bitter rancid flavor is expected if the ADV is more than 1.0 (Ishler and Roberts 2002).

When an individual goat's milk is subject to spontaneous lipolysis, the milk initially tastes normal but deteriorates rapidly with storage in the refrigerator. The problem can be controlled by heating the milk to 135°F (57°C) immediately after collection to partially inactivate the enzyme. This process is called heat treatment to avoid upsetting owners who have a strong aversion to anything suggestive of pasteurization. Unless the milk will be made into an aged cheese (more than sixty days), pasteurization is still advised. Pasteurization, and even boiling, do not completely inactivate lipase in goat milk (Jandal 1995).

Low Butterfat

The normal butterfat concentration of most European dairy goat breeds under temperate conditions is approximately 3.8%, whereas Nubians and Pygmy goats traditionally give a richer milk (Jenness 1980; Haenlein and Caccese 1984). Goat milk fat is higher in medium chain triglycerides than that of cow milk (Sanz Sampelayo et al. 2007). The same authors review the effects of diet on the fatty acid profile of goat milk. Genetic selection for high volume secretion of milk without consideration of solids composition gradually causes decreased butterfat concentrations. As butterfat levels decrease, there is a decrease in cheese yield. Also, the milk may no longer achieve legal standards for marketing.

Dietary Roughage versus Concentrates and Dietary Fat

One of the most common causes of low butterfat is a ratio of dietary concentrates to roughages of more than 2:1. This typically occurs in herds striving for increased milk production. A concentrate mixture that contains more than 35% heat-treated starchy grains such as corn, milo, and barley has also been incriminated (Adams 1986). Normal milk fat production requires maintaining cellulose-digesting, acetate-producing microbes in the rumen. Rapid digestion of concentrates and decreased saliva flow result in a decrease in rumen pH to a level unfavorable for the bacteria producing acetate. In general, dietary concen-

trates do not have a detrimental effect on butterfat if limited to 50% or less of the total diet (Morand-Fehr et al. 2000).

How the concentrates are distributed to the goat also affects rumen acidosis and butterfat production. Thus, roughage should be fed before grain in the morning. Dividing the concentrate portion of the diet into more than two meals per day is also helpful. Long alfalfa hay supports higher butterfat concentration than a chopped dehydrated product (Morand-Fehr et al. 1999). Additional discussion is provided in Chapter 19.

Excessive dietary fat can decrease butterfat production by coating rumen fiber and interfering with its digestion. However, rumen protected fats at up to 8% of the diet increase butterfat without detrimental effects on milk protein production (Morand-Fehr et al. 2000). Contrary to what occurs in cows, supplementation of the goat's diet with vegetable oils rich in polyunsaturated fatty acids does not decrease butterfat production (Sanz Sampelayo et al. 2007).

Use of Buffers

Roughage is more effective than sodium bicarbonate in elevating ruminal pH and acetate molar fraction (Hadjipanayiotou 1982). However, supplementing a low roughage diet with NaHCO$_3$ (at 4% of the concentrates) significantly increases milk fat production. The improvement is noticeable two to three weeks after incorporating the buffer into the diet (Hadjipanayiotou 1988). Supplementing the low fiber diet with bicarbonate at 1% to 1.5% of total dry matter intake tends to increase butterfat and adding probiotics may also be beneficial (Morand-Fehr et al. 2000).

Environmental Temperature

High environmental temperatures contribute to low butterfat through their effect on roughage consumption (Devendra 1982). The heat-stressed goat eats less roughage or preferentially selects the more digestible portions of the roughage available. This decreases the heat of digestion liberated in the rumen but also decreases acetate production, and thereby butterfat synthesis. Providing good ventilation, plentiful water, and multiple smaller meals helps to alleviate the effects of environmental temperature.

Other Techniques for Increasing Butterfat

Feeding larger quantities of dried brewer's grains has resulted in increased butterfat production (Sauvant et al. 1987). More complete milk out also increases the butterfat percentage (Morand-Fehr et al. 1999).

When all else has failed, or often long before appropriate changes in management have been made, a producer may purchase several Nubian goats to raise the herd butterfat concentration to exceed the minimum legal limit in the state or country.

RAW MILK AND OTHER SAFETY ISSUES

Few topics elicit such heated discussion among goat owners as the raw versus pasteurized milk controversy. People who have drunk raw milk all their lives or whose babies returned to good health after being switched from cow to goat milk find it hard to believe that such a "natural" food should be anything but healthful. People who have for centuries prepared certain types of cheeses from raw milk complain that the result is not the same if pasteurized milk is used. Also, pasteurization destroys the stability and keeping qualities of milk, which is critical where refrigeration is not available.

Zoonotic Diseases

Many industrialized countries have regulations requiring pasteurization of milk to be sold unless very stringent sanitary requirements are adhered to. These laws were generally formulated in an attempt to prevent human infection with brucellosis or tuberculosis. In regions where those two diseases have been eradicated, the laws seem, to the layman, quite antiquated. In the meantime, however, an ever-growing number of additional infectious agents have been isolated from goat milk (Pritchard 1987; Klinger and Rosenthal 1997). These are listed in Table 14.2.

Supporting references for acquiring these conditions from goat milk products include: brucellosis (Stiles 1950; Renoux 1957; Young and Suvannoparrat 1975; Wallach et al. 1994; Vogt and Hasler 1999; Wyatt 2005; Gupta et al. 2006), caseous lymphadenitis (Goldberger et al. 1981; Schreuder et al. 1990), listeriosis (Løken et al. 1982; Tham 1988; Azadian et al. 1989; Eilertz et al. 1993; Abou Eleinin et al. 2000), louping-ill (Reid et al. 1984) and other tick-borne encephalitis diseases (Heinz and Kunz 2004), melioidosis (Olds and Lewis 1954), Q fever (Caminopetros 1948a, 1948b; Ruppaner et al. 1978; Fishbein and Raoult 1992; Hatchette et al. 2001; Berri et al. 2005), staphylococcal food poisoning (Geringer 1983; Gross et al. 1988; Hahn et al. 1992), *Streptococcus zooepidemicus* (Kuusi et al. 2006), toxoplasmosis (Riemann et al. 1975; Sacks et al. 1982; Chiari and Neves 1985; Skinner et al. 1990), campylobacteriosis (Jackson 1985; Jelley 1985; Harris et al. 1987), *E. coli* (McIntyre et al. 2002), salmonellosis (Jensen and Hughes 1980; Galbraith et al. 1982; Desenclos 1996), and yersiniosis (Hughes and Jensen 1981; Walker and Gilmour 1986).

Many of these diseases are not serious in immunecompetent, healthy people. Chronically ill babies, old people, pregnant women, people receiving cancer therapy, and those infected with the AIDS (acquired immune deficiency syndrome) virus are less able to

withstand infection with these agents. Goat owners wishing to avoid legal or moral responsibility for illness in their milk-drinking customers should continue to pasteurize or at the very least explain the need for and method of pasteurization of the milk they sell. The American Veterinary Medical Association has taken a stand against the use of raw milk (Summers and New 1985).

In the UK, 47% of one hundred samples of raw goat milk offered for sale did not meet the regulatory dairy product standards (Little and de Louvois 1999). When raw milk is to be used for cheese production, standard coliform screening detects lapses in proper milk hygiene and thus an increased likelihood of potentially dangerous fecal contaminants.

Home Pasteurization

Several types of commercial home pasteurizers are available to simplify making goat milk safe for human consumption. They are also very convenient for implementing programs to control milk-borne diseases of goats such as CAE and mycoplasmosis. A variety of time and temperature combinations are suitable for controlling zoonotic agents. These include heating the milk to 145°F (63°C) for thirty minutes or 161°F (72°C) for fifteen seconds. For home pasteurization, longer times are often recommended to ensure that all of the milk reaches the desired temperature (e.g., 150°F to 155°F [65.5°C to 68.3°C] for thirty minutes, 165°F to 170°F [73.8°C to 76.6°C] for thirty seconds) (Vasavada 1986). The pasteurized milk must then be cooled rapidly and transferred carefully to a sterile container for storage in the refrigerator. Post-pasteurization contamination of milk is a very real risk, both in the home and in the large scale dairy plant.

When a pasteurizer is not available, the milk can be treated in a similar way in a double boiler or in glass jars placed in a heated water bath. A cooking thermometer and frequent stirring and heat adjustment are necessary. Alternatively, once the milk has been heated to the desired temperature, it can be poured into a thermos that was preheated with boiling water. The milk must be checked at the end of the holding period to verify that it remained at or above the target temperature. Finally, although testing with *Listeria* and *Coxiella* has not been performed, the home microwave oven has been shown capable of greatly reducing bacterial counts and increasing shelf life of goat milk. Heating to 149°F (65°C) for thirty minutes is recommended, using a temperature probe with "temperature hold" feature (Thompson and Thompson 1990).

Alkaline phosphatase activity is reported to be low in goat milk relative to cow milk, and the activity in sheep milk is ten to twenty times higher than in goat milk (Raynal-Ljutovac et al. 2007). Bovine standards for phosphatase activity as evidence of proper pasteurization may not be applicable to goat milk (Klinger and Rosenthal 1997; Vamvakaki et al. 2006) and psychrotrophic bacteria multiplying in the refrigerator may produce alkaline phosphatase resistant to destruction by proper pasteurization (Raynal-Ljutovac et al. 2007).

Toxins Excreted in Milk

The possible presence of toxins of feed or iatrogenic origin is not limited to raw milk or necessarily affected by pasteurization. However, home produced goat milk is more likely than commercially marketed milk to cause human illness because the protective effects of toxin dilution by admixture with normal milk are often lost. It should be noted that pasteurization does not destroy preformed staphylococcal enterotoxins, which may be present in the milk of goats with either *Staphylococcus aureus* or coagulase negative staphyloccal infections (Valle et al. 1990). The potential for contamination of milk by natural plant toxins has been reviewed (Panter and James 1990). Numerous other chemicals, including pesticides, have the potential to be excreted in milk and are unlikely to be affected by pasteurization. Research performed with cattle should be largely applicable to goat milk. Neonates, because of incompletely developed detoxification pathways, may be especially susceptible.

Pyrrolizidine Alkaloids

Plants of the genera *Senecio*, *Crotalaria*, *Heliotropium*, *Echium*, *Amsinckia*, *Symphytum*, *Cynoglossum*, and *Festuca* contain pyrrolizidine alkaloids that cause hepatotoxic and veno-occlusive disease and may be carcinogenic. These toxins may be excreted in goat milk (Dickinson and King 1978; Deinzer et al. 1982; Goeger et al. 1982). Of special concern is *Symphytum* (comfrey), because some goat owners intentionally feed this plant to their livestock.

Tremetol

Ageratina altissima (white snakeroot, synonym *Eupatorium rugosum*) and *Haplopappus* (*Aplopappus*) sp. (rayless goldenrod, synonym *Isocoma wrightii* [McGinty 1987]) both contain tremetol, a higher alcohol that is excreted in milk and not destroyed by pasteurization. A syndrome called milk sickness (weakness, prostration, nausea) occurs in people ingesting milk from animals grazing the plants. Goat kids may also develop muscular tremors and recumbency from consuming the toxin in milk.

Other Plant Toxins and Mycotoxins

There is a single report of skeletal abnormalities and red cell aplasia in a child in California whose mother drank goat milk from goats grazing lupine (*Lupinus*

latifolius) (Ortega and Lazerson 1987). Puppies from a dog fed the same goat milk were also malformed, as were several aborted goat kids. Quinolizidine alkaloids such as anagyrine were thought to be responsible for this outbreak, which resembled crooked calf disease. Anagyrine appeared in the milk of a goat experimentally fed lupine seeds (Kilgore et al. 1981).

Milk collected from cows and ewes consuming *Astragalus lentiginosus* contains a toxin (probably swainsonine) that causes foamy cytoplasmic vacuolation when the milk is fed to the animals (James and Hartley 1977). Swainsonine inhibits α-mannosidase, causing a lysosomal storage disease.

At least of theoretic concern is the occurrence of carcinogenic, toxic, and mutagenic compounds (ptaquiloside) in the milk of cows grazing bracken fern (*Pteridium aquilinum*) (Hopkins 1990). Also of note is the goitrogenic effect of milk from goats fed goitrogenic plants (White and Cheeke 1983). Thiocyanate has been shown to transfer from dams administered potassium cyanide (KCN) daily to suckling kids via the milk (Soto-Blanco and Górniak 2004).

Aflatoxins, and especially aflatoxin M1, are excreted in the milk of dairy cows consuming moldy feeds (Osweiler et al. 1985). The potential for contamination of goat milk should not be ignored, because this has been demonstrated experimentally (Smith et al. 1994). Aflatoxin-producing fungi can also contaminate cheese.

Antibiotics and Anthelmintics

Antibiotic contamination from intramammary or systemic medication of the goat or from consumption of "medicated" feeds may lead to allergic reactions in sensitive people, interference with cultured products, or regulatory action against the producer. As noted before, the commonly used *B. stearothermophilus* assay may be inappropriate for goat milk. Because withdrawal periods have rarely been established for goat milk, especially for sick animals, veterinarians should advise exaggerated withdrawals (longer than for dairy cattle) to allow for different rates of metabolism or excretion. If goats kid less than two months after receiving a dry period intramammary treatment, a withdrawal of fourteen days has been recommended (Bergonier et al. 2003). Toxic parasiticides that have not been approved for dairy cows should not be used for dairy goats either.

Thiabendazole has antifungal properties that inhibit *Penicillium* while enhancing several undesirable mold species. Thus, thiabendazole at 200 mg/kg clearly interfered with proper curing of goat cheese while 50 or 100 mg/kg sometimes did so, especially in milk from animals with low production (Toussaint et al. 1976). By contrast, pyrantel (25 mg/kg), morantel

(10 mg/kg), or double these doses did not perturb the fabrication, appearance, or taste of the cheese. In another study, a taste panel detected a decrease in quality of a soft cheese made from milk of goats treated with netobimin (20 mg/kg twelve hours before) or albendazole (8 mg/kg twenty-four hours before). Morantel tartrate (10 mg/kg), pyrantel tartrate (20 mg/kg), oxfendazole (5 mg/kg), and diamfenetide (240 mg/kg) had no effect, while the deleterious effect of tetramisole (12 mg/kg twenty-four hours before) was judged to be not significant (Cabaret et al. 1987). Even if the chemical cannot be tasted in the finished product and the consumer is not allergic, the sale of milk or cheese containing these compounds is illegal.

Wasting Diseases

The loss of weight without other obvious signs of disease, also known as wasting or ill thrift, is a common clinical presentation in goats (Figure 15.1). While any given goat may present with weight loss for individual reasons, the abnormally thin goat is often a sentinel of serious herd problems of infectious, parasitic, or management origin. If thin goats are noticed during a farm visit, the veterinarian should ask to examine them even if they were not the reason for the call.

Ill thrift in mature animals is taken to mean that a loss of weight in individual goats has occurred and the goat has become abnormally thin. In growing animals it can also mean that the animal has lost weight, or alternately, that the rate of weight gain is less than expected from past experience, known breed standards, or in comparison with other animals on the premises. Some conditions discussed in this chapter may cause either actual weight loss or a failure to gain weight in growing animals.

CLINICAL EXAMINATION FOR DIAGNOSIS OF WEIGHT LOSS

Clinical examination of the goat is covered in detail in Chapter 1. Aspects relevant to the problem of ill thrift are briefly reviewed here.

History Taking

A number of the causes of weight loss are infectious diseases with chronic, subclinical, or carrier forms, notably caprine arthritis encephalitis, caseous lymphadenitis, and paratuberculosis. Therefore, it is important to establish how long the herd or flock has been in existence, whether or not the owner knows the origi-nal sources of animals in the herd, the disease status of those herds of origin, and whether any pre-purchase testing for these or other diseases was performed on animals brought into the herd.

Determine if and when there have been any previous cases of weight loss. If similar cases occurred in previous years, it suggests an endemic condition. Any patterns of occurrence within a certain age group or with regard to season, housing, pasturing, feeding, or other management conditions should be evaluated. Questions regarding current cases should include information about the possibility of recent stressful situations such as parturition, purchase and introduction into the herd, transport and attendance at sales or shows, or episodes of acute disease, since such stresses can trigger latent paratuberculosis or expose the animal to new infections. Evaluation of parasite control programs is important. Determine that control efforts are directed at all important types of internal and external parasites. Establish that the anthelmintics employed are appropriate and effective and determine how available pastures are used for grazing, including information about rotation and stocking rates.

The history related to feeding may be critical in many cases. Solicit information on the basic ration fed to the group or groups showing weight loss and any recent changes in feedstuffs, feeding methods, feeder space, feeder design, or number of animals fed per group. Be sure that feeding programs are appropriate for the level and type of production being called for in each group. Nutrient requirements for different levels and types of production are given in Chapter 19.

Figure 15.1. Wasting goats such as this one, with no other localizing signs, present a diagnostic challenge for the veterinary practitioner. This particular doe was ultimately diagnosed with paratuberculosis. (Courtesy Dr. Daan Dercksen.)

Physical Examination

All animals in contact with the thin animal should be examined at least from a distance to detect any clinical signs, such as coughing or diarrhea, which might represent conditions that could manifest in a chronic form as weight loss. An assessment of body condition in herd mates by digital palpation of the back, ribs, and sternum is essential to establish the body condition perceived as normal by the owner and to determine the prevalence of thin goats in the group. This is particularly important in Angora goats, in which the fleece may hide body condition. For veterinarians more familiar with dairy breeds, the normal Angora goat feels thin because these animals are more slightly built by nature.

On direct examination, weakness, dullness, lack of appetite, and a rough hair coat are all nonspecific signs associated with ill thrift that may accompany weight loss. Careful physical examination may reveal additional abnormalities undetected by the owner that can help in diagnosis. Some specific points to consider are as follows.

Examine the skin for lice, keds, or fleas by carefully parting the hair on the face, body, and limbs and look in the ears and under the tail for ticks.

A thorough oral examination may reveal brachygnathism, tooth loss, gum or alveolar abscesses, painful sores, or other abnormalities that might interfere with normal prehension, mastication, or swallowing. Evaluate the gums and other mucous membranes for anemia or icterus suggestive of chronic helminthiasis or liver

fluke infestation. Check for nasal discharges that could indicate lung disease or nasal adenocarcinomas.

Routine palpation of all superficial lymph nodes is essential because several causes of weight loss may cause lymph node enlargement. These include caseous lymphadenitis, melioidosis, tuberculosis, trypanosomosis, and lymphosarcoma. In thin goats, however, be aware that lymph nodes may be more readily palpable, giving a false impression of enlargement. In this case, asymmetrically sized nodes are of greater significance. Careful auscultation of the lungs may reveal abnormalities consistent with chronic pneumonia. Displacement of the heart by a mediastinal mass may alter normal heart sounds. Because congenital heart disease may occasionally occur and lead to ill thrift, cardiac murmurs should be noted when present.

Establish the presence of normal rumination and gut motility. Assess the animal for ascites or rumen impaction by ballotment or observation of the abdominal contour.

Foot and joint problems should not be overlooked as a cause of inefficient grazing that can result in weight loss. Check the interdigital space for foot scald and pare out the feet to assess for foot rot. Palpate all joints carefully. Forced exercise may help identify signs of limb problems, chronic pneumonia, or anemia.

Environmental Examination

The level of general sanitation is important in confinement operations. Manure buildup contributes to the spread of coccidiosis, paratuberculosis, and chronic mastitis. Overcrowding can facilitate transmission of lice and pneumonia and predispose to herd outbreaks of enteric diseases, some of which can assume chronic forms. Poorly drained paddocks and barns can contribute to foot problems and coccidiosis.

All components of the ration should be inspected for spoilage, molds, and palatability. Look for fouled or frozen water supplies, which can reduce water and feed intake. Chronic weight loss can be related to the way animals are fed. If young animals can climb or defecate in feeders, then fecal contamination promotes the spread of coccidiosis. Keyhole-type feeders common in goat dairies may facilitate the rupture of lymph node abscesses on the head and neck during feeding, causing contamination of feed and spread of caseous lymphadenitis. Inadequate feeder space in either keyhole-type or trough-type feeding systems may deprive individual animals, low in the social pecking order, of adequate feed intake.

In range systems the stocking rate; availability and quality of forage, water, and supplemental feeds; and current weather conditions must be considered when thin animals are observed. Angora goats have specialized needs for supplemental protein and energy at different times in their fiber production and reproduc-

tive cycles and these requirements can be heightened by harsh weather.

Laboratory Diagnosis and Necropsy

Despite thorough clinical examination and knowledge of the likely causes, the definitive diagnosis of chronic weight loss may remain elusive. Hematology and clinical chemistry are often unrewarding, merely confirming the presence of undifferentiated chronic disease. Serology, however, can be helpful in the diagnosis of some infectious causes of weight loss, especially CAE and paratuberculosis. Fecal examination can assist in the diagnosis of various endoparasitisms.

When multiple animals are affected in commercial herds or flocks, sacrifice of an individual animal for post mortem examination is justifiable on economic grounds. The animal should be checked thoroughly for evidence of gastrointestinal, pulmonary, and hepatic parasites and for internal abscesses. The degree of rumen fill and the general body condition should be noted. Emaciated goats with obvious loss of muscle mass and perirenal fat, paradoxically, may still have noticeable fat deposits in the mesentery. This should not be interpreted as evidence of good body condition because goats preferentially store whatever fat they have intra-abdominally rather than subcutaneously.

For field necropsy, tissues submitted for histopathological examination in addition to any gross lesions should include kidney, carpal synovial tissue, and ileocecal lymph node and valve for diagnosis of amyloidosis, CAEV infection, and paratuberculosis, respectively, because these conditions may not be evident from gross findings.

CAUSES OF WASTING DISEASE

In this section, likely causes of weight loss in goats are given by etiologic category. The main intent is to provide a list for differential diagnosis, including only that information that may help to determine its relevance to the case at hand. Additional information about the diagnosis, treatment, and prevention of each disease is provided elsewhere in this volume along with references. In general, nutritional deficiencies, parasitisms, and dental disease are the conditions most amenable to treatment.

Nutrition-related Causes

Nutrition-related causes of chronic weight loss fit in either of two categories: primary cases resulting from the unavailability of appropriate feed or specific nutrients, or secondary cases caused by the inability of animals to obtain or use feed when available.

Primary Nutritional Problems

In extensive systems, feed availability can be curtailed by sustained, severe weather conditions such as drought or heavy snow cover, and also by overgrazing, overstocking, or failure to provide supplemental feed when nutrition requirements are not being met. Weight loss, emaciation, or even outright starvation may occur under these circumstances. In confinement systems, inadequate feeder space can lead to weight loss. This should become apparent if animals are observed during feeding. In any management system, specific nutritional deficiencies may be caused by inappropriate feedstuffs, unexpected feed shortages, unbalanced rations, inexperience with livestock feeding, and occasionally, neglect.

Regarding specific deficiencies, inadequate energy and protein levels are most commonly involved in cases of primary nutritional weight loss. Feed analysis may be necessary to establish the availability of protein and energy in the overall ration. The results of such analyses must be compared with established nutrient requirements for goats in the relevant type and stage of production and climatic region.

Cobalt deficiency may be a specific cause of progressive emaciation with no localizing signs in goats. In the United States, portions of New England, the upper midwest, and the southeast have cobalt-deficient soils, as do parts of New Zealand, Australia, the UK, Germany, the Netherlands, and Kenya. Goats grazing cobalt-deficient pastures show loss of appetite, rough hair coat, weakness, muscle wasting, and anemia, and may die after several weeks to months. In pastured animals, cobalt deficiency must be differentiated from gastrointestinal helminthiasis, which produces similar signs. Diagnosis of cobalt deficiency can be established by response to parenteral vitamin B_{12} administration or oral cobalt chloride. Appetite returns within a few days of treatment.

Copper deficiency can cause inadequate weight gains in growing goats. Diagnosis may be aided by the presence of other clinical signs including anemia, pigmentation defects in the hair coat, conjunctivitis, prolonged diarrhea, and incoordination in newborn (swayback) and young goats (enzootic ataxia). Copper deficiency can also increase susceptibility to gastrointestinal parasitism and adult goats with copper deficiency and parasites may be emaciated, anemic, and hypoproteinemic.

Where forage quality is extremely poor, with little or no fresh green forage available, hypovitaminosis A may contribute to progressive emaciation. Other signs of vitamin A deficiency may include night blindness, corneal cloudiness, ocular discharge, and neurologic signs including convulsive seizures.

Secondary Nutritional Problems

A variety of possibilities must be considered which could limit the animal's ability to obtain or use feed. These include the following:

BEHAVIORAL PROBLEMS. Even when feeder space is adequate, goats with a low social standing in the herd hierarchy may have their attempts to eat thwarted by more dominant goats who drive them away from feeders. This can be determined by observation at feeding time. Regrouping animals or feeding affected individuals separately may resolve the problem.

During the breeding season, bucks, though otherwise healthy, often become quite thin, presumably because of less time spent eating and more time and energy spent in amorous pursuits. It is imperative that bucks enter the breeding season in good health and good body condition because a certain amount of weight loss is inevitable.

ORAL PROBLEMS. Goats with marked brachygnathism may be unable to prehend and masticate efficiently and not do well under extensive management. In confinement feeding systems, affected animals are usually able to consume adequate feed.

The excessive wear or loss of teeth, a common cause of thin ewe syndrome, can also occur in goats, though it is less frequent. This is because goats are more likely than sheep to browse in range and pasture and therefore less likely to wear away teeth by grazing low to the ground on abrasive soils. Nevertheless, thin does, particularly older does, should be checked for tooth loss. Tooth wear may be aggravated by inadequate dietary calcium or calcium/phosphorus imbalance resulting in softer teeth, or by fluoride toxicity. When cutting and grinding surfaces of teeth are excessively worn, prehension and mastication become inefficient and feed intake and utilization decrease. Water intake can also diminish because worn teeth are more sensitive to cold temperatures. Animals with dental attrition become progressively weaker and emaciated and can succumb to secondary disease processes, particularly pneumonia and pregnancy toxemia.

Periodontal disease can be an additional cause of tooth loss. Coarse feeds or awns of certain plants may pack between gums and teeth, initiating a progressive cycle of infection, tooth loosening, tooth socket deterioration, and additional impaction of foreign material until teeth are dramatically loosened or expelled. Osteomyelitis of the jawbones may also result.

Signs of molar loss include pouching of the cheeks from feed impaction in empty molar sockets, dribbling of fluid from the mouth, excessive staining of the lips and teeth, and a necrotic or stale feed odor to the breath. When a molar is missing, the normally apposing molar grows excessively long because of a lack of occlusal wear, causing trauma to soft tissues in the mouth.

Animals with severe dental attrition or periodontal disease should be culled. The productive life of animals with moderate dental disease can be prolonged by placing them on lusher pasture, feeding processed feeds in confinement, and floating sharp teeth with a flat file. Supplementing calcium and balancing it with phosphorus are indicated as preventive and therapeutic measures in herds in which the diet was previously inadequate.

SOFT TISSUE INFECTIONS. Contagious ecthyma is common in goats worldwide and can produce painful, scabby lesions on the lips that persist from three to six weeks or longer if secondary bacterial infections occur. These lesions can impair feed intake and lead to weight loss. Less common or geographically restricted causes of stomatitis that can cause dysphagia, inappetence, and weight loss are discussed in Chapter 10. Peste des petits ruminants causes severe stomatitis, affecting the gums, tongue, lips, and palate. These lesions may be slow to heal in nonfatal cases, leading to prolonged reduction in feed intake and weight loss. Foot and mouth disease can also affect goats, but foot lesions tend to be more common and severe than oral lesions.

BLINDNESS. Animals fed in confinement can readily adapt to sudden blindness if surroundings are unchanged. Grazing animals on sparse rangelands, however, probably depend heavily on sight for adequate feed intake. Angora goats with excessive hair covering of the face, an inherited trait, graze inefficiently because of impaired vision. They may become thin and often succumb to secondary disease problems.

Blindness in goats may be caused by gid, hypovitaminosis A, permanent corneal damage after outbreaks of infectious keratoconjunctivitis, or as a sequel to polioencephalomalacia.

LOCOMOTOR PROBLEMS. Foot and leg problems can interfere with efficient grazing or produce sufficient pain to keep animals recumbent instead of standing at the feeders. Weight loss associated with a reluctance of ambulate and eat may precede outward signs of lameness.

Numerous conditions can lead to impaired locomotion. Foot rot, foot scald, and foot abscesses occur in goats. Chronic bacterial polyarthritis can occur in very young kids after navel infection. *Mycoplasma* spp. are an important cause of arthritis in goats worldwide and the caprine arthritis encephalitis (CAE) virus has been recognized as a major cause of arthritis and lameness since 1980. Where it occurs, foot and mouth disease can affect goats and produce lameness with impaired locomotion. Noninfectious conditions that cause impaired mobility and reduced intake include fractures, other traumatic limb injuries, peripheral nerve damage, or rickets secondary to mineral imbalances.

Viral and Prion Causes of Chronic Weight Loss

Caprine Arthritis Encephalitis Virus (CAEV)

It is the arthritic form of CAEV infection which is generally associated with weight loss. This form most often appears clinically between one and two years of age, with great variability in the progression and sever-

ity of signs. The first sign of CAE may be unexplained weight loss, followed by stiffness and reluctance to move. Periods of recumbency increase, food intake diminishes, and weight loss becomes more pronounced. Some goats become severely crippled within a few months while others may show only intermittent lameness or stiffness for years, and remain that way indefinitely.

Far less commonly, a pneumonic form of CAE occurs in mature goats that produces long-term interstitial pneumonia with intermittent secondary bacterial pneumonia, exercise intolerance, and weight loss.

Weight loss may occur independently of arthritic or pneumonic signs in goats that are infected with the virus as demonstrated by serology. Because CAEV infection is a chronic infection, wasting may be an effect of endogenous cytokine release, and may not depend only on decreased ambulation and feed intake. Because many serologically positive goats never show any signs of disease, however, other possible causes for weight loss must also be considered in thin, otherwise normal goats with positive CAE serologic tests.

Other Viral and Prion Diseases

Contagious ecthyma is discussed above under oral problems. Foot and mouth disease usually produces mild clinical signs in goats, but lameness and oral lesions may impair feed intake sufficiently to cause weight loss.

Scrapie, a prion infection of small ruminants, is less common in goats as compared to sheep, but a case with weight loss as the principal sign of scrapie in a goat has been reported from Britain. An affected herd mate showed the more typical scrapie signs of progressive incoordination and intense pruritus, while the goat in question showed only progressive weight loss, listlessness, and a premature cessation of milk production. Diagnosis was confirmed by histopathologic examination of the brain.

Peste des petits ruminants can cause pronounced weight loss and debilitation in goats during the prolonged convalescent periods that may follow recovery from the acute diarrheal and respiratory phase of the disease. As mentioned above, severe stomatitis in the acute phase may also contribute to decreased feed intake.

Pulmonary adenomatosis, or jaagsiekte, is a neoplastic transformation of the lung caused by a retrovirus distinct from CAEV. It is primarily a sheep disease but has been reported in goats. The disease produces a syndrome of progressive dyspnea and weight loss with pronounced nasal discharge over a period of several months. Moist lung sounds are audible and considerable fluid drains from the lungs if the animal is held vertically with the head hanging down. Diagnosis is by histopathologic examination of the lungs.

Bacterial Causes of Chronic Weight Loss

Paratuberculosis (Johne's Disease)

It is very likely that paratuberculosis is a frequent but undiagnosed cause of progressive weight loss in adult goats. Failure to diagnose this condition usually results from three factors. First, chronic diarrhea, the cardinal sign of paratuberculosis in cattle, is rarely observed in goats, so veterinarians familiar with the cattle disease may not consider paratuberculosis when confronted with a thin goat. Second, rapid, reliable laboratory tests have not been readily available as aids to clinical diagnosis. Last, gross post mortem lesions of intestinal thickening, common in cattle, are uncommonly seen in affected goats. In most cases, histopathologic examination of intestinal tissue with acid-fast staining and/or mycobacterial culture of feces or intestine must be performed to establish paratuberculosis as the cause of chronic weight loss. Such examinations are warranted in unexplained caprine wasting disease because of the relative importance of paratuberculosis as a cause of weight loss that is commonly overlooked in goats.

Caseous Lymphadenitis

This important chronic infectious disease of goats caused by *Corynebacterium pseudotuberculosis (C. ovis)* is best known by the superficial lymphadenopathy it produces. However, abscesses of internal lymph nodes and viscera also occur, though less commonly. While the impact of superficial lymph node abscesses on general health in goats is not remarkable, a stronger association exists between progressive emaciation and internal abscesses.

Antemortem diagnosis of internal abscesses can be difficult. Goats with internal abscesses often do not have concurrent superficial abscesses. Physical exam rarely establishes proof of an internal lymph node abscess, although large abscesses in the chest may alter normal heart and lung sounds and large abdominal abscesses are sometimes palpable. Radiography or ultrasonography may be helpful if large or focally calcified abscesses are present. Neutrophilia and hypergammaglobulinemia may support the diagnosis but are not pathognomonic. At necropsy, thoracic and abdominal organs should be examined and abscesses cultured because other pyogenic organisms may be involved. Tuberculosis may present similarly.

Tuberculosis

Tuberculosis is uncommon in goats but sporadic cases continue to be reported. *Mycobacterium bovis* is the most common cause, but *M. avium* and *M. tuberculosis* also occur, and the zoonotic potential of the disease should be respected. Tuberculous goats often are commingled with cattle. The presentation of weight loss is

variable. It may precede other clinical signs, accompany them, or not occur at all. Clinical tuberculosis most often manifests as chronic pneumonia with a moist, persistent, productive cough. Intestinal tuberculosis also occurs with diarrhea as a presenting sign. Antemortem diagnosis is by intradermal skin test. At post mortem examination, obvious caseated, sometimes calcified, parenchymal or lymph node granulomas are present. Tuberculosis coincident with paratuberculosis in goats has been reported from Spain. In such cases, definitive diagnosis depends on mycobacterial culture of granulomatous lesions.

Melioidosis

This infection caused by a soil saprophyte, *Burkholderia* (*Pseudomonas*) *pseudomallei*, is reported from tropical regions, primarily southeast Asia and Australia. It may be endemic in some regions and outbreaks are associated with flooding of pastures. Acute and chronic forms are seen in goats. Clinical manifestations are varied and include high fever, nasal discharge, pneumonia, lymphadenopathy, mastitis, orchitis, polyarthritis, and frequently neurologic signs including ataxia, head tilt, nystagmus, or circling. Acute deaths may occur within twenty-four to forty-eight hours after fever, weakness, and recumbency. Animals that survive may have any of the signs noted in addition to pronounced weight loss. Asymptomatic infections can also occur in the herd. The organism may be transmitted in goat milk and the disease is zoonotic.

Ante mortem diagnosis may be accomplished by bacterial culture of milk, nasal discharges, or aspirates of swollen lymph nodes; skin testing with meliodin; or serologic methods, including complement fixation and indirect hemagglutination assays. Necropsy usually reveals multiple abscesses in numerous organs, especially spleen, liver, and lungs. These abscesses should be cultured (see Chapter 3).

Chronic Bacterial Infection

Any prolonged infection may contribute to a process of progressive debilitation and wasting, referred to as cachexia, which in and of itself can contribute to an adverse patient outcome. The mechanisms of cachexia are multifactorial and not fully understood. Alterations in carbohydrate, protein, and lipid metabolism all contribute to the loss of tissue and body mass. It is believed that these metabolic changes are driven by an inflammatory response and are mediated in part by dysregulated production of proinflammatory cytokines such as interleukin 1, interleukin 6, and tissue necrosis factor. Current knowledge on the mechanisms of cachexia have been recently reviewed (Delano and Moldawer 2006). The mechanisms of cachexia have not been studied directly in the goat, but the process is certainly at play in chronic caprine infections such as

paratuberculosis, tuberculosis, and melioidosis, as discussed above. Other chronic bacterial infections likely to be associated with weight loss in goats are as follows:

Pasteurella and *Mannheimia* pneumonias of goats are common and often become chronic due to failure of early detection coupled with inadequate therapy. Chronic pasteurellosis is often complicated by secondary lung abscessation due to *Arcanobacterium pyogenes.* Careful auscultation and radiology may confirm the presence of chronic pneumonia and abscessation.

Chronic mastitis cases are generally culled from commercial goat dairies in a timely fashion. Hobbyists, however, may show a marked reluctance to cull mastitic does. Typically, affected does with chronic mastitis appear thin and depressed, and have a pendulous udder containing extensive fibrotic areas and multiple large firm abscesses, often caused by *Arcanobacterium pyogenes* (Figure 15.2).

Figure 15.2. A thin doe with chronic mastitis due to *Arcanobacterium pyogenes.* **Note the characteristic, large, nodular, multiple abscesses in the udder. (Courtesy Dr. David M. Sherman.)**

Peritonitis can occur secondary to a number of conditions. These include rumenitis resulting from grain overload, migration of liver flukes through abdominal organs, administration of irritating drugs intraperitoneally, the rupture of internal abscesses, and as sequelae to abdominal surgery or septicemia. Abscesses, adhesions, and bowel stenosis can occur as a result. Diagnosis is based on history of predisposing conditions, evidence of fever and abdominal pain, digestive dysfunction, an inflammatory blood picture, and supportive abdominocentesis findings. Thin animals with evidence of peritonitis should be culled.

Salmonellosis and enterotoxemia present most often as causes of acute, frequently fatal, enteritis or toxemia. Chronic forms of both diseases, however, occasionally occur in adult goats, and their clinical presentations are quite similar. Both conditions are characterized by periodic intermittent diarrhea accompanied by fever, loss of appetite, and depression. Sporadic recurrences may be observed over several months, accompanied by progressive weight loss. Notably, the chronic form of enterotoxemia can occur even in animals with a strong vaccination history against *Clostridium perfringens* type D. Definitive diagnosis depends on isolation of *Salmonella* spp. during episodes of active diarrhea or, in the case of enterotoxemia, identification of epsilon toxin in diarrheic feces or gut content.

Parasitic Causes of Chronic Weight Loss

Both ectoparasites and endoparasites can contribute significantly to progressive weight loss in goats, either primarily or in association with malnutrition or concurrent disease.

Gastrointestinal Parasitism

Coccidiosis. Coccidiosis is easily diagnosed as a cause of diarrhea, dysentery, dehydration, and often death in young kids. However, less obvious is the fact that animals that survive clinical coccidiosis often suffer sufficient damage to the intestinal mucosa that normal growth and development are permanently impaired, presumably due to occurrence of intestinal malabsorption. Specific diagnosis of this condition is difficult. A history of coccidiosis on the farm and exclusion of other likely causes of poor growth or inadequate weight gain may lead to a presumptive diagnosis of chronic intestinal damage secondary to coccidiosis.

Nematodiasis. Nematodiasis is the most important parasitism contributing to ill thrift. Young animals between two and twenty-four months of age are most often affected, but age-related resistance to parasitism is not as strong in goats as it is in cattle, and clinical parasitism is not uncommon in older animals, particularly when concurrent disease or poor nutrition is present. Clinical evidence of gastrointestinal parasitism includes pale mucous membranes, fluid accumulation between the jaws (bottle jaw), weakness, decreased growth rate or milk production, rough hair coat, and progressive weight loss or emaciation. Diarrhea is not a consistent finding.

Cestodiasis. Tapeworms occur in goats worldwide. Their contributory role in the development of weight loss is controversial, but in general they are not considered to be clinically important unless heavy infestations are found in animals younger than six months of age, in which case they may contribute to poor growth. An inordinate amount of importance is placed on tapeworm infestation by goat owners because they can readily observe tapeworm segments (proglottids) in goat feces.

The goat can serve as an intermediate host for tapeworms of the genera *Taenia* and *Echinococcus*, resulting in cysticercosis and hydatidosis, respectively. These conditions usually remain subclinical, producing no signs other than poor weight gain in young animals. Sometimes they produce peritonitis with accompanying fever, depression, and weakness. Diagnosis is usually accomplished at slaughter or necropsy when numerous, large, larval cysts are found in abdominal viscera, mesentery, and lungs.

Trematodiasis. Four species of liver flukes affect goats: *Fasciola hepatica*, *F. gigantica*, *Fascioloides magna*, and *Dicrocoelium dendriticum.* While acute and chronic forms of liver fluke disease occur, it is the chronic form caused by *Fasciola* spp. that is associated with weight loss. This results from localization and persistence of adult flukes in the bile ducts, where they consume blood and produce bile duct irritation with resultant liver dysfunction. The clinical syndrome produced may be indistinguishable from gastrointestinal nematodiasis, although icterus is sometimes seen. Ova may be found in feces using sedimentation techniques, but diagnosis is easiest at necropsy, where adult flukes and their excretions are found in the bile ducts. Note that *Fascioloides magna* infestation can cause weight loss and death without the appearance of eggs in the feces.

Pancreatic flukes of the genus *Eurytrema* can also produce emaciation in goats. The condition is discussed further in Chapter 11.

Schistosomosis can produce ill thrift in goats in Asia, Africa, the Middle East, South and Central America, and the Mediterranean region. The disease occurs where livestock are exposed to aquatic snails, the intermediate parasite hosts. In the nasal form, weight loss is accompanied by snoring, sneezing, and dyspnea, and in the intestinal form, by diarrhea and anemia. This form may be clinically indistinguishable from gastrointestinal nematodiasis. Diagnosis is based on identifying parasite eggs in feces, urine, liver biopsy specimens, or nasal discharges.

Lungworm Infestations

Three species of lungworms affect goats in the United States. *Dictyocaulus filaria* has a direct life cycle and is considered the most pathogenic. *Protostrongylus rufescens* and *Muellerius capillaris* both have snail intermediate hosts and are considered less pathogenic. All are likely to occur in cool, wet, autumnal weather when younger stock on lowland or irrigated pastures ingest infective larvae or snails. While adult *Dictyocaulus* and *Protostrongylus* cause obvious coughing in affected goats by irritating airways, adult forms of *Muellerius capillaris* do not because they do not reach the airways. They reside in the alveoli, producing small, gray-green nodules visible at necropsy on the surface of the diaphragmatic lobes. Weight loss may accompany respiratory signs in *Dictyocaulus* infection, but may be the only clinical sign of severe *Muellerius* infection.

External Parasites

Ectoparasites can contribute to ill thrift when infestations are severe and concurrent diseases are present. Biting lice such as *Damalina caprae* may cause irritation to affected hosts, leading to reduced feeding efficiency. The blue louse of goats, *Linognathus stenopsis*, feeds on host blood using piercing mouth parts and causes anemia and weight loss. Lice are more common in winter months and are promoted by confinement and overcrowding. Parasites are visible when the hair is parted and the skin carefully observed.

Among the mange mites affecting goats, *Sarcoptes*, and to a lesser extent, *Chorioptes*, can produce intense pruritus which torments the host and results in decreased feeding activity and weight loss. Generalized crusting and flaking of the skin with alopecia are apparent and skin scrapings should confirm the diagnosis. The sheep ked, *Melophagus ovinus*, also affects goats and can produce intense pruritus, particularly in winter. A period of ill thrift has been observed in goats with demodectic mange and also in association with heavy ear mite infestation.

In tropical regions, heavy infestations of goats with fleas of the genus *Ctenocephalides* can cause anorexia, anemia, weight loss, and even death. Kid goats are most severely affected.

Hemoparasites

Trypanosomosis affects goats in the tsetse fly regions of Africa. Acute, subacute, and chronic forms occur. Severe emaciation is associated with chronic disease. Additional clinical signs may include anemia, depression, anorexia, lack of rumen motility, and peripheral lymphadenopathy. Diagnosis is by identifying the hemoparasite on stained blood smears.

Rarely, eperythrozoonosis may be a cause of anemia and ill thrift in goats. Infection is usually subclinical.

Caprine infection is reported in Pakistan, South Africa, Australia, and Cuba.

Miscellaneous Causes of Chronic Weight Loss

Plant Toxicities

A wide variety of poisonous plants may affect goats on pasture or range. Most plant intoxications produce sudden death or an acute disease syndrome which does not involve weight loss. One important exception is toxicity due to locoweed (*Astragalus* spp.), a chronic intoxication characterized by mild nervous signs, muscular incoordination, fetal abnormality or abortion, and chronic, progressive weight loss. Locoism is seen most commonly in the western United States. Goats are susceptible, though the disease is seen more often in sheep. Lupinosis, a common cause of weight loss, anorexia, depression, and jaundice in sheep in Europe, Australia, New Zealand, and South Africa, is not reported to occur in goats. In Germany, Austria, and Switzerland (Braun et al. 2000), a syndrome of vitamin D toxicity causing progressive weight loss, lameness, decreased milk production, and calcification of soft tissues has been observed in goats consuming yellow oat grass (*Trisetum flavescens*), which contains 1,25 dihydroxycholecalciferol. This golden oat grass intoxication may also cause cardiovascular abnormalities and is discussed further in Chapter 8.

Gastrointestinal Foreign Bodies

In South Africa, phytobezoars consisting of seed hairs of karoo bushes can cause abomasal impaction in grazing goats. Progressive weight loss accompanied by progressive abdominal distension suggests this diagnosis. Recently, anorexia and progressive weight loss of six weeks duration was reported in three Angora goats, subsequently confirmed by necropsy of two and rumenotomy of the third to have multiple hair balls (trichobezoars) in their rumens (Baillie and Anzuino 2006).

Consumption of plastic trash bags is common where rubbish disposal is uncontrolled and where goats forage in urban areas, as is common in Africa, the Middle East, and South Asia (Figure 15.3). Baling twine can be ingested when confined goats are fed baled hay. These foreign bodies can lead to partial gastrointestinal obstructions, chronic indigestion, abdominal distension, and weight loss. In a study from Jordan, 4.5% of 722 adult goat cases presented at a veterinary teaching hospital over a 3.75-year period were diagnosed with soft foreign bodies (plastic) in their rumens and reticuli (Hailat et al. 1998).

Neoplasia

In general, tumors are an uncommon finding in goats and therefore are a relatively infrequent cause of

progressive emaciation. However, neoplasia still should be considered in a differential diagnosis of chronic weight loss, especially in older goats kept as pets, because they are often kept to very advanced ages, with a concurrent increase in the likelihood of neoplasia. Sporadic cases of neoplasia, including intestinal adenocarcinomas, have been diagnosed at necropsy in adult goats after a prolonged course of ill

Figure 15.3. Urban goats foraging in trash bins. Consumption of plastic bags can lead to blockage of the reticulo-omasal orifice, resulting in chronic indigestion and weight loss. (Courtesy Dr. Laurie C. Miller.)

thrift. More consistently, enzootic intranasal tumors of goats have been reported, primarily in Europe. Affected goats show persistent, profuse, often unilateral, serous nasal discharge; progressive dyspnea; and chronic weight loss. It has been demonstrated by transmission studies that these nasal adenocarcinomas are caused by a retrovirus (De las Heras et al. 1995). The disease is discussed further in Chapter 9.

Amyloidosis

Goats are used extensively in research and industry to produce antibodies for commerce or research. Repeated immune stimulation in these animals with adjuvanted antigens can stimulate the production and deposition of renal amyloid. Renal amyloidosis manifests clinically as progressive emaciation with weakness, anorexia, depression, and possible edema and ascites caused by hypoproteinemia subsequent to proteinuria. Diarrhea may also be present, caused by hypoproteinemia or concurrent intestinal amyloidosis. Diagnosis is aided by urinalysis and kidney biopsy. There is no treatment for the condition. Although amyloidosis is an unlikely cause of chronic weight loss in the general goat population, it may occur frequently in this specialized group of antibody-producing goats.

Other Sporadic Causes

Though an uncommon occurrence, congenital ventricular septal defect results in poor growth in young, affected goats. Stunted growth may also result from chronic aspiration pneumonia associated with cleft palate or other causes (Figure 15.4). In Nubian goats,
Figure 15.4. Two seven-month-old Saanen doeling sisters. The stunted goat in the foreground was diagnosed at presentation with a cleft palate. (Courtesy Dr. David M. Sherman.)

the inherited lysosomal storage disease mucopolysaccharidosis IIID can cause muscle wasting in homozygous, affected individuals, resulting in weakness and ill-thrift. The condition is discussed further in Chapter 5.

Sudden Death

The goat that is healthy one night and found dead the next morning poses a particular problem for the owner and the veterinarian. If an explanation for the death cannot be found, appropriate steps cannot be taken to prevent additional losses. On the other hand, a full necropsy by a diagnostic pathologist may be expensive. Not all owners are eager to pay much to get a diagnosis if the condition seems to be sporadic, and if the rest of the herd is not at risk. Note that in Germany, and possibly other countries, on-farm necropsies by owners or private veterinarians are forbidden by law, to avoid potential contamination of the environment with body fluids laden with infectious organisms. Thus, local regulations supercede the advice presented in this chapter.

PRELIMINARY DECISIONS

As a guide for deciding what course to follow, the answers to these questions should be reviewed.

1. Was the animal really healthy when last observed, or did it show some signs, albeit vague, such as poor appetite, weight loss, or lassitude? Is the body emaciated? The goat may have had a prolonged or chronic infection or parasitism, and others in the herd may also be affected.
2. Was the animal larger than, (tending to eat more), smaller than (with tendency for chronic disease, social hierarchy problems), older than, or younger than the others in its group? Was it persistently harassed by other animals or children?
3. Is any information to be gathered from the position of the carcass? Was a pygmy goat or obese animal stuck on its back where it died of bloat? Is the bedding disturbed, as by convulsions?

Has the goat been strangled by a collar? Was lightning strike or electrocution possible?
4. Is this the first death, or is a pattern developing?
5. Has there been any change in feed? This includes different amounts or new feeds, even new batches of what is thought to be the same feed. Has the goat recently foraged where it does not usually go: in the garden, a cultivated field, or the grain room? Have children been hand-feeding it bread or other treats? Have irregularities occurred in availability of feed or water?
6. Was the animal recently treated with any anthelminthic, injectable selenium, or other medication?
7. What was the vaccination status of the animal?

Now what? The first decision must be made rapidly. If the body is not to be examined, then it should be disposed of at once, by burning, deep burial, or composting (Koebel et al. 2003), according to local regulations. Rendering companies in the United States usually do not accept carcasses of small ruminants because of the perceived risk of scrapie transmission. The body should not be left for domestic or wild animals to tear apart and drag all over the farm, thereby possibly spreading infectious disease (including hydatidosis) to animals and man; neither should it be buried near a water supply or left as a breeding ground for flies.

Almost every sudden death warrants some degree of investigation. This even includes the aborted fetus in a herd that has had no previous abortions. Because placenta or fetus may not be available from later cases, the first observed abortion becomes very important. The reader should refer to Chapter 13 for a

detailed discussion of abortion diagnosis and zoonotic concerns.

The presence of unclotted blood at body orifices raises the specter of anthrax (Okoh 1981; de Vos and Turnbull 2004), and this possibility radically changes the options available. The body should not be opened, because exposure to air promotes sporulation of the causative bacteria. Instead, a veterinarian should take a blood sample in an evacuated tube from the jugular vein to be examined for the anthrax bacillus. Alternatively, an impression smear of ear blood can be used; an ear is grasped with a gloved hand, severed, and sealed in the everted glove for transport. Technicians or other laboratory personnel receiving or handling the specimen should be cautioned regarding possible danger. Anthrax is discussed in Chapter 7.

Examination by the Owner

The level of examination to be chosen varies with the knowledge of the owner and the availability and cost of the services of a veterinarian or diagnostic laboratory. It may also be influenced by the time of day, day of the week, and ambient temperature. It is often better for an owner to do what he can rather than wait for expert evaluation until the next day in hot weather or until two days later in a cold climate. If death is suspected to be caused by dog attack, local laws may permit indemnity payment if the proper authorities are notified before the necropsy is begun.

The practitioner on emergency duty should be prepared to relay instructions if there is no time to personally perform a necropsy. If the owner routinely does home slaughtering, it is often possible for him or her to recognize something in an organ as being different, even if the exact problem cannot be diagnosed. Digital photographs are helpful for documenting these findings. Also, when the examination is guided by the veterinarian, the normality of some organs can be established and recorded to help rule out certain conditions. If the owner does the initial or only examination, then it is exceedingly important that dogs be tied up and that protective, waterproof gloves be worn. Pregnant women should be dissuaded from performing necropsies without full protective garb, including a face mask. Organs or tissues with suspected lesions can be placed in waterproof containers and refrigerated until a veterinarian can examine them. If possible, they should be delivered immediately to the veterinarian's office rather than being stored in a home refrigerator where contamination of food might occur. An insulated box and several plastic jugs of ice provide a temporary cooler.

Necropsy Technique

Every veterinarian has had some instruction in field necropsies, but some may have forgotten important

details. The first is to wear protective gloves and to plan ahead for safe disposal of carcass remnants. The next involves writing down the findings, including history, identification (tags and tattoos, color), weight, and age. The owner's statement of age should be compared with the teeth and tattoo.

The color of mucous membranes should be noted relative to possible anemia or icterus. Are the hindquarters soiled with feces (diarrhea) or are formed fecal pellets present in the rectum? Discharges from body orifices should be noted. Anthrax has already been mentioned as a cause of bloody discharges, but it should be noted that a bloody froth is commonly present at the nostrils of animals dead for a myriad of reasons, especially in warm weather.

The body should always be placed in the same position relative to the prosector (e.g., on its left side, head directed to the examiner's right [King 1983]). The necropsy should be performed in a routine and complete manner (Hindson and Winter 2002; King et al. 2005). A sharp post mortem knife is a great asset, but if necessary, the goat can be dissected with a disposable scalpel blade and a pair of foot trimming shears. Begin with a skin incision in the right axilla and cut through muscles beneath the scapula until the front limb can be folded back out of the way. Next, make an incision into the right hip joint and surrounding muscles, to fold back the hind limb. Connect the first two incisions by cutting the skin from the inside out and peeling it back off the thorax and abdomen. Carefully enter the abdominal cavity along the costal arch and reflect the abdominal wall. Observe the amount of omental fat and the position of the viscera. Animals lacking omental fat are in very poor body condition (Figure 16.1). If omental fat is present, verify that there is muscle and fat present over the lumbar vertebrae. The animal that began its illness with copious internal fat may give the false appearance of good body condition, even though it actually has severe muscle wasting.

Next, puncture the diaphragm and listen for the normal inrush of air as the lungs collapse. Cut the diaphragm off the rib cage. Foot trimmers permit cutting of the ribs at the costochondral junction, even in adults. The rib cage of a kid is folded back as one section. In an old goat, it may be necessary to use heavy tree branch loppers or to cut between the ribs and break one at a time near the spinal column. Examine the viscera in the thorax and abdomen systematically and note any fluid accumulations.

The brain of a young kid can be exposed by cutting the calvarium with heavy scissors, but a saw is needed when removing the brain of an adult. Remove skin from the top of the skull and make a first transverse saw cut just caudal to the zygomatic process of the frontal bone. Then make sagittal cuts on each side from just medial to the occipital condyle to join the first cut
Figure 16.1. Emaciated goat lacking omental fat. The intestines should not be easily seen until the omentum has been removed. (Courtesy Dr. M.C. Smith.)

(King et al. 2005). Alternatively, four saw cuts can be made in a diamond pattern, with the anterior point of the diamond on the midline between the eyes. If the goat has large horns, the first transverse cut is made on the forehead anterior to the horns and angled caudally. The sagittal cuts are slanted toward the midline, and the skull cap with horns can then be lifted off, as illustrated in Figure 16.2.

Heart blood, urine (50 ml if possible), and cerebrospinal fluid (at the atlanto-occipital space) can be aspirated in a clean fashion and set aside for later examination. For instance, glucose is usually present in the urine of a goat that dies of enterotoxemia. Unfortunately, information regarding sensitivity and specificity of various findings in specified reference populations (for example, the percentage of goats dying in New York State with enterotoxemia that have glucosuria [equals sensitivity] or the percentage dying of something other than enterotoxemia that do not have glucosuria [equals specificity] is rarely available). Until the published literature provides such information, practitioners should tabulate their own records as to gross necropsy findings, simple test results, and final diagnosis. This permits later estimation of sensitivity, specificity, and even prior probability in a given practice setting.

Appropriate tissues or swabs (for example, abnormal lung, mammary gland, abscesses, or tied-off section of intestine) should be taken for bacteriologic and virologic testing. The laboratory to receive the specimens should be consulted relative to transport media, packaging, and shipping instructions. Sections should be taken for histologic study from the major organs (i.e., lung, liver, kidney, heart, mesenteric lymph node, brain stem, cerebellum, and cerebrum) and from

Figure 16.2. Opening the cranial cavity of a horned goat. (Courtesy Dr. M.C. Smith; Mr. Patrick Burke, prosector.)

a

b

Figure 16.2b. The sagittal cuts are almost horizontal.

c

Figure 16.2c. The horns and top of the calvarium have been lifted off to expose the brain and frontal sinus.

all suspected lesions. The kidney section should include cortex, medulla, and pelvic epithelium. Whenever possible, some normal tissue at the edge of a lesion should be included. Slices must be thin (no more than 5 mm) and the tissues should be preserved in at least ten times their volume of 10% formalin. A history should accompany the samples to the laboratory. Saving tissues preserved in formalin is advisable, even if the owner does not currently wish to pay for histologic examination.

The gastrointestinal tract should not be opened until the rest of the necropsy is finished, to avoid contamination. At the appropriate time, rumen contents should be examined for pH level, color, smell, and identifiable roughages or grain. A sample of at least 200 g should be labeled and frozen for later reference if toxicity has not yet been ruled out. At the same time, large pieces (at least 100 g each) of liver and kidney should be frozen (King 1983). Liver also may be useful for monitoring trace mineral status of the herd. Plant fragments requiring identification should be dried between layers of newspaper. The abomasum and small intestine should be examined closely for parasites; this serves a herd-monitoring function, even if parasitism did not directly kill the goat (Figure 16.3). A quantitative fecal examination may be warranted. Peyer's patches and mesenteric, bronchial, and mediastinal lymph nodes deserve special attention, and the presence or absence of white foci in the wall of the intestine (coccidiosis) should be determined. Impression smears of intestinal mucosa may be helpful for diagnosis of coccidiosis, cryptosporidiosis, paratuberculosis, and (if the necropsy is done less than four hours after death) enterotoxemia.

INTERPRETATION OF THE FINDINGS

Table 16.1 is an incomplete listing of conditions causing sudden death. A more complete list can be found in the Internet resource Consultant (White 2008). If the carcass is emaciated, refer first to the chapter on wasting diseases. Death may have been sudden, but a long-term problem often exists as the cause of death or predisposition to some terminal accident or infection.

Most of these conditions are discussed elsewhere in this book and will not be repeated here. The situation of the kid found dead shortly after delivery deserves special comment. It is important to determine whether the kid was born alive and whether it breathed; if so, its lung tissue is inflated and floats. If the kid was stillborn, more consideration should be given to the long list of diseases causing abortion. It is critical to know whether the kid ever nursed (milk in the abomasum) as opposed to being too weak at birth to get up and nurse (because of in utero infection, swayback, congenital defects, prematurity, or nutritional muscular dystrophy) or having a dam with malnutrition, udder problems, or poor maternal behavior so that no milk could be obtained. Death from exposure is more common if the abomasum is empty, whereas other explanations should be sought if the kid has a full stomach. One should also evaluate body fat deposits on the pericardial sac and around the kidneys. These fat stores are normally light tan and extensive at birth but quickly become dark red and reduced in volume with starvation. An ileal impression smear is helpful in diagnosing the cause of death of kids that lived long enough to die of enterotoxigenic *E. coli* (packets of Gram-negative rods in microcolonies) or clostridial enterotoxemia (many large Gram-positive rods).

A complete necropsy can provide other information of use in the management of the herd, even if it does not directly pertain to the sudden death of the goat at hand. A record of whether a doe is pregnant and the number of fetuses in the uterus is important for the differential diagnosis of pregnancy toxemia, but it is also needed for monitoring the reproductive efficiency of the herd. Joint diseases are not expected to cause sudden death, but necropsy is an excellent way to verify the presence of arthritis due to caprine arthritis encephalitis virus or mycoplasma infection. Soft bones and a rachitic rosary on the ribs suggest a mineral imbalance in the ration that should be corrected. They may also remind the prosector to examine the vertebral column more closely for a pathologic fracture as cause of the sudden death.

The practitioner should never underestimate how fast a dead goat can rot, even in the winter. A heavy Angora fleece or a body cavity full of fat makes many conditions difficult to diagnose after as little as four

Table 16.1. Conditions causing sudden death in goats.

Diagnosis	Comments
All ages	
Trauma, including predation	Subcutaneous hemorrhage, broken bones, ruptured internal viscus. If the eyes are absent, post mortem damage to the carcass by birds is likely.
Exposure	Cold stress caused by exposure to rain and wind after shearing.
Lightning strike, electrical shock	Subcutaneous hemorrhage, singe marks, often no lesions.
Snake bite	Fang marks in localized edematous swelling.
Anesthesia overdose, idiosyncratic reaction	Verify dose actually given.
Anaphylaxis	Death immediately after administration of penicillin, tetanus antitoxin, autogenous bacterins.
Anthrax	Petechiae and echhymoses throughout, large hemorrhagic lymph nodes; may lack bloody discharges from orifices or greatly enlarged pulpy spleen.
Clostridial wound infections	Crepitant (*C. chauvoei*) or edematous (*C. septicum*) tissues with odor of rancid butter (King et al. 2005); confirm by culture or fluorescent antibody.
Enterotoxemia	Fluid and fibrin in pericardial sac, glucosuria; kidneys rot quickly; fresh ileal impression smear shows many Gram-positive rods.
Polioencephalomalacia	Fluorescence of cerebral cortex under Wood's lamp suggestive but may be absent if acute course.
Encephalitis or meningitis	Impression smear of meninges if cloudy, to look for neutrophils or bacteria; evaluation and culture of CSF.
Tetanus	Limbs extended; diagnosis probably not possible if no clinical signs observed; history may include recent dehorning, dystocia, or other wound for entry of the organism.
Pseudorabies	Fluorescent antibody test on liver and brain stem, viral isolation; history of exposure to pigs or syringe contaminated with live virus vaccine.
Poisonous plants (see Table 19.7)	Examine rumen contents carefully; venous blood bright red with cyanide, dark with nitrates.
Chemical poisoning, including insecticides and anthelmintics	Check history, package label. The antibiotic tilmicosin has caused sudden death of goats (U.S. FDA 2006).
Rumensin toxicity	Histologic myocardial damage; may not be visible grossly in acute case; access to improperly mixed feeds or cattle pellets.
Urea toxicity	Rumen pH >7.5; access to improperly mixed feeds, de-icing products, or fertilizer.
Rumen acidosis	Rumen fluid milky, pH <5.5 if rapid death but returns to normal range as saliva enters rumen; sloughing of mucosa also occurs with simple autolysis.
Bloat	Bloat line in esophagus; edema of hindquarters.
Choke	Bolus of food at larynx.
Intestinal volvulus	Dark discoloration of only the involved portion of intestine.
Cecal or abomasal torsion	Rare in goats.
Haemonchosis (not in neonates)	Muscles and other tissues very pale; "barber pole" worms may be numerous in abomasum or absent (King 1983); may have submandibular edema.
Fascioliasis and fascioloidosis	Extensive necrosis and hemorrhage from fluke migration in liver; sometimes live rupture or *Clostridium novyi* infection (black disease).
Inhalation pneumonia	History of force feeding kids or of drenching goats of any age; nutritional muscular dystrophy or neurologic disease can result in inhalation.
Mannheimia and *Pasteurella* pneumonia Pulmonary edema	Cranioventral lung lobes firm, red; grossly similar to inhalation pneumonia but less septic. Red watery fluid in lung parenchyma, froth in airways; may have cardiac malformation or history of dog attack.
Heartwater (*Ehrlichia ruminantium*)	Tick-borne disease common in Africa and Caribbean; if noticed ill, history of fever, neurologic signs; look for edema of thoracic contents.

Table 16.1. *Continued*

Diagnosis	Comments
More common in kids	
Exposure of neonate to heat or cold, starvation	No milk in abomasum or intestine if kid did not nurse.
Congenital cardiac malformation	Heart may appear globular.
Brain damage from disbudding	Open calvarium to check surface of brain.
Cryptosporidiosis	Demonstrate organisms with acid-fast or other stain, but may be incidental finding.
Coccidiosis	White foci in wall of intestine. Some kids bleed out into intestine acutely.
Ruptured abomasum	Edges of rupture have curled if this happened antemortem.
Nutritional muscular dystrophy of heart	Not always grossly visible; liver edges may be rounded; excess fluid may be present in abdomen or thorax. Gossypol toxicity, from cottonseed, similar.
Ionophore toxicity	Myocardial necrosis; foot and mouth disease can affect kids similarly.
Septicemia	Splenomegaly, possibly polyarthritis; culture the spleen if fresh necropsy; use impression smear to demonstrate *Streptococcus pneumoniae* (Buddle et al. 1986; Vaissaire et al. 1989).
Anemia from sucking lice	Lice macroscopic; Angoras especially susceptible.
More common in adults	
Gangrenous or toxic mastitis	Cut surface of udder changes color; skin may be blue, secretion red.
Listeriosis	Gross lesions seldom visible in acute case; histology of brain stem is indicated if cause of death not evident after gross examination.
Ruptured aneurysm	Blood in body cavity.
Pregnancy toxemia	At least two well-developed kids in uterus, fatty liver, ketones in urine.
Rupture of uterus	Fetus often in anterior presentation with head back.
Rupture of uterine artery	May occur as long as several days after kidding.
Hypocalcemia	Sudden dietary changes or periparturient condition predisposes.
Vegetative endocarditis	Look for predisposing chronic infection, arthritis, or cardiac malformation; common where researchers use indwelling jugular catheters.

hours. Recognition of typical changes resulting from autolysis helps to avoid misdiagnoses. These include greenish or black discoloration of tissues adjacent to the intestine, and pale, even bubbly foci in the liver. A partial list of agonal and postmortem changes (Roth and King 1982; King et al. 2005) follows.

Pseudolesions Resulting from Agonal Death or Autolysis

- **Livor mortis**: Settling of blood to dependent parts of the body.
- Rumen contents in oral or nasal discharge.
- Ingesta in lungs without evidence of inflammation.
- **Rectal or vaginal prolapse**: Caused by post mortem bloat.
- **Pulpy kidney**: Not significant if rest of body also autolytic, otherwise suggestive of enterotoxemia.
- **Tracheal froth**: Agonal. May be significant if signs of pulmonary edema also present.
- **Endocardial, myocardial, epicardial hemorrhages**: Agonal.
- **Rumen mucosal sloughing**: Often an early autolytic change.
- **Post mortem abomasal rupture**: Along greater curvature, but lacks fibrin, hemorrhage.
- **Tiger striping in large intestine**: Terminal tenesmus.
- **Pseudomelanosis**: Blackening of tissues, especially adjacent to autolytic intestine.
- **Melanosis**: Normal black pigment in various organs.

Anesthesia

Goats are obviously sensitive to pain and vocalize loudly, sometimes even before being hurt. Most hobby goat owners prefer paying for tranquilization or anesthesia to observing the distress of a loved animal. In addition, goats seem to be prone to shock or perhaps to catecholamine-induced ventricular fibrillation (Gray and McDonell 1986a). Some die quickly after a surgical experience, and these losses can usually be prevented with adequate analgesia. Finally, in some countries humane laws dictate analgesia for surgical operations.

Consideration must be given to withdrawal times when tranquilizers or general anesthetics are given to meat or dairy animals. Because none of the drugs discussed in this chapter is approved for use in goats in the United States, withdrawals should be based on information supplied by the Food Animal Residue Avoidance Databank (FARAD) if available. In most instances, recommendations published for cattle are appropriate for goats, but a twenty-four-hour withdrawal period is recommended to meet the extended withdrawal required for extralabel drug use under AMDUCA, the Animal Medicinal Drug Use Clarification Act, if the cattle withdrawal is zero (Craigmill et al. 1997). See Table 17.1 for some FARAD guidelines for withdrawals in goats.

FARAD specifically declined to provide a withdrawal recommendation for tiletamine hydrochloride and zolazepam (Craigmill et al. 1997) or acepromazine (Haskell et al. 2003). Recommendations are also lacking for medetomidine, bupivacaine, morphine, and butorphanol, although FARAD personnel tend to suggest thirty days for such drugs when scientific data are not available.

Intravenous injections are given easily in the jugular vein (Figure 1.1) of goats. One person can restrain an adult dairy goat by straddling its neck and holding the head to one side with an elbow, leaving both hands free to distend the jugular vein and manipulate a needle and syringe. The presence of both horns and mohair on Angoras makes venipuncture more difficult and an assistant may be welcome. If a goat is short and squirmy, the operator may choose to lift the animal's front quarters off the ground and hold them clamped between the knees for better restraint during venipuncture. The cephalic vein and the recurrent tarsal vein are suitable for placement of butterfly catheters, and some may find 19- or 21-gauge butterfly catheters

Table 17.1. FARAD recommended withdrawal (WD) intervals for tranquilizers and general anesthetics in goats (Craigmill et al. 1997; Haskell et al. 2003).

Drug	Dose (mg/kg)	Meat WD (d)	Milk WD (h)
Acepromazine (Canada)	Up to 0.13 IV; up to 0.44 IM	7	48
Atropine	Adjunct to anesthesia	7	24
Detomidine	Up to 0.08 IM or IV	3	72
Guaifenesin	Up to 100 IV	3	48
Ketamine	Up to 2 IV, 10 IM	3	48
Lidocaine with epinenephrine	Infiltration, epidural	1	24
Tolazoline (cattle)	2 to 4 IV	8	48
Ultra-short acting barbiturates	Thiamylal (up to 5.5) Thialbarbitone (up to 9.4)	1	24
Xylazine	Up to 0.1 IV, 0.3 IM	5	72
Xylazine (cattle)	Up to 0.3 IM	4	24
Yohimbine	Up to 0.3 IV	7	72

convenient for rapid administration of drugs via the jugular vein.

LOCAL AND REGIONAL ANALGESIA

Local analgesia is commonly used for procedures such as dehorning, castration, cyst removal, and wound repair. Lidocaine is probably the local analgesic agent most commonly used for goats in the United States; other agents include 2% procaine, 2% mepivacaine, and 0.25% to 0.5% bupivacaine solutions. Mixtures of lidocaine and bupivacaine are used to provide immediate analgesia and prolonged duration of pain relief, though meat and milk withdrawals have not been established for bupivacaine. An estimated maximum dose for bupivacaine is 2 mg/kg (Snyder 2007) and it has a greater margin of safety than lidocaine (Skarda and Tranquilli 2007). The use of lidocaine is prohibited

in food-producing animals in the UK, where the only licensed product is 5% procaine with epinephrine (Hodgkinson and Dawson 2007).

Lidocaine

Lidocaine has a historical reputation of being toxic to goats. This can be easily demonstrated if small kids are injected without consideration of the total drug dosage being administered per unit bodyweight. In most species the convulsive threshold dose of lidocaine hydrochloride is 10 mg/kg intramuscularly (Gray and McDonell 1986a). For a kid that weighs 3 kg, a 10 mg/kg dose would be equivalent to 1.5 ml of 2% lidocaine. In general, a dosage of 5 mg/kg should be safe. Dilution of the lidocaine to 1% or even 0.5% with saline permits use of a larger volume of analgesic before the toxic level is approached (Skarda and Tranquilli 2007). This is especially helpful if the local blocks (a total of four injections) are to be used when disbudding newborn kids or a line block is used for a large abdominal incision.

Drowsiness, nystagmus, and convulsions are early signs of lidocaine toxicity (Covino and Vassallo 1976). Hypotension, respiratory arrest, and circulatory arrest occur at about five to six times the convulsive dose (Gray and McDonald 1986a). Goats suffering from slight overdoses recover spontaneously, whereas severely affected animals should receive oxygen therapy (if available) and 0.5 mg/kg diazepam intravenously or a short-acting barbiturate to control convulsions. When P_{CO_2} is increased, the convulsive threshold is lowered (Covino and Vassallo 1976).

In human medicine, and less frequently in veterinary medicine, lidocaine has been buffered with sodium bicarbonate to reduce pain associated with intradermal or subdermal injection. A mixture of com-

mercial 2% lidocaine is diluted 5:1 or 10:1 with 8.4% sodium bicarbonate. The resulting solution has a more physiologic pH (7.3 rather than the 6.2 of the straight lidocaine) but the exact mechanism of pain relief is not known (Palmon et al. 1998). No trials have been published concerning efficacy of buffered lidocaine for controlling injection pain in goats.

Paravertebral Block

A line block or an inverted L-block 2 to 3 cm cranial and dorsal to the proposed incision site provides good analgesia for celiotomies. The distal paravertebral block is an alternative, although it requires a better remembrance of anatomy. The thirteenth thoracic and first two or three lumbar nerves are blocked; up to 5 ml of analgesic is injected into each nerve, mostly below the intertransverse ligament but with some above the ligament (Hall et al. 2001) in a fan-shaped pattern near the anterior aspect of the tip of the transverse processes of L1 to L4. The most caudal palpable transverse process is L5, and this is used as a landmark for counting forward to locate L1, which is shortened and often difficult to palpate on an obese animal (Hodgkinson and Dawson 2007). Respect a maximum total lidocaine dose of 6 mg/kg to avoid toxicity.

Alternative injection sites, closer to the midline (proximal paravertebral), have also been described (Gray and McDonell 1986a; Hodgkinson and Dawson 2007; Skarda and Tranquilli 2007). In an adult dairy goat, the transverse processes of L1 and L3 are located and a point marked over the center of each approximately 3 cm (1.25 inches) from the midline. A small subcutaneous bleb of analgesic may be placed at these two spots. Then a 20-gauge, 6-cm spinal needle is introduced through the skin at the point over L1, directed straight down onto the transverse process, and walked off the anterior edge of the bone. When the needle pops through the intertransverse ligament, aspiration is performed to assure no venous injection, and 3 to 5 ml of 1% lidocaine or a lidocaine-bupivacaine mixture is deposited just ventral to the ligament. The needle is then withdrawn slightly and an additional 2 ml deposited above the ligament to block the dorsal branch of the nerve. Next, the needle is walked off the caudal aspect of the transverse process of L1, where 5 ml is deposited below and 2 ml above the intertransverse ligament. The spinal needle is then moved to L3, where the injections are repeated anterior to the transverse process only, unless analgesia of L4 is also desired. In this case, the injections are also repeated caudal to the transverse process of L3. Analgesia persists for approximately one hour.

Intravenous Regional Analgesia

The distal limb of a goat can be anesthetized easily by injecting a local anesthetic into a superficial vein of the limb distal to a tourniquet (Babalola and Oke 1983). This is most desirable when treating serious wounds of the extremity or when amputating a digit. The tourniquet (such as an Esmarch rubber bandage) is applied above the elbow or hock to raise the cephalic vein (crosses the anterior aspect of the middle third of the forearm) or the recurrent tarsal vein (in front of the gastrocnemius tendon laterally). A volume of 3 to 4 ml of 2% lidocaine solution delivered intravenously distal to the tourniquet has been recommended for pygmy goats. Five to 7 ml is appropriate for larger goats (Gray and McDonell 1986a). For a distal lesion, the tourniquet may be applied in the midmetacarpal or midmetatarsal region, a superficial vein located, and a smaller volume of analgesic injected intravenously if this is deemed desirable. The likelihood of hematoma formation can be reduced by draining off some blood before injection, using a fine gauge needle, and applying pressure over the injection site post injection. Analgesia is complete within ten minutes and lasts until the tourniquet is removed. To avoid potential lidocaine toxicity, do not remove the tourniquet for at least fifteen to twenty minutes after the injection (Taylor 1991). The tourniquet should remain on the limb for no longer than forty-five or fifty minutes to avoid postsurgical or delayed ligamentous and neuropathic pain.

Caudal Epidural Block

The most cranial moveable joint of the tail is usually between the first and second caudal vertebrae. Either the sacrocaudal or the first intercaudal (intercoccygeal) space is suitable for caudal epidural injection (Skarda and Tranquilli 2007). Lidocaine, procaine, or mepivacaine (all 2% solutions) can be used. A standard dose to anesthetize the perineum and vagina of an adult without interfering with motor function of the hind limbs is 2 to 4 ml. A 19- or 20-gauge needle is appropriate. If the needle is properly placed, an air bubble in the syringe will not be compressed during injection (Hodgkinson and Dawson 2007).

A longer duration of local anesthesia and a block that extends forward to provide adequate anesthesia after forty to fifty minutes for flank laparotomy or caesarean section can be achieved by adding xylazine at 0.07 mg/kg to the lidocaine (Scott 2000). Although this technique was originally developed for sheep, it also appears to work for goats. Mild ataxia may develop and persist for several hours. Analgesia of perineal tissues appears to last for more than twenty-four hours.

Anterior Epidural Anesthesia

Mammary gland surgery, vasectomy, laparotomy, embryo transfer, prolapse repair, and treatment of hind limb fractures are among the procedures that may be performed under spinal anesthesia. The anterior epi-

dural block is performed at the lumbosacral junction, using a 1.5- to 3-inch 20-gauge spinal needle with stylet. The site is a palpable depression between the tuber coxae; it should be clipped widely and the skin prepared as for surgery. If the animal is restrained in lateral recumbency with the lumbosacral spine flexed, the opening between vertebrae at the lumbosacral junction is effectively larger. The skin may be desensitized with 1 to 2 ml of local anesthetic and an initial skin puncture made with a large bore needle. The finer spinal needle is then directed straight into the space between vertebrae. Appearance of spinal fluid at the hub of the needle usually occurs when the subarachnoid space had been entered. Approximately 1 ml of anesthetic, such as a 2% lidocaine or 2% mepivacaine solution, is injected slowly into the subarachnoid space for each 10 kg of bodyweight.

Loss of sensation to the rear limbs is delayed (five to ten minutes) if the anesthetic is placed epidurally (Riese 1987). Some authors prefer to always give the injection in the epidural location, using 1 ml of 2% lidocaine solution with epinephrine/5 kg (Nelson et al. 1979; Gray and McDonell 1986a), and to routinely give intravenous fluids and a vasopressor drug such as methoxamine at 5 to 10 mg/kg or phenylephrine at perhaps 0.005 to 0.01 mg/kg if hypotension occurs (Hall et al. 2001). After epidural injection, the animal is rolled immediately onto its back if bilateral diffusion of the anesthetic is desired or maintained in lateral recumbency with the side to be desensitized undermost for unilateral analgesia. Paralysis lasts approximately three hours, at least in animals that have been sedated with xylazine (0.1 mg/kg intramuscularly). Recovery is delayed (often longer than eleven hours) when 0.75% bupivacaine is used for epidural anesthesia (Trim 1989). Linzell (1964) recommends performing an epidural injection while the goat is standing and using a lumbar epidural block (5 ml of 1.5% lidocaine plus epinephrine between L1 and L2) to anesthetize the abdominal wall without paralyzing the limbs.

Extradural anesthesia using xylazine at 0.07 mg/kg diluted in sterile water to a volume of 2.5 ml provides adequate anesthesia for a flank incision for caesarean section of ewes forty to fifty minutes later, whether the xylazine is given at the lumbosacral or the previously discussed sacrocaudal site (Scott and Gessert 1997). Medetomidine (0.020 mg/kg in 5 ml of sterile water) administered epidurally at the lumbosacaral site provides adequate anesthesia for flank surgery of goats within five to ten minutes (Mpanduji et al. 2000), although the observed effect may actually represent systemic absorption. Analgesia extends forward to the thorax, front limbs, and neck. Intravenous atipamezole at 0.08 mg/kg rapidly reverses the analgesia and the cardiopulmonary depression effects induced by the medetomidine (Mpanduji et al. 2001). Lumbosacral epidural xylazine at 0.025 mg/kg combined with ketamine at 2.5 mg/kg has been used to produce surgical anesthesia of the perineal region of normal and uremic goats (Singh et al. 2007).

Lumbosacral subarachnoid administration of xylazine at 0.05 mg/kg and of medetomidine at 0.01 mg/kg have been used to provide flank, hind limb, and perineal anesthesia in goats (Kinjavdekar et al. 2000). Doses of 0.001 to 0.002 mg/kg medetomidine may be adequate. Use of subarachnoid ketamine at 3 mg/kg and of subarachnoid xylazine at 0.1 mg/kg has also been reported (DeRossi et al. 2003).

Sacral Paravertebral Alcohol Block

Long-term (four to six weeks) control of straining associated with rectal or vaginal prolapses can be achieved by injecting isopropyl alcohol (70%) where the sacral nerves exit from the spinal column (Eness 1987; Skarda and Tranquilli 2007). A caudal epidural injection of lidocaine simplifies the procedure. A right-handed person inserts the left index finger into the rectum to locate the small bony indentations which mark the junction between two vertebrae. Six injections of 0.25 to 0.5 ml each are made. The first injections are made bilaterally at sacral spinal nerve S5, directly lateral to the sacrococcygeal junction. An 18-gauge 1 to 1.5-inch needle is directed down, about 1 cm from the midline, until the point of the needle can barely be felt with the finger positioned in the rectum. The procedure is repeated at S4 and S3 bilaterally. The S3 injections are omitted for males because prolapse of the prepuce might otherwise occur. If the goat has a problem requiring culling, it should be adequately identified; otherwise complete recovery from the current prolapse will tempt the owner to forget genetic predispositions.

SINGLE AND COMBINATION AGENTS FOR GENERAL ANESTHESIA

A variety of injectable and inhalant anesthetic agents have been used successfully in goats to achieve chemical restraint or general anesthesia. Electrical current and acupuncture stimulation have also been used.

Short-acting Barbiturates

Thiopental sodium (15 to 20 mg/kg in a 2.5% solution given rapidly intravenously) can be used for induction of anesthesia. It produces thirty to fifty seconds of apnea; intubation is easiest to perform during this period, as long as a stylet is used to stiffen the tube. Thiamylal sodium (Surital®, Parke-Davis) has similar effects at 10 mg/kg (Gray and McDonell 1986b). Methohexital sodium (Brevital®) at 4 mg/kg intravenously is said to provide five to seven minutes of anesthesia (Hall et al. 2001). Excitement during recovery can be avoided by premedication with mid-

azolam, diazepam, medetomidine, or xylazine, and the latter two permit use of a lower barbiturate dose for induction. When xylazine has been used, recovery time to standing is shortened by reversal with intravenous yohimbine at 0.125 mg/kg (Mora et al. 1993).

Other Barbiturates

The intravenous dose of pentobarbital for adult goats is 30 mg/kg (Linzell 1964). The animal regains its feet in twenty to sixty minutes unless additional doses to total 6 to 36 mg/kg per hour are administered. Animals vary in their response to this drug, and recovery may be prolonged (Hall et al. 2001). Commercial solutions of pentobarbital often contain propylene glycol, which causes hemolysis and hematuria in goats and sheep (Linzell 1964). Instead, a solution may be prepared by dissolving powdered pentobarbitone in 10% ethyl alcohol in a saline solution.

Laryngospasm sometimes occurs shortly after the administration of barbiturates, especially pentobarbital, and especially during anesthesia of young goats (Bryant 1969). The animal exhibits gasping, ineffective ventilation, and dilated pupils. The emergency requires forceful intubation (or an emergency tracheostomy). Spraying a local anesthetic on the larynx simplifies intubation in this instance.

Xylazine

Xylazine is an excellent drug for sedating goats, although it is not approved for this purpose in the United States. For many minor procedures such as oral and ocular exams, 0.03 to 0.04 mg/kg intravenously provides a brief (ten minutes) period of complacency. For painful procedures, it is safest to use a modest dose (0.05 mg/kg intravenously or 0.10 mg/kg intramuscularly) in combination with local analgesia (Gray and McDonell 1986a). Dosages should be calculated carefully; a 20 mg/ml solution and a tuberculin syringe make it easier to draw up the correct quantity, but beware of extra xylazine in the hub of the needle when the injection is given intravenously. Male goats and those with central nervous system diseases such a listeriosis seem to be especially susceptible to overdosing (M.C. Smith, personal observations). Salivation, bloat, and hyperglycemia are expected complications whenever xylazine is used. The drug has been shown to cause increased myometrial activity, depression of maternal and fetal heart rates, and marked depression of maternal and fetal arterial oxygen partial pressure (PaO_2) when given to late pregnant Rambouillet cross ewes at a dosage of 10 mg intramuscularly. The fetuses recovered within sixty minutes (Jansen et al. 1984). Conservative doses of xylazine are not contra-indicated in healthy pregnant goats and are preferable to the stress associated with physically restraining an excited or painful goat.

Doses of xylazine more than 0.15 mg/kg intravenously are not recommended for sheep and goats because these doses may cause severe cardiovascular and respiratory depression (Gray and McDonell 1986b). Even at the 0.15 mg/kg dosage, clinically important respiratory depression and hypoxemia have been reported in sheep (Doherty et al. 1986), though less consistently in goats (Kutter et al. 2006). PaO_2 decreases by approximately half, and a paradoxical respiratory rhythm has been observed where the thoracic cage collapses on inspiration. The sheep become cyanotic. Later research in sheep has explained how the hypoxemia develops by demonstrating that xylazine at 0.15 mg/kg intravenously causes damage to the capillary endothelium, intra-alveolar hemorrhage, and interstitial and alveolar edema, changes that clear within twelve hours (Celly et al. 1999).

The adverse effects of xylazine can be partially reversed by the α_2-adrenergic receptor antagonists yohimbine at 0.125 mg/kg or tolazoline at 1.5 mg/kg intravenously and administration of oxygen. Yohimbine produces a more rapid and persistent reversal of xylazine than does doxapram (0.4 mg/kg intravenously). Tolazoline may be more effective than yohimbine in ruminants (Gross and Tranquilli 1989). Yohimbine at 0.25 mg/kg in combination with 4-aminopyridine at 0.4 mg/kg, both given intravenously, is more effective than either drug alone (Ndeereh et al. 2001).

Ketamine, Ketamine plus Diazepam

Ketamine alone may be used for anesthetic procedures where muscle relaxation is not important (Kellar and Bauman 1978). A dose of 11 mg/kg intramuscularly or 6 mg/kg intravenously (Hall et al. 2001) supplies fifteen to thirty minutes of adequate anesthesia to adult goats. Larger doses have been recommended for young kids or longer surgery. The eyes remain open (use a lubricating ointment) and nystagmus may occur, as may involuntary limb movements. The animal retains the ability to eructate, cough, and swallow. This is desirable if intubation is not possible but does not guarantee that aspiration will not occur. Diazepam at 0.25 mg/kg combined in the same syringe with ketamine at 5 to 7.5 mg intravenously has been recommended for ten to fifteen minutes of anesthesia (Hall et al. 2001); a similar duration has been reported for diazepam at 0.11 mg/kg plus ketamine at 4.4 mg/kg (Riebold et al. 1995).

Xylazine and Ketamine

Xylazine and ketamine are frequently combined for general anesthesia in goats when inhalation anesthesia is not available. The period of analgesia is prolonged, but so is the recovery time relative to ketamine alone. A frequently quoted regimen is 0.22 mg/kg xylazine

followed by 11 mg/kg ketamine ten minutes later; both drugs are given intramuscularly (Kumar et al 1976; Thurmon 1986). Also possible is a single-intramuscular injection of 0.22 mg/kg xylazine and 11 mg/kg ketamine, although the time until immobilization occurs is increased. Anesthesia lasts approximately forty-five minutes and recovery to standing occurs in approximately one and a half hours (Kumar et al. 1983). Increments of 6 mg/kg ketamine are given intramuscularly if prolongation of anesthesia is necessary. Decreased dosage rates (0.10 mg/kg xylazine followed by 5 mg/kg ketamine) are more appropriate for procedures that require fifteen to twenty minutes of anesthesia (Gray and McDonell 1986b).

A xylazine/ketamine/atropine combination has been recommended for disbudding of kids (Pieterse and van Dieten 1995). The dosages are 0.04 mg/kg xylazine, 10 mg/kg ketamine, and 0.1 mg/kg atropine all in one intramuscular injection providing onset of surgical anesthesia in an average of twelve minutes. Note that the combination of xylazine and atropine has been found to cause hypertension and infarction in small animal species. Another intramuscular combination is created by adding 1 ml = 10 mg of butorphanol and 1 ml = 100 mg equine xylazine to a 10-ml vial of 100 mg/ml ketamine. The dose of the cocktail is 1 ml/100 pounds IV or 1 ml/50 pounds IM. Create a new controlled substance recording form for this vial, to simplify required paperwork.

Time to standing (but not to eating) is shortened by intravenous administration of 0.25 mg/kg yohimbine and 0.6 mg/kg 4-aminopyridine (Kruse-Elliott et al. 1987). Intravenous tolazoline at 2.1 mg/kg also significantly shortens the period of recumbency in goats anesthetized with xylazine-ketamine (Dew 1988).

Xylazine Congeners

Clonidine, medetomidine, dexmedetomidine, and detomidine are alpha-2 adrenergic agonists similar in action to xylazine. Intravenous clonidine doses of 0.2 to 7 µg/kg in goats cause dose-dependent sedation ranging from quiet behavior with maintenance of appetite to a sleep-like state (Eriksson and Tuomisto 1983). Intravenous medetomidine at 5 µg/kg causes deep clinical sedation, metabolic alkalosis, and hyperglycemia (Raekallio et al. 1994). Intramuscular medetomidine at 15 µg/kg results in sedation and lateral recumbency, beginning at approximately ten minutes, and lasting approximately one hour. Side effects include bradycardia, hypothermia, rumen stasis, bloating, frequent urination, salivation, and dyspnea, but disappear within two hours after return to standing (Mohammad et al. 1991). Dexmedetomidine (the active d- enantiomer of medetomidine) at 2 ug/kg has recently been shown to severely decrease PaO_2 in goats (Kutter et al. 2006). Detomidine causes mild to moder-

ate sedation and analgesia approximately fifteen minutes after intramuscular injection at 10 to 20 ug/kg (Clark et al. 1993).

Intramuscular medetomidine at 15 ug/kg (fifteen minutes after 0.1 mg/kg atropine) provides sedation that begins approximately seven minutes after injection and lasts approximately forty minutes. When the same doses of medetomidine are followed ten minutes later with 5 mg/kg ketamine intramuscularly, anesthesia onset is rapid and lasts approximately forty-five minutes. Salivation and diuresis are marked. When atipamezole is given intravenously at 15 ug/kg as a reversal agent thirty minutes after medetomidine, the goats are able to walk normally in two to three minutes (Tiwari et al. 1997). Similarly, when an intravenous medetomidine dose of 20 ug/kg was reversed twenty-five minutes later with intravenous atipamezole at 100 ug/kg, the goats stood up an average of one and a half minutes later but were agitated and vocalized (Carroll et al. 2005).

Tiletamine and Zolazepam

Telazol® (Fort Dodge Animal Health) is a nonnarcotic, nonbarbiturate anesthetic agent approved in the United States for intramuscular injection in dogs and cats. It is a combination of a ketamine-like drug, tiletamine (50 mg/ml), and the tranquilizer zolazepam (50 mg/ml). It produces cataleptoid or dissociative anesthesia. Few reports are published on its use in small ruminants, but the drug is effective in sheep and goats. Intramuscular injection of a dosage of 7.5 to 10 mg/kg provides anesthesia within ten minutes and lasting fifteen to thirty-five minutes (Clark et al. 1995). A dosage of 8 to 16 mg/kg was used intravenously to anesthetize eighty laboratory sheep for various surgeries, including celiotomies. The average duration of surgical anesthesia was two and a half hours, and the average time from injection to recovery was 5.6 hours (Conner et al. 1974). A 5.5 mg/kg dosage intravenously provides rapid induction of goats, and additional doses of 0.5 to 1 mg/kg can be used to prolong the surgical anesthesia as needed. Adding butorphanol at 0.1 mg/kg intravenously is not beneficial (Carroll et al. 1997).

Premedication with atropine decreases salivation but is not necessary because the swallowing reflex is preserved. Intubation or at the very least positioning the head low is advised in case regurgitation of rumen contents occurs. An oxygen source and means of assisted ventilation are also desirable (Carroll et al. 1997). Initial screening suggested that doxapram HCl (Dopram-V, A.H. Robins) is useful for arousing dogs that have been overdosed with Telazol® (Hatch et al. 1988). An approximate dose is 5 mg/kg intravenously. There are no reports available of similar testing in goats.

Althesin

Althesin (Saffan®, Schering-Plough) was previously approved as an anesthetic for sheep and goats in New Zealand. This agent contained 9 mg of alphaxalone and 3 mg of alphadolone per ml. The drug is no longer marketed in the United States or New Zealand. The dosage for healthy adult sheep and goats is 2.2 to 3 mg/kg given intravenously to produce ten minutes of surgical anesthesia. Recovery to standing occurs about twenty minutes after injection. An increased dose (6 mg/kg) has been used for disbudding kids (McKeating and Pilsworth 1984; Williams 1985). Althesin causes depression of myocardial contractility in goats (Foéx and Prys-Roberts 1972) and has been reported to cause anaphylaxis in dogs and cats due to the castor oil based vehicle.

Propofol

Propofol is another injectable induction agent with rapid onset of anesthesia, short duration of action, and smooth recovery. In a dose titration study, 5.1 mg/kg given rapidly intravenously was the median effective dose required for induction of anesthesia adequate for intubation in unpremedicated goats (Pablo et al. 1997). The mean induction time was twenty-three seconds, and twenty-seven of twenty-eight goats experienced apnea (mean duration seventy-three seconds). Another study found a dose of 4 mg/kg adequate for induction with only one of five goats experiencing apnea (Reid et al. 1993). Additional doses of propofol should be available if needed to complete induction, and ventilation should be supported if apnea persists. The dose of propofol can be reduced in sedated animals (Branson and Gross 1994). One such protocol uses intramuscular detomidine at 10 µg/kg combined with butorphanol at 0.1 mg/kg before induction with 3 to 4 mg/kg propofol IV (Carroll et al. 1998). Anesthesia can be maintained with intermittent boluses of propofol. An alternative protocol reported is induction with intravenous ketamine (3 mg/kg) and propofol (1 mg/kg) followed by infusion of ketamine (0.03 mg/kg/min) and propofol (0.3 mg/kg/min) and 100% inspired oxygen for maintenance of anesthesia (Larenza et al. 2005).

Opioid Immobilization

Etorphine and carfentanil, more commonly used for capture or immobilization of exotic species, have been evaluated in domestic goats at 5 to 40 µg/kg. Intramuscular carfentanil provides faster catatonic immobilization (five minutes or less) than does etorphine (five to ten minutes; transient struggling occurs attributed to injection site pain). Recovery is slower after carfentanil, as the goat remains recumbent for more than two hours. Blood pressure increases while heart rate decreases (Heard et al. 1996). Oral administration of carfentanil combined with detomidine results in an undesirable prolonged induction time and excitement phase (Sheeman et al. 1997).

Halothane

Halothane has been largely supplanted by newer agents but was once a popular nonexplosive anesthetic among practitioners owning a gas anesthesia machine. Halothane takes effect quickly enough that a small goat can be induced through a mask, though more often an injectable drug such as xylazine or thiamylal sodium is used in older animals (Dhindsa et al. 1970). Recovery from the effects of the gas anesthesia is rapid, and fetal depression is minimal. In light of this, halothane could be used for cesarean section when general anesthesia is desired, although isoflurane is a safer choice.

During mask induction, 4% halothane solution is administered. This takes three to four minutes with a tightly fitting face mask. A canine face mask is suitable, or a mask can be fashioned by cutting the bottom out of a 500-ml plastic bottle and padding the edges with cotton and tape. After intubation, the goat is maintained on a 1% to 2% halothane vaporizer setting at a flow rate of 1 liter of oxygen per minute. Semiclosed circuits require a greater oxygen flow rate than do completely closed circuits.

Occasionally, an acute, massive liver necrosis occurs after halothane anesthesia of seemingly healthy goats (Fetcher 1983; O'Brien et al. 1986). Signs usually occur within twenty-four hours and include depression, inappetence, salivation, teeth grinding, head pressing, and icterus. Serum levels of aspartate aminotransferase (AST), bilirubin, alkaline phosphatase, creatinine, and blood urea nitrogen levels are increased. Death typically occurs within four days. Necropsy reveals centrilobular or massive liver necrosis. In some cases, there is necrosis of the proximal renal tubules, abomasal ulceration, and hepatic encephalopathy. It has been postulated that hypotension and liver hypoxia encourage reductive metabolism of halothane, leading to production of toxic, free radicals. Although unproven, use of xylazine in conjunction with halothane may be a contributing factor because of depressive effects on the circulatory system. Prolonged anesthesia is also a risk factor. Halothane administered for forty-five to 125 minutes did not cause liver injury in young healthy goats premedicated with xylazine at 0.1 mg/kg IM (McEwen et al. 2000).

Methoxyflurane

Methoxyflurane has no advantage over halothane unless the practitioner owns only a Metophane machine. Induction and recovery are slower than with halothane. Methoxyflurane can be used to supplement nitrous oxide (4 l/minute) and oxygen (2 l/minute) in a nonrebreathing system.

Isoflurane and Other Inhalants

Depending on availability and personal preferences of the anesthetist, other agents may be used in goats. These include enflurane (Antognini and Eisele 1993), isoflurane (Ewing 1990), and sevoflurane (Larenza et al. 2005). Mask induction can be done with 3% to 4% isoflurane, with or without nitrous oxide at 50% of the total gas flow (Riebold et al. 1995). Nitrous oxide should be discontinued after induction, to avoid accumulation in the rumen. Anesthesia is maintained with a lower concentration, such as 1% to 2% isoflurane in oxygen. The concentration of isoflurane needed can be further reduced by intravenous morphine at 2 mg/kg (Doherty et al. 2004). Because these agents cause some respiratory depression, controlled ventilation is preferable to spontaneous breathing (Antognini and Eisele 1993). Portable tabletop isoflurane anesthesia units are now available and appropriate for field anesthesia situations.

Ether is undesirable because it produces profuse salivation and a prolonged, unpleasant induction and is highly flammable.

Electroanesthesia

There are several reports of the use of an alternating electric current to anesthetize goats. For instance, a 700 cycle/second alternating sine wave current of 25 milliamps and 10 volts was used for bone plating in one pregnant doe (Vijaykumar and Ramakrishna 1983). It has been suggested that electroimmobilization is unpleasant to ruminants (they show aversion in behavior trials) and also that the technique is inhumane if surgery is performed without additional local analgesia (Thurmon 1986; Trim 1987).

Acupuncture Analgesia

Beginning in the 1970s, acupuncture stimulation has been used in Western countries in both small animal and human medicine to decrease the amount of anesthetic needed or to control postoperative pain. Complex mechanisms of action have been proposed (Janssens 1988), and release of endorphins and encephalins is involved. Because acupuncture lacks sedative effects, goats with a quiet temperament or those extremely depressed because of illness presumably are most suitable for acupuncture analgesia. Otherwise, mild sedation, as with xylazine, should be considered. Few specific reports of the use of either bodypoint or earpoint acupuncture for surgery in goats have been published. Practitioners, then, should fall back on their experience with other species.

PREANESTHETIC CONSIDERATIONS AND TRANQUILIZATION

Anemia from endoparasitism is relatively common in goats. The color of the mucous membranes, specifically the conjunctiva, should be evaluated as part of the preanesthesia physical examination. Determination of a packed cell volume aids in detecting anemia if there is doubt, and it may be prudent to postpone elective surgery until after anthelmintics and good nutrition have corrected the anemia.

Preoperative starvation reduces the volume of digesta in the rumen. The activity of the microfloral population is also reduced; gas production (bloat) during surgery is then reduced. An undesirable effect of starvation is that it makes the digesta more fluid, increasing the risk of regurgitation. Lactation decreases, and there is a risk of pregnancy toxemia in late pregnancy. In general, adults should not be held off feed longer than twelve to twenty-four hours, and four hours is adequate for unweaned kids. Longer periods without food slow the recovery of ruminal activity and appetite of adults and predispose kids to hypoglycemia and hypothermia. Neonatal kids should not be fasted (Riebold et al. 1995).

Premedication with atropine is generally considered unnecessary. A dose small enough to avoid undesirable tachycardia and pupil dilation does not prevent salivation, but merely makes the saliva more viscid and more difficult to clear from the airways (Hall et al. 2001). Some anesthetists use glycopyrrolate as an antisialogogue. Rarely, therapeutic use of atropine at 0.02 mg/kg intravenously has been recommended if bradycardia develops during anesthesia (Trim 1987).

Preanesthetic sedation with acepromazine maleate (0.05 to 0.10 mg/kg intravenously), midazolam (0.4 mg/kg intravenously), or diazepam (0.50 mg/kg intravenously) has been recommended to simplify restraint and reduce the dose of drugs needed to achieve induction (Gray and McDonell 1986b; Larenza et al. 2005). These drugs are considered to cause less cardiopulmonary depression than xylazine. A chlorpromazine dosage of 2 to 2.5 mg/kg intravenously has been suggested for preanesthetic tranquilization of goats (Nawaz 1981). At decreased doses, both diazepam (0.04 mg/kg intravenously) and chlorpromazine (0.5 mg/kg intravenously) have been used to stimulate appetite in goats (Anika 1985). The positive effect on feeding lasts approximately thirty minutes.

INTUBATION

Endotracheal intubation with a cuffed tube is advisable whenever general anesthesia is induced in an adult goat to prevent inhalation of saliva and regurgitated rumen contents (Taylor 1991). A variety of rapidly acting drugs may be used to facilitate intubation. These include short-acting barbiturates, ketamine, xylazine, and halothane or isoflurane (by mask). Intramuscular administration of midazolam at 0.4 mg/kg followed by ketamine at 4 mg/kg intravenously is adequate for

Table 17.2. Endotracheal tube sizes for goats.

Weight of goat	Tube size
15 kg	5–6 mm
25 kg	7–8 mm
30–40 kg	9–10 mm
Adult dairy goat	11–12 mm

intubation (Stegmann 1998). Another option is propofol (Waterman 1988) at 3 to 4 mg/kg slowly intravenously (Taylor 1991).

Laryngospasm has been reported, especially during intubation of young goats. This potentially fatal complication can be prevented by spraying the larynx with a local anesthetic at least thirty seconds before attempting intubation (Taylor 1991). Lidocaine is preferred to benzocaine, to avoid methemoglobinemia (Reibold et al. 1995). The endotracheal tube should be left in place until coughing and swallowing reflexes are regained.

Endotracheal Tube Size

The recommendations given in Table 17.2 aid selection of an appropriate tube (Linzell 1964; Gray and McDonell 1986b). A 35-cm long tube is appropriate for an adult goat. Cuffs should be inflated for at least five minutes before induction to detect any slow leaks. It is helpful to stiffen the tube with a wire stylet, which is withdrawn when the tube is in the trachea. Alternatively, a human endotracheal tube exchanger can be preplaced and the endotracheal tube advanced over it (Bush 1996). After intubation, a wooden bite bar can be taped in place to protect the tube.

Intubation Under Visual Observation

Direct observation with a laryngoscope is considered ideal for intubation. The anesthetized goat is left in sternal recumbency, and the head is directed toward the ceiling or the goat is placed on its back with its head and neck fully extended. The latter procedure theoretically increases the risk of regurgitation occurring before intubation can be completed. An assistant holds the tongue out of the mouth using a gauze sponge for a better grip. Gauze loops also allow an assistant to hold the jaws open without being in the way (Figure 17.1). The lower gauze loop could go over the tongue. The anesthetist passes a laryngoscope with a long blade (8 to 11 inches, 20 to 27.5 cm) to behind the base of the tongue, then lifts the blade to expose the larynx and vocal cords. If a long laryngoscope blade is not available, one can be prepared by welding an extension on a shorter blade to achieve a total length of 257 mm or longer (Tillman and Brooks 1983). It is

also possible to pass a lubricated endotracheal tube via the inferior nasal meatus, although the tube diameter must be smaller than is listed in Table 17.2 and intubation forceps may be needed (Hall et al. 2001).

Blind Intubation

Blind intubation is worth learning, not only because laryngoscopes are expensive, but also because the batteries lose their charge. The goat is placed in lateral recumbency with the head in slight extension, in line with the thoracic spine. The thumb and first finger of one hand hold the tongue and lower jaw, while the other fingers of the hand press against the hard palate to hold the mouth open. The endotracheal tube is held with the other hand and passed into the pharynx with its concave side against the tongue until its tip is felt to touch the larynx. The tube is then twisted and advanced until the characteristic feel of its passage over the tracheal rings is detected (Hecker 1974).

Others prefer to advance the tube into the pharynx with its convex surface against the tongue, then rotate the tube 180 degrees to ensure that the tip of the tube is not trapped beneath the epiglottis. With this technique, which has been well illustrated by radiographic studies, the larynx is pushed upward with one hand to occlude the esophagus while the other advances the tube (Gray and McDonell 1986b).

PRECAUTIONS DURING ANESTHESIA

Judging the depth of general anesthesia requires assessment of several reflexes and, more importantly, response to surgical manipulations (Gray and McDonell 1986b). Some jaw tone persists under deep anesthesia, but swallowing motions usually mean that the anesthetic depth is lightening. Palpebral reflexes are usually lost during surgical anesthesia, but the corneal reflex is maintained at all levels. The pupils dilate during light anesthesia or when cerebral hypoxia occurs during deep anesthesia. Some authors report that the globe does not rotate in response to depth of anesthesia of the goat (Riebold et al. 1995; Riebold 2007), while others claim that it does (Hall et al. 2001).

Arterial blood pressure can be monitored as an indicator of circulatory adequacy during anesthesia (Wagner and Brodbelt 1997). The normal mean arterial pressure during anesthesia is 75 to 100 mm Hg (Riebold et al. 1995). Hypotension (defined as mean arterial pressure less than 60 mm of Hg) results in underperfusion of the brain and kidneys. An over-the-needle teflon catheter is inserted into an auricular, saphenous, or common digital artery for direct blood pressure measurement, or an ultrasonic flow detector can be placed over a limb artery (Wagner and Brodbelt 1997; Hall et al. 2001; Riebold 2007). Administering intravenous fluids and decreasing the depth of anesthesia

usually improve blood pressure. When available, a pulse oximeter attached to tongue, ear, interdigital skin, teat, rectum, or tail permits monitoring of pulse rate and hemoglobin saturation (Haskins 1996; Hodgkinson and Dawson 2007; Snyder 2007).

When anesthesia is apt to be prolonged, lateral recumbency is preferred to dorsal recumbency. Left lateral recumbency reduces the risk or regurgitation, compared with positioning on the other side (Trim 1987). While the animal is in dorsal recumbency, the weight of the rumen and intestinal contents (and the pregnant uterus) compresses the aorta and posterior vena cava and restricts movement of the diaphragm. The function of the lungs is also markedly impaired in lateral recumbency, so efficiency during surgery becomes important to the survival of the goat. Intermittent positive pressure ventilation via use of an Ambu bag and oxygen supply is helpful for correcting respiratory acidosis when general anesthesia is prolonged.

If an endotracheal tube is not used (e.g., when abdominal surgery is performed under tranquilization and local anesthesia), the goat should then be placed on a slanted surface so that the abdomen is below the thorax. This reduces the pressure of abdominal viscera on the lungs. Rumen fluid is less likely to rise to the mouth and be inhaled. At the same time, the head should be placed lower than the neck to permit saliva to drain from the mouth. Ruminal tympany can be controlled by passing a stomach tube or by centesis of the rumen with a 14-gauge needle or trocar. After surgery is complete, the goat should be propped in sternal recumbency to facilitate eructation.

During prolonged general anesthesia (longer than two hours) the goat may lose a large quantity of saliva (up to 500 ml/hour). This leads to acidosis unless intravenous replacement fluids containing sodium bicarbonate are supplied. It is also possible to collect the saliva in a bucket and return it to the goat via stomach tube after surgery (Linzell 1964). Barbiturate anesthesia is associated with a greater loss of saliva and hence of bicarbonate than is inhalant anesthesia with halothane or methoxyflurane (Edjtehadi and Howard 1978). Hypothermia is another serious problem associated with general anesthesia, especially in neonates or if the animal has been held off feed. When surgery is performed on the farm, the goat should be kept in a heated building or supplied with a heating pad, heating blanket, or lamp, or with hot water bottles until it is up and actively feeding again.

If the goat is pregnant, care should be taken to minimize the risk to the fetus (Ludders 1988). This means reducing the dosage of preanesthetics and anesthetics to the minimum necessary for the procedure, avoiding

hypoxemia and hypovolemia of the dam, using increased oxygen flow and intra-operative intravenous fluid administration, and keeping the patient warm to speed recovery. If good placental perfusion and oxygenation are not maintained, the fetus may be aborted after the anesthetic episode.

POSTSURGICAL PAIN RELIEF

It is difficult to assess pain in goats, especially if the animals are not habituated to contact with people. Goats are famous for screaming when subjected to nothing more than manual restraint, and yet do not always vocalize or show restless behavior or struggling after surgery that might be expected to cause pain. Inappetence and depression are possible indicators of pain (Hendrickson et al. 1996), as are trembling and bruxism. Analgesics are most effective if administered before pain actually develops (preemptive analgesia).

Morphine has been used as an epidural for pain relief after abdominal or limb surgery (Pablo 1993; Hall et al. 2001). Morphine binds to opiate receptors in the central and peripheral nervous system and inhibits release of pain-related neurotransmitters. Preservative free morphine is diluted in saline and administered at 0.1 mg/kg in the lumbosacral space, using aseptic technique and a spinal needle. Duration of action may be as long as twenty-four hours. Epidural bupivacaine at 1.5 mg/kg affords some pain relief but causes prolonged recumbency (Hendrickson et al. 1996). Lesser doses of bupivacaine are mixed with morphine to provide surgical analgesia and postoperative pain relief.

Intramuscular opioids have also been used, including butorphanol at 0.2 mg/kg and pethidine at 2 to 4 mg/kg (Hall et al. 2001) and morphine at 0.1 mg/kg. Buprenorphine (at 0.02 mg/kg intramuscular or intravenous) does not appear to be suitable for postsurgical pain relief, because it causes agitation and inhibits rumination (Ingvast-Larsson et al. 2007).

Fentanyl is a synthetic opioid agonist that has a short duration of action when given intravenously (Kyles 1998; Carroll et al. 1999). Transdermal fentanyl can be administered via a commercially available patch to provide more prolonged blood concentrations. Hair is clipped on the side of the neck and a 50-μg/hour patch is applied to the skin of an adult goat, under a protective bandage. The patch should be placed twelve to twenty-four hours before surgery for best effect. Because goats show variable and inconsistent absorption of fentanyl from the patch (Carroll et al. 1999), they need to be monitored closely in case additional analgesia is required.

A variety of nonsteroidal anti-inflammatory drugs have been administered to goats, often extrapolating

from pharmacokinetic and pharmacodynamic data collected for other species (Lees et al. 2004) and with the assumption that pain relief is also supplied. Salicylates are poorly absorbed from the rumen (Davis and Westfall 1972) and thus aspirin is unlikely to be very effective, even at doses as high as 100 mg/kg. Oral ibuprofen is well absorbed and an appropriate caprine dose may be similar to human doses on a mg/kg basis (DeGraves et al. 1993); however, this drug is not approved for food producing animals in the United States. Flunixin meglumine is an irritating drug that is best given intravenously but is also well absorbed orally (Königsson et al. 2003) and has frequently been given by the subcutaneous route. This is the preferred nonsteroidal drug for use in goats in the United States, because it is approved for other food animals (cattle and swine). A typical dose is 1.1 to 2.2 mg/kg once or twice a day. The extralabel use of nonsteroidal anti-inflammatory drugs in cattle in the United States has been reviewed recently (Smith et al. 2008) and the same decision-making processes for drug selection are applicable for goats.

In other countries, preference might be given to intravenous or intramuscular ketoprofen at 3 mg/kg daily (Arifah et al. 2003) or oral carprofen. The extralabel withdrawal times suggested by FARAD when ketoprofen is given to goats are twenty-four hours for milk and seven days for meat (Damian et al. 1997). Carprofen has been used in England at an anecdotal dose of 50 mg once daily for dairy goats, with a seven-day milk withholding time, and at 20 mg daily for pygmy goats (Matthews 2005). Another suggested carprofen dose is 1.4 mg/kg subcutaneously or intravenously (Hodgkinson and Dawson 2007). Very preliminary studies for meloxicam in goats suggest a dose of 0.5 mg/kg intravenously repeated perhaps every twelve hours, because goats clear the drug rapidly (Hodgkinson and Dawson 2007; Shukla et al. 2007).

EUTHANASIA AND SLAUGHTER

When euthanasia of a pet or hospitalized patient is required, overdose of an intravenous barbiturate is usually most appropriate. If an intravenous catheter is not already in place, use of a 19-gauge butterfly catheter reduces the risk of perivascular drug deposition. For commercial animals or for salvage slaughter on the farm, gunshot or penetrating captive bolt to the head is a humane alternative (AVMA 2001), as long as the operator is aware of the landmarks and the brain is not needed for rabies testing or other diagnostic evaluation. The animal is restrained with a halter and offered food if able to eat. The captive bolt gun or firearm is aimed from the top of the skull down toward the spine (Figure 17.2) or from the back of the skull, between the

Figure 17.2. Placement of captive bolt for euthanasia from the top of the head, directed toward the spine. (Courtesy Dr. M.C. Smith.)

base of the horns, toward the mouth (Figure 17.3) (Longair et al. 1991; Grandin 1994).

Goats are commonly killed by Muslim or Jewish ritual slaughter. A very sharp knife is used to cut the carotid arteries near the jaw, thereby causing rapid exsanguination, without first stunning the animal. Although ritual slaughter is exempt from humane slaughter laws in the United States (Grandin 1994), the animal should not be unduly stressed by inhumane restraint (such as shackling and hoisting upside down from a chain) before slaughter. Welfare during halal or kosher slaughter can be improved by restraining the goat in an upright position with its head and neck extended (Thonney 2007).

Dehorning and Descenting

DEHORNING

Horns have evolved in goats, as in other species, because of the protection they afford against predators and the improved social status they impart within a herd. Goats joust frequently to establish and verify social rank. The goat rears up on its hindquarters, twists its head down and to one side, and crashes against the opponent's horns. Ridges on the anterior surface of the horns help to prevent a sudden slipping or shearing motion, and neck muscles are well developed, so that fractured cervical vertebrae are avoided (Reed and Schaffer 1972). In many confrontations (e.g., when food is involved), the abrupt presentation of horns is enough to drive off a subordinate goat; however, when adults are put together for the first time or after even a brief separation, actual contact occurs.

The number of horns is variable: none (polled condition) or two horns are generally present. Goats with more than two horns (as many as eight) have been reported, and the polycerate condition is believed to be inherited (Lush 1926).

The basic anatomy of goat horns resembles that of cattle horns. Each horn is composed of closely packed tubules which are produced by corium and germinal epithelium. The corium in turn is attached to the periosteum of the cornual process of the frontal bone. The cornual diverticulum of the frontal sinus forms a cavity within the horn. The cornual artery, a branch of the superficial temporal, supplies the horn. The nervous supply is described here under disbudding.

Reasons For and Against Dehorning Goats

What is appropriate for wild goats may be undesirable in large herds or for animals in close confinement. If one goat does not acknowledge another's dominance, severe crushing injuries or lacerations may occur. Young kids may be killed by a buck or a dominant doe because they are too slow to take evasive action. If none of the goats in a herd has horns, then fewer serious injuries occur during social interactions. The total absence of horns, however, does not greatly alter social behavior. Goats still rear up and crash down toward each other, sometimes missing by the distance equivalent to two sets of horns. Young kids and subordinate does are still kept away from the feed trough, although biting of ears may be the threat used to enforce territorial rights.

One of the major reasons for dehorning goats, then, is to limit injuries inflicted on herd mates. By the same token, injuries to children and adult goat keepers can be minimized by removing the goats' natural weapons. Destruction of fences and pen partitions is slowed, and the annoying tendency of goats to stick a head through a fence, then yank back and get caught, can be almost totally eliminated. This prevents deaths by hanging and also avoids complaints from passers-by. A final reason for dehorning goats is that, in the United States, dairy goats cannot be registered or shown if they have horns. Horns are permitted in pygmy and pygora goats. It is common for meat goat shows to require that horns be tipped (blunted) if present.

A goat should not be dehorned without due consideration given to the dangers associated with the operation. A placid adult kept as a pet or family goat should not be subjected to the surgery if no children or small animals are nearby to be inadvertently injured. An animal that is destined to live its life on a tether should probably be left with horns so that it can defend itself against marauding dogs. Angora goats also usually need their horns for protection. Large bucks can be led by the horns. Removing the horns from a breeding buck may make it less able to compete with other bucks for females. The dehorned buck may also be perceived as less "macho" in some human societies and may therefore not be chosen for breeding. Finally, the stresses associated with the surgery and adverse sequelae may interfere with milk or sperm production or even cause death of the goat.

The Polled Goat Alternative

It seems logical to avoid all the problems and dangers of dehorning by simply selecting for the absence of horns. Although this works in some breeds, the U.S. dairy goats of European extraction (i.e., Saanen, Alpine, Toggenburg) unfortunately have a serious genetic reproductive disorder linked to the polled condition. In these breeds, the presence of horns is determined by a recessive gene. The polled trait is dominant but is linked to a recessive gene for infertility. A female goat that is homozygous for the polled gene develops into a sterile intersex. The homozygous polled male has an increased risk of developing sperm granulomas in the head of the epididymis. These problems are discussed in Chapter 13. Polled goats of normal reproductive potential can be obtained if one member of each breeding pair is polled and one is naturally horned; eliminating all horned goats from the breeding program results in the production of many infertile goats.

Disbudding Kids

If either parent was polled, then the kid may be naturally polled and thus not require disbudding. Some owners ignore this possibility and simply destroy skin in the place where horns would normally be while descenting the kid. For future breeding plans (to avoid intersexes), however, it is important to know whether the kid was polled. Horned kids have a twist of hair over each horn bud (Mackenzie 1975; Ricordeau and Bouillon 1969) (Figure 18.1). The skin of the horn bud is tightly affixed to the underlying bone. Polled kids have just a central whorl of hair on top of the head (Figure 18.2).

Age for Disbudding

For doe kids of European breeds, five to seven days is an ideal age for disbudding. Buck kids have larger

Figure 18.1. Horned kid with twist of hair over each bud. (Courtesy Dr. M.C. Smith.)

Figure 18.2. Polled kid with central hair whorl. (Courtesy Dr. M.C. Smith.)

horn buds than doe kids of the same age; therefore, disbudding at three to five days of age is preferable for bucks. Disbudding of kids that were very small at birth and of most female Nubians and pygmy goats can usually be delayed until two weeks, as long as the operation is performed carefully (Williams 1990).

Methods

The secret to successful disbudding is to destroy all of the corium from which horn is destined to grow. Although options include surgical removal of a circle of skin, heat cautery, and cryosurgery, only heat cautery will be discussed in detail.

Dehorning paste should be avoided; it can injure the eyes of the kid or eat holes elsewhere in the skin of the kid or other animals in contact with it. These risks can be controlled to some degree by clipping hair, applying a peripheral ring of vaseline to limit spread of the paste, and restraining the kid for thirty minutes. The

pain associated with paste dehorning persists longer than does pain from heat cautery. Occasionally, the paste even destroys the calvarium underlying the horn bud, thereby permitting penetration of bacteria to the brain.

Heat cautery is the most commonly used technique in most parts of the world. An electric dehorning iron with a tip of 3/4 to 1 inch diameter is convenient, as long as it becomes and remains hot enough (cherry red) to destroy the skin rapidly. A Rhinehart® dehorner with a half-inch tip (Hoegger Supply, Fayetteville, GA) is more appropriate for pygmy and Nigerian dwarf doe kids. Less expensive, low-wattage dehorners must be applied longer to achieve the same results, with more risk of overheating the brain. Thus, a dehorner producing 200 Watts is applied for five to ten seconds while a 125-Watt dehorner may require twenty seconds of burning (Anonymous 1988). Long extension cords decrease the heat of the iron. Clipping hair from the head improves visibility, decreases burning time, and limits smoke inhalation. When the horn bud is very small, a dehorning tip with a sharp edge can be applied with enough pressure that a ring is burned through the full thickness of the skin. The isolated central circle of skin containing the horn bud can then be lifted off (Figure 18.3). Where electricity is not available, a butane-heated calf dehorner (Portasol®, Nasco, Fort Atkinson, WI) also works well on young goats. Alternatively, a length of metal pipe of the appropriate diameter can be heated in a fire or with a blow torch until cherry red. A 25-mm steel nut can be welded onto a branding iron and heated in the same way (Baxendell 1984).

Some kids, especially bucks, are presented for disbudding when the entire horn bud no longer fits within the dehorner tip. The hot dehorner is applied with less pressure and slid around to burn a larger circle than is

Figure 18.3. Removing horn bud with butane heated dehorner. (Courtesy Dr. M.C. Smith.)

required for does. Operators should not aim for a fixed time, but instead, should check each horn bud to determine that the full thickness of skin has been destroyed. This is the case when the skin has turned copper-colored and that color cannot be scraped off with a fingernail. All of the horn corium must be within the final copper ring; the author prefers to burn the center of the ring until it, too, turns copper-colored. On buck kids, an additional crescent toward the front is also burned. If the initial burn is not adequate, then that side of the head should be allowed to cool and the dehorner allowed to reheat before continuing.

Many other variants exist. Some practitioners without a dehorning iron excise a circle of skin with a scalpel blade. Spark gap electrodesiccation with a Hyfrecator® electrosurgery instrument (previously Birtcher Corp., now CONMED Corp., Utica, New York) has produced good results for some (Koger and McNiece 1982) but regrowth of deformed horns for others (Wright 1983). Disbudding of two-day-old kids with cryosurgery has been reported to be successful and problem-free (Anonymous 1977).

Restraint and Sedation

Restraint for disbudding is done in as many different ways as the surgery itself. In the United States and Australia, disbudding is commonly done without anesthesia, whereas in Great Britain, anesthesia is required by law. In defense of the many who simply hold the kid flat on its side while kneeling on the ground or wrapped in a towel or placed in a narrow wooden box from which only its head protrudes (Williams 1990), it should be noted that all signs of discomfort disappear as soon as the hot iron is removed and the kid is released. The kid immediately resumes nursing, playing, or even sucking on the fingers of the person who held it.

If available, halothane or isoflurane administered through a face mask is an easy way to supply general anesthesia, as long as the oxygen mask is taken away before a hot iron is applied (Buttle et al. 1986). An intramuscular cocktail of injectable drugs is commonly used, such as xylazine, ketamine, and atropine (Pieterse and van Dieten 1995) or xylazine, ketamine, and butorphanol, as described in Chapter 17. Xylazine alone, at doses large enough to produce several hours of somnolence, often does not prevent vocalization during disbudding.

Nerve Block for Disbudding

Local nerve blocks can be used for anesthesia when disbudding young kids, as long as care is taken to avoid a toxic dose of the local anesthetic agent (see Chapter 17). Two nerves supply each horn (Vitums 1954; Elmore 1981). The cornual branch of the lacrimal nerve passes along the temporal line behind

Figure 18.4. Injection sites for the cornual branches of the lacrimal (a) and infratrochlear (b) nerves.

the supraorbital process, between the lateral canthus of the eye and the posterior aspect of the horn. The cornual branch of the infratrochlear nerve passes over the dorsomedial rim of the orbit before it divides into cornual and frontal branches. It can be anesthetized with a line block along the rim of the orbit dorsomedially (Skarda 1986). See Figure 18.4 for location of the nerve blocks. It is the author's preference to dilute 1 ml of 2% lidocaine with epinephrine to 0.5% lidocaine by adding 3 ml of sterile water or saline. This permits the injection of 1 ml over each of the four nerves of a young kid weighing approximately 3 kg. Dilution is not necessary if 0.25 ml of 2% lidocaine can be accurately placed over each nerve. A 1% solution of lidocaine (1 ml per nerve) can be used in older, larger kids and works better.

Dehorning Older Kids

By the time a kid is a few weeks old, a distinct nubbin of horn already extends above the surface of the skull. This horn prevents most dehorner tips from reaching the skin. Heat cautery can still be successful, but first the tip of the horn bud must be removed with a pen knife, hoof trimmer, or shears. A small Barnes calf dehorner can also be used for this purpose as long as it is opened just far enough to remove the protruding bud; a wide enough cut to remove all the skin from which horn might grow could easily go deep enough to expose the goat's brain. Next, the cautery tip is applied to the edges of the wound to achieve a full thickness burn. The tip is slid around to cover a larger area, with particular attention paid to destroying skin over the anterior ridge of the horn.

As the kid grows older, the horn enlarges and both bone and frontal sinus develop within the horn. By the time the kid is six or eight weeks old, it is often simplest to treat it as a small-scale adult and dehorn with scalpel and obstetrical wire or saw.

Dehorning Adults

When facilities are available, general anesthesia makes dehorning of the adult goat more pleasant for the surgeon. However, under field conditions when no one but the owner is available through recovery from anesthesia, sedation with xylazine or diazepam combined with local nerve blocks is an acceptable alternative. Depending on the size of the goat, 2 to 3 ml of 1% or 2% lidocaine is injected for each nerve block, as described under disbudding. There is no anesthesia to the mucous membrane and periosteum lining the horn, however, and supplemental sedation is advisable with older goats (Skarda 1987). The author finds a dose of 0.06 mg/kg xylazine intravenously suitable. Larger doses of xylazine (up to 0.1 mg/kg) have been recommended by others (Bowen 1977; Hague and Hooper 1997), but the associated risks are greater. Recovery is delayed, and supplemental heat may be necessary to avoid hypothermia in cold barns in the winter.

Hair is then clipped widely from around and between the horns, using a razor blade between the horns if necessary. It is helpful to outline the desired skin incisions with an indelible felt-tipped marker before scrubbing and disinfecting the skin. This ensures that the two incisions made will have the same proportions. Except that a narrow strip of skin should be left intact between the horns to speed healing, at least 1 cm of skin should be removed all the way around (Bowen 1977; Turner and McIlwraith 1982). Even more skin must be removed rostrally; the entire base of the ridge that rises to the rostral-medial corner of the horn should be included.

A scalpel blade is used to cut quickly full-thickness through the skin all the way around the horn and to undermine the caudal flap of skin. The person sawing is positioned in front of the goat. An assistant now holds head and horn firmly while obstetrical wire is slipped around the horn and seated in the incision on each side of the horn and under the flap (Figure 18.5). If the horn is not held back during sawing, the frontal bone may splinter. If sedation is not deep enough or too much time has elapsed since xylazine administration, the goat may vocalize or try to rise as the wire passes through the center of the horn. A flat-backed dehorning or miter saw can be used in place of obstetrical wire to remove the horn (Baker 1981). When the first horn is off, the major artery (superficial temporal) situated laterally should be pulled, ligated, or cauterized (Linzell 1964; Turner and McIlwraith 1982). Cotton or gauze is then placed over the wound while the second horn is removed. Then an electric dehorner or firing iron can be used to cauterize smaller bleeders. Blood clots should be carefully removed from the sinuses and an antibiotic or disinfectant powder or spray applied.

Figure 18.5. Use of a wire saw to removed the horns of an adult doe. (Courtesy Dr. M.C. Smith.)

An owner who watches the dehorning of an adult goat for the first time is impressed by the quantity of blood shed and the size of the holes left in skin and skull by the surgery. This is an excellent time to mention how much less stressful disbudding is than dehorning. If the owner does not observe and great efforts are made to clean up the goat and bandage its head, the owner may be left with the false impression that dehorning is normally postponed until goats mature.

Cosmetic dehorning of adult goats reduces the risks of sinusitis and myiasis, especially in warm climates (Mobini 1991). The technique is most applicable to animals with a small horn base. The skin is incised 1 cm from the base of the horn. Skin is then undermined and pulled away from the horn to permit slightly deeper placement of the obstetrical wire and facilitate subsequent skin closure. After the horn has been removed, hemorrhage is controlled and the surgical site is flushed to remove bone dust and blood clots. An antibiotic powder is dusted into the frontal sinus. Skin closure is achieved with horizontal mattress tension sutures placed well back and simple interrupted sutures at the wound edges, using nonabsorable suture material. General anesthesia, postoperative penicillin for five to seven days, and bandaging for ten to fourteen days until the sutures are removed are all advised. It may not be possible to close the incisions in goats that had very large horns. Another description of cosmetic dehorning under tranquilization and local anesthesia (Hague and Hooper 1997) suggests leaving a rim of only 1 to 2 mm of skin attached to the horn and extending the skin incision 5 to 10 mm at the craniomedial and caudolateral aspects to facilitate undermining of the skin. After removing the horn with a wire saw, the frontal bone is contoured to a smooth shape using rongeurs to allow skin closure with minimal tension and a Ford interlocking pattern.

Elastrator bands are not recommended for dehorning goats. It is difficult to keep the band in position on skin; if it slips upward, the tip of the horn falls off but growth continues at the base. Six to eight weeks are required for a mature doe's horns to fall off; pain may be intense during much of this time. Also, the risk of tetanus is increased in unvaccinated animals.

Some owners request removal of only the horn tips, to avoid the pain and prolonged healing time associated with complete dehorning. Other reasons for partial horn removal are to prevent misdirected horns or scurs from penetrating the skin, or to make meat goats eligible for showing. A radiograph identifies the extent of the horn sinus and bony cornual process. Vascularized corium extends slightly farther into the horn than the bone, and the horn should be transected distal to the corium. If there is no radiograph to guide the surgery, make an initial transection at a location where the horn feels cool to the touch, meaning that large blood vessels are not present. If an even shorter horn is desired, small sections are sawed off, working in from the tip, until a satisfactory length is obtained or a few drops of blood are observed. Xylazine tranquilization simplifies the procedure.

Postoperative Care

Antibiotic therapy is normally not necessary but should be instituted if the goat develops anorexia or fever. Routine use of a broad-spectrum antibiotic such as long-acting oxytetracycline has been suggested to prevent bacterial invasion of the brain through damaged bone after disbudding by heat cautery (Thompson et al. 2005). An analgesic such as flunixin meglumine or ibuprofen (see Chapter 17) is appropriate, especially if surgical dehorning rather than heat cautery was performed.

Bandaging

Whether the older goat's head should be bandaged depends on many factors. If the animal is to be transported home in a compact car, a bandage is certainly in order. One is likewise needed if bleeding cannot be controlled by pulling arteries and applying cautery. If the goat will be fed from an overhead hay rack, the bandage will keep hay out of the sinuses. On the debit side, any bandage that extends under the jaws is apt to make eating and rumination painful. Sinusitis may develop unnoticed under the bandage, and a dry scab cannot form until the wounds are left exposed to the air. Many dehorning wounds heal well without any bandage. In Greece, beeswax is used to cover the opening to the sinus when an adult goat is dehorned (G. Christodoulopoulos, personal communication).

If the decision is made to bandage, many options are available. One possibility is to hold the wound dressing in place with a length of orthopedic

stockinette (Bowen 1977); eye holes are cut after the two ends of the stockinette are taped around the goat's head and neck. Also easy to apply is a 2- or 3-inch wide elastic bandage (Elastikon, Johnson and Johnson, New Brunswick, N.J.) over a nonadhesive dressing; the first turn of tape around the head extends onto the skin rostral to the dehorning wounds and the second turn comes up behind one ear, then extends forward to the forehead between the eyes. Notches are cut in the tape to uncover the eyes and permit free movement of the eyelids. After one or two days, the "chin strap" (portion of the bandage below the level of the eye and ear) should be removed to lessen the tug on the wounds during chewing. The remainder of the bandage can be removed after one week (Figure 18.6). Continued use of a fly repellant is appropriate in warm seasons. Final

a

healing of the wound typically occurs in six to eight weeks, though even more time is required for large bucks. Sometimes when mature bucks are dehorned, the large holes that are created never close (Williams 1990).

Tetanus Prophylaxis

The practitioner should never dehorn a goat whose tetanus vaccination status is unknown without administering tetanus antitoxin: 250 to 300 IU to a kid and 500 IU to an adult. Death from tetanus can occur before antibodies are produced in response to an initial vaccination. Tetanus toxoid and antitoxin can be given simultaneously, as long as different syringes and different injection sites are used.

If the goat is known to have been vaccinated with toxoid (not antitoxin—many owners don't understand the distinction) then a booster dose should suffice. It is good policy to administer (and record in writing) a dose of tetanus toxoid or tetanus-enterotoxemia vaccine at the time an appointment is made for future dehorning of an adult. This permits giving the second dose in the series at the time of surgery. When the vaccination is a booster, maximum protection from a rise in titer is achieved for surgery.

Young kids normally receive adequate protection if the dam received a tetanus booster late in pregnancy and large amounts of colostrum were consumed. In disease eradication schemes that replace caprine with bovine colostrum, this protection is lacking unless a point is made of repeatedly vaccinating the donor cows. (If this is done, both tetanus and enterotoxemia vaccine should be given to the cows.) When the owner performs both vaccination of does and disbudding of kids, full dependence is generally placed on colostral protection. The practitioner who offers the service of disbudding kids might well prefer to administer tetanus antitoxin routinely rather than have to worry about the consequences of occasional failure of passive transfer.

Problems Associated with Dehorning

Tetanus is not the only disaster than can result from dehorning. Except in the very young kid, the procedure is accompanied by much stress to the goat. Selecting the time for optional dehorning of adults requires careful balancing of the relative dangers of dehorning at different times. Times to be avoided if possible include lactation (because of a likely drop in milk production) and late pregnancy (risk of pregnancy toxemia) (Bowen 1977). Winter is preferable to summer, assuming the local winters are cold enough to inhibit flies (Wright et al. 1983). In general, however, it is better to dehorn a two-month-old goat in the summer than to wait six months for winter because wound size and stress on the goat increase as the animal grows.

Heat Meningitis

Prolonged application of a hot iron to a young kid's horn buds can damage the underlying bone, meninges, or brain (Linzell 1964; Wright et al. 1984; Sanford 1989; Thompson et al. 2005). The frontal bone is thin and the frontal sinus is not yet developed at the time ideal for disbudding. Coagulative necrosis of meningeal vessels can result in thrombosis and infarction of the underlying cerebrum (Thompson et al. 2005). Problems are most apt to occur when a dehorner is not hot enough to rapidly sear the skin (Williams 1985). The longer the iron must be applied, the more heat will penetrate to deeper layers. Allowing the head to cool before finishing the disbudding is advisable if the dehorner is not very hot. Goat kids that appear unresponsive or are unable to nurse at one or two days after disbudding may have reversible damage or may be able to relearn with undamaged portions of the brain. Owners should be instructed to keep these kids warm and tube feed them if necessary. Antibiotics (in case the bone is necrotic) and anti-inflammatory agents should also be administered.

Brain Abscesses

Heat cautery or paste dehorning may destroy bone overlying the brain, thereby permitting entrance of bacteria (Figure 18.7). Too low a saw cut on a mature goat can also penetrate to the brain. The animal that develops neurologic signs referable to the cerebral hemispheres several weeks after dehorning may have a brain abscess, as discussed in Chapter 5. The prognosis is grave.

Sinusitis

Even when great care is taken to prepare the skin for surgery, infection of an opened sinus may occur. This infection may ascend from the nasal passages or

Figure 18.7. Brain abscess subsequent to bone damage by use of disbudding paste. (Courtesy Dr. M.C. Smith.)

result from foreign matter falling into the wounds. Nasal discharge, head shaking or rubbing, or an abnormal odor suggest sinusitis in the bandaged goat or in one whose sinus has already scabbed over (Turner and McIlwraith 1982). Pus in the sinus is more quickly noticed when the wounds are left unbandaged. Bandage, scabs, and any fragments of necrotic bone should be removed. The sinus should be rinsed with a mild disinfectant solution to remove all pus. Topical antibiotics (spray or mastitis infusion products) and regular cleaning usually control the infection. Depressed or febrile animals should also receive systemic antibiotics, such as penicillin.

Loss of Social Status

It is difficult to quantify the social stress experienced by the newly dehorned goat, but owners report radical upheavals and alterations in rank order in the herd as a consequence. This is especially true if a dominant individual is dehorned because it has been attacking and injuring others in the herd. When this goat has lost the means of enforcing its dominance over others, it may find itself in turn the victim of aggression. In some instances the herd behavior resembles revenge. The emotional effects on the dehorned goat may cause it to stop eating and "give up." In other circumstances, the dehorned goat is able to bite its way back to the top of the social order.

Ketosis

Decreased feed consumption, whether related to pain, infection, or loss of social status, is very dangerous to the doe in late pregnancy or early lactation. If ketosis develops, the resultant further decrease in food intake may be fatal. Does should be monitored closely in the first few days after surgery and given analgesics (aspirin 100 mg/kg orally twice daily, phenylbutazone 10 mg/kg orally once daily, flunixin meglumine 50 mg intramuscularly or orally as needed, all extra-label) if they appear to be severely depressed or in pain. Penning separate from (but within sight of) other goats and hand-feeding may encourage feed consumption. Ketosis is discussed in detail in Chapter 19.

Listeriosis

It is the author's experience that occasional goats develop clinical signs of listeriosis (i.e., depression, facial nerve paralysis, ataxia, torticollis, etc.) a few days after surgery. Presumably a latent infection has been activated by stress. Early treatment with penicillin or oxytetracycline, before signs are unequivocal, is indicated.

Scurs

The regrowth of small, deformed horns or large but rather blunt horns is a common phenomenon if corium

Figure 18.8. Scurs from incomplete disbudding of a buck kid. (Courtesy Dr. M.C. Smith.)

Figure 18.9. Location of skin to be cauterized or extirpated for descenting.

is incompletely removed (Figure 18.8). Practitioners or owners lacking experience with the disbudding procedure should expect their initial efforts to be accompanied occasionally by these aesthetically displeasing scurs. This is especially true when dealing with bucks and intersex goats. For this reason, buck kids should generally be disbudded at an earlier age than doelings, and a wider ring of skin should be removed from around the horn base of adult bucks.

The author always warns the owner at the time of surgery that scurs may occur. The first signs of regrowth are usually visible by the time the initial wound has healed. If the scur is in the form of a thin strip, like a piece of ribbon candy, the owner is instructed to keep it trimmed with hoof trimmers. Otherwise, the scur may grow around in a circle and press against the skull or the eye, requiring trimming with a (wire) saw as far back toward the head as the scur feels cool. If the scur has a broad base and is accompanied by outgrowth of bone, a second operation is performed; this, too, may be followed by scur formation. Poorly attached scurs are commonly dislodged during fighting and the skin may bleed profusely, but medical attention is rarely required. These scurs also regrow.

DESCENTING

Much of the odor of intact male goats emanates from multilobular sebaceous glands located caudomedially to the horns or the bosses of a polled goat (Figure 18.9). These scent glands are testosterone responsive, and one chemical produced has been identified as 6-trans nonenal (Smith et al. 1984). The odor of the buck is most rank during the fall breeding season (Jenkinson et al. 1967; Van Lancker et al. 2005). The scent glands and other sebaceous glands in the skin on the neck and shoulders are more active at this time of year, because
of increased testosterone secretion. The sexually active buck also urinates on his head and forelegs, but the buck odor is absent from urine. Toggenburg bucks have a stronger buck odor than pygmy goats (Van Lancker et al. 2005). Does and castrated males only rarely produce noticeable buck odor. The odor is very marked in intersexes, which are genetically female but produce testosterone.

The skin over the scent glands can be kept clipped and scrubbed to remove as much secretion as possible. If owners or neighbors have sensitive noses, the scent glands can be destroyed, although the buck is not rendered odor-free by surgery (Bowen 1981) and may be less efficient at detecting and stimulating signs of estrus.

Descenting is easiest to do at the time of disbudding. An additional crescent of skin is burned caudomedial to each horn. Some owners choose to do this to doe kids also, theorizing that the occasional doe develops a slight buck odor.

When an adult buck is dehorned, additional skin can be removed to extirpate the scent glands. During the breeding season, this hairless skin is elevated and shiny, with large pores. If dehorning is not desired or has already been done, the glands should be located and a crescent of skin surgically removed. Tranquilization and local infiltration with lidocaine provide analgesia. The edges of the wound may be cauterized to control hemorrhage. If much skin is removed, the wound edges can be sutured (Bailey 1984). Sometimes the scent glands extend to an increased distance from the horns and may be easier to locate if a triangular flap of skin (apex of the triangle on the midline 3 to 4 cm in front of the anterior aspect of the horns) is
Figure 18.10. Surgical reflection of skin to locate scent glands of mature buck. (Redrawn from Johnson and Steward 1984.)

reflected caudally (Figure 18.10). The glands are then located underneath the flap and extirpated and the skin flap is sutured back into place (Johnson and Steward 1984).

Nutrition and Metabolic Diseases

Goat keepers must assimilate much information regarding nutrition to raise healthy, productive animals. At least in the United States, some owners begin with absolutely no agricultural background. Their concept of nutrition has been molded by years of simply opening cans or bags of commercial pet food.

As a first step, one needs to learn the various nutritional requirements of the goat (i.e., energy, protein, fiber, vitamins, major minerals, trace minerals, and water) for whatever production is to be required of the goat. Types of production include maintenance, growth, finishing, gestation, milk production for raising kids, maximum milk production, and mohair or cashmere production. The educated owner can easily see analogies with regular dog food, puppy chow, and the limited diet necessary to stave off obesity in an older pet. But very rarely are goats fed a commercially prepared complete ration. After all, the importance of the goat in many parts of the world

depends on its ability to subsist and produce on whatever grows there. It becomes necessary, then, to learn the nutritional value and relative cost of feeds available locally. This information can be gained from standard references, where concentrates are concerned, but forage quality is highly variable. The American goat keeper must either learn to accurately distinguish different types and maturities of forages or make use of feed analyses to determine the nutrient content of hays and silages.

Voluntary dry matter intake is another important consideration. What is the capacity of the goat to consume various feeds? Even more important, how much can the goat eat without deranging rumen function or the goat's own metabolism? Feeding any ruminant is first and foremost a question of properly feeding a rumen vat full of bacteria and protozoa. The energy, nitrogen, and all other requirements of bacteria must be met, and all nutrients must be provided in suitable proportions and at appropriate intervals to avoid malnutrition of the microbial population or its destruction via rumen acidosis. The ruminant needs a steady diet; unlike the situation with a monogastric animal (such as man) it is not enough to just be sure that a certain number of "servings" of hay or grain, energy or protein, have been consumed during one week or even one day. Even the physical form of the feed is important because grinding and pelleting of forages tend to decrease digestibility by decreasing the time the particles remain in the rumen.

As an additional complication, the digestibility of a given feedstuff varies with the energy and protein content of other components of the ration. Also, the energy content of a given feed or ration depends on the production function for which it is to be used. These and other problems give trained nutritionists much to argue about and go far beyond the scope of this book. The current chapter can only offer a brief overview of nutrition while trying to make the specific requirements of the goat understandable to the veterinarian or owner. As the level of production of the goat increases, the feeding must also be improved, and therefore other sources of information must be consulted to permit fine-tuning of a ration. Recently, the nutrient requirements of small ruminants, including goats, have been summarized (NRC 2007). An online ration balancer and calculator for the energy, protein, calcium, and phosphorus needs of the individual animal based on the equations used by the NRC is also available (Gipson et al. 2007) and makes the data more accessible to the potential user.

One final concern is the difference between the nutrient value of the feed offered and of the feed actually consumed (Brown and Weir 1987). Normal feeding behavior of a goat involves continual picking and choosing. When high production is required, the goat must be allowed enough extra feed that it can choose what it eats. It thereby achieves an increased level of feed intake and a richer ration, but at the expense of leaving perhaps 15% to 20% of the offered forage in the manger. Knowing the analysis values for a certain alfalfa hay is not the same as knowing the nutrient content of the leaves that were picked one by one off the stems (Morand-Fehr 1981a)! Furthermore, because of normal caprine behavior, the "choosiness" of a goat usually varies with its social status in the herd unless it is housed and fed individually. The dominant goat in the herd can stand for hours at the manger, eating what she will. Meanwhile, subordinate does and kids have to grab a mouthful and run, or even pick up discarded hay off the floor. Putting enough high quality forage into the manger to exceed the requirements of all the animals present does not ensure that one or more goats will not die of starvation.

ENERGY

All discussions of nutrition seem to begin with energy, probably because this is the best defined requirement of farm animals and is expensive. In addition, shortages of energy are translated immediately into a drop in production in dairy animals. Over a longer period of time, other effects such as retarded growth, delayed puberty, and decreased fertility become apparent.

Energy Systems

Energy is expressed in many different ways and units, which vary from system to system and country to country. This lack of uniform methodology slows the acquisition and application of knowledge relative to goat nutrition (Morand-Fehr 2005). American goat keepers should become familiar with total digestible nutrients (TDN). This system assumes that the energy value of a feed depends only on its content in terms of digestible elements. Thus, TDN (expressed as a weight or as a percentage of the feedstuff) is the sum of digestible crude protein, digestible carbohydrate, and 2.25 × digestible crude fat. A single predetermined yield in energy is assumed to apply to all types of feeds, whether forages or concentrates. With this system, energy requirements can be expressed in terms of grams of TDN, kcal of digestible energy (DE), or kcal of metabolizable energy (ME).

These units are interrelated as shown in Figure 19.1 and Table 19.1. In this example, 1 kg of TDN represents 4,409 kcal of DE, and 76 kcal DE yields 62 kcal ME (NRC 1981b). In fact, the numerical relationships vary from feed to feed. From this point, a lumper can use a global yield in net energy (NE), for instance that 62 kcal ME gives 35 kcal NE. Splitters, who are prevalent in dairy nutrition, admit that the energy losses associated with various types of production vary. Within the TDN

system, one can distinguish net energy for maintenance (NE_m) with a yield of $0.72 \times ME$, NE for lactation (NE_l) with a yield of $0.60 \times ME$, and NE for growth or fattening (NE_g), with a yield of $0.45 \times ME$ (Sauvant 1981). This compares rather poorly with the global estimate of 0.56 cited above and demonstrated in Table 19.1. However, as long as care is taken to express requirements and nutritional content in the same type of NE, the results should be the same. The system does overestimate the energy value of forages compared with concentrates.

The French system, like newer American systems for cattle, is based on NE_l and NE_g, and recognizes that different feeds have different yields in energy at each stage in the digestion/metabolism process (Vermorel 1978). For instance, long stem forages are associated with more energy losses in the form of heat of fermentation and methane gas (eructated from the rumen) than are concentrates. As in the TDN system, NE_m can be approximated by $0.72 \times ME$ (although the actual range is 0.66 to 0.76). Similarly, NE_l is often assumed to be $0.60 \times ME$ (actual range 0.54 to 0.68), which corresponds to the actual yield given a typical dairy ration in which 0.57 of the ingested energy appears as metabolizable energy. For all rations, the NE_l yield is

proportional to the NE_m yield, such that net energy requirements for both maintenance and lactation can be expressed in terms of NE_l. Current French tables of nutrient composition and requirements use a new unit, the UFL, which is equivalent to 1,700 kcal of net energy for lactation (INRA 2007). The corresponding unit for net energy for growth is the UFV, equivalent to 1,820 kcal of net energy for growth.

The energy requirements for goats that will now be outlined follow French recommendations because much work has been devoted in that country specifically to the nutrition of the dairy goat. In addition, much of the original research has been summarized in one text (Morand-Fehr 1991), and updated tables are available (INRA 2007). Forage analysis reports currently available in the United States through the Dairy Herd Improvement Association and many computerized ration calculation programs also deal with NE_l. Readers who prefer the TDN system may refer to the National Research Council (NRC) publication Nutrient Requirements of Small Ruminants (2007). If goats differing greatly from European dairy breeds are to be fed, or if the climate is not temperate, then the estimates of other authors may be more appropriate (Rajpoot et al. 1981).

Maintenance

The energy required for maintenance of a goat depends in a specific way on the bw of the animal. However, this is not a linear relationship and most people without access to calculators prefer consulting a table such as NRC (2007) or INRA (2007) to working through the arithmetic. Numerous studies for various breeds and ages of goats have each produced a different equation meant to represent the energy requirements. These equations may calculate either metabolizable energy or net energy and energy units may be in either kcal (total digestible energy system) or kilojoules (SI or International System) units. One such equation (Vermorel 1978) demonstrates that the daily NE_l needed in kcal for maintenance is proportional to the metabolic weight. The weight is expressed in kilograms (1 kg is equal to 2.204 pounds) and this is raised to the 0.75 power.

$$\text{Maintenance } (NE_l) = 65.3 \times W_{kg}^{0.75}$$

Gross Energy (energy released by completely burning 1 kg of the feed)

└── energy in feces (undigested feed + endogenous products)

Digestible Energy (GE – fecal energy) = Total digestible nutrients

├── energy in urine and combustible gases (methane)

├── heat released during fermentation

Metabolizable Energy (DE – urine, gas, and heat losses)

├── additional heat associated with production (variable)

Net Energy for Maintenance NE_m | Net Energy for Lactation NE_l | Net Energy for Fattening NE_g

Table 19.2. Maintenance energy requirements for goats.

Weight (kg)	Weight (lb)	Metabolic Wt (kg)	Daily NE$_1$ (kcal)	Daily NE$_1$ (MJoule)
10	22	5.62	367	1.536
20	44	9.46	618	2.586
30	66	12.82	837	3.502
40	88	15.91	1039	4.347
50	110	18.80	1228	5.138
60	132	21.56	1408	5.891
70	154	24.20	1580	6.611
80	176	26.75	1747	7.309
90	198	29.22	1908	7.983
100	220	31.62	2065	8.640

Table 19.2 indicates the metabolic bodyweights and NE$_1$ requirements for goats of various weights using this equation as an example. It can be used in conjunction with NRC requirement tables, with 1 Mcal equal to 1,000 kcal. For countries using SI units, note that 1 kilojoule = 0.239 kcal, and 1 kcal = 4.184 kilojoules.

Recently, many equations have been summarized and used as the basis for the energy recommendations in the 2007 NRC tables (Luo et al. 2004c; Nsahlai et al. 2004a; Sahlu et al. 2004). The factor by which the metabolic weight is multiplied depends on the age and breed of goat under consideration. This in turn makes the resultant tables more accurate when applied to a given class of goats.

Environment

The energy requirements for maintenance also vary with environmental conditions (such as temperature, humidity, and wind) and with exercise. The heat of fermentation normally lost during digestion helps to maintain body temperature of ruminants in a cold environment. In fact, a goat on a high roughage diet has the benefit of an internal hot water bottle, the rumen, to keep it warm. Supplemental grain feeding further increases the heat production from the rumen, even though the proportion of the digestible energy of concentrate feeds released as heat is less. Animals without active rumen function must shiver to maintain body temperature. For this reason a "goat coat" (i.e., a sweatshirt) or a blanket is often beneficial to an animal off feed because of illness or surgery.

The thermoneutral zone (TNZ) is the temperature range in which the animal is most productive with least stress and is approximately 32°F to 86°F (0°C to 30°C) in goats (Constantinou 1987). The upper critical temperature is the upper limit of the thermoneutral zone; above this temperature the animal experiences heat stress. High producing animals, with increased metabolic heat, are more susceptible to heat stress (NRC 1981a). The lower critical temperature is the lower limit of the thermoneutral zone. The lower critical temperature varies between animals and depends on hair coat, presence of insulating fat, and level of feeding. Shearing during cold weather increases the energy needs of hair goats and often leads to deaths.

Energy requirements need to be adjusted for very cold weather. When a goat is outside its thermoneutral zone, more energy is required for maintenance. For instance, for every degree centigrade below the thermoneutral zone, an additional 0.7 could be added to the 65.3 factor in the equation given above (figure used for beef cattle) (Simons and Hand 1986). The effect of wind velocity can be crudely estimated to be equivalent to a decrease of 0.6°C (1.08°F) for each mile per hour. Thus, for a temperature 10°C (18°F) less than the TNZ in the presence of a 20-mph wind, the equivalent temperature difference would be 10 + 0.6 (20°F) or 22°C, equivalent to a difference of 39.6°F. The maintenance requirement for a 50-kg goat would then be $(65.3 + 22\,(.7)) \times 50^{0.75}$ or $(65.3 + 15.4)\,(18.8) = 1{,}517$ kcal rather than the usual 1228 kcal. Wetness causes an additional decrease in "effective temperature" below that calculated by the wind chill factor. These corrections need to be verified for goats. Perhaps an increase of 1% in the maintenance energy for each degree C below the thermoneutral zone is a reasonable starting estimate.

Adjustment in the energy density of the diet may be required, because even though voluntary intake increases in cold weather, the energy requirement for maintenance usually increases more rapidly (Ames 1987).

Activity

An increase in NE$_1$ of 20% to 25% more than the maintenance requirements for stabled animals has been suggested for goats engaged in light grazing. Animals traveling longer distances to find food and water need substantially more, but the exact amount is hard to quantify. An additional 40% more than simple

maintenance is suggested for distances of four miles a day (6.5 km), and 60% for six miles (Morand-Fehr and Sauvant 1978). The increase suggested by NRC (1981b) for long distances and great changes in altitude is 75%. Thus, a goat weighing 60 kg is estimated to need 1,408 kcal a day if it stays in the barn, 1,690 if it grazes nearby, and approximately 2,250 if it travels six miles. Activity level and energy expenditure among goats in a single herd are actually quite variable.

Lactation

The proportion of ME that is used for lactation is independent of the level of production. However, it is necessary to adjust the NE_l requirements as the fat, protein, and lactose content of the milk changes. Using a reference milk containing 3.5% fat, 3.1% protein, and 4.3% lactose, the energy requirement per kg of milk produced is 676 kcal NE_l (INRA 2007). If the fat content of the milk differs markedly from 3.5%, the NRC (1981b) recommendation to change the ME needed by 16.28 kcal for each 0.5% fat would translate to adjusting the NE_l by 12 kcal.

Growth and Weight Gain

Yearling goats are still growing during lactation, and need extra nutrients to support this growth. In addition, high producing goats lose weight (up to 7 kg [INRA 2007]) during the first months of lactation because they mobilize body reserves to produce milk. They will eventually need to regain this weight. Approximately 6 kcal NE_l is needed for each gram of live weight gain. The average mature Alpine goat replacing her reserves needs 270 kcal/day extra for this purpose (Morand-Fehr and Sauvant 1978). This represents a weight gain of 45 g/day. By way of comparison, NRC (2007) uses values of 5.52 kcal ME/g daily gain of meat and dairy kids and 6.81 kcal ME/g of weight gain for mature animals.

Gestation

There is no extra energy requirement until the last two months of pregnancy. French workers use the bw at breeding time to calculate maintenance energy for a doe and then add 830 kcal NE_l /day for the last two months. In the experimental data used to derive this, the average weight of the kids at birth was 7.6 kg; 1 kg of kid thus required 109 kcal/day extra energy. In general, if the supplemental energy for pregnancy is dropped to less than 500 kcal the goats will be prone to pregnancy toxemia, while above 1,100 additional kcal of NE_l there will be digestive accidents, difficult births, and poor milk production in the subsequent lactation (Sauvant 1981). These situations are discussed in detail later in this chapter. The current French recommendation is to multiply the maintenance energy requirement by 1.15 to 1.30 for the last two months of

gestation (INRA 2007). The current NRC tables (2007) distinguish between dairy and nondairy does carrying singles, twins, or three or more kids when determining the energy (and protein) requirements.

PROTEIN

Proteins are needed throughout life for growth and repair of the body and for synthesis of products such as enzymes, hormones, mucin, milk, and hair. As is true of monogastric animals, the ruminants' protein requirements consist mainly of amino acids that are absorbed from the small intestine. However, these amino acids come from two sources. The first is dietary protein that escapes degradation in the rumen but is digested to amino acids in the intestine. The second source is microbial protein. Almost all soluble protein, any nonprotein nitrogen, and approximately one-third of the insoluble protein in the diet are broken down in the rumen to release ammonia. This represents 40% to 70% of the nitrogen in green forages and 45% to 65% of the nitrogen in mixed rations. If energy supplies are adequate, this ammonia is then built into protein by rumen microbes. The microbes pass out of the rumen and are killed by the acidity of the abomasum. The dead microbes become available for digestion into amino acids in the intestine.

Because the rumen microbial population synthesizes all of the amino acids essential to a goat, sheep, or cow from dietary protein and nonprotein nitrogen and sulfur, the amino acid composition of the feedstuffs is relatively unimportant. However, for maximum milk production it is advantageous to supply some additional amino acids in the form of rumen undegradable protein or rumen protected amino acids. For dairy cattle, methionine and lysine are considered to be the most limiting amino acids relative to high milk production. Fishmeal as a bypass protein is a good source of methionine but heat treated soybean meal is not. Zinc-methionine and zinc-lysine chelates have been used to supplement these amino acids in dairy cattle (Kung and Rode 1996). There is very limited evidence that supplementation with protected methionine or lysine improves milk production in goats that are not deficient in zinc (Salama et al. 2003; Madsen et al. 2005; Kholif et al. 2006; Poljicak-Milas and Marenjak 2007). The possible benefits of additional cysteine and methionine for fiber growth are discussed below, under Special Consideration for Feeding Angora and Cashmere Goats.

Protein Systems and Requirements

Protein requirements for the goat were originally expressed in terms of total crude protein, which is simply determined by multiplying the nitrogen content of the feed by 6.25. This figure is used because most proteins contain 16% nitrogen. Nonprotein nitrogen

(NPN) substances in the feed thus enter into the calculation as if they were true protein, but this is not a serious flaw because the rumen microbes can transform NPN into protein. The previous NRC for goats (1981b) computed protein requirements from a simple calorie-to-protein ratio. Thus, the tables in this publication required 32 g of total protein for each Mcal of digestible energy. Efforts to express requirements in terms of digestible protein (apparently digested protein, determined by subtracting fecal nitrogen from dietary nitrogen) are not believed to be more accurate because metabolic fecal nitrogen (i.e., digestive enzymes, sloughed epithelial cells, etc.) comprises a variable proportion of the total fecal nitrogen. Also, ammonia released in the rumen in excess of what the microbial population can use for synthesis is absorbed into the bloodstream. This ammonia is converted by the liver to urea, some of which is recycled into the rumen by diffusion or via saliva so that it may be used between meals when the rumen ammonia levels fall, but some is lost in the urine.

When high production is desired it is necessary to refine the protein requirements beyond crude protein and digestible protein. Ruminants need both rumen degradable and rumen bypass protein (Waldo and Glenn 1984; Eastridge 1990). Newer systems for goats specify protein requirements in terms of metabolizable protein (MP). MP is defined as the true protein, derived from a combination of dietary and microbial protein, that is digested postruminally and from which the constituent amino acids are absorbed from the intestine (NRC 2007). The recent NRC (2007) determines metabolizable protein (MP) requirements from equations summarized by Sahlu et al. (2004) and others (Luo et al. 2004a; Nsahlai et al. 2004b) and available online (Gipson and Goetsch). The protein requirement for goats of various classes is expressed in grams MP/day but also converted to a crude protein requirement that depends on the proportion of the dietary protein that is rumen undegradable (UIP, undegradable intake protein). The formula used for the conversion of metabolic protein to crude protein is

$$CP = MP/((64 + (0.16 \times \% \ UIP))/100)$$

Beyond the protein required for maintenance (expressed on a metabolic weight basis), goats need additional protein for growth (0.29 g MP/g average daily gain for dairy and indigenous goats, 0.40 g MP/g daily gain for meat goats). Each g of milk protein requires 1.45 g MP, while each g of clean mohair fiber requires 1.65 g MP. Further protein is required for growth of the mammary gland, uterus, and fetuses during pregnancy.

The 2007 NRC composition tables specify CP, MP, and often UIP for each feedstuff. For forages, actual values determined by laboratory testing often give a better approximation of protein content than do book values. Overheating that occurs when hay is stored too wet or silage is stored too dry results in complexing of sugars with amino acids that reduces the digestibility of nitrogen. This nitrogen ends up in the acid detergent fiber fraction during forage analysis (Eastridge 1990). Some laboratories determine available protein (or adjusted crude protein) on forages to reflect this loss in feed value.

The amount of microbial protein formed with each feed actually depends on whether energy or nitrogen is the limiting factor for microbial reproduction and growth. Thus, with most concentrates, there is more than enough energy in the feed to fix ammonia released from rumen digestion into microbial protein; the nitrogen supply is what limits bacterial growth. With many forages not all of the ammonia liberated can be fixed because of an energy shortage, and the unused nitrogen is lost to the body, mainly through the urine.

Recent French composition tables give two metabolizable protein figures for each feedstuff (Morand-Fehr and Sauvant 1978; INRA 2007). One indicates the sum of digestible protein escaping the rumen and of the microbial protein that could be formed if all of the nitrogen released in the rumen could be converted into protein (PDIN in French usage, i.e., if energy were not limiting). The other (PDIE) is the sum of alimentary protein digested in the intestine and of the microbial protein that could be formed if all of the energy available for the rumen organisms could be used for their growth (i.e., if nitrogen were not limiting). When a single feed is fed, it is the smaller of the two values that represents the metabolizable protein. However, when feeds are combined, the ruminant (and the nutritionist) can add up all the PDIE values to give a global PDIE for the ration and can likewise obtain a global PDIN. If PDIE exceeds PDIN, it may be possible to add NPN to make use of the excess available energy, assuming that this can be done in such a way that the ammonia supplied and the energy released from digestion of carbohydrates are present simultaneously in the rumen. If PDIN exceeds PDIE, the diet could be better balanced by adding more energy or removing some nitrogen, depending on which of these options gives better economic results. Protecting some of the dietary protein from degradation in the rumen (as by heat or formaldehyde treatment) so that it can be digested in the intestine is one way of avoiding nitrogen losses associated with excess PDIN.

Milk Urea Nitrogen

Dairy cattle nutritionists pay close attention to milk urea nitrogen (MUN), the portion of the measured milk protein that is derived from blood urea nitrogen rather than casein or whey proteins. Ammonia pro-

duced during digestion that is not converted into microbial protein is absorbed from the rumen and converted to urea in the liver. This urea is recycled via saliva into the rumen but diffuses into milk. High MUN values are seen when too much crude protein or rumen degradable protein is fed relative to fermentable carbohydrate (Roseler et al. 1993) or when rumen acidosis slows microbial protein production. Low MUN values suggest that there is not enough ammonia produced in the rumen for optimum microbial growth, as might occur with inadequate rumen degradable protein intake. High MUN has also been associated with reduced conception rates in cows, though some say that this adverse effect actually reflects the presence of phytoestrogens in the soybean products that are typically the source of excessive dietary protein in the dairy cow studies (Piotrowska et al. 2006). Normal MUN values for cows are approximately 8 to 14 mg/dl. A brief report of MUN evaluation in dairy sheep on varying diets produced a range of average MUN values from 26 to 56 mg/dl (Cannas et al. 1995).

Little research has been done relative to interpretation of MUN in goats. Brun-Bellut et al. (1991) proposed a normal range of 28 to 32 mg/dl. A study comparing Alpine goats fed alfalfa hay or pasture and varying levels of concentrates found a range of MUN values of 18 to 22 mg/dl (Min et al. 2005). When varying amounts of tallow were added to the diet in another study, the MUN varied from 24 to 26 mg/dl (Brown-Crowder et al. 2001). In a long-term study that compared a forage based diet with one formulated with sunflower seeds, cassava, coconut meal, and cottonseed, the MUN was lower for the forage diet (approximately 15 mg/dl) than for the nonforage diet (approximately 30 mg/dl), even though milk yield was similar (Bava et al. 2001). It seems apparent that MUN values in goats are generally higher than those reported for dairy cattle. A French study that evaluated 2083 milk samples from 260 goat herds found an average MUN of 47 mg/dl, with 90% of the values falling between 35 and 55 mg/dl (Jourdain 2005). The author concluded that the average MUN values were too similar across feeding systems and the individual values too variable among goats on the same diet for the test to be useful for guiding ration adjustment. Some laboratories routinely test goat milk for this component without calibrating the equipment for goat milk, which further complicates interpretation of results.

How nutrition might influence true milk protein content in dairy goats has been reviewed by Chamberlain (1997).

Urea Toxicity

As is commonly done with dairy cattle, urea can be fed to goats as a nonprotein nitrogen source because rumen organisms can convert it to microbial protein if adequate energy sources are available (Harmeyer and Martens 1980). Much of the urea that reaches the plasma (absorbed from the gastrointestinal tract or produced in the liver) is recycled to the rumen via saliva.

Pathogenesis and Epidemiology

Toxicity is expected to occur if 30 to 50 g urea/100 kg bw is consumed in a single meal by an unadapted or hungry ruminant. This is because the urea is degraded to ammonia and excessive nonionized ammonia in the rumen diffuses out into the bloodstream. Toxic levels are reached when the liver's ability to convert ammonia back into urea is overwhelmed. The citrate cycle is inhibited by the ammonia (Lloyd 1986).

Improperly mixed feed and urea fertilizers are potential sources for toxicity. Nonprotein nitrogen is particularly dangerous when animals are fed high fiber diets lacking readily digestible carbohydrate. In one instance, a goat and other livestock at a fair died after drinking water contaminated by transport in a tanker that usually hauled a liquid fertilizer composed of urea and ammonium nitrate (Campagnolo et al. 2002).

Clinical Signs

Toxicity in small ruminants (Fujimoto and Tajima 1953; Obasju et al. 1980; McLennan et al. 1987; Ortolani et al. 2000) typically occurs within one hour after ingestion, and death after a few hours. Signs include muscle and skin tremors, salivation, frequent urination and defecation, incoordination, dyspnea, loud bleating, bloat, tetany or convulsions, and death. Laboratory findings include elevations in blood packed cell volume, potassium, phosphorus, and urea nitrogen. Sometimes, but not always, the rumen fluid pH exceeds 7.5 (Lloyd 1986), and ammonia concentration in rumen fluid exceeds 500 ppm (Ortolani et al. 2000, Campagnolo et al. 2002).

Treatment

The best antidote available is 0.5 to 1 liter of vinegar (typically 5% acetic acid), which may be given by stomach tube to decrease rumen pH (Osweiler et al. 1985). A potentially equivalent vinegar dosage is 10 ml/kg. At a lower pH, the ionized ammonium ion diffuses less readily through the rumen wall into the circulation, and free ammonia already in the blood may actually return to the rumen. If the goat is already in tetany, emergency surgery to empty the rumen has been suggested as the one method that might possibly save the animal's life (Bartley et al. 1976). Intravenous lactated Ringer's solution (for its acidifying effect) and B vitamins have also been proposed, among other

treatments, as beneficial in treating animals with chronic consumption of excess urea (Hazarika et al. 2002).

Prevention

In the absence of PDIN/PDIE values for dietary components used by French nutritionists, other guidelines may be used to predict a safe level of urea use. For instance, in American literature there is often a statement that urea should not exceed 1.5% of a finished (total) ration (Adams 1986). It has also been recommended that urea supply no more than one-third of the total crude protein (CP) in forage or roughage diets and that it be no more than one-half of the CP in the concentrate part of the ration (NRC 1981b; Fernandez et al. 1997). At least three weeks are required for the rumen microflora to adapt to such a high level of urea feeding, and therefore, gradually increasing the concentration of urea in the feed is advisable. Not all goats are willing to eat grain containing so much urea (Skjevdal 1981).

FIBER

Insoluble dietary fiber is indigestible or slowly digesting organic material of feeds that occupies space in the digestive tract (Mertens 2003). Fiber is mostly cell wall material consisting of cellulose, hemicellulose, and lignin. Different roughages contain different amounts of these constituents. During analysis procedures, roughages are subjected to several treatments that distinguish these constituents (Figure 19.2). Thus, acid detergent fiber (ADF) is a measure of cellulose plus lignin, while neutral detergent fiber (NDF) represents the total cell wall content. Because pectin in the cell wall is highly soluble and lost from the NDF fraction, fiber is underestimated in pectin-rich feeds such as alfalfa or citrus pulp. The difference between ADF and NDF is essentially the hemicellulose content of the roughage. Laboratories usually calculate the energy value of a feed from the ADF and a formula appropriate for the class of feedstuff.

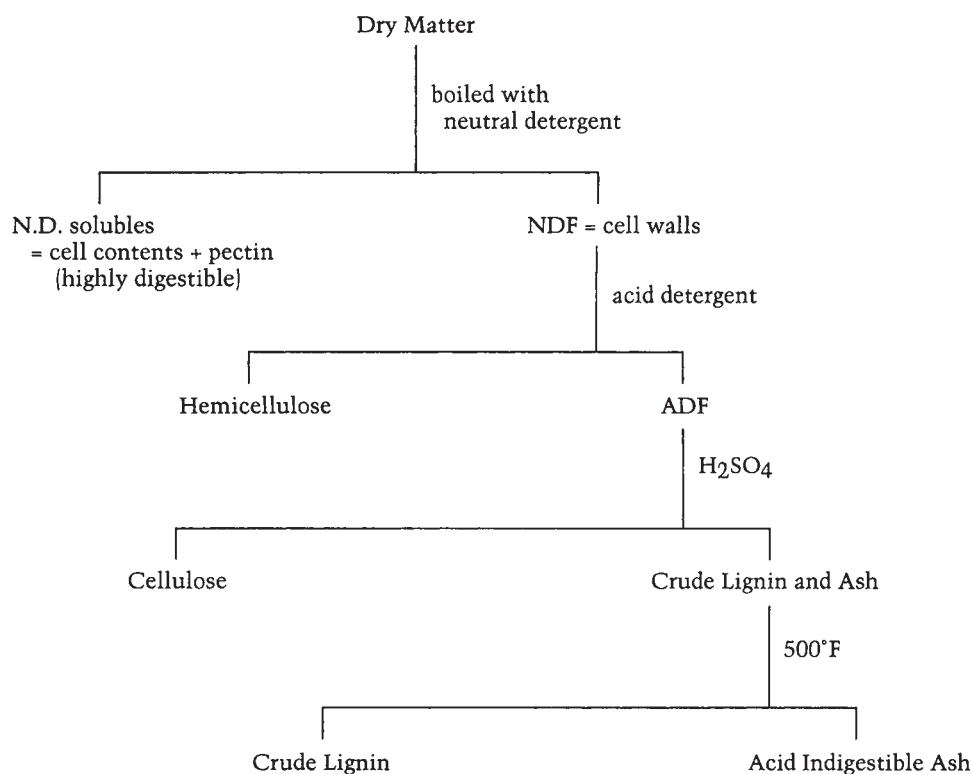
The goat, like other ruminants, is able to digest fiber such as cellulose and hemicellulose into volatile fatty acids by means of fermentation in the rumen. There is conflicting evidence whether goats are more efficient at digesting fiber than are other species of ruminants. In some instances, the apparent superiority of the goat to survive on poor roughages is because of its ability to choose the most digestible parts of the plant. Lignin in the cell wall bonds to cellulose and imparts structural strength to the plant as it matures, but markedly reduces its susceptibility to microbial digestion in the


Figure 19.2. Laboratory scheme for fiber analysis. ND = neutral detergent, NDF = neutral detergent fiber, ADF = acid detergent fiber.

rumen (NRC 2007). Mature grasses with increased lignin content have lowered digestibility.

Goats undoubtedly have a requirement for fiber to maintain healthy rumen function and butterfat production (Santini et al. 1991, Lu et al. 2005). Little research data is available to document exactly how much NDF or ADF should be included in a goat's rations. Meanwhile, recommendations for dairy cows (more than 25% NDF and more than 19% ADF) may be used as a starting point. One recent paper suggests 18% to 20% ADF or 41% NDF for high producing lactating dairy goats, and 23% ADF for growing kids (Lu et al. 2005). Particle size is also important, because it determines the time required for mastication and the amount of saliva produced to buffer rumen contents.

VITAMINS

The fat-soluble vitamins are important in goat nutrition, as they are in the feeding of other domestic animals and humans. Water-soluble vitamins other than thiamine and niacin are generally ignored when formulating caprine rations.

Vitamin A

Beta-carotene is the standard dietary precursor of vitamin A, although some other carotenoids also have biological activity. Previously (NRC 1981b), 1 mg of beta-carotene was judged to be equivalent to approximately 400 IU vitamin A. Currently recommended conversions are 671 IU of vitamin A/mg of beta-carotene and 436 IU/mg of other common carotenoids such as cryptoxanthine in yellow corn (NRC 2007). As little as 10% of dietary beta-carotene escapes degradation in the rumen. Absorption, metabolism, and storage of the remainder require a healthy digestive epithelium and liver (Ferrando and Barlet 1978).

Vitamin A can also be expressed as retinol equivalents (RE), where 1 IU = 0.3 µg of retinol. The biopotency of 1 RE for goats is expressed as the vitamin A activity of 1 µg of all-*trans* retinol, 5 µg of all-*trans* beta-carotene, or 7.6 µg of other carotenoids with vitamin A activity (NRC 2007). The vitamin A requirement tables in this reference book use the RE unit. The RE can be converted back to IU of vitamin A by multiplying by 3.33, thus 1 RE = approximately 3.33 IU of vitamin A.

Signs of Deficiency

Poor appetite, weight loss, unthrifty appearance with a poor hair coat, night blindness, and a thick nasal discharge have resulted from experimental vitamin A deficiency in goats (Schmidt 1941). Especially in young animals, a deficiency predisposes to diarrheal and respiratory disease and to parasitism. To further compound the problem, kids with coccidiosis have an increased vitamin A requirement because of impaired absorption. Adult goats may have a decreased fertility rate (related to inadequate steroid hormone synthesis) in addition to an increased susceptibility to disease. Vitamin A deficiency may promote desquamation of urinary epithelium and nidus formation with subsequent urolithiasis (Schmidt 1941).

Dietary Recommendations and Supplementation

The NRC applies sheep requirements to goats. According to its 2007 recommendations, the daily maintenance requirement is 31.4 RE/kg body weight or 104.7 IU/kg. The 50-kg goat at maintenance should receive 1,570 RE or approximately 5,235 IU of vitamin A/day while the 90-kg goat needs approximately 9,423 IU. To this is to be added 45.5 RE/kg (152 IU/kg)/day for late pregnancy and 100 RE/kg (333 IU/kg) for growing goats. The NRC 2007 additional requirement for lactation is now 53.5 RE/kg and disregards the level of milk production. A simplified recommendation from the French is 5,000 IU vitamin A/kg dry matter of feed across the board (Morand-Fehr 1981b). Browse and green leafy hays are good sources of vitamin A, while old or weathered hay is a poor source. After six months of storage, all beta-carotene in hay has been destroyed (Ferrando and Barlet 1978). Vitamin A palmitate is commonly added to mineral mixes and commercial concentrates. Because vitamin A is fat-soluble and stored in the liver and other body fat, the adult goat can tolerate several months of low carotene intake without developing clinical signs of deficiency. Vitamin A toxicity does not occur when natural diets are fed but could occur with mixing errors. A maximum of 6,000 µg of retinol/kg bodyweight/day is recommended (NRC 2007).

Colostrum is a very rich source of vitamin A, and before its consumption kids have minimal stores. When kids receive colostrum from does that are primiparous (decreased concentration of vitamin A), or only limited amounts of colostrum, an oral vitamin A palmitate supplement is desirable. Injectable vitamin A is less valuable because of rapid peroxidation at the injection site.

Vitamin D

There are two principal forms of vitamin D. The first is vitamin D_2 (ergocalciferol) that is obtained from irradiation of the plant sterol ergosterol. Vitamin D_2 is thus abundant in sun-cured hay. The second form, vitamin D_3 (cholecalciferol), is found in liver oil from marine fishes, but it is also synthesized in the mammalian epidermis under the influence of ultraviolet light. One mg of either D_2 or D_3 is ascribed an antirachitic activity of 40,000 IU.

The metabolism of vitamin D_3 involves several steps. First, it is carried from the skin or digestive tract to the liver, where it is transformed to 25-hydroxy-cholecalciferol. Next, it passes to the kidney where a

second hydroxylation creates 1,25-dihydroxycholecal-ciferol. This metabolite acts as a steroid hormone in increasing phosphorus absorption and inducing synthesis of calcium binding hormone in the intestine. Synthesis of 1,25-dihydroxycholecalciferol is stimulated by any decrease in blood calcium or phosphorus levels and by parathyroid hormone.

Signs of Deficiency

The effect of 1,25-dihydroxycholecalciferol on bone metabolism is important but complex. It stimulates both the fixation and release of calcium and phosphorus from the skeleton. Young, growing animals raised in dark conditions, whose dams were similarly housed and deprived of a vitamin D supplement, develop rickets. Signs include bowed limbs, enlarged joints, stiffness, and a rachitic rosary on the ribs. Growth rate and body condition are poor. Adults deficient in vitamin D develop osteomalacia or osteoporosis, especially if dietary Ca and P are not properly balanced. Blood calcium and phosphorus levels may be decreased, but this is not a consistent finding (Ferrando and Barlet 1978). See Chapter 4 for further discussion of metabolic bone diseases.

Dietary Recommendations and Supplementation

The exact vitamin D requirements for goats have not been determined. A level of 5.6 IU/kg bw/day has been recommended for both sheep and goats (NRC 2007). The NRC recommends an additional 54 IU/day for every 50 g daily weight gain and 213 IU/day for late pregnancy, and allows 760 IU/kg of milk produced. Colostrum is rich in vitamin D_3, and goat milk contains approximately 20 IU/liter. If adults are on pasture or fed much sun-cured hay, their needs should be easily met. Stabled animals fed much concentrate, especially if high milk producers, need a supplement.

Vitamin D Toxicity

Excess vitamin D activity from certain toxic plants (Mello 2003) such as yellow oat grass (*Trisetum flavescens*, Braun et al. 2000) in Europe and day-blooming jasmine (*Cestrum diurnum*) in the southeastern United States causes calcinosis of tendons and other soft tissues. The same effect can be had by large overdoses of oral or injectable vitamin D supplements (Singh and Prasad 1989).

Vitamin E

Vitamin E (1 mg dl-alpha tocopheryl acetate = 1 IU) is present in colostrum, milk, and many natural feeds, especially green forage. Ruminants do not synthesize vitamin E, but require it in their diet (Van Metre and Calan 2001). Its main action is as an antioxidant; it stabilizes polyunsaturated fatty acids, vitamin A, and various hormones and enzymes. Vitamin E and selenium are closely interrelated; a deficiency of one can be at least partially offset by increasing the intake of the other.

Signs of Deficiency

Vitamin E deficiency alone can cause nutritional muscular dystrophy (white muscle disease). This is most likely to occur with feeding of silage or old hay, because the vitamin is lost in storage. Kids may have muscle disease at birth and be too weak to suckle (Kolb and Kaskous 2003). Sudden death related to Zenker's necrosis of heart muscle or diaphragm may occur, even in kids with normal selenium status (Byrne 1992). Inhalation pneumonia can also result from muscle weakness of the larynx and pharynx. Affected kids are sometimes noted to cough or have milk run out the nose after drinking. Kids may also develop muscle stiffness after exercise. The diagnosis of nutritional muscular dystrophy is discussed in Chapter 4. Fastest growing animals are at the greatest risk.

Adults may show poor uterine involution and retained placenta. Undesirable milk flavors related to oxidation of milk fat might be expected to occur with vitamin E/selenium deficiency. Ventral edema of Angora goats (see Chapter 3) has also been associated with vitamin E deficiency.

Vitamin E is also very important for optimizing immune responses. Beneficial effects have been demonstrated in ruminants on phagocytosis by polymorphonuclear cells and on cell mediated immunity (NRC 2007). Obviously, increased incidence or severity of infectious diseases is a very nonspecific sign of vitamin E deficiency, but is part of the reason for recent increases in the dietary recommendation.

Plasma vitamin E concentrations of less than 1.5 µmol/l (65 µg/dl) in preparturient does and less than 1 µmol/l (43 µg/dl) in suckling kids have been associated with increased risk of myopathy (Jones et al. 1988). A normal range in goat serum of 60 to 150 µg/dl has been proposed by the Colorado Veterinary Diagnostic Laboratory (Van Metre and Callan 2001). Note that the blood sample needs to be handled very carefully (no hemolysis, rapid refrigeration and removal of the plasma or serum from the erythrocytes) if accurate results are to be obtained. Liver vitamin E concentration can also be determined and may better reflect the nutritional status of the animal (Liesegang et al. 2008). A normal caprine liver concentration of greater than 250 µg/100 g wet weight has been proposed (Van Metre and Callan 2001).

Dietary Recommendations and Supplementation

In the absence of selenium deficiency, the daily requirement of vitamin E for preventing nutritional muscular dystrophy in preruminant lambs and calves,

and presumably, kids was previously given as 0.1 to 0.3 IU/kg bw (Ferrando and Barlet 1978). This was to be doubled when feeding milk replacers. Later, it was advised to add 25 to 50 mg of vitamin E/kg of concentrate for adults and 50 to 100 mg/kg of concentrate for kids (Ferrando and Barlet 1978). Note that vitamin E is relatively nontoxic and 75 IU/kg bw daily is presumed safe (NRC 2007). The current recommendation of 10 mg/kg bw daily (NRC 2007) takes into account the diverse functions of the vitamin beyond prevention of mypoathy.

Vitamin E is oxidized by iron (or copper) in the feed, and thus diets with high iron content may have less vitamin E available. Rapidly growing green plants have a high content of polyunsaturated fatty acids (PUFAs) and animals on lush pasture also have a higher need for antioxidants such as vitamin E because of increased incorporation of PUFAs into cell membranes and thus increased susceptibility to lipid peroxidation (Van Metre and Calan 2001). Oil seeds also contain high concentrations of PUFAs.

The vitamin E content of colostrum depends on the nutrition of the dam during pregnancy. At the end of the winter, when most goats in temperate climates kid, the hay cut the previous year is very low in vitamin E. Supplementation of the pregnant doe is important for optimizing kid health.

Some injectable preparations such as vitamin A and D include vitamin E as an antioxidant to stabilize the other fat-soluble vitamins; the quantity of vitamin E is inadequate for therapeutic purposes. Similarly, some vitamin E/selenium preparations contain relatively little vitamin E. Injectable preparations of vitamin E alone are available, with labeled recommendations of 600 to 900 IU to lambs at birth or weaning and 1,200 to 1,500 IU to ewes prepartum or at lambing.

B Vitamins

B vitamins are normally synthesized in adequate amounts by rumen microbes and thus supplementation of the adult goat's diet is not required. Colostrum is a good source of B vitamins. Older kids that do not yet have a fully developed rumen may need a dietary source of B complex vitamins, and supplementation of milk replacers is advisable. B vitamins also should be added to the diet or administered by injection to sick animals and those with poor rumen function or marked change in diet (NRC 1981b). Dietary supplementation with niacin is sometimes recommended for prevention of pregnancy toxemia (see below). There is currently no evidence that additional biotin promotes hoof health in goats (NRC 2007). Supplementation of periparturient does with rumen-protected choline may increase milk production, although the effect likely reflects dietary methionine availability (D'Ambrosio et al. 2007).

There are two instances in which B vitamin deficiency assumes primary clinical importance. The first is when a cobalt deficiency prevents synthesis of adequate vitamin B_{12}; this is discussed under cobalt requirements. The second problem is polioencephalomalacia, which can be caused by a thiamin (vitamin B_1) deficiency and results in severe neurologic signs. In this disease, rumen microbes fail to synthesize adequate thiamin or a toxic fern provides a thiaminase (Pritchard and Eggleston 1978) or, more commonly, an abnormal population of rumen microbes produces a thiaminase (Thomas et al. 1987). An excessive proportion of concentrates to roughage in the ration predisposes to polioencephalomalacia, as described under indigestion and rumen acidosis. In addition to the changes in rumen microbes that occur with grain feeding, decreased rumen pH values optimize the action of bacterial thiaminase (Brent 1976). Polioencephalomalacia is considered in detail in Chapter 5.

MAJOR MINERALS

The major minerals to be discussed are calcium, phosphorus, magnesium, potassium, sulfur, sodium, and chloride. The literature on mineral nutrition of dairy goats has been reviewed by Haenlein (1980) and Kessler (1991).

Calcium

Approximately 99% of the calcium in the body is found in the skeleton in combination with phosphorus (Ca:P ratio of 2.2:1). The remainder of the calcium is very important for diverse body functions, including muscle contraction, neuromuscular excitation, and blood coagulation. Absorption of calcium in the proximal small intestine involves calcium binding protein. Absorption is regulated by 1,25-dihydroxycholecalciferol, which is synthesized in the kidney from vitamin D. Parathyroid hormone increases osteolysis, while calcitonin (from the thyroid gland) decreases osteolysis. These hormones are in turn regulated by the blood calcium concentration. The normal serum calcium concentration for goats is approximately 9 to 11.6 mg/dl (4.5 to 5.8 mEq/L).

Signs of Deficiency or Excess

Young, growing kids are subject to retarded growth and rickets if calcium intake or vitamin D is inadequate, as discussed in Chapter 4. If doelings are bred when too young or too small, especially if they are carrying the weight of multiple fetuses, it is common to have bowing of the limbs and lameness develop because of high calcium requirements and inadequate calcium intake.

Veterinarians must be aware of related and clinically similar problems in the same type of animal (Anderson and Adams 1983) and in young, rapidly

growing kids (Baxendell 1984). In this instance, the animals develop metabolic bone disease (epiphysitis) because of excessive calcium intake, often in the form of oyster shell or similar supplement to a legume hay.

A severe imbalance of calcium and phosphorus (relatively too much phosphorus from a mostly grain diet) can cause osteodystrophia fibrosa in goats, discussed in Chapter 4. The lower jaws are enlarged but soft and rubbery, with medial angulation of the crowns of the cheek teeth (Andrews et al. 1983). Rarefaction of all bone and long bone fractures may also occur. Clinically, this problem often occurs when the owner increases the grain in the diet with the thought of speeding the young goat's growth.

The occurrence of milk fever (periparturient hypocalcemia) in goats is discussed below. Lactation diets low in calcium lead to decreased milk production.

Dietary Requirements and Supplementation

Intestinal absorption of calcium is quite efficient for preruminants but probably less than 40% in adults when forage is the calcium source; realistically, the figure is approximately 30% (Kessler 1991). The most recent NRC (2007) uses an absorption coefficient of 0.45. Absorption rates are increased from inorganic sources such as calcium monophosphate and calcium chloride. When calcium intake is decreased, absorption efficacy increases (though usually not above 45%). Absorption decreases rapidly if intake is high. Legumes and cruciferous plants are typically rich in calcium, as are bone meal and fish meal. Dicalcium phosphate, ground limestone, and oyster shells are alternate sources. Little is known regarding calcium absorption in goats, and thus values established for sheep are used. It is best to include a wide margin of safety in stating mineral requirements in general, and this is particularly true of calcium, which is relatively inexpensive.

The calcium contained in milk is readily absorbed by the kid, but forages and concentrates are less available sources. After weaning, the calcium requirement of kids depends markedly on expected growth rate. For instance, according to the NRC (2007), a 20-kg dairy doeling needs 1.4 g calcium/day at maintenance but 5.1 g/day if gaining 150 g body weight/day. As a doeling matures and its growth rate drops, so does the daily calcium requirement. The absorbability of calcium (and phosphorus) varies with the feedstuff, and recent French composition tables report both total and absorbable values, rather than assuming one generic absorbability coefficient. According to the French (INRA 2007), doelings need 2.3 g absorbable calcium/day during the first three months of life. They need approximately 1.8 g absorbable calcium/day during the sixth month, for maintenance and growth.

A mineral supplement must never be recommended for the growing goat without first ascertaining if the current dietary intake is deficient or excessive. A good quality mixed legume/grass hay and modest quantities of grain usually provide balanced calcium and phosphorus intake.

Adult goats at maintenance need approximately 3.5 to 6 g of calcium in the diet/day for goats weighing 50 to 100 kg (Morand-Fehr and Sauvant 1978). This requirement can be expressed on a metabolic weight basis as 0.19 g calcium per $kg^{0.75}$ (Kessler 1981). Skeletal growth, mineralization of the fetuses, and milk production all increase the goat's need for calcium. The NRC (1981) allows only 2 grams per day extra for late pregnancy, while French recommendations have varied from an extra 6 grams total dietary calcium per day (Morand-Fehr and Sauvant 1978) to 1 to 1.1 g additional absorbable calcium (INRA 2007). Current NRC (2007) recommendations take into account the litter size. If dietary sources are inadequate during pregnancy, the goat can draw on its skeletal reserves at this time, as long as an increased intake during lactation permits repletion of the reserves.

Goat milk contains approximately 1.4 g of calcium/kg (NRC 1981b), and the NRC (1981) suggests feeding 2 to 3 g/liter, depending on the fat content of the milk. This assumes a more efficient absorption of calcium than might be expected from forage sources, and thus the French use a value of approximately 4 g/liter to calculate requirements. Others have made a similar recommendation of 4.3 g per kg milk (Kessler 1981). (See Table 19.3.)

Phosphorus

Phosphorus is required for both soft tissue and bone growth. It plays an important part in nucleic acid synthesis, energy metabolism, and acid-base balance. The normal serum phosphorus concentration is approximately 4.2 to 9.8 mg/dl for adult goats and 8.3 to 10.3 mg/dl for juveniles (Sherman and Robinson 1983).

Signs of Deficiency

Clinical signs of a deficiency include slowed growth, pica (appetite for abnormal substances), an

Table 19.3. Summary of major mineral requirements for dairy goats (Kessler 1981).

| | Daily Requirement (g) | | | |
	Ca	P	Mg	Na
Maintenance per $kg^{0.75}$	0.19	0.14	0.045	0.045
Lactation per kg milk	4.3	1.7	0.7	0.5
Late pregnancy supplement	6	1.5	0.5	0.5

Ca: calcium; P: potassium; Mg: magnesium; Na: sodium.

unthrifty appearance, and decreased serum phosphorus levels. As with calcium, a temporary phosphorus deficiency in the adult can be met from body reserves, but milk production decreases with a prolonged deficiency.

Dietary Recommendations and Supplementation

Phosphorus is absorbed mainly from the small intestine but also from the stomachs. Phosphorus absorption is much more efficient than and is independent of calcium absorption. The true absorption coefficient of phosphorus for goats seems to be higher than for sheep. The NRC (2007) uses a value of 65%, Meschy (2000) uses 70%, and other texts propose that 64% to 75% of dietary phosphorus is typically absorbed. Some natural phosphates are relatively insoluble and poorly absorbed. Goats recycle phosphorus efficiently through saliva (NRC 2007).

The maintenance requirement is 2.5 to 5 g dietary phosphorus/day for goats weighing 50 to 100 kg (Morand-Fehr and Sauvant 1978). On a metabolic weight basis, this has been expressed as 0.14 g phosphorus per $kg^{0.75}$ (Kessler 1981). For late pregnancy, an additional 1.5 grams per day is in order. Goat milk contains 0.84 to 2.1 g P/liter, which can be supplied by adding to the diet 1.4 to 2.1 g P/liter milk produced. A suitable average is 1.7 g P/kg milk. The growing doeling needs a total of 1.4 g absorbable P/day during the first month of life and 2.4 to 2.5 grams absorbable P/day from months three to six (INRA 2007) or 1.4 g total P/day above maintenance to support a weight gain of 150 grams per day (NRC 1981b, 2007).

Animals fed a large quantity of concentrates, which typically contain 3 to 5 g P/kg, usually have adequate phosphorus intake, and in this instance a relative calcium deficiency may occur. In general, the Ca:P ratio in the diet should not be less than 1.2:1 (2:1 for males). Grazing goats rarely develop a phosphorus deficiency because of their tendency to browse varied and phosphorus-rich plants.

Magnesium

Magnesium has received far less study than have calcium and phosphorus, although the metabolism of these minerals is interrelated. Approximately 62% of body magnesium is deposited in bone, 37% in cells, and 1% in extracellular fluid (Stelletta et al. 2008). Magnesium is required for many enzyme systems (including those necessary for energy metabolism and for synthesis of RNA and DNA) and for normal neuromuscular function (Hoffsis et al. 1989).

Signs of Deficiency

The normal serum magnesium concentration for goats is 2.8 to 3.6 mg/dl (see Chapter 4). Hypomagnesemic tetany typically occurs if the serum level drops below 1.1 mg/dl (Stelletta et al. 2008). An average serum concentration of 0.79 mg/dl was reported in five goats with uncharacterized clinical signs of hypomagenesemia in India (Vihan and Rai 1984). Serum calcium may be low because magnesium is required for the release and action of parathyroid hormone (Hoffsis et al. 1989).

A magnesium deficiency may lead to anorexia or hyperexcitability. Hypomagnesemia is sometimes referred to as grass tetany. Although review articles such as Martens and Schweigel (2000) report clinical signs in dairy animals that include decreased production, teeth grinding, salivation, tetany, seizures, recumbency, and death, actual case reports in goats are lacking. Experimental magnesium deficiency has caused poor growth and reduced feed efficiency in West African dwarf goats (Aina 1997). Goats can compensate somewhat for a dietary magnesium deficiency by decreasing output of both milk and urine.

Dietary Recommendations and Supplementation

The percent magnesium absorption probably varies considerably with the diet and is not regulated by a hormonal feedback system (Martens and Schweigel 2000). NRC (2007) has proposed using an absorption coefficient of 0.20. Much is thought to be absorbed from the forestomachs (Poncelet 1983; Martens and Schweigel 2000), and transit time that is too rapid or a potassium excess may hinder magnesium absorption. A wide margin of safety is desirable. The possible contribution of a magnesium excess to urolithiasis in males, however, must not be ignored. Grasses growing rapidly in cool, wet weather or after heavy fertilization are often low in magnesium and high in potassium. Forages containing less than 0.2% Mg on a dry matter intake (DM) basis have been associated with hypomagnesemic syndromes in ruminants (Hoffsis et al. 1989). Whole goat milk also occasionally supplies inadequate magnesium, and kids might develop tetany if not supplemented (Hines et al. 1986).

There is little goat specific data available from which to calculate dietary requirements. AFRC (1998) and the French suggest using the levels indicated for sheep. For an animal that weighs 60 kg, then, total daily intake of magnesium is 1 g for maintenance (approximately $0.045 g/kg^{0.75}$), plus 1.5 g for late gestation. The approximate magnesium supplement needed per kg of milk is 0.7 g (Kessler 1981). When additional magnesium is needed in the diet, it is often supplied at MgO, although $MgCO_3$, $MgSO_4$, and $MgCl_2$ are other, although less palatable or more laxative possibilities. On spring pastures, provision of NaCl in loose or block form helps to counter high dietary potassium and maintain absorption of magnesium from the rumen. A magnesium source can also be mixed with the salt.

Potassium

Potassium is the major intracellular cation in the tissues of the goat. Although large amounts of potassium are required for health, this mineral is normally present in abundance in forage-based diets and is well absorbed.

Signs of Deficiency

Possible signs of potassium deficiency include reduced feed intake, poor growth, and reduced milk production. Severe deficiencies may cause emaciation and muscle weakness. Dietary potassium is also important in the maintenance of plasma sodium concentration.

Dietary Recommendations and Supplementation

Potassium levels of 0.5% of the diet for growing kids and 0.8% for lactating goats have been recommended, based on requirements for other ruminant species. Lush forages with high potassium content can contribute to the development of hypocalcemia and hypomagnesemic tetany by antagonizing magnesium absorption from the rumen (Underwood and Suttle 1999).

Salt, Sodium Chloride

Ordinary diets are more apt to be deficient in sodium than in chloride.

Signs of Deficiency

Goats that lack sodium may lick dirt. They also may show reduced growth and feed intake and reduced milk production with increased butterfat concentration (Schellner 1972). Goat milk from European breeds contains approximately 0.4 g/kg sodium.

Dietary Recommendations and Supplementation

Dietary sodium recommendations of $0.045 \text{ g/kg}^{0.75}$ and 0.5 g/kg milk have been specified (Kessler 1981). The goat normally will eat salt to supply its sodium requirement, then stop. Sodium chloride can be provided free choice or mixed with the feed at 0.5% of the complete ration dry matter. A higher inclusion rate in feed is often used to promote water intake and diuresis to prevent urolithiasis. Either blocks or loose salt can be used. Consumption is typically increased with a loose salt but the goat that needs more salt is willing to chew on a block to get it. A mild excess only leads to increased water consumption and urination. However, high consumption of salt results in high salt content in the manure, which in turn can inhibit plant growth when the manure is used as a soil amendment. Excessive consumption of salt prepartum may contribute to udder edema, as it does in cattle.

When salt is used as a vehicle for trace minerals or medicaments and is fed free choice, it is important that the goat have no other source of sodium (plain salt or bicarbonate of soda) to satisfy its cravings. Goat keepers who offer a smorgasbord of supplements are ascribing greater nutritional wisdom to the goat than it actually possesses.

Sulfur

Sulfur is important in body proteins because it occurs in sulfur-containing amino acids such as methionine and cystine. The sulfur content in hair is especially high. Dietary supplementation of cashmere goats with dl-methionine increased hair yield much more than it increased cashmere yield (Ash and Norton 1987).

Signs of Deficiency

Salivation, lacrimation, and alopecia are reported with marked sulfur deficiency (NRC 1981b, 2007). A less severe deficiency may cause poor growth rate.

Dietary Recommendations and Supplementation

An S:N ratio of 1:10 is commonly recommended (NRC 1981b). This is necessary to meet the growth requirements of rumen microorganisms and thereby assure increased production by the goat. The presence of increased levels of tannins in certain range plants may interfere with sulfur availability (Gartner and Hurwood 1976). Likewise, if feeds are grown on certain deficient soils or if a high proportion of NPN is fed (Bhandari et al. 1973), supplementation of the ration with sodium sulfate or ammonium sulfate may be required. A sulfur concentration of 0.15% of ration dry matter with classic rations and 0.20% with rations high in NPN is appropriate. More recently, the estimated sulfur requirements have been increased to 0.22% for maintenance, gestation, and growth of goats and 0.26% for lactating goats, with a S:N ratio of 1:10.4 (NRC 2007).

Large excesses of sulfates interfere with trace mineral (copper and selenium) absorption and have been implicated in the development of polioencephalomalacia (Rousseaux et al. 1991; Gould 1998). Extrapolating from recommendations for cattle and sheep, the maximum tolerable dietary sulfur level in high concentrate diets is 0.30% and 0.50% if the diet contains at least 40% forage. Drinking water should contain less than 600 mg sulfate/L for high concentrate diets, whereas 2,500 mg sulfate/L is acceptable with higher forage intake (NRC 2005).

TRACE MINERALS

Trace minerals are needed in smaller quantities than are major minerals, but are still indispensable for the health of the goat. Requirements have been reviewed by Lamand (1981) (see Table 19.4). Other authors make slightly different suggestions. In particular, the AFRC

Table 19.4. Summary of trace mineral requirements of goats (Lamand 1981; Kessler 1991; Meschy 2000).

Element	Deficiency limit	Diet requirements, standard diet	Diet with interference from other minerals
Cobalt	0.07	0.1	0.1
Copper	7	10	14
Iron	15	30	30
Iodine	0.15	0.6	1
Manganese	45	40–60	120
Molybdenum	0.1	0.1	0.1
Nickel	0.1	1	1
Selenium	0.1	0.1	0.1
Zinc	45	45–50	75

Measured in mg/kg dry matter (parts per million).

Technical Committee (1998) proposes similar levels for most of the trace minerals but a lower requirement of only 0.05 mg/kg diet for selenium.

Cobalt

Cobalt is a component of vitamin B_{12}, and in the absence of cobalt rumen microorganisms cannot synthesize this essential vitamin. Vitamin B_{12} is required as a coenzyme for methyl malonyl-CoA mutase, needed for the transformation of propionate to succinyl CoA, which then can enter the citric acid (Krebs) cycle. Methionine synthase is also vitamin B_{12} dependent (Underwood and Suttle 1999).

Signs of Deficiency

Signs of cobalt deficiency include inappetence, poor production, weight loss, weakness, and anemia. Diarrhea is noted and is related to disequilibrium of the digestive flora, which also need cobalt, and to increased susceptibility to strongyles. White liver disease (i.e., hepatic lipodystrophy associated with low vitamin B_{12} levels in sheep; see Chapter 11) has been reported in young goats in New Zealand and responded to vitamin B_{12} injections and pasture topdressing with cobalt (Black et al. 1988). The condition has also been produced experimentally in young goats (Johnson et al. 2004).

Dietary Recommendations and Supplementation

For sheep, 0.1 mg/kg DM (ppm) of cobalt in the diet is probably adequate and 1 mg/kg ensures maximum vitamin B_{12} levels. Goats presumably have similar requirements, although several authors have found goats to be less sensitive to cobalt deficiency than sheep (Clark et al. 1987). A dietary level of 0.11 mg/kg DM has been specifically recommended for goats (NRC 2007). Some studies suggest that this level is

marginal, as demonstrated by improved growth of young goats when supplemented with injectable vitamin B_{12} (Kadim et al. 2006). In regions where the soil is deficient in cobalt, commercial trace mineralized salt mixtures may not supply enough cobalt to meet the goat's needs (Mackenzie 1975). Cobalt chloride or cobalt sulfate can be added to the salt at a rate of 12 g/100 kg salt (NRC 1981b). Slow release rumen bullets or boluses may be an alternative to dietary supplementation or top-dressing of deficient pastures with cobalt salts (Underwood and Suttle 1999; Radostits et al. 2007).

Copper and Molybdenum

These two minerals are closely interrelated. High molybdenum (above 3 mg/kg) in the feed results in a relative copper deficiency, probably through formation of copper-molybdenum complexes in the tissues.

Signs of Deficiency

Inappetence, poor growth, weight loss, and decreased milk production are nonspecific signs of copper deficiency (Anke et al. 1972) related to decreased cytochrome oxidase activity. Anemia occurs because ceruloplasmin is required to mobilize stored iron for synthesis of hemoglobin and myoglobin. Decoloration of the hair occurs because a copper-containing enzyme is necessary for melanin production. Swayback and enzootic ataxia in kids (see Chapter 5) are related to defective myelination. Cardiac insufficiency is probably due to a combination of problems, including inadequate cytochrome oxidase activity and anemia. Osteoporosis and spontaneous bone fractures are also related to effects on copper-dependent enzymes. Abortions and stillbirths also occur. In addition, copper is required for proper function of the immune system.

Dietary Recommendations and Supplementation

Deficiency symptoms occur when dietary copper is less than 7 mg/kg and molybdenum is normal. A suitable level for ration formulation is 10 to 20 mg/kg DM (Lamand 1978; AFRC 1998), and it is generally recommended to keep the Cu:Mo ratio above 2:1 and below 10:1 (Buck 1986). Excessive calcium and sulfur both interfere with copper absorption (Senf 1974), as does excessive dietary iron (Schonewille et al. 1995). With feeding of corn silage or sulfur, dietary copper should be at least 14 mg/kg. Note that copper oxide is only one-third as digestible as copper sulfate. When the basal diet is deficient in copper or contains markedly excessive amounts of molybdenum, copper oxide wires (Copasure, Butler, Columbus, Ohio) administered orally in a gelatin capsule provide long-term (six-month) supplementation because they lodge in the abomasum and release copper slowly (Lazzaro

2007). An injectable supplement containing chelated copper is available in the United States labeled for goats (Multimin USA Inc., Porterville, California).

Copper Toxicity

Adult goats are not as susceptible to copper toxicity as sheep (Søli and Nafstad 1978), in part because of lower uptake by the liver (Meschy 2000). Liver copper stores are approximately ten times lower in normal goats than in sheep and cattle. In a toxicity study, hepatic copper concentrations were six to nine times higher in three-month-old lambs than kids (Zervas et al. 1990). A deficiency of molybdenum (less than 0.1 mg/kg (Kessler 1991), then, does not generally induce copper toxicity but rather interferes with normal growth and fertility (Anke et al. 1978). Also, goats can safely consume a trace mineralized salt preparation formulated for cattle or a horse grain mix, whereas this is dangerous for sheep. Young kids, however, are sensitive to increased copper levels in the feed (Morand-Fehr 1981c). One example of copper toxicity was reported in young Angora goat kids receiving milk replacer formulated for calves (10 mg/kg copper on a DM basis) in New Zealand. The kids died of a copper-associated hemolytic crisis (Humphries et al. 1987). It is likely that the preruminant kid absorbs copper more efficiently than does the adult goat. Fatal hepatic necrosis without hemolysis has also occurred in adult goats fed an improperly formulated mineral mix (Cornish et al. 2007), as discussed in Chapter 11.

Fluorine

Although fluorine is now viewed as an essential mineral (Kessler 1991), deficiency apparently does not occur under natural conditions. Excessive fluoride compounds from feed, water, and soil cause a chronic toxicosis in goats. Fluorosis is discussed in Chapter 4.

Iodine

In the absence of adequate iodine, the thyroid gland synthesizes an uniodinated inactive prehormone rather than thyroxine. In response to lower thyroxine levels the pituitary gland secretes thyroid stimulating hormone (TSH). As a result, the thyroid gland hypertrophies and produces the clinical condition goiter.

Goats may produce kids with goiter on the same property where sheep and their lambs remain healthy. This is because the goats' browsing habits result in less soil ingestion compared with the grazing sheep.

Signs of Deficiency

In addition to the goiter, signs of deficiency include birth of weak or dead kids and a poor hair coat. Kids may appear "dumb" or unwilling to suckle. Growth rate of kids is reduced, as is the fertility of does. These problems are discussed in Chapters 3 and 13.

Dietary Recommendations and Supplementation

The requirements of ruminants can usually be met by feeding 0.8 mg/kg iodine to lactating females and 0.5 mg/kg to the remainder of the herd (Lamand 1978; NRC 2007). Cruciferous plants increase the iodine requirement to 2 mg/kg in the ration dry matter for lactation and 1.3 mg/kg for other animals. Iodized salt is a simple way to prevent deficiency, but it should not be force fed. A maximum tolerable dietary iodine level of 50 mg/kg has been established for cattle and sheep, with the proviso that the iodine concentration in the milk of animals on such a diet may be undesirable for humans (NRC 2005). Owners should likewise be discouraged from feeding large quantities of kelp and other concentrated iodine supplements.

Iron

Hemoglobin and myoglobin contain iron, as do some enzyme systems such as cytochrome oxidase and catalase. Grazing animals rarely develop iron deficiency except in association with continual blood loss. Bloodsucking strongyles (*Haemonchus*) and bloodsucking lice (especially in Angoras) can create such a situation. An increased proportion of *Allium* (onion-type) plants in the diet can also cause iron deficiency because *n*-propyl disulfide in these plants induces hemolytic anemia.

Signs of Deficiency

An iron deficiency causes a microcytic or normocytic hypochromic anemia (reduced mean corpuscular hemoglobin concentration in anemic animals). Appetite is often reduced. A copper or cobalt deficiency may cause similar signs. Anemia is discussed in Chapter 7.

Dietary Recommendations and Supplementation

The current recommendation for dietary iron for goats is 35 mg/kg dry matter (ppm) in the ration of pregnant and lactating goats and 95 mg/kg diet for growing goats. An additional 5 mg/kg has been proposed for Angoras to support mohair production (NRC 2007). If supplementation is necessary it is useful to know that the iron in ferrous sulfate and ferric citrate is more available than that in ferric oxide. The maximum tolerable dietary level of iron is 500 mg/kg (NRC 2005).

Young kids on an all milk diet routinely become deficient and can be treated with injectable iron dextran if diet modification is not possible. A dose of 150 mg iron dextran/kid at two- to three-week intervals has been recommended (Bretzlaff et al. 1991). Such supplementation is not needed if the kids have access to solid feed (Wanner and Boss 1978). Anaphylaxis occasionally occurs after repeated injections of iron dextran and can be fatal (Ladiges and Garlinghouse 1981).

Manganese

Signs of manganese deficiency in goats include reluctance to walk, deformed forelimbs (caused by defective cartilage formation), excessively straight hocks, and reduced fertility (including silent estrus) or abortion in does (Anke et al. 1977a). Buck kids appear to show a greater depression in growth rate than doe kids when fed an extremely manganese-deficient diet (1.9 mg/kg) (Hennig et al. 1972). The recommended dietary level for goats by various authors has ranged from 20 to 120 mg/kg (NRC 2007), but 60 mg/kg allows for interference with absorption, as by excess calcium.

Nickel

Nickel is required by goats, but a deficiency is unlikely to occur under normal management conditions. Signs of experimental deficiency include skin disease typical of zinc deficiency, death of kids, and decreased first service conception rate in adults (Anke et al. 1977a, 1977b). An increase in feed intake and hence in growth rate was seen in kids when a basal corn based diet containing 0.3 mg/kg nickel was supplemented with chelated nickel (Adeloye and Yousouf 2001).

Selenium

Selenium deficiency occurs when the soil in a locality is deficient (less than 0.5 mg Se/kg of soil) and locally harvested feeds are fed (less than 0.1 mg Se/kg of feed) (Meschy 2000; Radostits et al. 2007). Selenium deficiency has occurred in animals and humans (Levander 1988) in many parts of the world, including the United States, China, Finland, New Zealand, and Australia.

Signs of Deficiency

Many selenium deficiency signs are identical to those of vitamin E deficiency, as mentioned earlier. Nutritional muscular dystrophy, which can be caused by either vitamin E or selenium deficiency, is discussed in detail in Chapter 4. Experimental selenium deficiency (less than 38 μg/kg DM) has produced lowered reproductive efficiency (apparent lowered conception rate) and decreased production of milk, milk fat, and milk protein in the following lactation (Anke et al. 1989). Selenoproteins act as antioxidants and are also involved in the conversion of T_4 to T_3 (Underwood and Suttle 1999; Surai 2006).

Increased supplementation with vitamin E masks a mild selenium deficiency. Potential selenium deficiency problems can be identified in clinically normal animals by evaluating their glutathione peroxidase status, because selenium is required for GSH-Px formation (Radostits et al. 2007). The activity of this enzyme in erythrocytes declines under conditions of selenium deficiency. Normals have not been well established for goats, but are discussed in Chapter 4. Analysis for glutathione peroxidase is typically performed on blood collected in EDTA and kept refrigerated until processed by the laboratory. Serum can be tested instead of erythrocytes, and serum GSH-Px activity changes more rapidly in response to alterations in selenium status (Wichtel et al. 1996).

Some diagnostic laboratories determine whole blood selenium instead; deficiency can be suspected if the goat has less than 5 μg selenium/dl blood (less than 0.05 mg/kg). Serum selenium concentrations less than 0.05 mg/kg have also been deemed to indicate deficiency (Puls 1994). Liver selenium content of animals that die or are slaughtered can be used to monitor the selenium status of the herd. Concentrations of 0.25 to 1.20 mg/kg wet weight are adequate, while concentrations of 0.01 to 0.10 mg/kg wet weight are deficient (Puls 1994). Maternal liver stores of selenium are decreased in advanced pregnancy as transfer to the fetus occurs (El Ghany-Hefnawy et al. 2007). When conversion of units is necessary for interpretation of laboratory reports, it helps to know that 1 μg selenium/dl is equivalent to 0.127 μmol/l.

Dietary Recommendations and Supplementation

Selenium should be present in the diet at a minimum of 0.1 mg/kg of feed. Some but not all commercial ruminant feeds are supplemented with selenium, but the level of supplementation in the United States is controlled by law. Sodium selenite and sodium selenate are permitted. Feed mills cannot add more than 0.3 mg/kg selenium to a complete ration for cattle or sheep or 90 mg/kg to a sheep salt-mineral mix, nor should the maximum daily intake of added selenium for sheep exceed 0.7 mg/head/day (Federal Register 1987; FDA 2004). A feed mill also cannot "fill a prescription" for an increased level of selenium supplementation.

Organic forms of selenium are more bioavailable than inorganic compounds for cattle, sheep, and goats, and transfer better into blood, colostrum, and milk (Aspila 1991; Surai 2006). Supplementation of goat diets with selenium yeast is specifically permitted in the United States, with up to 0.3 mg/kg added selenium in this form allowed in complete feeds (FDA 2005). In the European Union, the maximum allowed selenium inclusion rate in the ruminant diet is 0.568 mg/kg, and feeding selenium yeast at ten times this level did not result in toxicity (Juniper et al. 2008). However, dairy goats receiving 0.5 mg/kg dietary selenium had markedly elevated glutathione peroxidase concentrations, suggesting that this level of supplementation is excessive (Dercksen et al. 2007).

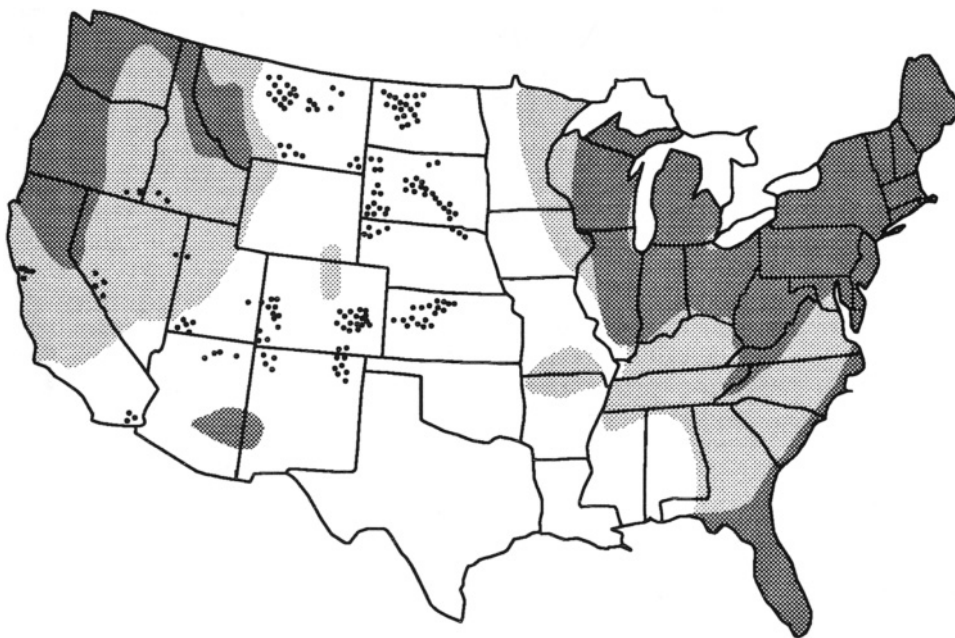
When the soil, and hence the roughages and grains grown on it, are deficient in selenium, several methods have been used to improve selenium content of feeds for goats. One is to use sodium selenate in fertilizer mixes applied to the fields. In Finland, this practice has increased the selenium content of feeds from 0.02 mg/kg DM to 0.2 mg/kg DM (Aspila 1991). Another technique is to use a foliar application of sodium selenite to growing plants approximately one week before harvest (Aspila 1991).

In selenium deficient regions, selenium by injection has been used as an alternative to oral supplementation (Kessler et al. 1986). It is common to incorporate a prescription vitamin E/selenium preparation into a herd health program at the times of year just prior to when deficiency symptoms are most likely to develop. These include shortly before breeding and four and/or six weeks before parturition for does, twice a year for bucks, and at birth and one month of age for kids. The dose administered is typically one to two times the labeled sheep dosage, with kids of normal size receiving the "minimum" dose at birth instead of two weeks of age. Because injectable selenium preparations available in the United States are not labeled for goats and

are labeled as not for use in pregnant sheep, practitioners should be cautious about prescribing them for pregnant goats without informed owner consent. Excretion of injectable selenium supplements is rapid and this route of administration does not provide the even and dependable supply ensured by daily dietary selenium.

Selenium Toxicity

There is a relatively narrow margin of safety with selenium; the maximum tolerable level in the feed of ruminants is currently estimated to be 5 mg/kg (NRC 2005). Certain soils are termed "seleniferous" because of an increased selenium content, and certain indicator plants require and accumulate increased concentrations of the mineral. Some of these plants found in the United States are *Stanleya*, *Haplopappus*, and some species of *Astragalus*. They are very useful for indicating that the soil is dangerous, but they are not the only plants that accumulate toxic levels. Most crop plants, grasses, and weeds can accumulate as much as 50 mg/kg selenium when grown on seleniferous soils (James and Shupe 1986). The map in Figure 19.3 gives an approximation of where selenium deficiency or toxic-

Figure 19.3. Regions of the United States with deficient or toxic levels of soil selenium. Redrawn from: Ammerman and Miller (1975).


Selenium availability:

▓ Low--80% of all forage and grain contains less than .05 ppm

▒ Variable--approximately 50% contains more than .1 ppm

☐ Adequate--80% contains more than .1 ppm selenium

· Local areas where accumulator plants contain over 50 ppm

ity might be expected to occur in the United States (Ammerman and Miller 1975). Local extension services can usually supply more detailed soil maps to guide the decision for or against selenium supplementation, when locally grown feeds are fed.

Acute selenium toxicosis (depression and dyspnea) has been produced experimentally in sheep with injections of 0.4 mg Se/kg bw, and the LD_{50} in this study was 0.7 mg Se/kg. Necropsy lesions included pulmonary edema and myocardial necrosis (Blodgett and Bevill 1987). Practitioners must guard against accidentally substituting an injectable selenium product marketed for adult cattle for the lower concentration calf and sheep product when small kids are treated. Selenium is less toxic when given orally. Daily oral doses of sodium selenite at 1 mg/kg body weight/day were nontoxic to growing Nubian goats, whereas a single dose of 40 mg/kg or two daily doses of 20 mg/kg were rapidly fatal (Ahmed et al. 1990).

Adverse reactions (deaths and abortions) in several flocks of pregnant sheep have led to the relabeling of injectable selenium in the United States as not for use in pregnant sheep. These products are not approved for goats, and thus the practitioner who prescribes injectable selenium for pregnant goats may be at increased risk of legal action should any adverse reactions or unrelated abortions occur.

Zinc

Zinc is required for formation of certain metalloenzymes, including alcohol dehydrogenase, alkaline phosphatase, carbonic anhydrase, and superoxide dismutase (Underwood and Suttle 1999).

Signs of Deficiency

The major metabolic abnormalities associated with a deficiency are caused by a blockage of protein synthesis, DNA synthesis, and cell division. Zinc deficiency in goats is reported to cause parakeratosis (see Chapter 2), joint stiffness, excessive salivation, swelling of the feet and deformities of the hooves, small testes, and low libido. Reduced feed intake and weight loss also occur. Appetite is said to return within a few hours after zinc supplementation.

Dietary recommendations and supplementation

Minimum dietary zinc requirements seem to be 10 mg/kg ration. Addition of excess calcium to the diet (but not the calcium in legumes) interferes with zinc absorption, as does excess sulfur. Male goats may require more zinc than female goats. Rapid intestinal transit time decreases absorption (young grass, ground feed). A reasonable feeding level to allow for variable absorption in different rations is 45 to 50 mg/kg. Organic forms such as chelated zinc methionine are not superior to inorganic salts as dietary sources of zinc (NRC 2007).

A proposed maximum tolerable level in the feed is 300 to 500 mg/kg (NRC 2005). Note that a 20% solution of zinc sulfate, as used in footbaths for sheep, can cause acute abomasal necrosis if drunk, apparently because the solution causes closure of the esophageal-reticular groove and the zinc passes directly into the abomasum (Dargatz et al. 1986). In sheep, a single dose of 200 mg zinc/kg bw may be fatal.

WATER

The normal body water content of a goat exceeds 60% of its live weight. With certain desert-adapted breeds water may reach 76% of body weight (Shkolnik et al. 1980). These goats can graze far from a water hole because they can store a three- to four-day supply of water in the rumen. Extracellular water includes blood, lymph, and water in the digestive tract. Intracellular water is rather constant, while extracellular water decreases with conditions that cause dehydration.

Water requirements are met by drinking but also from water in ingested feed and metabolic water released as energy stores are oxidized. Water is lost from the body in feces, urine, and milk. Evaporation of water from the lungs and skin is very important for temperature control in hot climates. Water intake increases markedly with elevated ambient temperature, while dry matter intake decreases under these conditions. Very cold water or eating snow as a water source increases energy requirements. The temperature of the rumen fluid may not return to normal until more than two hours after a cold drink. Water consumption increases with salt intake.

Goats in confinement generally drink three to five times daily. Lactating goats typically ingest 3.5 to 4 kg of water for each kg of dry matter consumed at environmental temperatures below 59°F (15°C) (Jarrige et al. 1978). Water ingested per kg DM consumed increases by 30%, 50%, and 100% at temperatures of 68°F, 77°F, and 86°F (20°C, 25°C, and 30°C), respectively (Jarrige 1988). A lower value (2 to 2.8 kg/kg DM) is observed for nonlactating goats in early gestation. Nonlactating animals on lush pasture can survive without additional water. In fact, in some tropical regions, goats may not learn to drink water unless owners make a conscious effort to introduce the animal to water at weaning time. These goats will be at a disadvantage if later moved to a drier region.

Kids raised in confinement systems should have water available to drink from a pan or bucket from a week of age, to assist with rumen development. Milk drunk bypasses the rumen because of closure of the esophageal groove, so plain water must be provided to mix with grain and hay in the rumen for best digestion. Supplying water from a nipple bottle can lead to hemolysis because too much is consumed by the kid at one time (Middleton et al. 1997).

Water requirements are difficult to specify, because they depend on breed, environmental factors, and diet. See NRC (2007) for a review. Maintenance levels of 107 g/kg metabolic weight have been suggested for European goats in temperate climates (Giger-Reverdin and Gihad 1991). These same animals have an additional requirement of 1.43 kg of water/kg of milk produced (Giger et al. 1981). Limited water supplies limit milk production. In general, goats should be provided with clean water ad lib (Figure 19.4). Goats are reluctant to drink from foul tasting water sources. This helps to protect them from water-borne infections and undesirable mineral intake, but may limit milk production and dry matter intake. Unpalatable or frozen water supplies also increase the risk of urolithiasis in male goats because water excretion through the urine is limited and minerals in the urine may not stay in solution.

Figure 19.4. A fill float mounted in the bucket ensures that water is available ad lib. (Courtesy Dr. M.C. Smith.)

DRY MATTER INTAKE

The nutrient values of feeds and the requirements of animals are usually converted to a dry matter basis to simplify ration calculation. Dry matter is also important in its own right.

Forages

The quantity of feed that an animal is actually capable of ingesting in a day often limits the nutritive value of a ration, even if it is offered free choice. This is especially true of forages. The rumen is normally filled with a mass of feed in the process of being digested. The volume in the body cavity that the rumen can occupy and the distension of the abdominal wall possibly are limiting factors in feed consumption. Individual particles can only leave the reticulorumen and pass to the omasum and abomasum when they have been reduced to a certain small size by mastication and microbial digestion. The quicker the feed can be broken down, the sooner it exits, and the larger the volume of feed that can be consumed at the next meal. Thus, the capacity of ingestion is limited by the digestibility and especially the fiber content of the feed in question. The cellulolytic activity of the microbial population is also important, and this depends in a major way on the energy in the diet available to support growth of the microbes. With some forages such as mature grass hay or straw, it is the nitrogen available in the rumen that limits microbial growth and thus the total dry matter intake (TDMI). In other instances, trace minerals become limiting. The quantity of water in a feed is usually unimportant unless green chops are harvested at an immature stage (less than 18% DM).

Concentrates

Concentrates are generally ingested and digested more rapidly than forages, such that the substitution on a DM basis of grams of grain per grams of forage is not 1:1. In moderate amounts, concentrates improve the digestibility of poor forages by supplying energy needed for growth of the microbial population. If consumed rapidly in large quantities, concentrates decrease the rumen pH level to a point at which activity of cellulolytic bacteria is compromised and digestion of the forage is slowed (see Indigestion and Rumen Acidosis, below). Dividing the concentrate portion of the ration into several smaller meals is thus desirable because acidosis is prevented. The consumption of hay can only be increased in a limited fashion (less than 10%) by offering multiple meals, but it is important that the forage be available for many hours each day to encourage consumption (Jarrige et al. 1978). A total mixed ration is ideal, but few goat farms can afford the equipment required to combine hay or silage and grain intimately and even then the goat may sort out preferred components of the ration.

Intake Limits

Some feeds are eaten in smaller than expected quantities because the goat finds them unappetizing. This is often true of heavily fermented silages or moldy feeds. Many goats refuse to eat hay that has fallen to the ground and been walked on. When the ration is adequately ingestible and digestible for the ruminant to meet its nutritional needs, the level of production often becomes the factor limiting ingestion. High-producing animals voluntarily consume a larger quantity of DM. For this reason, tables ordinarily increase the TDMI for each kg of milk produced or gram of bw gained.

Voluntary dry matter intake is often expressed based on bw or metabolic weight, depending on whether animals are of similar or very different sizes. This is not a very accurate approach because it ignores the variations in digestibility and substitution. It does, however, permit discussion of gross trends in DM intake. During growth of a goat kid, the TDMI increases as the bw increases. This is because both maintenance requirements and volume of the rumen increase. The TDMI relative to bw decreases during growth. This is especially true at the end of the finishing period, when internal body fat limits rumen volume. It remains nearly constant when expressed in terms of metabolic bw. Similarly, in late pregnancy, the increased volume of the uterus results in a relative decrease in TDMI, although high estrogen levels are also involved. After kidding, TDMI increases as the volume available for the rumen is increased by the involution of the uterus and the rumen epithelium develops to improve absorption of the end-products of digestion. However, the requirements for high milk production increase even more rapidly than does TDMI, and thus the goat must either mobilize body reserves or give less milk.

The maximum dry matter intake for goats approaches 5 to 6 kg/100 kg bw, and animals with such elevated intake are naturally the best producers in the herd (Morand-Fehr 1981a). In goats fed alfalfa hay and grain during lactation, the average dry matter intake varies from 2.8 to 4.2 kg DM/100 kg according to the stage of lactation. During lactation, daily dry matter intake as hay may reach 3% to 3.5% of live weight. Intake is decreased during gestation. Typically the total DM intake is 2.2 to 2.8 kg/100 kg bw during the last eight weeks of pregnancy. Intake of hay varies from 1.7 to 2.3 kg/100 kg bw during this time.

These figures were obtained from Alpine dairy goats. For the same type of goat, a regression equation has been constructed based on 11,600 daily rations consisting of alfalfa hay and grain (Morand-Fehr and Sauvant 1978).

$$\text{Total DM} = 423.2 \times \text{Milk} + 27.8 \times W_{kg}^{0.75} + 13.2 \times \text{Gain} + 6.75 \times \text{Forage}$$

where

$\quad$ DM = dry matter intake in g/day
$\quad$ Milk = kg/d of 3.5% milk
$\quad$ Gain = weight gain in g/day
$\quad$ Forage = percent of roughage in the ration

Such an equation only applies to the particular forage for which it was constructed. Similar trends have been demonstrated in West African Dwarf goats, in which voluntary intake of pelleted alfalfa during peak lactation was almost double that of nonlactating goats of a similar age. Goats suckling twins had greater TDMI levels than goats suckling singles (Adenuga et al. 1991). Recently, many studies have been summarized to produce predictions of the voluntary dry matter intake of lactating, Angora, growing, and mature goats, independent of the forage consumed (Luo et al. 2004d).

Encumbrance

French nutritionists have proposed a unit of encumbrance or fill unit system as a better way of determining TDMI of various rations (Demarquilly et al. 1978; Jarrige 1988; INRA 2007). In this system each category of animal has a single value for capacity of ingestion, while each forage has several ingestability values, determined by the category of ruminant. At first, "standard" sheep (wethers at the end of their growth period) were used to determine ingestibility values. The quantity of a forage eaten by the sheep was then divided into the amount of a reference forage consumed (young pasture grass of a certain energy density) to obtain the encumbrance value, EV. Ingestibility values were later determined for lactating dairy cattle (units of encumbrance for lactation, UEL, or milk fill units, MFU) and also fattening cattle. Encumbrance has been applied to dairy goats (Morand Fehr and Sauvant 1988; INRA 2007). The "standard" goat weighs 60 kg and produces 4 kg of milk with 3.5% butterfat. It consumes 2.65 MFU per day. Capacity is adjusted by 0.23 MFU for each kg of 3.5% fat corrected milk. Voluntary dry matter intake increases in a nonlinear fashion after parturition until its maximum at approximately eight weeks of lactation. For dairy goats, the DMI is approximately 72%, 85%, 92%, 95%, and 98% of the maximum value during weeks one, two, three, four, and five, respectively, of lactation (Sauvant et al. 1991b; INRA 2007).

Tables have been constructed for goats of varying bodyweights, weeks in lactation, and levels of milk production. Selected values have been compiled from the INRA 2007 tables to create Table 19.5. These numbers presume a refusal level of 15% and digestible forage.

Encumbrance values are not routinely included in American feed tables. They are most useful when

Table 19.5. Daily dry matter intake (in kg) and capacity for ingestion (MFU).

Live weight of goat	50 kg		60 kg		70 kg	
	DM	MFU	DM	MF	DM	MFU
Last month gestation	1.16	1.14	1.32	1.30	1.49	1.46
After peak lactation (milk production)						
1 l	1.57	1.38	1.74	1.54	1.90	1.70
2 l	1.90	1.62	2.06	1.78	2.22	1.94
3 l	2.22	1.86	2.38	2.02	2.54	2.18
4 l	2.54	2.10	2.70	2.26	2.86	2.42
5 l	2.86	2.34	3.02	2.50	3.18	2.66
6 l	3.18	2.58	3.34	2.74	3.50	2.90

DM = dry matter intake, MFU = capacity for ingestion in milk fill units.

forages of variable quality are fed. These principles can be demonstrated by several examples. A 60-kg goat at maintenance can consume 1.30 MFU. An early cut grass hay might have an EV of 1.06 MFU/kg DM if it was cut in good weather. Hay from the same field cut late and rained on might have an EV of 1.25 for dairy cattle and goats (but 1.98 for sheep). For the first hay, the goat can eat 1.30/1.06 = 1.51 kg DM. For the weathered hay, she would eat only 1.30/1.25 = 1.04 kg DM. The French tables for TDMI (as given in Table 19.5) are constructed for a ration based on alfalfa hay or corn silage supplemented with concentrates (Morand-Fehr and Sauvant 1988). The NRC tables, on the other hand, indicate not the capacity for TDMI, but the amount of DM to be consumed when a ration has a certain energy density, to meet the energy requirements of the goat at maintenance. The ability of the goat to do this is not considered.

Substitution

When feeding concentrates in addition to the forage, it is helpful to know by how many grams the ingestion of forage DM decreases for each 100 g of concentrate DM consumed. This depends on the forage and the percent of the final ration that will be grain. The substitution rate is appreciably less than 1 when small amounts of concentrates are combined with energy-poor forage. In fact, when feeding weathered grass hay with an EV of 1.9 and an energy density of 0.76 Mcal NE_1/kg DM (0.35 Mcal/pound), the substitution rate varies from 0.02 to 0.21, depending on whether 10% or 70% of the diet is grain. Thus, the TDMI increases substantially. The substitution of one feed for another on a dry matter basis also seems to depend on stage of lactation. For instance, if 100 g more grain is fed to a goat in gestation, she will eat 62 g less alfalfa hay. In early lactation, for 100 g more grain the goat will eat 78 g less hay. After the first two months of lactation there is almost an equivalent substitution of grain for good hay on a dry matter basis.

Conclusions Concerning Dry Matter

Out of all this confusion comes one clear message. Anyone constructing on paper or computer a ration for goats must subsequently verify that the animals in question will actually consume it. This means weighing forage fed, refusals, and the grain consumed. If the animals are not eating as much forage as they need, the amount of grain must be decreased or the forage quality improved. Of course, the situation with pastured goats is trickier. Here, the goat raiser needs both experience and experimentation to feed the herd properly.

GENERAL RATION BALANCING CONSIDERATIONS FOR GOATS

In large herds, it is generally impractical to feed each goat individually. The milking process is slowed and the risk of indigestion is increased if all of the concentrate ration is fed in the parlor. Inevitably, some goats fed in a group are overfed and others are underfed. A measure of control can be maintained by grouping goats according to age and production (Skjevdal 1981). Using locking stanchions or short chains that clip onto collars and manger dividers permits each goat to consume its allotted share of concentrates without gross interference by more dominant does. The goats are then released because they normally consume more hay if they can move freely from hay to water or salt block and back to hay (Morand-Fehr 1981a).

Another problem associated with large herds that have gone beyond the hobby stage is that grain is sometimes cheaper (on a kcals of energy basis) than high quality forage, and grain is certainly easier to store and feed than hay. Thus, owners may choose to

overfeed concentrates without considering the adverse effects on health related to this practice.

Zero-Grazing

Zero-grazing is an important step toward intensification of goat raising. The grazing goat eats slowly, carefully choosing young stems and leaves. It wastes a lot of forage, and does not achieve maximum dry matter intake unless supplemented in the barn. Some of these problems can be avoided by careful grazing management, including high density stocking, frequent rotation, and adequate rest periods for the pastures. Even under such a system, goats do not graze as closely as sheep (Jagusch et al. 1981). A much greater production of milk per acre often can be obtained by cutting the forage and bringing it to the goats. This forage can then be analyzed and it becomes possible to identify deficiencies and excesses in the total ration. At the same time, there is no need to maintain fences, the energy requirements for maintenance of the goats are reduced, and there should be less trouble with predators and internal parasites other than coccidiosis. However, an exercise lot at least twice the area of the stable is still desirable (Toussaint 1974).

Even in total confinement, goats often waste more than 40% of forage in the manger. The goal should be to limit the leftovers to no more than 20% of the feed offered. This means not distributing a plethora of forage and constructing mangers that impede the goat's tendency to remove its head and drop part of every mouthful on the ground. Slanted manger bars are preferable to keyhole feeders. On the other hand, goats do not achieve maximum intake if they are not allowed to exhibit their normal choosiness in eating; a bare manger indicates submaximal consumption. If hay is of poor quality, a greater excess should be distributed to encourage intake. Ideally, another livestock species (such as a pony or sheep) should be available on the farm to make use of the daily manger hay-sweepings. Goats spend more time eating each day than do sheep. They ruminate approximately eight hours a day, six of which occur at night.

Traditionally, dairy goats have been offered a basal ration of forage (such as hay) free choice, with concentrates fed individually, according to production. Hay should be fed before concentrates, to decrease the risk of low rumen pH resulting from rapid digestion of nonstructural carbohydrates in the grain. A total mixed ration can be fed to avoid excessive wasting of the forage and indigestion associated with "slug" feeding of concentrates and to improve consumption of less palatable feeds (Rapetti and Bava 2008). Chopped hay, grain, minerals, and vitamins are mixed with ensiled products (haylage, beet pulp) to obtain a final dust-free mixture. The formulation of the mixture is readjusted frequently during lactation to ensure that each goat consumes adequate fiber (optimum 1 kg hay) even when production and intake have dropped in late lactation (Hervieu 1990).

Forage Quality

Grasses and legumes typically give the highest yield in net energy and protein if they are harvested at the early budding stage (Fick and Mueller 1989). In more advanced stages of maturity, the proportion that is stem increases, as does indigestible fiber such as lignin, while the amount that can be consumed daily decreases. Mineral content also decreases in mature forages. Because of the increase in digestible energy and protein, a smaller quantity of concentrate with a lower protein level can be fed when forage is cut early.

Owners purchasing hay should use both subjective and objective evaluations. Hay should be bright green (not yellow or brown), leafy, sweet-smelling, and free of mold or weeds. If possible, the cutting number, cutting date or weeks of regrowth, and year should be ascertained. First cutting hay can be very early to very late cut, depending on local weather and farming practices. Moldy, weedy, badly weathered, or severely overripe hay should be rejected. Large round hay bales that have been stored uncovered in rainy climates are suspect, because the outer moldy part is a large proportion (often 25% to 30%) of the bale and rain water will have leached soluble nutrients out of the hay in the center of the bale. If the hay appears palatable but its nutritional value is questionable, crude protein, available protein, ADF, and NDF should be determined by a forage testing laboratory. This is especially important with grass hays in which stage of maturity is more difficult to judge than with alfalfa hays.

Owners of small herds probably do not buy at auctions, where hay has been analyzed and graded to reflect nutritional value. Some are fortunate and find a local, well-managed farm where representative twenty core hay samples have been taken and analyzed from each batch of hay (Putnam 2002). Alternatively, a cooperative extension office might lend the equipment and the hay seller might be willing to share the cost of the hay testing or pay for the testing with the understanding that the price of the hay will be determined by its quality. Sellers unwilling to cooperate often have poor hay.

Stored forages have decreased vitamin content. Thus, supplementation with vitamins A, D, and E is usually imperative when hays or silages are fed many months after harvest.

Silage

Because of weather constraints, it is often easier to make young herbage into ensilage than into good quality hay. For best results, including highest intakes, a preservative such as formic acid (0.2% to 0.5% added

to the direct cut crop) is used (Nedkvitne and Robstad 1981). When silage is fed, it is still important to offer an excess of feed, allowing at least 10% to 15% refusals, to obtain maximum dry matter intake. Bunks should be cleaned daily to prevent spoilage. Though good milk production can be obtained when goats are fed silage in place of hay, the danger of listeriosis associated with silage feeding must be kept in mind. The herbage must be free of dirt that might carry *Listeria* organisms, and the silage must be properly made so that it maintains an acid pH (less than 5) unfavorable for additional multiplication of the bacteria. In small herds, ensiling is often impractical unless plastic bags are used. A few animals do not eat enough to prevent spoilage at the leading edge of a pile or conventional silo.

Corn silage (stalks, leaves, and ears chopped together) is commonly fed to livestock in the United States. When kernels are well developed at the time of harvest and moisture content of the plant is appropriate, there is adequate carbohydrate to permit good fermentation and attainment of a low pH. Contamination with soil (during harvest or packing) and surface spoilage can still permit dangerous growth of *Listeria*. Manger sweepings of corn silage from cattle farms should not be fed to goats. Additionally, goats pick the corn kernels out of the silage by choice and eat proportionately less roughage or else eat the roughage portion of their diet after the grain has been consumed.

Palatability

Goats show great individual differences in what they prefer to eat. Texture and taste are both important. Thus, goats generally dislike dusty feeds. Molasses makes a grain mixture more appetizing (Morand-Fehr 1981a). However, feeds with more than 5% to 6% molasses should be avoided (Adams 1986) because of possible adverse effects on rumen function. Coarse textured grains (i.e., rolled, cracked, crimped, flaked) and pellets are more acceptable than finely ground meals.

Past dietary experience is also important in determining what an individual goat will eat. This is important in range situations, when more palatable forages may be scare or potentially toxic secondary metabolites are present in many plant species. Goats appear to adjust their intake of available plant species to maximize nutritive value while avoiding toxicity (Papachristou et al. 2005). Young goats may learn which species to consume in part by observing more experienced members of the herd, and feed preferences developed in the second to fourth months may persist for life (Biquand and Biquand-Guyot 1992; Provenza et al. 2003). For this reason, converting a herd to a new feed resource base (different plant species, new region of the country, hay to silage, silage to cubes,

etc.) may require a full year or even a full generation before previous productivity is restored.

Body Condition Scoring

In the adult goat, proper body weight is a function of breed, frame size, and stage of gestation or lactation. Accurate scales on which to weigh goats are often not available. The frame size of an individual adult is constant, but deposition of fat and muscle (body condition) varies with nutritional and physiologic status. Body condition is a measure of the animal's lipid and protein reserves. These reserves are used in late gestation, early lactation, and times of environmental adversity.

Although sophisticated methods to determine body composition based on slaughter or biopsy techniques have been developed for goats (Morand-Fehr et al. 1992), a practical method must rely on palpation and visual assessment of the animals. A lumbar score has been applied to meat goats in Australia, using scores of 1 (very lean), 2 (lean), 3 (medium), or 4 (fat) (Mitchell 1986; McGregor and Butler 2008). A similar scheme using one-fourth or one-half-point increments from 1 to 4 has been developed for indigenous goats of the Small East African type (Honhold et al. 1989). In score 1 goats, there is almost no muscle covering the intervertebral articulations; a score of 4 corresponds to muscle completely covering the vertical and horizontal processes of the lumbar vertebrae. In these animals, a change of 1 in the condition score represents an average of a 12% change in body weight.

Lumbar systems originally designed for sheep and cattle are not directly applicable to dairy goats because most of the dairy goat's body fat is stored in the omentum and perirenal tissues (Chilliard et al. 1981). Even obese animals have little subcutaneous fat. A system has been developed specifically for dairy goats but is appropriate for all breeds. This body condition score is an average of lumbar and sternal scores, each of which is divided into 0.25-point divisions. Integer scores from 0 to 5 used in this method are described in Table 19.6 (Morand-Fehr et al. 1989; Santucci et al. 1991; Hervieu and Morand-Fehr 1999).

The goat is evaluated while relaxed and standing evenly on all four feet. The sternal score correlates better with the proportion of adipose tissue in the goat, while the lumbar score (determined over the second to fifth lumbar vertebrae) better reflects body protein (Morand-Fehr et al. 1992). Each 0.25 change in the final score corresponds to approximately 1.5% lipid content of the body (Morand-Fehr et al. 1992). Owners are advised to select and score fifteen lactating goats one to two months before breeding will begin. Three of these animals should be high producers, nine average producers, and three low producers. The same fifteen goats are scored again at the end of lactation and

Table 19.6. Body condition scoring scheme for dairy goats.

Lumbar score

0   The animal is extremely emaciated. The intervertebral articulations are easily felt and the skin seems to be in direct contact with the bones.

1   Muscle extends at most two-thirds of the distance out along the transverse spinal processes. Intervertebral articulations are still palpable but barely visible.

2   Dorsal and transverse spinous processes are prominent, and the skin forms a concave line between them.

3   Spinous processes are still easily felt. The space in the vertebral angle is filled with muscle and the skin determines a straight line between dorsal and transverse processes.

4   Dorsal and transverse spinous processes are difficult to detect and the skin forms a convex line between them.

5   There is a prominent groove down the back line and the fat and muscles mound up on each side of this groove.

Sternal score

0   Costo-sternal articulations are very prominent. The bony surface of the sternum is easily felt. The skin callous over the sternum lacks mobility.

1   Costo-sternal articulations are more rounded but still easily felt. The depression over the sternum is not filled in but the callous is movable.

2   Costo-sternal articulations are difficult to feel. Internal fat pads develop under the muscle layers on each side of the sternum, and subcutaneous fat partially fills the central depression.

3   The central depression is completely filled with a thin and mobile mass of subcutaneous fat. Distinct depressions are palpable on each side between the mass of fat and muscle and the bones. The costo-chondral articulations are palpable.

4   Sternum and ribs are no longer palpable but a depression is still palpable on each side of a thick mass of subcutaneous fat.

5   Subcutaneous fat is no longer mobile. No depressions are palpable laterally or caudally.

immediately after parturition. A sick or injured goat is replaced with an animal of equivalent milk production. The lumbar score for Alpines and Saanens in France averages 2.5 to 2.75 at dry off, 2 to 2.25 at parturition, and 2.25 to 2.5 before the breeding season. The average sternal scores for the same time periods are 3 to 3.25, 2.5 to 2.75, and 2.75 to 3. The combined score should not drop by more than 0.5 points during the dry period (Herview and Morand-Fehr 1999). A group of ten doelings can be followed in a similar fashion to monitor the nutrition and well-being of that age group.

A very similar scoring system for meat goats also takes into consideration the degree of fat deposition over the rib cage. This body condition scoring system has been illustrated with videos and photographs of individual goats with each whole integer score (Langston University 2000).

Body condition scoring is useful for monitoring the adequacy of the feeding program under intensive and extensive conditions. Critical times for scoring goats might include dry-off, the last two weeks of gestation, six weeks into lactation, at turn-out onto pasture, at the beginning of the dry season, and at the beginning of the breeding season (Morand-Fehr et al. 1989). Dairy goats need body reserves at parturition to support maximum milk production in the subsequent lactation. Angoras kidding in good body condition also produce more milk, thereby limiting kid losses because of starvation. Under French intensive dairy goat conditions, the body condition score should be more than 2.25 and less than 3.5 at dry-off, and more than 2.75 and at or less than 3.5 at parturition. The score should not be less than 2 at peak lactation (forty-five days) nor should it have decreased more than 1.25 points from parturition (Morand-Fehr et al. 1992).

Target scores need to be established for extensively managed goats to obtain satisfactory production and reproduction (Santucci et al. 1991). For instance, recently shorn Angora goats with a low body condition score have a greater risk of dying during inclement weather (McGregor and Butler 2008). Body condition also should be considered when implementing a selective deworming program (see Chapter 10).

Apparent Starvation in the Face of Plenty

When an individual in the herd appears to be malnourished despite free access (including protection from competition) to a palatable and nutritious ration, other reasons for reduced consumption or utilization of nutrients must be investigated. These include dental disease, lameness, blindness, and chronic infectious and parasitic diseases. The clinical approach to such an animal is described in Chapter 15.

FEEDING PREGNANT GOATS

During gestation goats accumulate protein, fat, minerals, and vitamins beyond what is incorporated into fetuses and placenta. The magnitude of this net bodyweight gain varies from less than 1 kg to 8 kg and is strongly influenced by the level of nutrition. Protein, but not energy, is accumulated more efficiently during gestation than when the goat is not pregnant.

Seventy percent of the weight of the kid is acquired between the one hundredth day of gestation and parturition. The weight of kids at birth as a percent of the doe's weight at breeding is twice the corresponding ratio of calf to cow. Undernourishment during late

pregnancy results in the birth of smaller kids that will in turn show increased mortality and slower growth rates (Bajhau and Kennedy 1990). Subsequent milk production will also be compromised (Sahlu et al. 1995). Particularly important is the potential adverse effect of an energy deficient diet on colostrum in the udder at delivery, as demonstrated in ewes (Banchero et al. 2006). The kids may die of hypothermia or starvation before adequate colostrum is produced.

If the doe is carrying multiple kids, especially three or more, then it will have to mobilize its fat reserves just before parturition to meet its own energy needs. This is because appetite often drops off at this time and the volume of the gravid uterus and of internal fat stores limits the volume of feed that can be consumed. When propionate supplies are inadequate, the acetate coming from mobilization of fat will be transformed into ketone bodies. Pregnancy toxemia may result, as discussed below.

A high quality, palatable hay should be fed during pregnancy. This permits limiting the grain to 200 g/day late in gestation. Goats that eat a lot of hay during gestation maintain that ability to ingest increased levels of roughage during lactation. Also, high concentrate consumption in pregnancy has been associated with slow parturition and poor cervical dilation and with poor persistence of lactation (Fehr et al. 1974). Recent reports suggest that protein should be fed to dairy goats at approximately 11.5% of ration dry matter during late gestation for fetal well-being (Sahlu et al. 1992) and for subsequent milk production (Sahlu et al. 1995), and supplying 14% crude protein did not improve performance. A supplement rich in rumen bypass protein is desirable at this time (Morand-Fehr and Sauvant 1988).

A recent experiment with a small number of late pregnant goats showed that they were capable of increasing dry matter intake and protein in the diet at this stage. In the last weeks before parturition, if allowed to choose from several hays and concentrates offered free choice, the goats increased their forage and protein intake by increasing consumption of alfalfa hay and chickpeas while decreasing grass hay and barley consumption. In the same study, goats fed only alfalfa hay and flaked barley increased their dry matter intake by the substitution effect of increasing consumption of the concentrate and protein consumption by eating only the more digestible portions of the hay (Fedele et al. 2002).

Abortion

Abortion as the result of inadequate nutrition has received the most attention in the Angora breed. Small, poorly grown animals or old does are most prone to abort. During inclement weather or after shearing, ad lib supplementation with whole grain treated with an alkali and ionophore prevents the spate of abortions that normally follows such stressful conditions, without causing rumen acidosis (Wentzel 1987). Lime, ionophore, and as much as 1.2% urea are mixed with molasses and water, then poured over whole grain and mixed in well. The final product contains 2% (by weight) slaked lime (calcium hydroxide, not calcium carbonate or field lime) and 20 mg/kg ionophore such as rumensin, salinomycin, or lasalocid. According to one recipe (Van der Westhuysen et al. 1988), 12.5 kg calcium hydroxide, 8 kg urea, 16 liters molasses, and the appropriate amount of ionophore are mixed with 20 liters of water, then poured over 560 kg of grain.

Native breeds are often observed to be less apt to abort than imported animals, especially dairy breeds, with higher nutritional demands (Mellado et al. 2006). It is difficult to separate the adverse effects on the placenta and fetus of nutritional deficiencies in high producing goats from lack of resistance to enzootic abortion diseases. However, within a herd in which feed or manger space is limited, the smaller, younger pregnant does whose nutritional needs cannot be met in the face of competition with mature, socially dominant adults are prone to abortion. Feeding these animals as a separate group alleviates the nutritional and social stresses.

Mineral and vitamin deficiencies and toxic plants that have been associated with abortion are reviewed in Chapter 13.

Pregnancy Toxemia

Goats are at risk of developing the metabolic condition termed "ketosis" at two stages: at the end of gestation (pregnancy toxemia) and during early lactation (i.e., lactational ketosis, as discussed later).

Etiology

Pregnancy toxemia is usually limited to the last six weeks of gestation, although one Indian study detected ketonuria in 3% of 120 inappetent lethargic does in the third month of pregnancy. By comparison, 24% of 160 does with a similar presentation in the fifth month of pregnancy were positive for acetoacetate in the urine (Lalitha et al. 2001). Its immediate causes can be crudely divided into undernutrition and overnutrition. In starvation ketosis, the animal has not been permitted access to enough nutrients, especially energy, to meet the demands of itself and its (usually) multiple fetuses. Low quality roughage is a particular risk because not enough can be consumed to meet requirements when the volume of the rumen is reduced by the presence in the abdomen of a large uterus (Bostedt and Hamadeh 1990). Secondary ketosis is similar, except that some other disease temporarily interferes with feed consumption by an otherwise properly fed doe. In overnutrition ("estate") ketosis, the goat has been overfed

until its massive internal fat stores plus the full uterus occupy so much of the body cavity that dry matter intake is severely curtailed at a time when increased energy consumption is required. Leptin, a hormone produced by adipose cells, may also contribute to a reduction in feed intake by decreasing the obese animal's appetite (Kolb and Kaskous 2004).

Excessive grain feeding itself can lead to pregnancy toxemia because the goat that eats inadequate roughage is apt to go off feed at this critical time. When goats are heavily fed on corn silage in late gestation they become obese. Their level of ingestion then decreases dramatically before parturition. Rumen acidosis from energy-rich silage may contribute to the development of pregnancy toxemia.

Figure 19.5 shows various determining factors for ketosis (Sauvant et al. 1984). Etiologic factors involved in the development of pregnancy toxemia have been reviewed (Sauvant et al. 1991a).

Pathogenesis

The central metabolic events are fat mobilization and the availability of glucose (Caple and McLean 1986; Herdt and Emery 1992). Pregnancy toxemia is typically more common than lactational ketosis, and occurs predominantly in "improved" breeds with high prolificacy. It is not a disease expected to occur in native breeds carrying a single kid under extensive management conditions. With proper management and nutrition, even the doe carrying quadruplets can remain clinically healthy, although concentrations of ketone bodies in the blood can be expected to be higher in those goats carrying large litters. In a study of 514 native goats managed under a semi-intensive pasture and concentrate system in India, no clinical ketosis was observed but about 10% of the animals had subclinical ketosis based on laboratory findings of hypoglycemia (<30 mg/dl serum glucose) and hyperketonemia (>4.5 mg/dl ketones) (Gupta et al. 2007).

The developing fetuses depend upon glucose (maternal hepatic gluconeogenesis) for their energy needs. Ketone bodies and free fatty acids do not cross the placenta in any substantial quantities (Reid 1968). Insulin levels in the late pregnant doe are decreased; this spares glucose for fetal needs while at the same time stimulating lipolysis and gluconeogenesis. Placental lactogen levels are greatly increased when multiple fetuses are present (Sardjana et al. 1988). Placental lactogen has growth hormone as well as prolactin activity and is probably crucial to meeting the metabolic needs of the fetuses at the expense (if necessary) of the dam. Thus, the late pregnant doe is often subclinically ketotic.

Clinical Signs

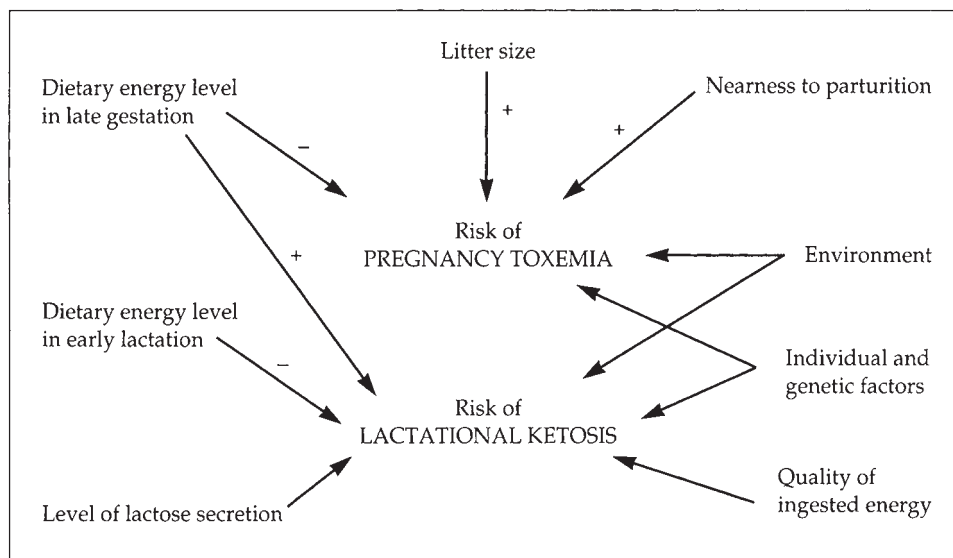
The early signs of pregnancy toxemia are vague. They probably originate from decreased glucose utilization by the doe's brain. The goat may be slow to get up or may lie off in a corner. It eats less and its eyes are dull. There is often a noticeable subcutaneous edema of the lower limbs. Teeth grinding and generalized weakness progress to more apparent neurologic abnormalities (blindness, loss of menace response, star gazing, nystagmus, ataxia, tremors), then to coma. The fecal output is reduced to a few small, dry, mucus coated pellets.


Figure 19.5. Factors determining the development of ketosis in dairy goats.

As metabolic acidosis develops the animal may breathe more rapidly. Thus, advanced primary ketosis may be difficult to distinguish from a primary pneumonia which has caused the goat to go off feed and develop a secondary ketosis. A careful physical examination is also necessary to identify other problems such as parasites, lameness, and bad teeth that might have contributed to the animal's present state.

In the terminal stages of pregnancy toxemia, the doe becomes recumbent. Death of the fetuses at this stage releases toxins and hastens the demise of the doe. Pulse and respiratory rates increase as endotoxic shock develops. The course of the untreated disease varies from twelve hours to one week.

Goats with pregnancy toxemia that do not die tend to have dystocias and higher kid mortality. They do not come to milk well. Similar problems are noted in obese goats, even when clinical pregnancy toxemia does not occur; in addition, these animals are at high risk of developing lactational ketosis.

Laboratory Tests

There are three major ketone bodies produced in the course of this metabolic disease: beta-hydroxybutyrate (BHB), acetoacetate, and acetone. In the past, these were sometimes measured together in a poorly defined way and reported as total ketones. Currently, BHB, which is the most stable ketone in blood and accounts for approximately 85% of the total ketones in sheep with pregnancy toxemia (Bostedt and Hamadeh 1990), receives the most attention in the laboratory.

Some people can detect an odor of ketones on the breath of ketotic animals. Others must depend on simple diagnostic reagents or laboratory tests. In the early stages of pregnancy toxemia, ketone bodies are easily detectable in the urine. The commonly used test strips and pills containing nitroprusside (Rothera reagent) turn purple in the presence of acetoacetate but react minimally with acetone and BHB. If the doe has only a trace ketonuria (physiologic when late pregnant with multiple fetuses), some other cause for its illness should be sought, but supportive treatment to prevent worsening of the ketosis should be given. Late stages are usually accompanied by renal failure; marked proteinuria, epithelial casts, and ketonuria are present (Kaufman and Bergman 1978). The veterinarian should have a collection cup close at hand whenever examining a late-pregnant goat. A doe often urinates when it first stands up on the approach of a stranger, as part of preparing for flight. If urination has not yet occurred by the end of the examination, then occluding the nostrils while an assistant holds the cup under the goat's vulva may be tried. However, even healthy goats rarely urinate in response to this stimulus, and the toxemic animal is typically dehydrated. The attempt must be abandoned before the goat is asphyxiated.

When urine is not available, plasma or serum can be checked with the ketone pills, powders, or strips. Recently, with the advent of hand-held meters for testing human blood for beta-hydroxybutyrate and glucose, precise BHB testing on farm has become possible. The test strips are inexpensive and the results determined rapidly. Unfortunately, specific BHB reference values have not been established for goats (Stelletta et al. 2008), but values established for sheep (Clarkson 2000) can be used by default. Thus, BHB values less than 1 mmol/l can be considered normal, values of 1.5 to 3 mmol/l can be considered indicative of severe undernutrition, and animals with pregnancy toxemia often show a BHB concentration greater than 3 mmol/l. For conversion to other units, note that BHB in mmol/l $\times$ 10.3 = BHB in mg/dl. If the animal is recently dead, aqueous humor or cerebrospinal fluid can be tested instead of blood (Scott et al. 1995), but the accuracy of the hand-held meters using these fluids has not been established.

Other laboratory tests are not commonly performed on field cases of pregnancy toxemia. Cortisol-induced changes in the hemogram (neutrophilia, lymphopenia, eosinopenia) and evidence of dehydration (elevated hematocrit and total protein) can be expected. Blood glucose levels are variable; severe hypoglycemia or terminal marked hyperglycemia are both possible (normal range 50 to 75 mg/dl; see Chapter 11).

Necropsy Findings

The doe that dies of pregnancy toxemia usually has multiple fetuses in the uterus, unless these were removed just before death. The fetuses may be fresh or decomposed. The doe's liver is enlarged and yellow because of infiltration with fat (Tontis and Zwahlen 1987). The doe's adrenal glands are enlarged. The carcass appears dehydrated. If urine remains in the bladder, it shows a strong ketone reaction.

Treatment

The treatment and prognosis depend on the stage of the disease. In the earliest clinical form, the goat readily eats offered grain. Its diet should be improved to include better quality roughage and increased concentrates. Propylene glycol is given orally by dosing syringe, at the rate of 60 ml two or three times daily as a glucose precursor. Although some authors suggest as much as 175 to 250 ml of propylene glycol twice a day (Bretzlaff et al. 1991), this dosage seems excessive and likely to overwhelm the ability of the rumen flora of an already sick goat to digest it. Overdoses of propylene glycol can be fatal, creating plasma hyperosmolality that impairs neurologic function. A commercial product that contains niacin as well as propylene glycol has been recommended, or the goat can be injected with enough mixed B vitamins to supply 1 gram of

niacin/day (Bowen 1998). Calcium borogluconate (60 ml of a 23% to 25% solution) is given subcutaneously to counteract any concurrent hypocalcemia; approximately 20% of sheep with pregnancy toxemia are also hypocalcemic (Kolb and Kaskous 2004). Some authors recommend the use of insulin, up to 40 units of protamine zinc insulin twice daily subcutaneously (Matthews 1999), but an approved veterinary product is not available in the United States.

If the animal is unwilling to eat or to rise, the prognosis is guarded. Intravenous glucose (25 to 50 grams, preferably as a 5% to 10% solution), mixed B vitamins, and force feeding are added to the regimen. One author has suggested giving 5 to 7 g glucose as a 50% solution six to eight times a day via an indwelling jugular catheter (Marteniuk and Herdt 1988). If the goat is breathing rapidly, acidosis is likely and intravenous therapy should be extended to 3 to 4 liters of fluid including 15 grams or more of sodium bicarbonate. Antibiotic therapy is begun for primary or secondary pneumonia.

If the goat is known to be within one week of its due date, hormonal induction of parturition (see Chapter 13) with 10 mg of prostaglandin F2 alpha will end the energy drain to the fetuses. If the due date is uncertain and the owner desires to save doe and kids, 20 to 25 mg dexamethasone may be preferred for its gluconeogenic effects and beneficial stimulus to appetite. Late gestation fetuses are born in approximately two days after corticosteroid administration, while more immature fetuses are not always aborted but may instead be carried to term successfully if the doe responds to medical management. If possible, transabdominal ultrasound examination of the uterus for evidence of fetal movement or heartbeat should be performed to verify that the fetuses are still alive. Dexamethasone induction requires a live fetus, and slaughter or euthanasia may be more appropriate in commercial situations if the kids are already dead.

If the valuable goat is down and very depressed or has failed to improve by the day after initiation of treatment, then a cesarean section should be performed immediately. Severely toxemic animals do not kid rapidly or dependably after receiving hormones, but dexamethasone on the first visit may prepare the lungs of marginally immature kids and thereby increase their chances of surviving a cesarean operation that can be delayed for twenty-four hours. Even with surgery and extensive fluid therapy, the prognosis is poor for survival of the recumbent goat in the late stages of pregnancy toxemia. The kids from these does also frequently are delivered dead or die within a few hours of surgery.

Prevention

If goats are already obese when the last trimester is reached, it is too late to propose a weight-reducing diet. Instead, animals must be fed high quality roughage and as much as 500 g of concentrate daily. Any conditions that disturb the comfort of the goat, such as lack of exercise, poor ventilation, or drafts, should be corrected. This means that the stall should be dry, well-bedded, and uncrowded. The goats should be let loose for at least two to three hours per day. Timid does and slow eaters should be housed separate from dominant, aggressive animals that might drive them away from the feeder. If fetal numbers have been determined by real-time ultrasonography (see Chapter 13), the goats can be grouped and fed according to litter size. Goats carrying three or more fetuses should receive the best quality roughage available in addition to adequate concentrate.

When one doe develops pregnancy toxemia, the diet of the rest of the herd must be evaluated and corrected as necessary. Concentrates should be introduced gradually and under strict control, to avoid indigestion. It is unrealistic to expect a large herd of commercial goats to be totally free of pregnancy toxemia. Routine monitoring of all late-pregnant does for urinary ketones is also unrealistic. Healthy does carrying large litters can be expected to excrete small quantities of ketones yet do not need treatment. Drenching with prophylactic propylene glycol (60 ml orally twice a day) is in itself a stress to a goat and should be reserved for those showing abnormal behavior or diminished appetite.

Some authors have recommended supplementing ruminant diets with niacin to help protect against the development of a ketotic state. Niacin (nicotinic acid) is antilipolytic and causes blood glucose and insulin to increase (Herdt and Emery 1992). There are anecdotal reports that 500 mg niacin/pound of grain fed works well for preventing pregnancy toxemia in goats (Bowen 1998). Published research documenting a beneficial effect of feeding niacin appears to be lacking in goats, but the practice does not appear to carry any risks.

Parturient Paresis (Milk Fever), Hypocalcemia

Although various authors, especially in lay publications, talk about the occurrence of milk fever in goats, this condition is apparently rare (Linzell 1965; Kessler 1981).

Pathogenesis

Parturient paresis is a failure of calcium homeostasis, which depends in turn on intestinal absorption and skeletal reserves. Intestinal absorption requires calcium binding protein. The synthesis of this transport protein is controlled by vitamin D_3 availability (Sauvant et al. 1991a).

There is a sudden increase in calcium and phosphorus requirements at the onset of lactation, and the

capacity for intestinal absorption of calcium increases more slowly than the requirement. Normal parturition in goats is accompanied by mild hypocalcemia. For instance, six healthy Alpine goats had an average plasma calcium concentration of 6.6 mg/dl three days after parturition, as compared with 8.4 mg/dl six days before and six days after kidding (Barlet et al. 1971). In another intensive study of healthy goats (six Saanens and one Alpine), plasma calcium concentrations as low as 6.7 mg/dl were encountered (Linzell 1965). When the hypocalcemia is extreme, milk fever can be expected to occur.

High producing dairy goats occasionally develop a severe hypocalcemic syndrome clinically similar to milk fever, except that the goat is one to three or more weeks after parturition (Barlet et al. 1971; Øverby and Ødegaard 1980; Ødegaard and Øverby 1993). The tendency of goats undergoing a high degree of lipid mobilization to have a significant increase in calcium and phosphorus content of their milk may be involved (Sauvant et al. 1991a).

Of forty Norwegian goats with hypocalcemia, seven were prepartum (two more than a week before kidding), ten were affected during kidding or the first day after kidding, eight more were within three weeks after kidding, and fifteen were more than three weeks into lactation. Older goats were affected; thirty-four of forty were starting their fourth or later lactation (Ødegaard and Øverby 1993).

Clinical Signs

Signs include a decrease in appetite, mild bloat or constipation, unsteady gait, and weakened uterine contractions, then an inability to rise and a decreased body temperature (Guss 1977; Øverby and Ødegaard 1980; Ødegaard and Øverby 1993). Affected goats are often somnolent and lie in sternal recumbency with the head turned back along the side of the body. Occasional goats lie in lateral recumbency, showing muscle spasms and screaming. There may be mucus at the nostrils or signs suggestive of pulmonary edema.

In forty Norwegian goats diagnosed as clinically hypocalcemic, the average plasma calcium concentration was 3.75 mg/dl (range 2.9 to 5.1), compared with an average of 9.91 mg/dl in thirty-six normal goats (Øverby and Ødegaard 1980). In an Indian study of nine mature goats of various breeds, in which the clinical signs of hypocalcemia were not described but diagnosis was based at least in part of response the therapy, the average calcium concentration was 6.66 mg/dl (Vihan and Rai 1984).

Treatment

The recommended therapy for either periparturient or lactational hypocalcemia is slow intravenous infusion of 50 to 100 ml of 23% calcium borogluconate. Rapid response to calcium therapy confirms the diagnosis if laboratory testing is not available. Additional calcium is sometimes administered subcutaneously or oral milk fever preparations are given. Calcium chloride gels should be avoided because of the risk of severe mucosal damage. Owners sometimes feed flavored calcium carbonate antacid pills to their does as a further calcium supplement, although this form of calcium is poorly absorbed until it is dissociated by acid in the abomasum (Thilsing-Hansen et al. 2002).

Most authors agree that the best response is achieved with early treatment. On the other hand, periparturient goats with clinical signs of excitability, posterior paresis, and constipation may not respond to calcium infusions (Kessler 1981). Perhaps some of the goats diagnosed as having milk fever are in fact victims of rumen acidosis caused by inadequate roughage consumption in late pregnancy.

Prevention

In dairy cattle, the avoidance during late pregnancy of feeds rich in calcium, such as alfalfa hay, was long considered central to preventing milk fever. More recent work in both cattle (Oetzel et al. 1988; Thilsing-Hansen et al. 2002) and goats (Fredeen et al. 1988) has shown that adjusting the cationic/anionic balance $((Na + K)/(Cl + S))$ by acidifying the late pregnancy diet with added anionic salts also prevents the condition. Dietary magnesium must be adequate for calcium mobilization from bone to occur.

Alfalfa has a cation excess which may be associated with decreased calcium absorption from the diet prepartum. In regions where alfalfa is plentiful or indeed the only hay readily available, the prevalence of milk fever in goats does not seem to be increased. This may be because goats tend to come into milk production more gradually than do dairy cows. A very low calcium diet is not needed in goats and in fact might lead to hypocalcemia, as it does in ewes.

Because the etiology of lactational hypocalcemia is poorly understood, prevention centers on avoiding anything that upsets feed intake or gastrointestinal function (Ødegaard and Øverby 1993).

FEEDING LACTATING GOATS

In the past, the best producing goats in a herd were usually the ones that consumed the most forage. This may be because of intensive selection pressure in herds in which little or no grain was fed. As feeding practices change, goats may adapt to using grain in preference to forage. However, it remains true that goats have an aptitude to consume much forage, a characteristic that makes them well adapted to many extensive agricultural situations.

The forage-to-concentrate ratio should always be kept in mind (Kawas et al. 1991). With an alfalfa hay/grain ration, a forage:concentrate (F:C) ratio of 2:1 gives excellent results. With mediocre hay, F:C ratios of 1:1 to 1:2 are more appropriate. For best production of milk and butterfat, hay consumption should be maximized while still maintaining a positive energy balance. This requires good forage that is not overmature and lignified. As the proportion of concentrates in the ration increases (especially above two-thirds), butterfat percentage drops. It is not economically sound to force hay consumption if the hay is of poor quality. Green chops and dehydrated forages are better than most hays.

In early lactation, when goats are mobilizing body fat as an energy source, it is important to feed adequate protein to support milk production. A crude protein concentration of 17% to 18% of DM has been recommended for high producing goats at this stage (Skjevdal 1981). During midlactation, total crude protein in the ration should be 13% to 16% of DM.

Lactation Curves

In recent years, numerous researchers have taken production data acquired in the course of milk recording schemes and attempted to fit mathematical functions to the data to describe dairy goat lactation curves (Gipson and Grossman 1990; Macciotta et al. 2008). Factors affecting the lactation curve include breed, parity, season of kidding, and level of production (Gipson and Grossman 1990). First parity does have decreased peak yields, peak later, and are more persistent than later parity does. Higher producing does are less persistent than low producers; milk production declines more steeply after peak yield. Does freshening with two kids produce more milk than does with singles, whether suckled or not (Macciotta et al. 2008). The mathematical equations permit prediction of the total milk yield for the entire lactation from a few tests in early lactation and are thus useful for selection and culling decisions.

Figure 19.6 depicts lactation curves (total milk) for goats of different parities freshening at different times of the year. These curves were derived from the original data of Gipson and Grossman (1989).

Lactation curves describing total milk, fat, and protein have been used by dairy cattle consultants as indicators of nutritional status of individual animals or herds. The validity of such an approach for goat herds needs additional evaluation (Gipson 1992). Comparison of lactation curves generated during research trials is useful for demonstrating the beneficial effects of providing appropriate dietary energy and protein (Sahlu et al. 1995) or other nutrients. Looking at the curves from a commercial herd and then trying to predict the adequacy of the diet is more problematic.
Figure 19.6. Lactation curves for dairy goats. Redrawn from: Gipson (1992).

Ketosis

Cows and goats have comparable milk production when the quantity of fat-corrected milk per kg metabolic body weight is considered. Goats and cows also have similar body reserves which are mobilized to support milk production (Sauvant et al. 1991a). Goats selected for high production but improperly fed may develop lactational ketosis.

Pathogenesis

Glucose is required by the mammary gland for synthesis of lactose. After parturition, the quantity of milk produced and thus the nutrient requirements of the goat increase more rapidly than does the level of intake. Plasma glucose is significantly influenced by digestibility of the diet, whereas the level of lipomobilization is more independent of the quality of the diet, increasing instead exponentially with production potential.

Older goats are generally larger and heavier and have an increased potential dry matter intake than yearlings. However, this increased intake is inadequate to compensate for their higher requirements which reflect higher milk production. The increased mammary uptake of glucose in high producers is not adequately offset by increased hepatic gluconeogenesis and increased absorption of glucogenic precursors. Thus, high producers tend to be hypoglycemic (Sauvant et al. 1984).

Clinical Signs and Treatment

In view of the typical signs of lactational ketosis in cattle, decreased appetite (especially for concentrates) and decreased milk production are to be expected in goats with ketosis. Ketonuria is present and some people can detect the odor of ketones on the animal's breath. Treatment consists of corticosteroids (2 to 6 mg dexamethasone [Braun 1989] or more) for their

gluconeogenic and appetite-stimulating effects and oral propylene glycol (60 ml two to three times daily). Intravenous dextrose may also be given, as discussed under pregnancy toxemia. Provision of tempting browse or force feeding with a slurry of pelleted complete horse feed is used if needed to increase feed consumption.

A more severe syndrome sometimes occurs in which the best producing goat in the herd suddenly collapses. A severe hypocalcemia frequently accompanies ketonuria. Dramatic recovery often results from "shotgun" therapy with intravenous fluids, dextrose, calcium, and B vitamins. The exact pathogenesis remains obscure. An indigestion or acidosis from excessive grain consumption when hay is of poor quality may be involved.

Prevention

It is important to limit the early lactation energy deficit as much as possible, to avoid clinical ketosis. This can be done by stimulating appetite and feeding a balanced ration that includes grain early in lactation. The quantity of grain is increased by 0.1 kg every three days until requirements are met. Peak energy intake can be achieved several weeks earlier than peak dry matter intake if concentrates are fed judiciously. This is because the capacity to ingest concentrates rises more rapidly than does the capacity to ingest forages. Normally the goat achieves a positive energy balance during the second month of lactation.

Indigestion and Rumen Acidosis

When a high proportion of concentrates is fed in the ration, indigestion can lead to a marked day to day variation in feed consumption. The goat has subacute ruminal acidosis, a metabolic disease which is considered to be economically important in dairy cattle but is poorly described in goats (Stelletta et al. 2008). With even higher concentrate intake, life-threatening rumen acidosis may occur. Nutritionally induced rumen bloat, which is also potentially life-threatening, is discussed in Chapter 10.

Pathogenesis

In general, roughages have an increased fiber content compared to concentrates and stimulate long periods of rumination. This in turn results in buffering of the rumen fluid by bicarbonate in saliva. The rumen pH remains in a range (6.0 to 6.8) favorable for cellulolytic bacteria. The major end product of roughage digestion is acetate. Grains lack long fiber. Because of a decreased rumination rate, less saliva reaches the rumen and the pH of the rumen contents drops when grain is consumed. This is desirable within limits, because the bacteria for degrading starches and sugars multiply best at a pH of 5.5 to 6.0. Also, the volatile fatty acids propionate and butyrate are produced in large quantities by digestion of concentrates and are absorbed faster at lower pH levels.

If too much grain is eaten at one time (improper diet or forced entry into the feed room), lactic acid producing streptococci overgrow in the rumen and the pH decreases even more to a point where lactobacilli can proliferate. The ensuing lactic acid production lowers the rumen pH below the physiologic limit of 5.5 and kills the normal flora and fauna. Bacteria produce both dextro- and levo-rotatory isomeric forms of lactic acid, but the mammalian liver is only able to efficiently degrade the L form. This allows the D form to build up in the blood, causing a systemic acidosis. Increased production of histamine and other toxins is associated with the occurrence of laminitis in some animals. Deranged synthesis of B vitamins or production of thiamine antimetabolites can lead to polioencephalomalacia (see Chapter 5). It should be noted that liver abscesses in goats are usually caused by *Corynebacterium pseudotuberculosis*, rather than other bacteria passing through a rumen epithelium damaged by toxic indigestion, as in cattle.

Clinical Findings and Clinical Pathology

Mild overeating of grain results in an off feed condition. Rumen motility decreases but does not stop. The goat may grind its teeth. Milk production decreases and diarrhea may develop. Because the goat stops eating for one or two days, the rumen pH levels increase to a near-neutral range and recovery follows.

Severe overloading is accompanied by a systemic and often fatal acidosis. Rumen motility ceases and the contents are initially firm; mild bloat may be present. Constipation followed by diarrhea, muscle tremors, teeth grinding, groaning or blatting, increased heart and respiratory rates, and even a low fever may be noted. As the disease progresses, splashy (abnormally liquid) rumen contents, abdominal distension, and dehydration (evidenced by sunken eyes, decreased skin turgor, and increased packed cell volume) develop. This is because the rumen contents become hyperosmotic and pull water from the systemic circulation into the rumen. The urine is acidic and blood pH and bicarbonate values may be markedly decreased. Blood lactate levels greater than 40 mg/dl can occur in severe cases, with levels in normal goats of 8 to 10 mg/dl. Significant decreases in blood calcium sometimes occur. Some cases are fatal within twenty-four hours, while less severe cases may develop over twenty-four to seventy-two hours.

Diagnosis and Necropsy Findings

Rumen acidosis should be suspected when a goat is depressed and off feed and has had chronic or acute
Figure 19.7. Homemade sound for obtaining rumen fluid from an adult goat.

access to large quantities of readily fermentable carbohydrates (i.e., grain, bread, sugar beets, apples) (Braun et al. 1992). If diarrhea is present, fecal pH may be reduced; in one experimental study feeding wheat flour, fecal pH dropped from above 7.0 to below 5.0 at twenty-four hours (Aslan et al. 1995).

A sample of rumen fluid obtained with the aid of a stomach tube (up to 1 cm diameter) or a specially designed device (a metal sound with many perforations; see Figure 19.7) or even a needle aspirate can be helpful both for establishing a diagnosis and for determining if a rumenotomy is justified. Ruminocentesis carries risks of peritonitis or localized abscesses, but these risks can be lessened by shearing and disinfection of the chosen site over the ventral rumen, restraining the goat to prevent sudden movement during the procedure, and avoiding needle insertion during a contraction of the ventral sac of the rumen (Stelletta et al. 2008).

A milky gray fluid with a sour smell and a pH level less than 5.0 is conclusive evidence of rumen acidosis. Slightly increased pH levels may result from contamination of the rumen fluid sample with saliva during collection. A pH level in the normal range (5.5 to 7.0) does not rule out rumen acidosis because absorption of acid, passage of ingesta to the abomasum, and flow of saliva cause increase of the pH level if the goat survives long enough. A Gram-stained smear of rumen fluid demonstrates an overwhelming preponderance of Gram-positive organisms when rumen acidosis has occurred. Rumen protozoa are dead or absent (Nour et al. 1998). In dairy goats in early lactation, the

advanced stages of rumen acidosis may mimic toxic mastitis or milk fever. Animals recumbent with milk fever are not dehydrated or diarrheic and respond to parenteral administration of calcium salts. Enterotoxemia occurs under similar circumstances of accidental or excessive exposure to carbohydrates and may have a similar clinical appearance. Enterotoxemia generally has a more rapid clinical course and the degree of systemic acidosis and dehydration is not as severe.

At necropsy, the same changes in rumen fluid are apparent. Additionally, there may be evidence of large quantities of grain in the rumen or of rumenitis and localized peritonitis. Abomasal ulcers, sometimes perforating, have been produced experimentally by grain overload (Aslan et al. 1995). Dehydration is evidenced by sunken eyes.

Treatment

When the indigestion is judged to be mild, offering hay is sufficient treatment, and mixed B vitamins may be given "on general principles" and to protect against development of polioencephalomalacia.

Early in the course of the indigestion, oral antacids (Baumgartner and Loibl 1986) should stop progression of the disease. Various suggested adult dosages include 10 to 20 g magnesium oxide, 50 g magnesium hydroxide, or 20 g sodium bicarbonate. In an experimental model that produced ruminal acidosis by feeding 80 g of wheat flour per kg bw, oral sodium bicarbonate at 1 g/kg twenty-four hours later was an effective treatment, whereas oral baking yeast at 1 g/kg was not helpful (Aslan et al. 1995). Oral tetracycline (single dose of 0.5 to 1 g) also helps to inhibit additional bacterial proliferation. Concentrate is withheld and palatable forage is offered free choice.

A rumenotomy to remove the rumen contents and rinse the mucosa may be life-saving in acute, severe cases. If the rumen fluid pH is near neutral, and especially if the rumen contents have a splashy consistency, rumenotomy is no longer of great benefit. Instead, as much fluid as possible is drained off with a stomach tube. Then warm water, antacids, and (if available) rumen fluid from a healthy animal are administered through the tube.

If available, determination of acid-base status is helpful in guiding therapy; the severely affected goat has a metabolic acidosis. The base deficit is multiplied by $0.3 \times$ bw in kg to determine the milliequivalents of bicarbonate (HCO_3^-) needed. Each gram of sodium bicarbonate supplies 12 mEq of bicarbonate. Even when clinical laboratory support is lacking, dehydrated goats should be treated intravenously with 3 to 5 liters or more of physiologic saline with added bicarbonate. A goat weighing 50 kg with moderate acidosis (base deficit of 12) needs approximately 15 g of sodium bicarbonate.

Thiamine (300 to 500 mg several times a day), other B vitamins, and calcium gluconate administered subcutaneously are commonly given. Glucose solutions are not necessary, and lactated Ringer's solution is contraindicated. Repeated oral administration of a liter of rumen fluid from a healthy cow, sheep, or goat (obtained fresh from a slaughterhouse or from a fistulated cow or with the aid of a rumen fluid sampling device) is very beneficial in restoring normal rumen flora and fauna (Braun et al. 1992).

Prevention

If the goat has two to (preferably) four weeks to adapt to gradually increasing quantities of grain, then many cases of indigestion can be avoided. Adaptation occurs in two ways. First, the rumen microorganisms that digest readily fermentable carbohydrates to volatile fatty acids increase in number. At the same time, certain bacteria (such as streptococci) produce lactic acid from starches and sugars, but still other species of bacteria with the ability to metabolize lactate to propionate have time to proliferate (Ogimoto and Giesecke 1974). Second, increased concentrations of propionic and butyric acid stimulate the development of rumen papillae so that there is an increased surface area for absorption of fatty acids. Rapid removal of volatile fatty acids from the rumen helps to keep the pH within physiologic bounds.

Another management technique that is very helpful with high concentrate feeding is to distribute the grain over three or more meals a day of 0.3 kg (2/3 pound) (Broqua 1990) per meal or slightly more. This results in a less drastic pH level decrease after each meal than if all the grain is fed at once. Grains that are digested very rapidly (e.g., wheat and high moisture corn) can be replaced by slower digesting grains (e.g., sorghum, dry corn). Whole grain is digested more slowly than finely ground grain that has more surface area for bacterial attack. Roughage should be fed before grain, first thing in the morning. Regular supplementation with buffers (bicarbonate of soda or calcium carbonate at 1.5% to 2% of concentrate) and magnesium (0.2% to 0.3%) (Broqua 1990) also reduces the risk of acidosis. Producers sometimes offer bicarbonate of soda free choice to goats on high grain diets. Corn silage should also be distributed three or more times a day; otherwise, the goat may initially select out a large quantity of corn grain from the silage, risking acidosis.

When individual feeding of grain is not possible, as when supplementing animals on range because of drought conditions, the use of alkali-treated grain with an ionophore has permitted feeding of relatively large quantities of grain to unadapted goats, as described above for prevention of abortion. Dried beet pulp, citrus pulp, and soybean hulls are other energy sources that carry less risk of acidosis than do standard grain products, because they are high in fermentable cell walls and support healthy rumen fermentation (DiTrana and Sepe 2008).

Enterotoxemia

Clostridium perfringens type D is a normal inhabitant of the goat's intestinal tract. Sudden changes in diet (consumption of unaccustomed quantities of grain or of lush pasture when first turned out in the spring) can result in incomplete digestion in the rumen. The ingesta that passes to the small intestine then favors overgrowth of the clostridia and production of epsilon toxin. This toxin is activated by trypsin and absorbed. The syndrome produced is called enterotoxemia or overeating disease and is described more fully in Chapter 10. Sudden death is common.

Because many of the same factors predispose to both enterotoxemia and to rumen acidosis, the two conditions can occur in the same outbreak and can be confused clinically. Necropsy findings (pH level less than 5.5 in rumen fluid for acute acidosis; fluid and fibrin in the pericardial sac, glucosuria, epsilon toxin in ingesta for enterotoxemia) can usually distinguish between the two diseases. Presence of epsilon toxin without other signs is not proof of enterotoxemia.

Milk Fat Depression

When a poor quality roughage is supplemented with concentrate, intakes of both dry matter and energy increase and milk production is increased. However, the amount of butterfat produced increases less than does the amount of milk, and thus butterfat percentage tends to drop (Morand-Fehr and Sauvant 1980). High concentrate, low roughage diets are associated, as discussed earlier, with decreases in rumen fluid pH and in the ratio of acetate to propionate produced in the rumen (Lu et al. 2005). These changes in turn are associated with decreased butterfat production, because acetate rather than propionate or butyrate is the main precursor of milk fat (Davis et al. 1964) and propionate stimulates insulin secretion, which inhibits release of fatty acids from adipose tissue (Emmanuel and Kennelly 1984). In many places where high-producing dairy goats are raised, good quality roughages to support production are unavailable or else very expensive. In select instances, it may be necessary to add a buffer, such as sodium bicarbonate at 4%, to the concentrate portion of the ration to maintain butterfat production (Hadjipanayiotou 1982). Other causes of milk fat depression are discussed in Chapter 14.

FEEDING NEWBORN KIDS

Depending on the intensification of the operation and the need to implement various disease control procedures, kids are either raised on the doe, switched to artificial rearing at the end of the colostrum period,

or fed by hand from birth. If the doe is well fed and has a healthy, well-suspended udder, the "natural" approach of leaving kids with the doe gives good results. Milk is clean, warm, and waiting whenever the kid is hungry. Introduction to solid foods occurs as the kid samples what its dam eats.

Colostrum

Proper colostrum feeding is critical to health and survival of goat kids (Mellor and Murray 1986; Kolb and Kaskous 2003). If the doe dies or is too sick or malnourished at parturition to produce colostrum (Banchero et al. 2006), or if kids are removed from the dam at birth, then the owner must understand the principles of colostrum feeding. The first is to give enough, and enough is probably 50 ml/kg four times during the first day after birth. For owners who are not comfortable with the metric system, 1 ounce/pound three times is a comparable total amount. These rules of thumb are equivalent to feeding approximately 20% of body weight. The second principle is to give the first feeding of colostrum soon, preferably within the first hour after birth, and certainly within six hours. The antibodies in colostrum need to be consumed before the kid sucks on dirty, pathogen-loaded parts of its mother or stall. Death from hypoglycemia or hypothermia is also likely in cold weather if feeding is delayed. The colostrum should be of good quality, nonmastitic, and not contaminated with environmental or milk-borne pathogens. Only first milking colostrum from healthy animals should be frozen for later feeding, and the colostrum from older animals that have been on the premises for several years is typically higher in antibody content against endemic pathogens than is colostrum from first fresheners. Revaccination of the doe against tetanus and enterotoxemia two to four weeks before the due date is commonly used to improve the protective value of the colostrum against these conditions. Failure of passive transfer is discussed in Chapter 7.

Owners should be taught to tube feed kids that are not suckling well. This avoids both delays in colostrum consumption and the risks of inhalation pneumonia associated with pouring liquids into a weak kid's mouth. An 18 French feeding tube or urethral catheter long enough to reach the last rib can be safely passed without a gag in a newborn kid. It can be palpated between trachea and cervical vertebrae as proof of proper positioning. Gravity flow through the barrel of a 60-ml syringe or slow, careful injection is used to administer colostrum or milk as needed. Tube feeding does not encourage a kid to imprint on people, so it does not interfere with nursing of the dam. The tube must be cleaned and sanitized between kids.

Heat treating of colostrum is an important part of control programs for several diseases, such as caprine arthritis encephalitis and mycoplasmosis. In some instances, first-milking cow colostrum is substituted for goat colostrum. Consideration should be given to pasteurizing cow colostrum to prevent diseases such as paratuberculosis, salmonellosis, and cryptosporidiosis. In addition, substituting cow colostrum may leave young kids susceptible to enterotoxemia, tetanus, caseous lymphadenitis, and contagious echthyma.

Low quality "colostrum substitutes" described in many lay publications should be avoided because they fail to provide antibodies to the kid (Scroggs 1989). In one study, feeding a total of 480 ml of heat treated goat colostrum was associated with an increase of mean serum immunoglobulin levels more than twenty-four hours after birth of 1,549 ± 425 mg/dl, whereas a powdered bovine whey concentrate gave an increase of 90 ± 80 mg/dl and a dried colostrum and whey bolus increased immunoglobulins by 290 ± 557 mg/dl (Sherman et al. 1990). Commercial products based on bovine plasma offer more promise, because adequate immunoglobulin is absorbed in lambs (Quigley et al. 2002).

Hypothermia and Hypoglycemia

The normal healthy neonate has a body temperature above 102°F or 39°C. Hypothermia occurs if the neonate, especially a small, wet one, is exposed to cold, wet, or windy conditions. A secondary hypothermia develops if the kid does not obtain enough colostrum and milk to replenish its body reserves in less inclement weather. If the hypothermic kid is less than five hours old, it should be dried and rewarmed (forced warm air, heating pad on low, or very cautious use of a heat lamp to avoid overheating the kid or burning the barn), then given colostrum at 50 ml/kg. Body temperature should be monitored closely during rewarming, because overheating is rapidly fatal.

If the kid is beyond five hours of age, the brown fat stores around kidney and heart, used for nonshivering thermogenesis, have probably been depleted. The older kid that can hold its head up is fed by stomach tube and rewarmed, but if it is too weak to hold up its head, hypoglycemia is likely and fatal convulsions may occur during rewarming. To prevent this, the kid is given an intraperitoneal injection of glucose (dextrose) before being rewarmed (Eales et al. 1984; Matthews 1999). Commercial 50% dextrose is diluted with sterile or boiled water to make a 20% solution (two parts 50% dextrose mixed with three parts water). This solution is warmed to normal body temperature before use. The kid is held suspended by its front legs and a spot one inch lateral to and 1 inch caudal to the umbilicus is treated with a disinfectant such as iodine. A 1-inch (25 mm) 20-g needle is inserted through the body wall at the marked location and directed at a 45-degree angle to the skin and toward the kid's rump.

After the glucose solution has been injected some-where into the abdomen where it can be rapidly absorbed, an antibiotic injection is given and the kid can be safely rewarmed, then tube fed when it is stronger. Providing a coat made from a sock with toe removed or a sweatshirt sleeve with holes cut for the front legs helps to maintain body temperature over the next few days.

First Weeks

The normal birth weight of kids, and how it is affected by breed, sex, and litter size, have been summarized by Morand-Fehr (1981c).

There are many schemes for raising young kids (Morand-Fehr 1981c). Breed, climate, and nutritional resources for both goat and owner must be considered. With larger dairy breeds, one schedule involves feeding 1 liter of milk/day by one week of age and 1.5 to 2 liters by three weeks of age, with no further increase. Other authors recommend substantially less milk per day (0.75 to 1 kg) (Adams 1986) but fail to allow for less than perfect environmental conditions, poor quality roughage, or inadequate concentrate consumption. An intake of 250 g fluid milk (13% solids) per kg live weight has been reported to give daily gains of 150 g (Jagusch et al. 1981). Intake of milk replacer dry matter needs to be 10% to 25% more than that of dry matter from goat milk, probably because of decreased digestibility (Morand-Fehr 1981c).

Milk replacer may be fed warm (95°F to 104°F, 35°C to 40°C) or cold (43°F to 50°F, 6°C to 10°C). Cold milk offers the advantages that the kid consume smaller and more frequent meals and there is limited opportunity for pathogens to grow in cold milk, but if the environment is cold, kids do better on warm milk. After the colostrum feeding period, milk may be fed one to three times per day or ad lib. Acceptable milk replacers are 20% to 28% protein and 16% to 24% fat (Morand-Fehr 1981c). One study showed improved consumption and rate of gain (but not feed efficiency) when dairy kids were offered ad lib milk replacer containing 23% protein and 26% fat, as compared with a milk replacer with a lower protein:energy ratio of 20% protein and 30% fat (Yeom et al. 2002). Soybean should be avoided as a source of protein, unless roasted or otherwise processed to improve digestibility and reduce immunoreactive properties (Ouédraogo et al. 1998).

Pygmy goat kids being reared artificially require less milk per day than larger breeds, but 15% of body-weight is still appropriate. During the first two weeks after birth, a 3-ounce bottle of milk is fed four times per day. The feeding frequency is maintained but the quantity fed per meal is increased to 4 ounces at two to six weeks of age and 5 ounces from six weeks until weaning at eight to twelve weeks of age (Kinne 2008).

Fresh green grass or mixed grass/legume hay and water are supplied free choice from the first week. Because male and castrated pygmy goats are at particular risk of urolithiasis, even as nursing kids, grain feeding of the male kid is usually avoided. These kids need early cut, high protein hay to meet their protein requirements. Some sources suggest feeding up to one cup of grain per day to growing pygmy goats (National Pygmy Goat Association 2006), but this practice is extremely risky.

Floppy Kid Syndrome

A poorly understood metabolic acidosis in young kids was first recognized in North America in the late 1980s and the first detailed clinical report was published in Canada (Tremblay et al. 1991). Owners in the United States and Canada soon named this the floppy kid syndrome. The names for the condition in French (chevreau mou), Portuguese (cabrito mole), and Spanish (borrachera de los cabritos) are equally descriptive of the poor muscle tone or softness and ataxia or apparent drunkenness that these kids display.

Etiology and Epidemiology

Kids of dairy, meat, and fiber breeds in confinement (but not on pasture) have been affected. Kids have been dam reared or fed goat milk, pasteurized goat milk, or milk replacer. There is usually no history of diarrhea or previous oral electrolyte therapy. The syndrome is a metabolic acidosis without dehydration. Morbidity approaches 100% on some farms in some years and mortality is very high if appropriate treatment is not given. A similarity with human infant botulism was noted early on, but researchers were unable to find botulinum toxin in affected kids and the observed response to just correction of acid-base status discounts botulism as a likely etiology. No association has been found with specific viral or bacterial pathogens of the neonatal kid (Bleul et al. 2006).

One proposed pathogenesis for the condition involves the over-consumption of milk (Riet-Correa et al. 2004), because kids are fed better or they nurse does that produce more milk than in previous seasons. The large amounts of milk in the digestive tract allow over-growth of bacteria that then produce D-lactate and unidentified toxins. The observed increase in morbidity near the end of the kidding season supports an infectious etiology and buildup of pathogens in the environment. Often, the disease disappears from the farm the next year, adding to the mystery surrounding its etiology and complicating on-farm research efforts. Similar syndromes have been reported in calves (Kasari and Naylor 1986) and a llama cria (Shepherd et al. 1993).

Clinical Signs

Kids are born healthy, usually have received colostrum, and are not affected until three to fourteen days of age or occasionally up to one month (Bleul et al. 2006). Reported clinical signs include depression, reluctance to suckle, ataxia, weakness or muscle flaccidity, trembling or shaking, and abdominal distension (Tremblay et al. 1991; Riet-Correa et al. 2004; Bleul et al. 2006). A sudden buckling of the limbs is responsible for the syndrome name of floppy kid. Diarrhea is conspicuously absent, and the kids are not dehydrated. As signs progress, extremities become cold and the body temperature drops. The kid may become comatose and die after twenty-four to thirty-six hours if not treated. There are anecdotal reports of spontaneous recoveries and relapses in a small percentage of affected kids.

Diagnosis

Diagnosis depends on finding a metabolic acidosis without dehydration. If venous blood gases can be analyzed, previously untreated kids will be found to have a blood pH below 7.2 (sometimes as low as 6.8) and a base excess of less than –5.0. Ketones and L-lactate are not elevated, but D-lactate is substantially elevated (Bleul et al. 2006). The D-lactate averaged 7.43 mmol/L in affected kids but only 0.26 mmol/L in control kids in this study. The D-lactate only partially explained the anionic gap observed in these kids, suggesting the involvement of some other organic acid absorbed from the gastrointestinal tract. Serum potassium is low or normal, averaging 4.2 mmol/L in forty-nine affected kids and 5.1 mmol/L in thirty-five control kids (Bleul et al. 2006). Chloride may be slightly elevated. Packed cell volume is below 38%.

For a diagnosis of floppy kid syndrome, the kid should show no antemortem or post mortem evidence of hypoglycemia, septicemia, meningitis, white muscle disease, severe pneumonia, enterotoxemia, or dehydration with acidosis secondary to neonatal diarrhea. Owners tend to over-diagnose the condition, because the weakness that is the most prominent clinical sign can be present with many other diseases (Cebra and Cebra 2002). Rapid response to bicarbonate therapy is often considered diagnostic of floppy kid syndrome.

Necropsy is important to rule out other conditions, but findings are usually minimal. The abomasum may be distended with clotted milk and small hemorrhages may be present in the mucosa (Riet-Correa et al. 2004).

Treatment

The most important and often only required treatment is correction of the acidosis. This can be accomplished by intravenous administration of 1.3% sodium bicarbonate, 125 to 200 ml over one to three hours. If laboratory testing has been performed, the initial treatment is based on the following formula:

Body Weight in kg $\times$ 0.5 $\times$ (– Base Excess) = mEq Sodium Bicarbonate

Other authors have recommended that a factor of 0.6 or even higher be substituted in this formula in place of 0.5, at least for calves with changes in posture and demeanor due to severe D-hyperlactataemia (Lorenz and Vogt 2006).

Owners treat kids successfully with oral bicarbonate of soda, using 2.5 to 3 grams (a little more than one-half teaspoon) mixed with cold water. If the condition is not complicated by another problem, kids respond dramatically to one treatment, although a second oral treatment is sometimes needed twelve hours later and the occasional kid requires repeated treatments for up to four days (Bleul et al. 2006). Other oral alkalinizing agents such as Pepto-Bismol® have also been used successfully, but the dose used has not been reported.

Another apparently important part of treatment is to restrict milk intake for twenty-four hours, offering oral electrolytes instead. Additionally, a broad-spectrum antibiotic to treat or prevent septicemia in compromised kids has been advocated (Tremblay et al. 1991; Riet-Correa et al. 2004).

Prevention

It is difficult to propose a means of preventing a disease whose etiology is not understood. However, moderating the amount of milk consumed if this is judged to be excessive seems to be a reasonable starting point. When kids are reared artificially, keeping the milk or milk replacer cold with frozen jugs of water discourages slug feeding. Maintaining good hygiene to limit the buildup of potential pathogens in the kid rearing area is of course desirable on any farm. During an outbreak, owners should be advised to watch closely for well fed kids that sleep more than usual or are slow to suckle, so that they can be treated early.

FEEDING GROWING KIDS

A distinction is generally made between diets for meat kids and for doe kids being raised as replacements. In many parts of The United States the market for chevon (cabrito, goat meat) is very seasonal, being linked to religious holidays such as Easter. Although 10 kg is often the preferred weight at slaughter, both lighter and heavier kids are sold at the same time. After the holiday, it may be impossible to recover feed costs, let alone labor, involved in raising kids.

When kids are raised for meat, it is possible to produce an acceptable carcass on a diet of milk alone. In one study in which buck kids were grown for twenty weeks (to a final weight of approximately 20 kg), carcass characteristics were acceptable but cholesterol and saturated fatty acid levels were higher in meat from milk-fed kids when compared with conventionally reared, weaned kids (Potchoiba et al. 1990).

Castration is of limited benefit when bucks are slaughtered at a few months of age. Intact males have an increased daily rate of gain, while castrates lay down more fat and the fat contains relatively lower percentages of branched and odd-chain fatty acids and increased stearic acid (Bas et al. 1981). Older bucklings and mature males have a strong "buck odor" and meat taint that many people find highly objectionable. Thus, male meat goats that are to be raised until sexual maturity are often castrated even though there will be a resultant decrease in rate of gain. When weaned kids and yearlings are raised for meat, concentrate feeding has little effect on palatability of the meat because the fat is deposited in the kidney and pelvic regions rather than in the muscle (Smith et al. 1978).

Before Weaning

Fine-stemmed, pliable hays are ideal for encouraging roughage consumption before weaning. Chopping the hay increases consumption. Concentrates should be offered as pellets or rolled grains, rather than as ground meals (Morand-Fehr 1981c). Free choice water is necessary to optimize consumption and digestion of hay and concentrates, because milk bypasses the rumen, whereas water enters the rumen.

The time to wean is often determined by existence of other markets for the milk to be fed. Weight, rather than age, is the best indicator of how well a goat kid will withstand the shock of weaning. There is almost no growth retardation in Alpine kids weaned at 10 kg, whereas weaning at lighter weights leads to reduced growth rates for one week or longer. For other breeds, weaning when kids have achieved a weight equal to two and a half times birth weight has been recommended (Morand-Fehr 1981c). If economics do not demand early weaning, dairy breed kids grow quite well while at the same time learning to eat solid food if provided with 1.5 liters of milk/day until three or four months of age. Delaying weaning of replacement doelings also aids in reaching breeding weight at a younger age (Palma and Galina 1995). The growth rate of kids is influenced by the initial birth weight and by breed and feeding programs (Bajhau and Kennedy 1990).

After Weaning

Older kids, after weaning, can be grown easily on a concentrate or corn silage based ration, as long as proper consideration is given to preventing urolithiasis (see below and Chapter 12). Male Alpine kids, for instance, can have a daily gain of 180 to 190 g. This gives a dressed carcass of 10 kg or more by one hundred days of age. If no roughage is provided and castration is not practiced, the subcutaneous fat may be undesirably soft. This phenomenon is less important than with lambs because of the limited quantity of subcutaneous fat on a goat carcass. Female kids (Alpine breed) weaned by five to six weeks onto hay and grain have an average daily gain of 170 g for the first twelve weeks, but then growth slows (Morand-Fehr 1981c).

Most goats raised for meat live in regions where subsistence farming is practiced and nutritional conditions are poor. When feed intake is low or dietary energy and protein concentrations are inadequate, the growth rate is decreased and the feed conversion rate is high. Most goat breeds other than the Boer also have not been selected for increased growth rates (Nandé and Hofmeyr 1981). Nutritional strategies which may improve meat production include increased use of crop residues including sweet potato vines, use of urea-molasses licks, and increased cultivation and feeding of forage plants such as *Leucaena*, *Manihot* (cassava), and *Sesbania* (Devendra 1987). Constraints on *Leucaena* feeding are discussed in Chapter 10.

Doelings raised as replacements should not be overfed on concentrates or other energy sources. There is limited evidence that high energy intake in prepubertal goats results in decreased secretory tissue and increased fat deposition in the developing udder (Bowden et al. 1995). It is important, however, that they be well grown at the time of breeding. The French recommend attaining 55% to 60% of adult weight by seven months for natural breeding at that age. A figure of 70% is preferred if synchronization and artificial insemination are to be used. To achieve both good growth and a low percentage of concentrates in the ration, it is once again necessary to feed a good quality roughage. With poor hays, energy and protein intake do not support adequate growth.

Available nutrient requirement tables usually express requirements in calories of energy and grams of protein. Using this information to formulate an appropriate diet is laborious and depends strongly on the desired rate of gain and the dry matter intake achieved. The following examples of rations for replacement kids are calculated from the NRC 2007 tables of requirements and DM intake, using the online calculator (Gipson and Goetsch). A 15-kg kid approximately three months old and gaining 150 g/d needs 1.80 Mcal/d of metabolizable energy (ME) or 0.50 kg of TDN. Its metabolizable protein (MP) requirement of 67 g/d can be met with a diet that contains 2.87 kcal/kg ME and 16.7% crude protein (CP), assuming a DMI of 3.79% of bodyweight and a forage plus concentrate

diet with 40% undegradable intake protein (UIP). A 30-kg dairy kid in its seventh month gaining 100 g/day needs 2.19 Mcal/day of ME or 0.61 kg of TDN. Its MP requirement of 68 g can be met with a diet that contains 2.39 kcal/kg ME and 10.7% crude protein, assuming a DMI of 3.03% of bodyweight and a similar diet with 40% UIP. Naturally, these levels must be increased to allow for activity or cold weather. Calcium and phosphorus recommendations for growing kids at varying growth rates have been summarized by Morand-Fehr (1981c) and the NRC (2007).

FEEDING BUCKS AND PET GOATS

Adult male goats and wethers should in general be fed a ration similar to what is appropriate for nonpregnant, nonlactating does. The energy requirements for maintenance are probably somewhat more for males than for females of equivalent metabolic body size. The French recommend an increase of 10% for males. An additional increase of 15% in energy and in protein and minerals is desirable beginning four to six weeks before the breeding season (Morand-Fehr and Sauvant 1978; Rankins et al. 2002). This normally needs to be supplied as grain (approximately 0.5 kg or 1 pound) because the buck may be so overexcited by the presence of his does that he does not take time to eat enough hay. Even with a supplement it is common for bucks to stop growing or lose weight during the breeding season (Louca et al. 1977; Gall 1981; Walkden-Brown et al. 1994). Feeding a poor quality ration (poor hay) to bucks is associated with a decreased scrotal circumference and poorer semen motility (Arbeiter 1963; Walkden-Brown et al. 1994).

Good quality grass forage and minimal grain, when supplemented with a trace mineralized salt and abundant fresh water, should generally meet most nutritional needs of goats at maintenance. Access to legumes should be limited to avoid calcium and protein excesses and nutritional bone disease (Adams 1986). Because forage quality is highly variable, owners should be encouraged to record the weight or girth tape measurement of their pets once a month. Restricted feeding or energy/protein supplementation can then be prescribed before the animal becomes either obese or emaciated.

Urolithiasis

Young male kids, breeding bucks, and wethers kept as pets or for fiber production are susceptible to urinary calculi. Commonly, when high concentrate feeding is practiced, a relative phosphorus excess predisposes to the precipitation of struvite (calcium, magnesium, and ammonium phosphates) crystals in the bladder. Urolithiasis is discussed in detail in Chapter 12.

Dietary recommendations to prevent the condition can be briefly summarized as follows. Dietary cal-

cium : phosphorus should be at least 2 : 1; some authors recommend 3 or 4 : 1 (Van der Westhuysen et al. 1988). Excessive phosphorus is undesirable, even if additional calcium is incorporated in the diet to adjust the ratio. Ideally, the total ration fed to a buck should not contain more than 2.5 g P/kg dry matter, though this level is exceeded by many roughages. Likewise, the magnesium in the diet should not exceed the requirement for proper growth or maintenance. If attention is only given to the calcium : phosphorus ratio, the total quantity of minerals to be excreted in urine often exceeds what can be kept in solution. In general, mature males should not receive dairy concentrates or large quantities of alfalfa or subterranean clover, because these feeds contain excessive calcium and protein. Good quality grass hay is ideal for bucks.

French recommendations specify that the quantity of grain fed to a buck should not exceed 500 grams/day (Morand-Fehr and Sauvant 1988). Feeding more roughage and avoiding pelleted feeds may also help to maintain a fiber mat in the rumen and increase fecal (as opposed to urinary) output of phosphorus (NRC 2007). Ammonium chloride may be added at 0.5% to 1% of the ration or 2% of the concentrate to acidify urine and thus discourage precipitation of struvite. Clean water should be available at all times. Salt can be added to the ration at 4% to 5% to increase water intake and diuresis.

Posthitis

If excessive dietary protein is fed to a male goat, especially a castrated animal, the quantity of urea in the urine is increased. Urea-splitting corynebacteria within the prepuce can then release free ammonia, which scalds the external skin and preputial mucosa and produces "pizzle rot," described in Chapters 12 and 13.

Arthritis

Diets containing excessive calcium have been associated with calcification of periarticular tissues, ankylosis, and a stiff gait (Guss 1977), although experimental reproduction of the syndrome in goats is lacking. The pathogenesis is considered to be hypercalcitoninism induced in nonlactating animals (such as heifers and breeding bulls [Rostkowski et al. 1981]) by dietary calcium levels appropriate for lactating animals. Published descriptions of the syndrome in goats mostly predate discovery of the caprine arthritis encephalitis virus; it is also possible that excess calcium speeds dystrophic calcification of periarticular tissues damaged by the CAE virus, as discussed in Chapter 4. To avoid both metabolic bone disease and exacerbation of CAE in bucks and nonlactating pet goats, dietary calcium should be limited to 4 to 6 grams daily for mature animals weighing 70 kg (NRC 1981b).

SPECIAL CONSIDERATIONS IN FEEDING ANGORA AND CASHMERE GOATS

When Angoras are selected for high mohair production, their resulting higher nutrient requirements leave them only marginally capable of meeting their needs under normal foraging conditions in the dry climates to which they are best adapted (Huston 1981). Supplemental protein and energy are typically needed for early growth, at breeding, during mid- and late gestation, and after parturition. Supplemental feeding and shelter are also important for prevention of "freeze loss" after shearing, as discussed in Chapter 2.

Mohair Production

To allow for growth of the fleece (1.8 to 6 kg/year, Di Trana and Sepe 2008), Angora goats should be fed additional nutrients above those specified for maintenance, activity, gestation, and lactation of other breeds. The NRC (1981b) recommended a daily energy supplement of 30 kcal of ME (which could be approximated by $0.72 \times 30 = 21.6$ kcal NE_1) per kg of annual fleece. The protein supplement for the same kg of fleece (calculated from a protein-to-energy ratio) is 4.3 g TP or 3 g DP. More recently, regression equations have been developed to try to predict the requirements of Angora goats for energy and protein (Luo et al. 2004b) but do little to help an owner with diet formulation. However, ration calculators are available online to convert the formulas into a diet for the goats (Gipson and Goetsch).

Increased sulfur in the diet is also necessary (Adams 1986; Bretzlaff 1990; Qi et al. 1994). Feeding inorganic sulfur is beneficial as long as the rumen microbes are supplied with adequate nitrogen and energy to synthesize sulfur-containing amino acids, especially methionine and cystine, which are required for keratin production. Feeding of rumen bypass proteins high in sulfur-containing amino acids such as rapeseed and fish meal has also been proposed (de Simiane 1990). Supplementing yearling Angoras averaging 47.5 kg bodyweight with 2.5 g/day of a commercial rumen protected methionine product increased mohair production by 46% (Galbraith 2000). However, feeding of zinc methionine to supply a rumen bypass form of this important amino acid had minimal effects on mohair production (Puchala et al. 1999).

It has been estimated that mature females require 9%, 10%, and 11% crude protein when they are, respectively, nonpregnant, late pregnant, and lactating. Except during dry years and in winter, the range diet is adequate. At times of increased need and decreased availability, a supplement of 40% cottonseed meal and 60% sorghum grain (24% crude protein and 3.25 Mcal digestible energy/kg) has proven adequate (Huston 1981). To avoid indigestions and metabolic diseases,

the proportion of grain in late gestation should be limited to 40% of DM (0.3 to 0.4 kg for a 35 kg doe). During lactation, the proportion of concentrates (DM basis) in the total ration should never exceed 60% (de Simiane 1990).

It is often noted that the diameter of the mohair fiber increases slightly with better nutrition. Thus, in one study of yearling males, the fiber diameter for a ration protein of 12% was 36 microns while for a ration protein of 18%, fiber diameter was 38 microns (Huston et al. 1971). In this same study, clean fleece weight increased from 6.5 to 9.9 pounds and pounds of feed per pound of mohair decreased from 84 to 61 with the higher protein. A later study showed that yearlings produced 31% more mohair when fed 16% protein as compared with an 8% protein diet (Jia et al. 1995). In another study using mature wethers, increasing the dietary crude protein level from 10% to 19% (DM basis) resulted in an 83% increase in live weight gain and a 38% increase in mohair produced over a 112-day feeding period (Calhoun et al. 1983). Intentionally depriving the Angora goat of protein is thus false economy, and causes negative effects on health, reproduction, feed conversion, and mohair yield. A more recent study reported that increasing stocking rate of mature Angoras on pasture can decrease fiber diameter by 4 microns via a decrease in bodyweight. Regression analysis showed that fiber diameter decreased 0.4 microns for each kg fasted live weight lost (McGregor 1986). Nutrition has minimal if any effects on medullation of mohair (Lupton et al. 1991).

When does are in poor body condition, flushing (feeding increased energy) at the beginning of the breeding season can markedly increase the number of kids produced, and best quality mohair is obtained from young animals. When grazing is poor, feeding a markedly increased energy to Angora does before mating increases the kidding percentage by 20% to 25%. This can be achieved by feeding 500 g of "chocolate grain" (whole grain treated with alkali-ionophore; see discussion of feeding the pregnant doe to prevent abortion) per day per doe from two weeks before to two weeks after introduction of the buck (Van der Westhuysen et al. 1988). Wheat treated with 2% slaked lime has been used in a similar fashion in Australia (McGregor 1998). Other flushing recommendations include feeding 250 to 500 g of corn/day or moving to fresh pasture (Bretzlaff et al. 1991).

Another management practice that affects both the nutritional status and the reproductive efficiency of Angoras is the selection for open faces. Hair-blind animals on range cannot forage selectively or reproduce well (Shelton 1961; Van Tonder 1975). However, length of facial hair is positively correlated to length of the fleece overall, and trimming the hair on the head to expose the eyes ("wigging") three months after each

body shearing is currently preferred to genetic selection for an open face.

Vitamin and mineral requirements for Angoras should be similar to those for other goats. Phosphorus is sometimes deficient in range forage, and mineral supplements offered should not have a calcium:phosphorus ratio more than 2:1 (Huston et al. 1971).

Angora Kid Growth

The growth rate required of Angora kids is less than what many producers desire for dairy kids. This is because the Angora typically is not bred until eighteen months of age, when it should weigh 25 kg. Adult females are expected to weigh 30 to 60 kg. It has been estimated that kids should weigh 15 kg by weaning and 20 kg by April 1 in the United States. A supplement is imperative to achieve even this moderate gain on winter range in Texas.

Cashmere Production

Cashmere fiber, a fine, downy fiber produced as an undercoat (see Chapter 2), is produced seasonally and in far smaller quantities per goat than is mohair. Annual production is often 300 g/head or less, and the requirements for amino acids are more easily met on a daily basis (Galbraith 2000). Increasing the dietary protein or providing sulfur containing amino acids above the requirements for maintenance and fleece production does not improve the quantity or quality of cashmere produced (Jia et al. 1995; Di Trana and Sepe 2008) and may cause an undesirable increase in fiber diameter. Likewise, feeding increased amounts of energy or decreasing the stocking rate do not increase cashmere production, although body weight and guard hair growth are increased (Russel 1992). McGregor (1998) has pointed out, however, that goats with a good genetic potential for fiber production produce more cashmere if they gain weight over summer and fall, with a total weight gain of 1 to 2 kg being desirable on an economic basis. Heavier animals produce more cashmere but as cashmere production increases, the fiber diameter increases. Wethers over 55 kg should be culled because of the lower price paid for coarse fiber (McGregor 1998). It is important to meet maintenance and growth requirements, which are similar to those of other breeds, for young goats during the anagen phase of fiber growth.

POISONOUS PLANTS

Goats, by their curiosity, browsing habits, and inhabitation of some environments where food is very scarce, are exposed to a myriad of plants containing toxic compounds. Often these are secondary metabolites that have evolved in perennial plants for protection against herbivores, especially insects. The NRC (2007) includes in its feed composition table 15–12 (Composition of pasture or range forage, browse, and other novel feedstuffs) a number of plants that are potentially toxic to goats. The goat's ability to assume a bipedal stance and its mobile upper lip contribute to its ability to use tree leaves for feed (Malecheck and Provenza 1981). This can be especially important in drought conditions when grass is no longer available. Grazing and browsing goats tend to move from plant to plant and species to species; thus, they are less apt to eat a fatal quantity of a given plant than is the more confined animal with sudden access to a single bush or tree. The hurried browsing of a hungry goat increases the risk of plant poisoning. Supplementing the diet of goats on range with additional energy and protein also decrease the risk of toxicity (Provenza et al. 2003).

For a plant to be called poisonous for goats, it needs to cause toxicity under natural settings, not just in laboratory experiments. The goat must eat enough of the plant to become ill when raised in the environment where the plant grows. Without proof from experimental feedings, a plant likewise cannot be firmly said to be toxic to goats. The absence of many species from the list of species toxic to goats in Table 19.7 represents, in part, a paucity of literature documenting plant poisonings in goats. Where information is largely limited to experimental studies, this is indicated by "exp" in the table. Other plants with reports of just spontaneous or experimental toxicity have been summarized by Dobereiner et al. (1987). When the plant (but not necessarily a report of toxicity) exists in the United States, this is indicated in the table. Most plants are not restricted to the countries mentioned.

Because the same toxic compounds are often present in multiple members of a genus or family of plants, practitioners in all countries should be suspicious of plants closely related to those in Table 19.7. However, even though this table omits some species names, not all members of a genus are equally or invariably toxic. A computer database on poisonous plants in the United States has been established and should help to keep information relative to goats up to date (Wagstaff et al. 1989).

When plants cause well recognized clinical signs they are discussed further and more references are supplied under the appropriate body system. Texts by other authors should also be consulted (Kingsbury 1964; Howard 1986; Dobereiner et al. 1987; Tokarnia et al. 2000; Burrows and Tyrl 2001; Frohne and Pfänder 2005; Kellerman et al. 2005). Cyanide and nitrate poisoning are discussed in Chapter 9 and plants causing oxalate poisoning in Chapter 12. When the identity of a suspect poisonous plant or its toxic principle is unknown, oral dosing of the sick goat with activated charcoal is appropriate.

Even the partial listing of poisonous species given here could confuse the veterinarian searching for an

Table 19.7. Plants poisonous to goats.

Plant	Family	Comments
Amanita phalloides	Agaricales	France; colic, liver necrosis (Cristea 1970).
Galenia africana	Aizoaceae	South Africa; ascites, liver, and cardiac disease.
Agave lecheguilla	Amaryllidaceae	U.S.A.; liver disease, icterus, photosensitization.
Nerium oleander	Apocynaceae	U.S.A.; weakness, muscle tremors, irregularities in heart beat; cardioactive glycosides.
Sarcostemma viminale	Apocynaceae	South Africa; hypersensitivity, tonic muscle spasms, opisthotonos.
Aristolochia bracteata	Aristolochiaceae	Sudan; enteritis (exp) (El Dirdiri et al. 1987).
Asclepias spp.	Asclepidaceae	U.S.A.; depression, weakness, seizures.
Acanthospermum hispidum	Asteraceae	Sudan; icterus, liver necrosis and portal fibroplasia, anemia (exp) (Ali and Adam 1978).
Baileya multiradiata	Asteraceae	U.S.A.; anorexia, emaciation, regurgitation, inhalation pneumonia (Dollahite 1960).
Chrysocoma ciliata = Chrysocoma tenuifolia	Asteraceae	South Africa; alopecia (kaalsiekte), hairballs, diarrhea of kids if dam eats plant.
Fluorensia cernua	Asteraceae	U.S.A.; abdominal pain, reluctance to move; unpalatable, fruits toxic (Mathews 1933).
Geigeria spp.	Asteraceae	South Africa; regurgitation, dilated esophagus, pneumonia, paralysis.
Gutierrezia microcephala	Asteraceae	U.S.A.; abortion, necrosis of liver and kidney (exp).
Hymenoxys spp.	Asteraceae	U.S.A.; gastrointestinal and neurologic signs.
Isocoma wrightii (*Aplopappus heterophyllus*)	Asteraceae	U.S.A.; trembling, recumbency, constipation, pale liver; tremetol excreted in milk (Bretzlaff 1990).
Sartwellia flaveriae	Asteraceae	U.S.A.; weight loss, ascites, liver cirrhosis (exp) (Mathews 1940).
Senecio (several species)	Asteraceae	U.S.A.; centrolobular liver degeneration, megalocytes, bile duct proliferation (Goeger et al. 1982). Goats are resistant enough to *S. jacobaea* to be used for biological control.
Vernonia mollissima	Asteraceae	Brazil; acute liver necrosis (exp) (Stolf et al. 1987).
Brassica spp.	Brassicaceae (Cruciferae)	U.S.A., Europe; Congenital goiter.
Descurainia sophia	Brassicaceae	U.S.A.; Congenital goiter (Knight and Stegelmeier 2007).
Lobelia spp.	Campanulaceae	U.S.A.; depression, coma, death; may survive if force fed.
Cadaba rotundifolia	Capparidaceae	Sudan; enteritis, liver and kidney necrosis (exp) (El Dirdiri et al. 1987).
Capparis tomentosa	Capparidaceae	Sudan; posterior paresis and ataxia, renal and hepatic necrosis (exp) (Ahmed and Adam 1980).
Drymaria spp.	Caryophyllaceae	U.S.A.; diarrhea, rapid death (McGinty 1987, Mathews 1933).
Celastrus scandens	Celastraceae	U.S.A.; central nervous system disturbance, gastroenteritis.
Ipomoea spp.	Convolvulaceae	Brazil, Sudan, South Africa; nervous signs including ataxia, nystagmus, and opisthotonos; anemia.
Coriaria myrtifolia	Coriariaceae	Mediterranean; convulsions, rapid death (Anonymous 1973).
Cotyledon orbiculata	Crassulaceae	South Africa; krimpsiekte; cardiotoxicity (bufadienolides) (Tustin et al. 1984).
Kalanchoe spp. (*Bryophyllum*)	Crassulaceae	Africa, Australia; bufadienolide cardiac glycosides, also neurotoxicity.
Tylecodon spp.	Crassulaceae	Africa; krimpsiekte (bufadienolides).
Cycas media	Cycadaceae	Australia; ataxia; neuronal swelling and demyelination (Hall 1964).
Dichapetalum spp.	Dichapetalaceae	Nigeria, South Africa; extreme depression, dyspnea, convulsions, sudden death. Monofluoracetate.
Kalmia and Rhododendron spp., *Pieris japonica*	Ericaceae	U.S.A.; grinding of teeth, colic, vomition (grayanotoxins) (Puschner et al. 2001; Plumlee et al. 1992).
Clethera arborea	Ericaceae	New Zealand; depression, ataxia, salivation, projectile vomition (Gibb and Taylor 1987).

Table 19.7. *Continued*

Plant	Family	Comments
Codiaeum variegatum	Euphorbiaceae	Sri Lanka; severe colic and ruminal distention.
Manihot spp.	Euphorbiaceae	Brazil; cyanide poisoning.
Abrus precatorius	Fabaceae	U.S.A., Sudan; bloody diarrhea, abdominal pain, hepatic and renal necrosis (exp; Barri et al. 1990).
Acacia berlandieri	Fabaceae	U.S.A.; ataxia, posterior paralysis after exclusive diet for nine months (Sperry et al. 1964).
Acacia leucophloea	Fabaceae	India; dyspnea, ataxia, bellowing, convulsions; HCN.
Acacia nilotica	Fabaceae	South Africa; methemoglobinemia, abortion.
Astragalus emoryanus	Fabaceae	U.S.A.; muscular incoordination and weight loss; toxicity may vary with soil type.
Cassia spp.	Fabaceae	U.S.A.; muscle degeneration and red urine (exp) (Dollahite et al. 1964; El Sayed et al. 1983).
Crotolaria burkeana	Fabaceae	South Africa; unknown toxin produces laminitis without liver disease.
Gymnocladus dioica	Fabaceae	U.S.A.; severe colic (Howard 1986).
Leucaena leucocephala	Fabaceae	Australia and Africa; mimosine toxic if not degraded by rumen microbes (Semenye 1990). Hypothyroidism (Jones and Megarrity 1983).
Lupinus formosus	Fabaceae	U.S.A.; cleft palate and skeletal deformities (exp).
Oxytropis ochrocephala	Fabaceae	China; depression, ataxia, dysphagia, weight loss; swainsonine causes α-mannosidase inhibition (Cao et al. 1992a).
Prosopis julifora	Fabaceae	Brazil; head tremors, difficulty chewing, salivation, emaciation after long-term consumption of pods (exp) (Tabosa et al. 2004).
Senna spp.	Fabaceae	U.S.A.; myopathy (exp).
Sesbania vesicaria	Fabaceae	U.S.A.; diarrhea, grinding of teeth, necrosis of abomasum, liver, and kidney.
Sophora spp.	Fabaceae	U.S.A.; muscle tremors, coma; seed very toxic if ground.
Quercus spp.	Fagaceae	U.S.A.; rumen stasis, constipation, gastritis, nephritis.
Brachiaria decumbens	Gramineae	Malaysia, Nigeria, Brazil; liver disease, photosensitization, icterus.
Cynodon dactylon	Gramineae	U.S.A.; ataxia and tremors (exp).
Pennisetum clandestinum	Gramineae	Australia; ataxia, abdominal pain, rumenitis; oxalates (Peet et al. 1990).
Trisetum flavescens	Gramineae	Europe; enzootic calcinosis from high vitamin D activity (Braun et al. 2000).
Dipcadi glaucum	Hyacinthaceae	South Africa; nervous signs and diarrhea.
Ornithogalum toxicarum	Hyacinthaceae	South Africa; cardiac glycosides.
Hypericum spp.	Hypericaceae	U.S.A.; primary photosensitization.
Persea americana	Lauraceae	U.S.A., Australia; cardiotoxicity, noninfectious mastitis.
Nolina texana	Liliaceae	U.S.A.; liver and kidney damage, secondary photosensitization; flowers and fruit toxic.
Stypandra imbricata and *S. glauca*	Liliaceae	Australia; degeneration of retina, optic nerve, and optic tract; "blindgrass."
Veratrum californicum	Liliaceae	U.S.A.; cyclopia if consumed on thirteenth to fifteenth day of pregnancy; collapse.
Mascagnia rigida	Malphighiaceae	Brazil; sudden death after eating plant for a long time.
Sida carpinifolia	Malvaceae	Brazil; ataxia, hypermetria, muscle tremors, lysosomal storage disease (Driemeier et al. 2000).
Clidemia hirta	Melastomaceae	Indonesia; tannins; liver and kidney degeneration (exp) (Murdiati et al. 1992).
Camptotheca acuminata	Nyssaceae	China; alkaloid camptothecin causes hemorrhagic diarrhea, coma, death (Cao et al. 1992b).
Tephrosia apollinea	Papilionaceae	Sudan; posterior paresis, ataxia, diarrhea, renal and hepatic necrosis (exp) (Suliman et al. 1982).
Plumbago scandens	Plumbaginaceae	Brazil; bloat, foamy salivation, dark urine, epithelial necrosis (Medeiros et al. 2004).

Table 19.7. *Continued*

Plant	Family	Comments
Fagopyrum spp.	Polygonaceae	U.S.A.; primary photosensitization.
Notholaena sinuata	Polypodiaceae	U.S.A.; trembling, ataxia, may die if forced to exercise; "jimmies" (Kingsbury 1964).
Portulaca oleracea	Portulacaceae	U.S.A.; diarrhea, muscle weakness partially due to oxalate content (Obied et al. 2003).
Karwinskia humboldtiana	Rhamnaceae	U.S.A.; degeneration of cardiac and skeletal muscle fibers, demyelination and Wallerian degeneration; "limberleg."
Prunus and *Malus* spp.	Rosaceae	U.S.A.; cyanogenic glycosides.
Fadogia spp.	Rubiaceae	South Africa; chronic fibrotic cardiomyopathy.
Pachystigma spp.	Rubiaceae	South Africa; cardiac insufficiency, sudden death.
Pavetta spp.	Rubiaceae	South Africa; cardiac insufficiency, sudden death.
Thamnosma texana	Rutaceae	U.S.A.; primary photosensitization.
Atropa belladonna	Solanaceae	Europe; excitement, dilated pupils, rumen atony (Ogilvie 1935).
Cestrum laevigatum	Solanaceae	South Africa, Brazil; apathy, ptyalism, mydriasis, gastrointestinal stasis, liver necrosis.
Solanum spp.	Solanaceae	U.S.A.; neurologic or enteric signs.
Solanum malacoxylon	Solanaceae	Brazil; enzootic calcinosis due to excess vitamin D (exp) (Górniak et al. 2007).
Vestia foetida	Solanaceae	New Zealand; ataxia, mydriasis, seizures, liver necrosis (McKeogh et al. 2005).
Taxus spp.	Taxaceae	U.S.A.; sudden death (Van Gelder et al. 1972, Casteel and Cook 1985).
Conium maculatum	Umbelliferae	U.S.A.; colic, diarrhea, convulsions (Copithorne 1937); teratogenic (exp) (Panter et al. 1992).
Ferula communis	Umbelliferae	Mediterranean; hemorrhagic syndrome (coumarins) (Girard 1934).
Lantana camara	Verbenaceae	U.S.A., South Africa.; liver disease (Pass 1986).
Kallstroemia spp.	Zygophyllaceae	U.S.A.; knuckling at fetlocks, paresis, convulsions (Mathews 1944).
Tribulus terrestris	Zygophyllaceae	U.S.A., South Africa; hepatogenic photosensitization (in combination with *Pithomyces chartarum*).

etiology for an undiagnosed illness. It is guaranteed to terrify the average goat owner. Dozens of species of plants that contain toxic principles are found on most pastures and ranges. The quantity consumed is a critical factor in determining if poisoning occurs, but both the quantity required for signs to occur and the amount eaten by an individual animal are usually imprecisely known. The stage of growth and the availability of alternative forage are other important factors. In general, most plant toxicities can be avoided by supplying supplemental hay and grain in times of drought, not overstocking pastures (Taylor and Ralphs 1992), not turning hungry animals out to forage, and preventing access of goats to ornamental plants (including trees and shrubs) and their clippings. Overgrazed pastures, snow coverage of more desirable forages, and unsanctioned entry into a garden or planted field are common situations in which poisoning occurs. Goats used for weed or brush control (Popay and Field 1996) or handfed potentially toxic plants in a cut and carry system are also at risk.

Herd Health Management and Preventive Medicine

In any livestock production system, certain diseases and production constraints can be anticipated on the basis of accumulated experience. Herd health management and preventive medicine programs are designed to minimize the potential adverse effects of these predictable constraints and to protect against unexpected ones. These goals are accomplished by timely and cost-effective application of suitable veterinary, nutritional, and management interventions before disease or lost production occurs.

The disease conditions and production constraints expected in any given livestock production system are a function primarily of the species of livestock kept, their intended use, and the management system in which they are kept. However, a range of geographic, climatic, cultural, and economic factors modify herd health and preventive medicine programs at the local level.

For example, free-ranging East African goats maintained for meat, milk, and hides in mixed herds with cattle and sheep by Maasai pastoralists in the savannahs of Kenya present quite a different set of circumstances from Saanen dairy goats maintained exclusively for milk production in total barn confinement in west central France. Yet, appropriate herd health management and preventive medicine programs can be designed and implemented for each situation. Appropriate means that the technology and methods employed are available, understandable, and implementable, that they are acceptable to the producer and the consumer, that they address a specifically identified disease or production problem which could potentially occur in the herd, and finally, that they produce a favorable cost/benefit ratio in terms of improved health or increased productivity relative to the labor and materials expended.

Because of their remarkable adaptability and utility, goats are maintained over a more diverse range of habitats and production systems than any other domestic livestock species. As a result, herd health recommendations for goats vary considerably and all possible situations cannot be covered here in the text. In general, intensified management not only allows, but also demands, more interventions than extensive management. As a result, there is a larger body of documented veterinary experience relating to herd health management of goats maintained intensively. In addition, as a general rule, veterinary services are more often available or used where goats are raised intensively rather than extensively. This also contributes to a greater knowledge of appropriate herd health programs in intensive management situations. Finally, specialization for the production of distinct commodities for established industries, such as milk for commercial cheese production or mohair for textile mills, helps to define and clarify meaningful health and

production targets within well-defined economic constraints. Not surprisingly, the largest body of information about goat herd health relates to intensively managed dairy goats and Angora goats maintained under semi-extensive conditions.

The coverage of herd health and preventive medicine programs in this text focuses mainly on dairy goats and fiber-producing goats. There are also more general comments on health and production issues related to goats kept for meat, goats kept for skins, transgenic goats, and goats raised under organic farming systems.

DAIRY GOAT HERD HEALTH MANAGEMENT AND PREVENTIVE MEDICINE

It is useful to think of the dairy goat herd as divided into separate management subgroups, each with its own set of herd health and preventive medicine requirements. For the purpose of this discussion, the following groups of goats are identified: newborn kids to weaning, weaned kids to breeding, bred doelings and dry does, milking does, and bucks. For each group, the common and expected diseases are presented, followed by suggested routine management procedures appropriate for the group. This analysis of subgroups within the herd is preceded by a brief discussion of issues relevant to the herd in general.

General Comments about Dairy Goat Herd Health

In general, commercial goat dairies should be managed as closed herds to minimize disease problems. Taking goats to shows and fairs should be discouraged. If showing is necessary for the financial well-being of the farm through the sale of breeding stock, then isolation and quarantine procedures should be followed for animals returning from outside. A separation period of three weeks from the herd is warranted. From the disease control point of view, artificial insemination is preferable to introduction of bucks or trucking of does to other farms for breeding.

Goats are very clever about undoing fasteners and gate closings, so gates and doors must be very secure to avoid unwanted escape and accidental access to feed and chemical storage areas which could result in engorgement toxemia, bloat, or poisoning. Goats are also notorious for chewing on the materials from which their enclosures are constructed. Therefore, old barns with lead based paints should be avoided as goat housing. When new housing is constructed, lumber treated with potentially toxic chemicals such as pentachlorophenol, used as wood preservatives, should be avoided.

Goats are also very hard on fences because of their propensity for climbing, and improper selection of fencing materials can be costly to owners. Fences with horizontal rungs or slats encourage climbing and destruction of fences. Chain link fences predispose goats to catching their limbs in the fence, with possible fractures resulting. If vertical slats or bars are used on gates or fencing, the spacing should be carefully evaluated to be sure that goats cannot become trapped and strangled, especially horned goats. For these reasons, electric fencing for goats is gaining in popularity.

Goats, like sheep, are susceptible to predation due to their small size and lack of potent defenses. Kids are particularly defenseless and may fall prey to raptors and ground-dwelling predators. Because the main defense of small ruminants is fleeing, the practice of tethering goats can be deadly where predators are common. Various defenses against predation are discussed in Chapter 4.

Goats, like other livestock, can experience suboptimal performance or overt disease from mineral deficiencies in feedstuffs related to soil composition in different parts of the world. The veterinarian and producer must be aware of the mineral deficiencies occurring locally. Deficiencies well documented to cause financial loss in goats are selenium, iodine, cobalt, and copper. Fertilization, top dressing of pastures, supplemental feeding, provision of trace mineral salt licks, or parenteral administration of needed substances can be used to address these problems, as discussed in Chapter 19. Another potential local problem for goats is consumption of noxious or toxic plants. Plants toxic to goats are listed in Chapter 19 and are discussed throughout this book related to the organ systems most affected. Plants that can cause sudden death, those that cause primary or secondary photosensitization, and those that cause off-flavors in milk are of particular concern.

Veterinarians interested in goats should encourage herd owners to have regularly scheduled herd health visits. When a knowledgeable veterinarian becomes familiar with the routine practices and seasonal activities of the goat herd, he or she is better able to spot incipient problems developing in the herd and initiate appropriate interventions before costly losses occur. As with dairy cattle, reproductive consultation is a good place to begin to show the herd owner how the veterinarian can help improve production efficiency through pregnancy checking, heat synchronization practices, and out-of-season breeding programs. Mastitis control is an important area where veterinary inputs can improve herd productivity. Nutritional management of metabolic diseases such as pregnancy toxemia is another area of potential input. The development and implementation of practical and realistic CAE control programs are important concerns of goat producers that should involve the counsel of veterinarians. Veterinarians can also carry out necropsy examinations on all goats that die in a herd. This is an effective means of tracking unexpected disease developments in the herd.

Management of Newborn Kids to Weaning

Disease Problems

At birth, the major obstacles to survival are hypoxia, hypothermia, hypoglycemia, and susceptibility to infectious disease. The latter is exacerbated by delayed or inadequate intake of colostrum rich in maternal immunoglobulins. Failure of passive transfer of maternal antibodies to newborn kids leads to increased morbidity and mortality throughout the postnatal period, particularly from septicemia in the first week of life, and later, from pneumonia as kids reach weaning age and diminishing concentrations of maternal antibodies have not been fully replaced by immunoglobulins actively produced by the kid. Failure to disinfect the navel after birth and maintaining kids in a dirty environment also lead to increased incidence of omphalophlebitis, septicemia, polyarthritis, and pneumonia. Diarrheal diseases are common in this period. Numerous etiologic agents can cause neonatal diarrhea over the first two weeks of life, as discussed in Chapter 10. After two weeks of age, coccidiosis is an increasing threat. A pneumoenteritis complex is sometimes seen in young kids, suggesting poor husbandry, heavy environmental pathogen loads, and inadequate colostral intake. Contagious ecthyma also may appear clinically in this age group if endemic on the premises or recently introduced.

Newborn kids should be inspected carefully for congenital defects such as cleft palate, rectovaginal fistula, atresia ani, hydrocephalus, umbilical hernia, and ventricular septal defect. The intersex condition is especially common in goats. Beta mannosidosis and mucopolysaccharidosis IIID are genetic diseases of Nubian kids. Kids identified with congenital defects should be culled immediately or designated for meat production.

Caprine arthritis encephalitis (CAE) virus infection is a major concern of dairy goat producers worldwide. Although clinical disease is rarely seen in kids younger than two months of age, newborn kids are the focus of CAE control programs because the virus is spread primarily from infected does to susceptible kids via colostrum and milk. Current kid-rearing techniques are defined in large part by practices aimed at reducing transmission of CAE to neonates, as discussed in Chapter 4.

Management Practices

Kidding should be a well-anticipated event, not an unexpected surprise. Being prepared for routine processing of kids at birth and being ready to respond to emergencies reduce neonatal losses. A clean, warm, dry, well-lit, well-bedded, well-ventilated kidding area should be designated and maintained. Appropriate supplies should be on hand such as towels for drying kids, feeding tubes for kids that do not suckle, and tincture of iodine for dipping navels. A colostrum management program relative to CAE control should be developed and in place before the onset of the kidding season. Evaluation of colostrum quality and colostrum requirements are discussed with failure of passive transfer in Chapter 7. Colostrum management programs are discussed in the section on CAE in Chapter 4.

The timed induction of parturition using prostaglandin has become popular as a technique for assuring attendance at birth and facilitating CAE control activities. Protocols are discussed in Chapter 13 along with recognition and management of dystocia, resuscitation, and proper care of the neonate at birth.

Proper identification and record keeping are signs of a well-managed farm. For identification of neonates, the rubber rings from canning bottles marked with an indelible marker are sometimes used as identifying collars. Subsequent ear tattooing of kids is recommended for permanent identification and should be performed after three months of age. If done too early, the tattoo dots comprising individual numbers or letters expand and separate as the ear grows and the markings become difficult to interpret. Green ink is recommended because the skin of some goat ears is black, making black ink tattoos unreadable. For the LaMancha breed with minimal external ear, tattooing is performed on the underside of the tail.

Kids can be housed in group pens but should not be overcrowded. Pen design should allow easy and thorough cleaning. The spread of diarrheal agents is exacerbated by poor sanitation and overstocking. Early culling or marketing of unwanted male kids reduces kid populations and the attendant risk of increased environmental contamination and the spread of infectious disease.

Disbudding of kids to prevent horn growth is commonly practiced to prevent horn related injuries between goats and to handlers later in life. In the United States, purebred diary goats cannot be shown if they have horns. Disbudding is usually done between three and fourteen days of age, depending on breed, size, and sex of kids as described in Chapter 18. When buck kids intended for future reproductive use are disbudded, damage to the pheromonic scent glands adjacent to the horn buds may reduce the buck's breeding efficiency later on. However, when buck kids are to be raised for meat or as pets, destruction of the scent glands is indicated.

Extra teats are common on doelings. These can be easily removed at the same time kids are disbudded, using curved scissors. If there is any doubt about which teats are the functional ones, extra teat removal should be delayed. Wattles can also be removed from goats at

a young age with minimal trauma using curved scissors. Though wattles potentially can become snagged or traumatized, this happens uncommonly and the decision to remove them is usually a cosmetic one.

Castration, when indicated, is best carried out between four and fourteen days of age. The reason for castration must be clearly defined. For meat kids, the intended market and the age at marketing determine the need for castration. In some ethnic markets, uncastrated goats are preferred. When the market calls for kids slaughtered by eight weeks of age, castration may not be required. If goats are kept longer for finishing, then they need to be castrated where the market will not tolerate a buck odor to the meat. If castrated males are destined to become pets, delaying castration until six to eight weeks of age may reduce later problems with obstructive urolithiasis, a common problem in pet wethers discussed in Chapter 12.

Vaccination and the timing of vaccinations of neonates depend a good deal on the overall herd vaccination program. If does have been vaccinated during the dry period and kids receive adequate colostrum from vaccinated does, then kids can be considered to be protected by maternal immunity for those specific diseases through the first six weeks of life. Because the waning of maternal antibody varies with initial concentration, vaccination of these kids should begin at four or five weeks of age with booster inoculations given at intervals prescribed for each vaccine.

Kids are immunocompetent at birth. If kids are born to unvaccinated does, vaccinations should begin during the first week of life and the kids should be boostered according to vaccine directions. Prophylactic antisera may be used during the first week concurrently with bacterin-toxoids to protect kids while active antibody is forming. Tetanus antitoxin and *Clostridium perfringens* type C and type D antitoxins are the products most commonly used in kids in this manner.

The vaccinations required for kids will vary with geography and management system. Nevertheless, a universal recommendation is the vaccination of kids for enterotoxemia due to *Clostridium perfringens* type C and type D as well as for tetanus. This is the minimum vaccination program for kids. Vaccination for contagious ecthyma is fairly common. The first time it is done, all goats on the premises should be vaccinated. In subsequent years, only kids need to be vaccinated because immunity persists in the adults. Maternal antibody may interfere with vaccination in kids vaccinated too early. Contagious ecthyma vaccination is discussed in detail in Chapter 2.

Other vaccines, such as paratuberculosis, foot and mouth, peste des petits ruminants or bluetongue vaccine may be mandated or recommended as part of national disease control programs. Still other vaccines, such as anthrax, blackleg, leptospirosis, or rabies vaccines, may be used on the basis of knowledge that the disease occurs commonly in a specific region. Specific details about vaccine availability and use in goats for various diseases are covered in each disease discussion throughout the text.

Indiscriminate use of vaccines should be avoided, especially the use of live vaccines not specifically designed for goats. For example, live intranasal infectious bovine rhinotracheitis (IBR) vaccine is sometimes given to goat kids in the United States to control respiratory disease problems without any confirmation of the role of IBR in the respiratory disease complex of goats.

Where soils are selenium-deficient, nutritional muscular dystrophy in young kids is a real concern, and parenteral administration of a combined vitamin E and sodium selenite injection to kids at birth or supplementation of the ration with selenium as discussed in Chapter 19 is indicated.

Feeding programs for kids are discussed in Chapter 19. Weaning may occur as early as six weeks or as late as twelve weeks of age, depending on the feeding system used and other management considerations. Regardless of the milk feeding regimen, it is important that kids be exposed to hay and grains early in life to promote proper rumen development. Abrupt cessation of milk feeding without adequate adaptation to solid feeds can predispose to indigestion, bloat, and possibly polioencephalomalacia.

Management of Kids from Weaning to Breeding

Disease Problems

Coccidiosis and pneumonia are the dominant problems in this age group, particularly under conditions of confinement housing. Regarding coccidiosis, the transition to a diet of solid feed encourages more ingestion of coccidial oocysts while feeding. With regard to pneumonia, the progressive decline of maternal antibodies and the stresses of weaning appear to predispose kids to respiratory infections after eight weeks of age. When kids are turned out to pasture during their first summer, they are very susceptible to gastrointestinal parasitism and lung worms due largely to the absence of a developed local immunity in the alimentary and respiratory tracts. The severity of clinical parasitism depends on the concentration of infective larvae on pasture, the stocking rate, weather conditions, and other factors as discussed in Chapter 10.

Other disease problems also may occur in this group. There is a recurrent risk of enterotoxemia when concentrates are fed. The neurologic form of CAE virus infection, a progressive paresis, is most often seen in kids between eight and sixteen weeks of age.

Management Practices

For housed kids, it is essential to maintain housing and feeding systems that minimize the incidence of

pneumonia and coccidiosis, as discussed, respectively, in Chapters 9 and 10. Regarding coccidiosis, clinical disease can occur even on the most conscientiously managed farms. Therefore, in addition to good sanitary practices, it may be necessary to use a coccidiostat in the feed or water.

Currently, there are few, if any vaccines that can be confidently recommended for controlling respiratory disease in young goats. The role of viruses usually implicated in bovine respiratory disease is unclear, and the available *Pasteurella* and *Mannheimia* bacterins are of unproven efficacy. There are no goat-specific respiratory virus vaccines available. Reliable vaccines against mycoplasmal pneumonias are increasingly available in affected countries. In countries where vaccination for caprine brucellosis is carried out, kids are usually vaccinated between three and eight months of age.

Regarding pasture parasites, young goats should be turned out to pastures that have not been in use for at least one year, and should be kept on separate pastures from adults if possible. A broad-spectrum anthelmintic should be administered before turnout, and parasite loads monitored throughout the pasture season by microscopic examination of composite fecal samples collected at pasture or in the case of *Haemonchus contortus*, by application of the FAMACHA© system to identify clinically affected individuals as discussed in Chapter 10. Tactical anthelmintic treatments can be given accordingly as needed.

When spring kids are weaned properly, fed optimally, and kept healthy, they can reach proper breeding size by the autumn of their birth year and subsequently kid on their first birthday. In North America, the target is 70 pounds by seven months of age for heavy breeds (e.g., Alpines, Saanens, and Nubians) and 60 pounds by seven months of age for light breeds (e.g., LaMancha and Toggenburg). Male and female kids should be segregated by three months of age to avoid unwanted breedings among sexually precocious individuals. External genitalia of all kids should be examined before breeding to identify any intersexes present.

In temperate regions, goats are seasonal breeders induced to begin estrous cycles by decreasing day length. There is much interest in manipulating the hormonal signals for estrus to permit goats to cycle year-round. Year-round breeding is particularly important to large scale commercial milk producers who must provide a consistent volume of product on a year-round basis. The two main techniques for bringing does and doelings into heat during the normally anestrous period of the year are the use of progesterone supplements and the manipulation of day length through confinement and exposure to artificial light. These, and other useful techniques are discussed in Chapter 13 and elsewhere (Haibel 1990; Bretzlaff and Romano 2001). Breeding techniques and confirmation of pregnancy in doelings and does are also discussed in Chapter 13.

Management of Bred Doelings and Dry Does

Disease Problems

The major concerns in this group are pregnancy toxemia and abortion. Pseudopregnancies are also common in goats and may be recognized during this period by ultrasound evaluation or by the spontaneous release of uterine fluids with no attendant fetus or placenta. The lay term for this phenomenon is, appropriately enough, cloudburst. Goats that are obese when they enter the dry period are at increased risk for pregnancy toxemia, vaginal prolapses during late gestation, and dystocia at parturition.

Management Practices

Does in lactation are usually given a dry period coincident with the last two to three months of gestation. Bred doelings that have not yet milked are also nonlactating in advanced pregnancy. The key objective for these animals is proper nutritional management to avoid obesity in early gestation (late lactation) and to provide adequate nutrients to support the rapid growth of fetuses in the last trimester of pregnancy. This is particularly important regarding pregnancy toxemia. The disease can be avoided by curtailing grain in late lactation (early gestation) when milk production no longer justifies it. These goats can be carried through midgestation on a high quality legume hay and little or no grain. Grain feeding should be resumed at the beginning of the last trimester and gradually increased until term. In herds already experiencing a pregnancy toxemia problem, periodic checking of urine samples from does and doelings for ketones with commercially available powders or dipsticks helps to detect incipient cases.

There are many potential infectious and noninfectious causes of late abortion in goats, as discussed in Chapter 13. To protect pregnant does from infectious abortion, no new animals should be introduced into the herd when pregnant animals are present. This includes breeding bucks. Any animal that aborts should be isolated immediately and the area where the abortion occurred quarantined and disinfected. Attempts should be made to make a definitive diagnosis of the cause of abortion. All fetal tissues and placentas not submitted for diagnosis should be buried or incinerated. In herds with a history of chlamydial abortion or past vaccination, each year's new crop of doelings should be vaccinated before breeding.

The dry period is the appropriate time to vaccinate pregnant does to increase the concentration of specific antibodies in the colostrum and thereby enhance passive immunity in the kids. Vaccines, such as

enterotoxemia, should be given to dry does three to five weeks before kidding.

Pregnant does with nematode gastrointestinal parasites may experience a periparturient egg rise with increased shedding of eggs around the time of kidding. This is a survival strategy of the parasite to enhance the likelihood of infecting a new generation of hosts. Therefore, pregnant does should be given a broad-spectrum anthelmintic two to three weeks before kidding. Though no anthelmintic at proper dose has been definitively shown to cause abortion or teratogenic effects in goats, levamisole and albendazole have been suspected to do so, thus inhibiting their use in pregnant does.

Management of Milking Does

Disease Problems

Not unexpectedly, mastitis is the major disease challenge in lactating does. A variety of pathogens has been identified in milking goats as discussed in Chapter 14. *Mycoplasma* mastitis can be epidemic in some herds with devastating results. Mastitis due to *Staphylococcus aureus* can also be costly and difficult to control if aggressive culling of affected goats is not practiced.

Caseous lymphadenitis can occur in goats of all ages but is particularly problematic in milking does. Abscessed lymph nodes most commonly occur on the head and neck. Restraining milking does in head catches for milking increases the risk of abscess rupture and transmission of the disease.

The mammary form of CAE virus infection often occurs at the onset of lactation. It is manifested by a distinct hypogalactia or agalactia associated with a firm udder. This is perhaps the most threatening form of CAE in that it strikes at the core of the animal's productivity. Herds with this problem must look carefully at implementation of CAE control programs as discussed in Chapter 4.

The arthritic form of CAE virus infection also shows up more frequently in does once they have entered the milk line. Epidemiologic studies in France suggest that clinical manifestations of swollen carpi are more likely to develop in infected goats that are subjected to conditions which increase trauma to the joints (Monicat 1989). Such conditions might include having to jump on to and off of milking stands, repeated banging of the carpi caused by improper stall or feeder design, hard floor surfaces, or being forced to rest for extended periods on the carpi because of stall confinement or tying up. Overgrown, inadequately trimmed hooves are another distinct predisposing factor.

Some weight loss is normal in early lactation, particularly in high-producing animals. The stresses of kidding and subsequent lactation, however, may trigger clinical manifestations of weight loss in carrier animals subclinically infected with *Mycobacterium avium* subsp. *paratuberculosis.* Animals that continue to lose weight during lactation should be tested for paratuberculosis, as discussed in Chapter 10.

When milking does are pastured, gastrointestinal parasitism must be anticipated as a potential problem. Though goats develop an age- and exposure-related resistance to parasites, it is not absolute. Even if adult milkers do not develop overt clinical parasitism, the subclinical effects of parasites on milk production may be significant (Farizy and Taranchon 1970; Hoste and Chartier 1998). Milk fever, or hypocalcemia, is uncommon in dairy goats relative to dairy cattle, but can be a recurring problem in certain herds. Management and feeding recommendations made for control of hypocalcemia in dairy cattle have not been proven applicable to goats, as discussed in Chapter 19. Abomasal displacement is another common problem in intensively raised dairy cattle that is virtually unknown in goats.

Management Practices

The major goal in managing lactating does is to maximize their milk output in a cost-efficient manner. To accomplish this, both general health and udder health must be maintained. The feeding program must optimize production and be tailored to suit the needs of individual goats, depending on their stage and level of lactation. In addition, a breeding and culling program that selects for superior milk production must be implemented. In support of these goals, health and production records, though they need not be elaborate, must be conscientiously maintained.

Preventive medicine procedures for milking does include vaccinations, foot care, and, when conditions dictate, deworming. Goats should be vaccinated at least twice a year for enterotoxemia, and, in problem herds, three times. Since one vaccination is given to dry does to enhance colostral antibody, these animals should receive one or two additional vaccinations during lactation. Vaccine products aimed at preventing abortion, such as chlamydial vaccines, are given before breeding.

Proper foot care in the form of regular hoof trimming is extremely important. It reduces the likelihood of foot rot, teat injuries, abnormal gait, and general sore-footedness leading to decreased feed intake. The technique for foot trimming is described in Chapter 4. The frequency of trimming depends to a large extent on the amount of exercise goats get. Natural wearing or trimming occurs through ambulation, especially on rough or rocky surfaces.

Pastured milkers should be checked periodically for nematode parasites by fecal examination. Milking does can be dewormed tactically as required but there are two concerns. One is that certain anthelmintics have antifungal and antibacterial properties that can damage

cheese cultures and disrupt cheese making. The second is that regulatory agencies often set a milk discard requirement following any sort of drug administration, leading to economic loss to the milk producer. Anthelmintics used should be those approved for lactating animals and appropriate milk discard times must be observed.

Good udder health depends on selecting for does with good udder conformation and attachment, providing clean, well-bedded living quarters for milking does, properly functioning milking equipment, and an established protocol of udder hygiene during milking. Intramammary infusions of antibiotics at the beginning of the dry period can be used in herds with an active mastitis problem. Clipping the hair on the udder and hindquarters decreases sediment in the milk.

Milk quality is an important issue in goat dairies. Too often in the past, milk odors and taints have dampened consumer acceptance of goat milk as a wholesome, desirable product. Buck contact with milking does should be kept to a minimum and bucks should not be maintained near milking parlors or milk storage areas because buck odor permeates the milk. Milking does should not be allowed to forage indiscriminately in unimproved pastures or woodlands because many plants may lead to off flavors or odors in milk. Proper handling of milk after extraction from the doe is extremely important. Excessive agitation and delays in pasteurization promote lipolysis of the fat in goat milk, adding to the so-called "goaty" flavor of the milk. "Off" flavors in milk are discussed further in Chapter 14.

High somatic cell counts in goat milk are a serious concern. For a variety of reasons, not all of which are elucidated, goats tend to have higher somatic cell counts than cattle, even when udder infections are not present. This causes regulatory conflicts when somatic cell count standards set for cow milk quality are applied to goat milk. This, and other issues related to milking procedures and milk quality, are discussed in detail in Chapter 14.

Feeding for optimal milk production is discussed in Chapter 19. No matter what is fed, there must be adequate trough or feeder space for each and every doe in the milking herd so that submissive does are not deprived of feed by dominant does. In addition, dominant does may be so busy bullying other goats that they may not eat adequately themselves and may need to be culled. Another point related to feeding is that the feeding of silage is associated, though not consistently, with the development of listeriosis in goats.

Management of Bucks

The reader will note that bucks are the last subgroup to be considered in this discussion. This reflects the typical position of the bucks in the herd when it comes to the implementation of herd health practices. The buck, by virtue of his offensive odor, is too often neglected in herd health program. This omission should be conscientiously avoided because healthy bucks play a key role in reproductive efficiency and overall improvement of herd productivity.

Disease Problems

Disease conditions unique to bucks are limited. Obstructive urolithiasis is probably the most important. Though more common in castrated males, urinary calculi can also cause obstructive disease in intact males and may result in their loss as breeding animals. The condition is discussed in Chapter 12. Bucks become quite aggressive in the breeding season and can injure each other while fighting. They can also injure people, and workers should always exercise caution around breeding bucks. A common problem associated with fighting is the breaking off of a horn scur, with profuse bleeding from the poll. These poorly attached scurs occur when male kids are improperly disbudded and residual germinal horn bud tissue produces a regrowth of malformed horn. The profuse bleeding, though rarely serious, is a frequent cause of alarm. Proper disbudding prevents this problem, as discussed in Chapter 18.

In the breeding season, bucks acquire the habit of urinating on themselves, particularly on the face and the back of the forelimbs. This can cause severe urine scald and secondary bacterial dermatitis. Petroleum jelly applied to the back of the forelimbs inhibits the development of serious problems.

Management Practices

To obtain maximum performance from bucks, they should be "tuned up" before the onset of the breeding season. There is a definite tendency for bucks to become thin as the breeding season progresses. This appears to be physiologic rather than pathologic. Nevertheless, it underscores the need for bucks to be in excellent body condition before breeding begins. This requires regular deworming and proper feeding, as discussed in Chapter 19.

Of equal importance is proper foot care. Mounting does for breeding puts considerable strain on the back legs, and poorly trimmed feet can produce sufficient pain to inhibit the buck from performing properly, particularly if the buck is used heavily. Proper foot care is too often overlooked because herdsmen do not want to handle smelly bucks. Similarly, bucks should not be left out of herd-wide vaccinations simply because they are a nuisance to handle.

A complete reproductive examination should be performed on breeding bucks prior to use. This should include a general physical examination, genital examination, semen evaluation, and assessment of libido, as discussed in Chapter 13. This should not be done too

long before the onset of the breeding season because semen quality may be diminished during the season of deep anestrus.

If bucks are housed in groups year-round, they get used to each other and even at the onset of the breeding season are unlikely to do serious damage to each other by fighting. However, introducing a brand new buck, especially a younger or smaller one, to the group during the breeding season could prove fatal to the newcomer.

Clipping the beards and hair of bucks, especially on the forequarters, may reduce the generally offensive odor of the buck that results from urine retention on the hair. This should be done before the onset of breeding activity. The presence of a buck near the does is quite helpful in detecting estrus. Fence line contact is adequate and the buck need not commingle with the does to elicit estrous behavior.

The above discussion is organized according to the needs of the various subgroups of animals within the dairy goat herd. Another approach to organizing herd health management activities is by the calendar. A typical seasonal calendar of herd health activities for dairy goats in North America is given in Table 20.1.

HAIR GOAT HERD HEALTH MANAGEMENT AND PREVENTIVE MEDICINE

The Angora goat is the source of the valued textile fiber mohair. Three main areas of mohair production in the world are the Anatolian plain of Turkey, where the Angora goat originated, the bushveld of the Karoo district of South Africa, and the Edwards Plateau region of Texas in the United States. All three regions are arid, with average annual rainfall generally less than 600 mm. They are also areas with elevations around 500 m above sea level. These attributes, among others, are highly favorable to the profitable exploitation of Angora goats for mohair under extensive or range management conditions. More recently, serious development and expansion of the mohair industries have successfully occurred in Australia and New Zealand. There have also been attempts to introduce Angora goats into colder, wetter climates such as are found in the upper midwestern United States. Success of these enterprises depends on a more intensive form of management.

Mohair production is a rather specialized agricultural enterprise, and an overall discussion of the indus-

Table 20.1. Seasonal herd health management and preventive medicine calendar for dairy goats in North America (Guss 1977).

Season	Preventive activities
Fall	Clean barn thoroughly before onset of bad weather.
	Clean and disinfect kidding pens and leave vacant.
	Administer anthelmintics to all goats coming off pasture.
	Use larvicidal anthelmintics.
	Check goats for lice; delouse entire herd if lice found.
	Check and trim feet as needed.
	Perform reproductive examination of bucks, including semen evaluation.
	Administer selenium prior to breeding if deficiencies expected.
Winter	Check goat housing for evidence of poor ventilation such as wet ceilings, wet bedding, or smell of ammonia.
	Correct ventilation deficiencies; identify and seal drafts.
	Check waterers for cleanliness and correct any leaks.
	Restock necessary kidding and kid rearing supplies.
	Deworm and vaccinate dry does three to five weeks prior to kidding.
	Clip hair on udder and hindquarters of pregnant does.
	Check and trim feet as needed.
Spring	Check and repair fences and gates around pastures and buildings.
	Remove sources of injury from lots and pastures.
	Administer anthelmintics at time of turnout to pasture.
	Check and trim feet as needed.
Summer	Ensure adequate shade and water for goats in hot weather.
	Monitor herd for parasites using composite fecal samples from pasture.
	Examine bucks for general condition and genital abnormalities; deworm and provide extra feed as needed.
	Check and trim feet as needed; include the bucks.

try is beyond the scope of this text. A good review of goat fiber production has been published (Shelton 1981). Health and reproductive problems related to fiber-producing goats in North America have been reviewed (Bretzlaff 1990). A history of the mohair industry in South Africa is available (van der Westhuysen et al. 1988), as is an overview of the health problems commonly seen in South African Angora goats (van Tonder 1975). A guide for mohair production under intensive management in cold climates is available (Drummond 1985), as is an excellent book on the developing goat fiber industry in New Zealand (Yerex 1986) and a good review of husbandry practices in the Australian Angora industry (Evans 1980).

One aspect of fiber production in goats rather unique to Australia and New Zealand is the capture and use of feral goats for crossing with Angoras to rapidly expand fiber production capacity in the face of limited access to purebred breeding stock. Feral goats, which tend to dwell in the mountainous regions of these countries, have a significant amount of hair that qualifies as cashmere on the basis of fiber diameter. The fiber from crossbred goats is known as cashgora.

The Cashmere goat, also known as the Kashmir or Pashmina goat, is the source of the textile fiber cashmere. As the name implies, the goat originated in the mountainous region of central Asia. The finest cashmere commercially available still comes from traditional sources in Mongolia and China. Coarser grades of cashmere have also been available in commercial quantities from Afghanistan, Iran, and the former Soviet Union. The remoteness of these regions from milling centers in Europe and North America, coupled with political instabilities in the region, have created increased demand for cashmere from other sources. As a result, nascent cashmere industries have developed primarily in Australia and New Zealand, but also in Europe and North America. Embryo transfer technology has played a significant role in the spread of cashmere production outside of traditional regions.

General Comments about Herd Health Management in Fiber-Producing Goats

Angora goats have a strong flocking instinct and a hierarchical social structure. The flock readily follows lead goats that can be trained to come by banging a grain bucket. Angoras do not respond well to herding dogs, especially if the dogs work in too close, in which case the flock may become disrupted and scatter. If goats and sheep are commingled and disturbed, sheep move downhill and goats uphill. Angoras do not readily jump fences, but assuredly find holes to go through or depressions to slide under. Fencing must therefore be kept in good repair. Electric fencing can be used to advantage with Angora goats. When

working goats in pens or yards, care must be taken not to overcrowd or frighten them. Goats pack up in corners and are trampled or smothered.

At range, wethers should be kept separately from does and doelings because the wethers are more active and mobile. Females may follow and spend too much time traveling and not enough eating.

Fiber and Fleece Characteristics

The attractiveness of mohair and cashmere as textile fibers lies primarily in the fineness of the hair. These hairs represent the "down" or insulating undercoat of the goat produced by secondary hair follicles. The characteristics of the fibers are discussed in detail in Chapter 2. The quality of the fleece and its economic value are affected by a number of faults, including a high presence of "kemp" or guard hairs arising from the primary follicles; the presence of non-white fibers; contamination with plastic twine fibers, inks, marks, or dyes related to husbandry practices such as breeding harnesses; and the presence of vegetable matter such as seed heads and burrs. This latter must be controlled by timing shearing to precede the development of seeds and burrs on pasture or range. Carbonization, a process used to remove vegetable matter from a sheep fleece after shearing, damages the more delicate mohair fleece.

Shearing

Mohair grows at a rate of about 2.5 cm/month. The length of one year's growth, about 30 cm, presents manufacturing problems, and Angora goats are usually shorn two, sometimes three, times a year. Kids, yearlings, and adults should be grouped and sheared separately, and fleeces sorted separately. The younger the goat, the finer the fiber diameter. Sheep shears can be used but should be run at a slower speed (1,500 rpm). A 20-tooth goat comb head should be used. Various shearing techniques are used successfully in goats, including laying the animal down with the feet tied, standing the animal in a head catch, or tipping the animal up on its rump. Goats do not tolerate tipping as well as sheep, presumably because of their bony, unpadded rumps. To make the goat comfortable, its head should be allowed to fall back behind and between the handler's knees, with the goat's weight supported on the small of its back rather than its rump. With all methods, care must be taken not to cut the goat's loose skin or to traumatize teats or the penis during shearing.

Cashmere goats shed their down in the spring of the year. Traditionally, the down has been harvested by combing out the shed fibers from the hair coat. Cashmere goats can be sheared, however, and the guard hairs separated from the down at processing. Cashmere goats are sheared once a year in the spring.

The timing of shearing is an important issue in fiber production and animal health. Stress associated with shearing and the increased susceptibility to cold stress after shearing can lead to abortions or death losses in does, as discussed in Chapter 2. This is one reason that wethers are considered desirable for mohair production. Windbreakers have been designed for shorn goats and may be applied to valuable breeding stock, but their use in large commercial flocks is not practical.

Nutrition

The nutritional demands of fiber production are very high, especially with regard to protein. Yet, compared with sheep, the body size of fiber-producing goats is smaller, and their feed intake capacity is less. In does, gestation may increase nutritional demands beyond maintenance and hair production to the point that abortions readily occur.

Similarly, borderline nutritional status at breeding time may diminish prolificacy, leading to reduced kid crops. This is of particular importance in Angora goats because young animals produce better quality fiber. Both male and female kids are kept for production and the mean age of herds is kept young. Small kid crops make this difficult to accomplish.

Finally, future fiber yields appear to depend on adequate nutrition to the fetus in late gestation and to the newborn kid. The concentration of secondary hair follicles from which mohair arises is conditioned by fetal nutrition, while overall kid survival and growth depend on adequate milk supply from the dam.

To address these various management and production issues related to nutrition, does should receive supplemental feeding for four weeks before mating, four weeks before kidding, and four weeks after kidding.

Hair cover on the face is a common fault in Angora goats. Under extensive management conditions, impaired vision associated with facial hair can limit feed intake with adverse consequences. Ideally, breeding programs should select against facial hair, but a positive correlation between facial hair and total fleece weight limits this approach.

Reproductive Problems

Fiber-producing goats are seasonal breeders, with estrus beginning in the late summer/early autumn with decreasing day length. Poor reproductive performance, as manifested by low ovulation rates and reduced fecundity, is correlated with small body size in Angora does. As mentioned above, supplemental feeding, or flushing, of does may improve ovulation rates and prolificacy.

In addition to the broad range of infectious and noninfectious causes of abortion affecting other types of goats, Angora does are particularly susceptible to stress-induced abortion caused by cold temperatures, marginal or inadequate nutrition, and poor condition associated with parasitism. Good management is aimed at providing adequate shelter, nutrition, and parasite control. The frequency of abortion in Angora does increases as mohair production increases relative to body size.

A costly, inherited abortion syndrome of Angora goats associated with adrenal insufficiency occurs in South African Angoras. It is discussed in Chapter 13.

Cryptorchidism is common in Angora males. Such individuals should not be used for breeding. Overworking bucks should be avoided. Depending on nutritional status, health status, topography, and distance, the buck-to-doe ratio should be between 1:25 and 1:75.

Mothering

Angora does kidding at pasture or range have a distinctly different mothering pattern than sheep. Producers familiar with sheep and new to goats may not recognize this. The doe "plants" her newly born kid, leaving it camped by itself or with other kids while the doe goes off to graze. It returns to feed the kid in the afternoon. Though planting behavior is natural for goats, it increases the susceptibility of kids to predation. When predation is a problem, does should kid in areas where woods or rock formations allow some camouflage or protection for the kids.

Because dams spend a good deal of time away from their kids, early, strong bonding between dam and kid is very important to ensure proper recognition and nurturing of kids. To accomplish this, the pair need a critical five minutes of undisturbed contact after birth. Therefore, it is essential that the kidding process not be disturbed by human intervention. Foraging does return to protect their kids if the kids issue a distress call. To take advantage of this behavior, does should kid on somewhat restricted and familiar foraging grounds so they can readily find and return to their kids. Gradually, kids begin to follow does on their foraging forays and the goats can be moved to larger pastures.

Newborn kids, especially those of low bodyweight, can freeze to death easily. Providing shelter may be necessary when inclement or cold weather occurs in conjunction with kidding.

Dehorning, Castration, and Marking

Horns are a mixed blessing on fiber-producing goats. Under extensive management, they may help goats defend themselves against predators, but the more common result of horns is increased fighting among horned goats. Horns also increase the risk of goats becoming trapped in fences, especially mesh

fences. Under intensive management, horns increase the requirement for bunk space and promote accidents and injuries. Angora kids can be disbudded by electro-cautery at two to three weeks of age. Horns on mature goats can be cut back with a hacksaw, as described in Chapter 18. Intact horns are favored in show goats and breeding stock.

Open castration, elastrator bands, or clamping can be used. The time of castration is variable. In Texas, castration of buck kids is often delayed until one year of age to ensure good sturdy horn growth for defense against predators. In Australia, goats are routinely cas-trated at four to six weeks of age. On humane grounds, elastrator bands should not be used in kids over three weeks of age.

For improved record keeping and management, goats need to be identified. Ear tattoos are useful for permanent identification and are indicated for breed-ing stock. However, tattoos do not allow easy recogni-tion of individual goats from afar. Ear tags are preferred for this purpose, but certain considerations apply. Any tag placed on the edge of the ear will readily tear out, especially metal tags. Penetrating, round button, flexi-ble plastic ear tags are preferred, placed through the center of the ear. Tagging is best delayed until four to six weeks of age. Ear notching and horn branding are alternative methods of identification.

Parasitism

Fiber-producing goats are particularly sensitive to the adverse effects of gastrointestinal parasitism. The increased nutritional demand of hair production coupled with the limited feed intake allowed by their diminutive body size demands efficient use of nutri-ents for preserving health and productivity. The hypoproteinemia and blood loss associated with gastrointestinal parasitism can tip the nutritional balance against the doe, causing decreased fertility, abortion, increased susceptibility to disease, or out-right death. Pasture management and strategic and tactical treatments with anthelmintic are integral parts of Angora goat management. Parasite control practices are discussed in Chapter 10.

Even though fiber-producing goats are usually managed extensively, there are times such as weaning, shearing, bad weather, and supplemental feeding when flocks are congregated in confined areas. This increases the risk of clinical coccidiosis in kids and weanlings. Conscientious attention to sanitation and hygiene, and the use of coccidiostats, are required to manage this problem, as discussed in Chapter 10.

Lice and keds are more than a nuisance on fiber-producing goats. They can cause itching, rubbing, and subsequent damage to the hair coat, as well as anemia. In cashmere goats, louse egg cases clinging to hair can alter the dyeing characteristics of the fiber. Routine

louse control should be practiced as discussed in Chapter 2. Some pour-ons may stain the fleece. If sprays or dips are used, it is important that goats not be chilled when wet.

Other Disease Problems

Soremouth is common in fiber-producing goats. Affected kids may have difficulty nursing and does may contract mastitis. In extensive management systems in which bottle or tube feeding is impractical, kid losses can result. Vaccination is indicated. Foot rot and foot scald occur but less frequently than in sheep. Preventive measures are discussed in Chapter 4. Fly strike also occurs in goats, but less commonly than in sheep.

Wethers are extremely susceptible to the formation of urinary calculi and development of obstructive urolithiasis. The calculi are most often composed of phosphate salts and the main approach to control is to ensure a proper ratio of calcium to phosphorus in the overall ration, as discussed in Chapter 12.

Caseous lymphadenitis can be a serious problem in fiber-producing goats. As in sheep, the main route of transmission is through shearing, when cuts and abra-sions in the skin are inoculated with bacteria from open abscesses on other sheared goats. The shearing equipment acts as a mechanical vector. Shearers must be knowledgeable about the disease and disinfect instruments between goats when necessary. Young, uninfected goats should be shorn first.

Pneumonia is a common occurrence in weanling goats and is exacerbated by changing, adverse weather or by housing, if ventilation is poor. Access to shelter in wet weather helps to reduce the incidence of pneumonia. Early recognition and mass medication are critical in controlling losses.

Hair goat breeds are susceptible to CAE virus infec-tion. However, the prevalence of the disease is dra-matically lower than in dairy goats. More must be learned about the epidemiology of CAE virus infection in hair goat breeds. At present, it is probably inadvis-able to commingle hair goats with dairy goats. Milk or colostrum from dairy goats should not be used to raise orphaned hair goat kids unless the source herd is certi-fied CAE free or the milk and colostrum have been properly heat treated to kill the virus.

As with dairy goats, the minimum vaccination program should include *Clostridium perfringens* types C and D combined with tetanus prophylaxis. In low-lying pasture areas, multivalent clostridial vaccines including protection against blackleg may be indi-cated. In selenium deficient areas, does should be drenched or injected with sodium selenite just before mating and again two to three weeks before kidding.

A herd health calendar for hair goat production is given in Table 20.2.

Table 20.2. Herd health management and preventive medicine calendar for fiber-producing goats in North America.

Season	Preventive activities
July and August	Check all goats for lice.
	Deworm spring kids.
	Vaccinate all goats for enterotoxemia.
	Begin supplemental feeding (flushing) of does to be bred.
	Ensure adequate number and quality of breeding bucks.
	Turn teaser bucks in with does if synchronized breeding is desired.
	Begin fall shearing.
September and October	Begin breeding; use marking harness and keep records.
	Check goats for parasites; deworm and delouse as needed.
	Check and trim feet.
November and December	Remove bucks from bred does.
	Perform pregnancy checks.
	Select rested pastures for kidding.
	Ensure adequate shelter facilities on kidding pastures.
	Begin preparations for indoor kidding, if an option.
January and February	Begin spring shearing; shear pregnant does three to six weeks prior to kidding; delouse goats after shearing.
	Boost feed levels to does due to kid four weeks prior to kidding date.
	Deworm and vaccinate does two to three weeks before kidding.
	Turn does out to kidding pastures to familiarize them with the pastures.
	Castrate buck kids from previous year.
	When kidding begins, keep accurate records of kidding activities.
March and April	Vaccinate kids at four weeks of age for enterotoxemia, tetanus, and soremouth.
	Place ear tags in goats at four to six weeks of age.
	Continue supplemental feeding of does for four weeks after kidding.
	When kids are following does, deworm goats and turn out from kidding pastures to larger grazing areas.
May and June	Wean kids and move does to a new pasture.
	Plan to cull does for poor health or poor reproductive performance.

MEAT GOAT HERD HEALTH MANAGEMENT AND PREVENTIVE MEDICINE

The use of goats for meat presents a paradox. On a worldwide basis, production of meat is the single most common usage of goats. However, goat meat production is the least developed aspect of goat husbandry in terms of an organized industry. This reflects the fact that the majority of goats intended for meat are found in the developing countries of the tropics and subtropics. These goats are maintained primarily by herders and smallholders and the goat meat they produce is used mainly for local consumption with relatively little marketing of meat outside the family or village. There is a limited but informative body of literature on the current status of goat meat production around the world and future needs for improvement (Dhanda et al. 2003; Alexandre and Mandonnet 2005).

Compared to the dairy breeds, comparatively little work has been done to breed goats specifically for meat production. Globally, the majority of goats used for meat are indigenous breeds in which little formal selection has been practiced. Historically, in North America, goats offered for slaughter were most commonly cull goats from dairy herds or fiber-producing flocks. In Australia and New Zealand, feral goats are harvested for meat.

There are two notable exceptions regarding selective breeding for meat production. In South Africa, a meat type goat, the Boer goat, has been developed (Mahan 2000). This animal has rates of feed conversion and weight gain and carcass characteristics approaching those of sheep. Advances with the Boer goat underscore the potential for improvement of meat production in other breeds. Indigenous breeds of African goats have been reported to have daily weight gains in the neighborhood of 90 g/day, while average Boer goat gains range from 170 to 200 g/day, with highly selected Boer goats on improved diets gaining as

much as 290 g/day. A second meat type goat, the Kiko goat, has been developed in New Zealand by crossing feral does with Nubian, Toggenburg, and Saanen bucks (Batten 1987). Other breeds recognized with the potential for improving goat production are the Fijian breed from Fiji, the Katjang breed of Indonesia, the Ma'tou of China, the Sirohi of India, and the Sudan Desert breed of Sudan (Devendra 1999).

The high prolificacy of goats compared to cattle and even sheep makes them attractive ruminants for exploitation in meat production systems. Three kiddings every two years is a very reasonable goal. Selective breeding for meat production allows producers to take advantage of this potential in goats. Future advances and improvements in meat goat husbandry and production will depend a great deal on accurate market research to determine the desired characteristics of goat meat in varied markets. Production practices will be dictated to a large extent by such issues as the preferred age and weight of carcasses, preferences of taste and tenderness, preferences for live goats over slaughtered goats, preference for castrated over intact males, religious constraints on slaughter procedures, and potential of export markets compared to local markets.

The basic principles for herd health management of meat goats are similar to those for dairy goats. In general, emphasis must be placed on kid rearing techniques to reduce neonatal mortality. Excessive death losses in kids negate the advantage of prolificacy inherent in goats. In goats surviving the neonatal period, diseases which inhibit the rapid, efficient growth of young kids should be carefully controlled. The conditions most likely to disrupt normal growth are pneumonia, coccidiosis, and gastrointestinal helminthiasis. If finishing programs evolve and young goats are pushed on concentrate feeds, the risk of bloat, lactic acidosis, and enterotoxemia increases. Goats should always be vaccinated for the latter disease.

Conditions that could cause markdowns or condemnations at slaughter also need to be controlled. These include caseous lymphadenitis leading to lymph node and visceral abscesses, cestode infestations such as *Taenia ovis* or *T. multiceps* which produce cysts in muscle and viscera, and liver flukes which damage livers. Finally, when therapeutic efficacy is not compromised, drugs and vaccines should be given subcutaneously rather than intramuscularly to minimize damage to muscle tissue.

Since the 1990s, there has been a dramatic and robust increase in meat goat production in the United States, especially in the south. Texas, Tennessee, Oklahoma, Georgia, Mississippi, and Kentucky have been particularly active in this area. While Spanish, Angora, and dairy breed goats are being used for meat production, there has also been significant growth in the pop-

ularity and number of Boer and, to a lesser extent, Kiko goats. Both of these breeds were initially imported but are now bred in the United States. In addition, so-called fainting goats, i.e., goats with myotonia congenita, are heavily muscled in the hindquarters and have become desirable as a meat goat breed, particularly in Tennessee. Myotonia congenita is discussed in Chapter 4.

Because of the persistent warm climate and the heavy reliance on pasture grazing in meat goat production systems in the southern states, gastrointestinal parasitism, particularly haemonchosis, has emerged as a significant constraint on health and production and threatens the vitality of the meat goat industry. This issue is discussed further in the nematode gastroenteritis section of Chapter 10. Opportunities for veterinary participation in herd health management for meat goat production are increasing in the United States.

Langston University in Oklahoma has developed a Web-based training and certification program for meat goat producers which reflects the rapid advance of meat goat production in the United States since the first edition of this book was published in 1994. It is available on the Internet at http://www.luresext.edu/goats/training/QAtoc.html. The program provides a very informative overview of all aspects of meat goat production and marketing. It contains a useful and detailed module on meat goat herd health (Dawson et al. 2000) and another which provides an overview of the important diseases of meat goats (Olcott and Dawson 2000). A basic herd health calendar for meat goats in the United States is presented in Table 20.3. Additional links to useful information on goat meat production and marketing are available through the Website of the Agricultural Marketing and Resource Center at http://www.agmrc.org/agmrc/commodity/livestock/goats/meat+goats.htm.

MAINTAINING QUALITY GOAT SKINS

Goat skins are a valuable commodity in their own right as sources of high quality leather. The goat skin can represent as much as 15% of the total slaughter value of the goat. To maintain the highest value for skins, certain management and disease control efforts should be observed. Good nutrition throughout life improves the strength of the skin. Infectious skin diseases, such as goat pox, and external parasites, such as lice, keds, ticks, warbles, and mange, must be controlled in the live animal to avoid excessive damage to skins and subsequent downgrading. Any tattoos, fire branding, or injections should be performed on the periphery of the animal, avoiding the flanks and back. Animals should be handled gently during transport to market to avoid subcutaneous hemorrhages that can damage skins.

Table 20.3. Herd health management and preventive medicine calendar for meat goats in North America (from Brown and Forrest 2004).

January	Evaluate pasture and forage conditions.
	Monitor body conditions of does; supplement if necessary.
	Prepare for kidding.
February	Sort pregnant from open does.
	Begin feeding pregnant does.
	Evaluate does and bucks; sell unsound or inferior animals.
	Treat for internal and external parasites.
March	Begin kidding; check teats for milk flow; identify kids.
	Separate singles from twins; if possible, pen individual does with their kids; feed does to maintain milk production.
April	Finish kidding.
	Continue to supplement lactating does.
May	Consider weaning small, stunted kids.
	Discontinue supplement feeding to does.
	Monitor internal parasites through fecal samples.
June	Begin looking for replacement bucks with good conformation, structural correctness, muscling, and a high weight per day of age.
July	Continue selecting replacement bucks.
August	Treat for internal and external parasites.
	Vaccinate kids.
	Select replacement does and bucks.
	Wean kids; supplement replacement does and bucks with a high-protein (21%), high-energy feed.
	Evaluate does and bucks; sell unsound and inferior animals.
	Criteria for culling:
	Barren female: missed two seasons in a row.
	Bad teats or udders: too big or too small (mastitis).
	Bad mouths: smooth or broken mouth or over- or undershot jaw.
	Structural defects: bad feet and legs or back.
	Bad testicles: too small or infected (epididymitis).
	Unthriftiness: due to old age or disease.
September	Begin flushing does and bucks; flush with fresh green pasture or 1/2 pound feed/head/day for two to three weeks before and after buck turnout.
	Treat for lice if necessary.
October	Turn out bucks with does; breeding ratio 1 buck/20 to 25 does, depending on pasture size and breeding conditions.
	Continue to flush does for two to three weeks after buck turnout.
November	Evaluate pasture and forage conditions.
	Determine does' body conditions and plan winter supplemental feeding program.
	Monitor internal parasites through fecal samples. If heavy, treat after first hard freeze.
December	Remove bucks and feed to regain body condition.
	Evaluate pasture and forage conditions.
	Watch body conditions of does; supplement if necessary.
	Check for lice and use a pour-on lice treatment if needed.

HERD HEALTH MANAGEMENT FOR ORGANICALLY RAISED GOATS

Based on perceived health and environmental benefits as well as personal lifestyle choices, consumer demand for organically raised food has been steadily increasing over the last two decades in developed countries. In response, a growing segment of farmers, including livestock producers, have been switching to organic production systems to meet that growing demand. Veterinarians serving clients who raise livestock organically must be aware of the opportunities and constraints, as well as the rules and regulations,

involved in maintaining animal health in an organic production system. It is suggested that veterinarians with clients raising goats organically read the section in Chapter 1 entitled "Special Considerations for Organic Goat Production" as well as this section.

The aim of organic farming is to establish and maintain soil-plant, plant-animal and animal-soil interdependence to create a closed and sustainable agroecological system based on local resources. To achieve this, organic farming uses what are considered environmentally friendly methods of crop and livestock production that exclude synthetic fertilizers, growth hormones, growth enhancing antibiotics, synthetic pesticides, and gene manipulation (Nardone et al. 2004). The focus of organic production systems is not on maximizing production, but rather on optimizing production in the context of the resources and management options available. As such, breeding programs for dairy goats, for example, might focus more on selection for disease or parasite resistance rather than increased milk production, while decisions on cropping and forage production might be driven by the decision not to include grains or concentrates produced off-farm in the animals' diet.

Livestock veterinarians used to working with clients in conventional farming systems may chafe at the constraints encountered in providing veterinary services to organic livestock producers, because many of the medicines routinely used in conventional livestock practice are not allowed in organically produced livestock. Most notable among these are the antibiotics. However, with an open mind, animal health care delivery for organic livestock production can offer opportunities for creativity and innovation in developing holistic herd health programs that place more emphasis on preventive medicine and progressive management designed to minimize the occurrence of disease and the need for antibiotics and other conventional therapies.

With regard to what is available for use in the treatment of organically raised livestock, the general rule is that all natural materials are allowed in organic agriculture, unless specifically prohibited, while all synthetic materials are prohibited unless specifically allowed (Karreman 2006). Synthetic materials allowed for use in organic livestock production under the regulations governing the National Organic Program in the United States are listed in the box titled "Synthetic Substances Allowed for Use in Organic Livestock Production." However, there is a petition process by which petitioners can approach the National Organic Standards Board (NOSB) to add additional approved materials, and this procedure has been used successfully. Some of the materials listed in Box 20.1 were added based on a petition initiated in 2001 (Karreman 2006).

Synthetic Substances Allowed for Use in Organic Livestock Production

From Section 205.603 of the United States Code of Federal Regulations at 7 CFR 205, National Organic Program. Items allowed as of December 12, 2007.

In accordance with restrictions specified in this section, the following synthetic substances may be used in organic livestock production:

(a) **As disinfectants, sanitizer, and medical treatments as applicable:**
   (1) Alcohols
       (i) Ethanol: disinfectant and sanitizer only, prohibited as a feed additive
       (ii) Isopropanol: disinfectant only
   (2) Aspirin: approved for health care use to reduce inflammation
   (3) Atropine*
   (4) Biologicals: Vaccines
   (5) Butorphanol*
   (6) Chlorhexidine: for surgical procedures conducted by a veterinarian
   (7) Chlorine materials: disinfecting and sanitizing facilities and equipment; residual chlorine levels in the water shall not exceed the maximum residual disinfectant limit under the Safe Drinking Water Act
       (i) Calcium hypochlorite
       (ii) Chlorine dioxide
       (iii) Sodium hypochlorite
   (8) Electrolytes: without antibiotic
   (9) Flunixin
   (10) Furosemide
   (11) Glucose
   (12) Glycerin: allowed as a livestock teat dip; must be produced through the hydrolysis of fats or oils
   (13) Hydrogen peroxide
   (14) Iodine
   (15) Magnesium hydroxide*
   (16) Magnesium sulfate
   (17) Oxytocin: use in postparturition therapeutic applications
   (18) Parasiticides—Ivermectin: prohibited in slaughter stock, allowed in emergency treatment for dairy and breeder stock when organic system plan-approved preventive management does not prevent infestation. Milk or milk products from a treated animal cannot be labeled as provided for in subpart D of this part for ninety days following treatment. In breeder stock, treatment cannot occur during the last third of gestation if the progeny will be sold as organic and must not be used during the lactation period of breeding stock.
   (19) Peroxyacetic/peracetic acid: for sanitizing facility and processing equipment
   (20) Phosphoric acid: allowed as an equipment cleaner, provided that no direct contact with organically managed livestock or land occurs

(21) Poloxalene: to be used only for emergency treatment of bloat

(22) Tolazoline*

(23) Xylazine*

(b) As topical treatment, external parasiticide, or local anesthetic as applicable:

(1) Copper sulfate

(2) Iodine

(3) Lidocaine: as a local anesthetic; use requires a withdrawal period of ninety days after administering to livestock intended for slaughter and seven days after administering to dairy animals

(4) Lime, hydrated: as an external pest control, not permitted to cauterize physical alterations or deodorize animal wastes

(5) Mineral oil: for topical use and as a lubricant

(6) Procaine: as a local anesthetic; use requires a withdrawal period of ninety days after administering to livestock intended for slaughter and seven days after administering to dairy animals

(7) Sucrose octanoate esters: in accordance with approved labeling

(c) As feed supplements: None

(d) As feed additives:

(1) Trace minerals, used for enrichment or fortification when FDA approved

(2) Vitamins, used for enrichment or fortification when FDA approved

*Federal law restricts this drug to use by or on the lawful written or oral order of a licensed veterinarian, in full compliance with the AMDUCA and 21 CFR part 530 of the Food and Drug Administration regulations. Additional restrictions may apply including extensions of meat and milk withdrawal times when the drug is used. For updates and specific restrictions, check Section 205.603 of the 7 CFR 205 directly at the Website of the National Organic Program at www.ams.usda.gov/nop/NOP/standards/FullRegTextOnly.html

Successful provision of animal health care in organic livestock production requires a strong partnership between the veterinarian and the producer. A "fire engine" approach to respond to disease problems after they occur is not effective, particularly with the constraints that exist on the drugs available for treatment. Instead, the producer and veterinarian should be proactive and develop an animal health plan for the operation. This should begin with a thorough review of existing facilities and management practices to identify situations conducive to the development of disease. Many conditions which require antibiotics for treatment, such as colisepticemia in kids, pneumonia and coccidiosis in weanlings, and mastitis in does, can be prevented or minimized with proper sanitation, housing design, ventilation, and management practices that promote good hygiene and minimize stress on the animals. In addition, veterinarians should recognize that the use of vaccines is not restricted in organic livestock production and vaccination represents a useful tool for preventing disease. Ration evaluation and nutritional counseling are also important because proper nutrition favors improved disease resistance.

The veterinarian should remain actively involved once the animal health plan is developed. Many farmers that enter organic production do so by making the transition from conventional production and have come to depend on conventional health interventions. The transition from conventional to certified organic farming may take three to four years, during which time unexpected health problems may arise due to the loss of familiar interventions and unfamiliarity with the new. The veterinarian should be ready to work through these difficult periods with the farmer and help with the transition.

Perhaps the biggest health challenge for organic goat production in the United States is control of gastrointestinal parasites, because the use of anthelmintics is currently limited to ivermectin and only under particular circumstances. The risk of parasitism in organic livestock production may be increased compared to conventional systems because organic production systems may depend heavily on use of pastures as a source of feed, and indirectly as a source of parasites. Interestingly, the accelerating development of anthelmintic resistance in recent years has spurred considerable interest and research in alternative parasite management strategies that depend less on anthelmintic use and more on alternative therapies and pasture management strategies.

Serendipitously, these approaches fit nicely with the objectives of organic livestock production systems, particularly goat production systems. Parasite control approaches compatible with organic livestock production include: grazing management strategies that minimize exposure to infective larvae at pasture, improved animal nutrition to promote parasite resistance, feeding or grazing of forages with high tannin content, selection and breeding programs for parasite resistance, biological control of parasitic nematodes using nematophagous fungi, and the development and use of vaccines against parasites. These options are discussed further in the section on nematode gastroenteritis in Chapter 10. In addition, there is renewed interest in a wide variety of traditional herbal and other phytotherapeutic remedies from around the world that have been reported to or are believed to control parasites. There is no doubt that some of these remedies are effective, and controlled studies are needed to identify those that are most efficacious.

A major component of organic animal health care is the use of alternative and complementary therapies including homeopathy, phytotherapy, acupuncture, immune augmentation, and vitamin and mineral supplementation. Herbs are used as treatments but may

also be sown in pastures to provide both nutrients and prophylaxis against disease, most notably parasites. While modern day veterinarians may bemoan the lack of access to antibiotics in controlling disease for organically raised animals, it is useful to recall that before the advent of antibiotics in the 1940s, our professional predecessors had to depend heavily on botanicals and other natural therapies to effect cures in livestock. Veterinary textbooks published in the 1930s are good sources of information on therapies that were considered useful or reliable before the advent of antibiotics (Karreman 2006).

There is a steadily increasing amount of useful information available to veterinarians interested in organic livestock production. Symposia have been held on veterinary issues in organic farming with published proceedings (Thamsborg et al. 2001; Hovi and Vaarst 2002). In addition, national governments and producer groups have produced guidelines, some of which are available via the Internet (Australian Government 2007).

HERD HEALTH MANAGEMENT FOR TRANSGENIC GOATS

Because many transgenic herds are maintained for the purpose of producing recombinant biopharmaceutical proteins in the milk of goats for subsequent separation and preparation of commercial products, these transgenic herds can be viewed in essence as dairy goat herds and the principles of dairy herd health management discussed at the beginning of this chapter generally apply. However, because of regulatory concerns related to the purity of milk-derived pharmaceutical products, particularly with regard to the possible risk of zoonotic disease transmission, there are additional special considerations for the herd health management of transgenic herds, whether they produce recombinant proteins in milk or other body fluids or tissues. These considerations relate mainly to the importance of establishing and maintaining a closed herd, excluding specific diseases that can affect product safety, the types of vaccines used in the herd, and the use of medications in the herd. Each of these issues is discussed in the following sections.

The Importance of Establishing and Maintaining a Closed Herd

From the perspective of controlling diseases in goats, and particularly in transgenic goats, developing and maintaining a closed herd must be given significant consideration. There is no doubt that the number one threat to spread of disease between goats comes from new introductions of animals into a herd. Additionally, the continued spread of disease within a herd most certainly comes from the infected or carrier animal(s) within a given herd.

Developing a closed herd is not a minor undertaking and must take into consideration a number of factors. First, one must consider the source of the nucleus herd to be derived. This can be either from the original existing herd at a given site/farm or the goats can be obtained from an outside source. This outside source can be a known entity with a defined Specific Pathogen Free (SPF) population of goats or these animals can be obtained through the open market, either within one's own country or imported from a known disease-free country. Second, one must consider cost because this significantly impacts the extent to which one will go to derive a closed SPF herd. Third, the specific diseases for which testing is required, the type of testing/assays that will be performed, and the period of time involved in assembling and testing the animals needs to be given appropriate consideration.

A significant amount of disease testing needs to be performed on the potential incoming or existing animals to ensure, as best possible, their disease-free status when developing/starting a closed herd. However, not all diagnostic tests have 100% sensitivity and specificity. It must be remembered that even the most intensive pre-screening program is only a "snapshot" of the animal's/herd's disease status and does not ensure that a given animal or herd is negative for certain diseases with long incubation times, such as Johne's disease or caprine arthritis encephalitis (CAE). The list of diseases and/or disease agents to be considered in developing an SPF goat herd should include the following, at a minimum:

- Tuberculosis
- Brucellosis
- Caprine arthritis encephalitis (CAE)
- *Mycobacterium avium*, subsp. *paratuberculosis* (paratuberculosis or Johne's disease)
- Contagious ecthyma (Orf)
- Caprine herspesvirus-1 (CapHV-1)
- *Coxiella burnetti* (Q fever)
- *Neospora caninum*
- *Corynebacterium pseudotuberculosis* (Caseous lymphadenitis)

Once the closed herd is established, the testing regimen must continue for a specified period of time going forward in order to identify latent or chronic infections such as CAE and Johne's disease, which may have been undetected by initial screening tests.

Finally, once the closed herd is established, clinical monitoring and veterinary evaluations must be aimed at optimizing overall herd health, decreasing general morbidity/mortality, and removing those disease entities that are associated with production environments. Monitoring, detecting, and removing sources

or animals that are carriers or contributors to clinical entities such as contagious mastitis, foot rot, certain bacterial or viral pneumonias are early priorities in a closed herd.

Specific Disease Implications for Transgenic Herds and Product Safety

For transgenic herds of goats producing recombinant human therapeutic proteins, the list of diseases one may want or need to test for most certainly is more extensive than the minimum set defined above. The rationale for screening for these additional entities is to identify agents that pose zoonotic risks or those that may be produced or detected in the tissue or fluid being used as a source material for recombinant protein production. There are additional viral- and prion-associated diseases, for example, scrapie, that need to be addressed due to the nature of the value-added product these goats are generating in a number of possible fluids or tissues. The following is a brief list of some of the additional viruses or family of viruses that should be considered, depending on the geographic region or emerging opportunistic nature of these entities around the world:

- Enzootic nasal tumor virus
- Ovine pulmonary adenocarcinoma virus (Jaagsiekte)
- Pestivirus (border disease)
- West Nile virus
- Respiratory syncytial virus
- Powassan virus
- Bunyavirus (Cache Valley fever)

Although the full list of potential viral problems may seem never-ending, the best approach to manage these possible threats is to first consider all viral agents that are known to infect goats. Second, address those that are known to be in the geographic locale of the flock or herd. Third, address those of specific concern for the herd, and last those which could potentially be found in the biological material being derived from the goats (milk, blood, serum, etc.). It may not be the intent of a given program for the SPF herd to be 100% viral free, and this may truly be unattainable, regardless of the type of operation.

Also, there are viruses, such as rotavirus and coronavirus, that may be manageable within a closed herd because they are typically found in young goats and are not problematic in the adult population from which biological materials are collected or harvested. This type of decision, as to which viruses will or will not be acceptable within a given herd, must be made on a case by case basis according on the nature of the operation, the type of biological product being produced,

and the guidance of regulatory agencies involved, e.g., USDA and FDA.

Vaccine Issues in Transgenic Goat Herds

While vaccines are an important component of any herd health program, their use in transgenic herds needs to be evaluated carefully. The use of modified live viral vaccines can pose potential regulatory challenges to product safety when biopharmaceutical proteins are being produced in biological fluids such as milk, blood, or serum. Because many vaccines are produced in some form of culture system (egg, mammalian, bacterial, etc.), the vaccine production environment itself poses potential routes of viral/bacterial contamination that must be considered. The use of bovine serum, porcine trypsin, or other animal derived materials potentially allows for adventitious agents to inadvertently be introduced into the final product and ultimately into the animals being administered the vaccine. Therefore, strategic use of vaccine during times when the animal is not producing a biological material for recombinant therapeutic protein production may need to be considered.

Alternatively, the use of killed vaccines (e.g. Rabies) or toxins/toxoids (e.g. *Clostridium perfringens* types C and D and Tetanus) offers a slightly higher safety margin from a regulatory perspective. However, use of these products may limit the protective nature of the vaccination so that the frequency of administration may need to be modified. Additionally, as with all pharmacological agents administered to transgenic animals in production, one must consider all the subcomponents (adjuvant, animal-derived materials) of any vaccine being administered. Particular attention should be given ultimately to final product safety relative to human use. Finally, any vaccines to be used within a closed transgenic herd must come from approved and reputable manufacturers and sources and should have appropriate documentation upon receipt.

Medication Issues in Transgenic Goat Herds

Any and all pharmacological or medicinal agents used in the course of either preventative or clinical herd health management must be carefully considered and even scrutinized before use in transgenic animal populations. A thorough understanding of all the components within these materials is critical to avoid administering something to a goat that could negatively impact any biological material being produced/collected from the animal. One must consider the potential for adventitious agents (viral or bacterial) inadvertently being administered. There have been a number of historical cases in which this has happened in goat herds or other animals, with significant detrimental effects to the animals or the loss of product due

to concerns of contamination. Reported examples include *inter alia*: sterile saline for injection contaminated with nonsteroidal anti-inflammatory drug (Gavin 2008); *C. perfringens* and *C. tetani* bacterin-toxiod contaminated with *Staphyloccus intermedius,* which caused abscesses and abortion in vaccinated goats (Ayres, 2008); fetal calf serum for use in vaccine production contaminated with bovine polyomavirus (Kappeler et al. 1996); contagious ecthyma vaccine contaminated with pestivirus, which caused clinical border disease in goats (Løken et al. 1991); and a combined canine distemper, adenovirus, parvovirus vaccine contaminated with bluetongue virus that caused abortion and death in vaccinated dogs (Akita et al. 1994). All of these products were contaminated at the point of manufacture and not during use.

For transgenic goats, the judicious use of antibiotics or any pharmacological agent that could potentially produce a withdrawal period (meat, milk, etc.) must be considered relative to the biological material and product being produced. Following the prescribed withdrawal time at a minimum is prudent, but one must also consider those cases and circumstances in which the standard withdrawal time may not be sufficient. Finally, one may want to consider whether additional testing is warranted to ensure that the medicinal agent has cleared, what level of assay detection will be used (depending on what biological material is being collected), the product being produced, and the final product safety and use.

Formulary of Some Drugs Used in Goats and Suggested Dosages

The appendix of the first edition of this textbook (Smith and Sherman 1994) assembled pharmacokinetic information on a diverse assortment of drugs. Many additional drugs and studies have become available in recent years, making the annotated bibliography format used in the first edition cumbersome. In addition, the advent of the Internet, with ready access to veterinary databases, has made retrieval of information on pharmacokinetic studies much easier. In lieu of providing pharmacokinetic data on selected drugs, this appendix lists the drug dosages discussed in each chapter of the current edition in tabular form for easy reference. Some of the drugs included are not available in the United States. Other available drugs are prohibited in goats because the species is classified as a food animal (Payne et al. 1999).

Information on pharmacokinetic terminology is retained from the first edition, to aid the reader in interpreting the literature. Pharmacodynamics, the study of the biochemical and physiological effects of drugs and the mechanisms of their actions, is a separate topic and beyond the scope of this appendix. It should be noted that knowledge of the pharmacokinetics of a drug in goats is helpful for selecting a route of administration and a dosing interval and for estimating withdrawal times but does not directly address the question of efficacy of a given dose. Clinical experience, in addition to pharmacokinetic data, must be taken into consideration (Martinez 1998d).

PHARMACOKINETIC TERMINOLOGY

Understanding of the literature in the field of pharmacology requires familiarity with a number of special concepts and terms. These are defined in textbooks (Baggot 1977; Riviere 1999) and review articles (Riviere 1988a, 1988b; Martinez 1998a, 1998b, 1998c, 1998d, 1998e), to which the reader is referred for additional information.

Pharmacokinetics is the mathematical description of concentration changes of drugs within the body. The drugs are described as distributing into and out of compartments, which are mathematical but not physiological entities. The drug distributes instantaneously and homogeneously into the central compartment when given intravenously. The central compartment is often equivalent to blood plasma and extracellular fluid of highly perfused organs. The peripheral compartment, into and out of which drugs may transfer more slowly, represents less well perfused tissues such as muscle, skin, and fat. Rate constants describe drug transfer between compartments and out of the body.

The volume of distribution (V_d) describes the relationship between the amount of drug in the body and its plasma concentration.

$$V_d(ml) = \frac{\text{Total drug in the body (mg)}}{\text{Concentration of the drug in plasma (mg/ml)}}$$

If the body appears to behave as a single homogeneous distribution compartment, drug disposition is described by a one-compartment open model. This model assumes that changes in tissue drug concentrations are reflected quantitatively by changes in plasma concentration. However, the drug concentrations are not necessarily the same in all body tissues at one time.

The term "open," when applied to a model, means that drug leaves the system.

The disposition of many drugs can be defined by a two-compartment open model, as depicted by the central and peripheral compartments, with elimination occurring only from the central compartment. With some drugs, a three-compartment open model is needed, because the plasma drug concentration over time can be best described by a triexponential curve.

The apparent volume of the central and peripheral compartments for each drug depends on blood flow, the drug's ability to enter the tissues from the circulation, and the extent of tissue binding. Increasing body water volume increases V_d, while dehydration or increasing the fraction of bound drug in the blood decreases the V_d. Drug binding in tissues can cause the apparent volume of distribution to exceed the real volume. Neonates have higher percent total body water than adults (Martinez 1998b). The volume of distribution tends to decrease with age.

In a two-compartment model, drugs are assumed to enter the system only via the central compartment and to leave it, by biotransformation and elimination, only from the central compartment. The rate of drug removal from a compartment is considered to be proportional to the concentration of drug in that compartment. During the initial or distribution phase, distribution to the peripheral compartment occurs simultaneously with elimination from the body. During the distribution phase, there is a rapid decline in plasma concentration described by an alpha rate constant or distribution half-life. After distribution is complete, elimination predominates, and the change in drug concentration is described by a beta rate constant or elimination half-life. In some drugs with extensive tissue binding, elimination slows later on during a gamma phase that is controlled by the rate of release of drug from its binding sites.

Total body clearance is a parameter that estimates drug elimination from the body by all routes relative to the concentration of drug in serum.

$$Cl = \frac{\text{rate of elimination}}{\text{serum drug concentration}}$$

It is expressed in terms of volume per unit time and represents the volume of serum completely cleared of the drug by all elimination processes per unit time. Serum protein binding influences clearance, as bound drug is often unavailable for glomerular filtration.

The elimination half-life is the time required for the total amount of drug in the body to decrease by half. The half-life in the body is directly related to the volume of distribution and inversely related to the clearance of the drug from the body by metabolism and/or excretion.

$$T_{1/2} = \frac{0.693 \times V_d}{Cl}$$

Although 97% of the drug is eliminated from the body in five half-lives, the half-life derived during pharmacokinetic studies depends on both the clearance and the volume of distribution and thus is altered by disease states.

The systemic availability, often expressed as a percent, is a measure of the extent of absorption of a drug given by something other than the intravenous route. For instance, the plasma concentration-time curve is plotted after oral (PO) and after intravenous (IV) administration. The area under the curve (AUC), expressed in $\mu g/ml/hour$, is calculated for the two curves and the ratio (AUC)PO:(AUC)IV gives the extent of absorption. Bioavailability also depends on the rate of absorption, which affects the peak plasma concentration achieved and the time to that peak. Absorption continues after the peak, but even if the drug has a high systemic availability, slow absorption may cause subtherapeutic plasma levels.

FORMULARY

Appendix A Table 1.1 is a partial list of drugs discussed in the text. Consult the chapter for details on duration of therapy and alternative treatments, as well as for warnings about use in meat or dairy animals. Numerous additional chemicals used to treat external parasites are listed in Table 2.1. Additional coccidiostats are listed in Table 10.7, anthelmintics in Table 10.8, and flukicides in Table 11.3. Supplements to correct nutritional deficiencies are discussed in Chapter 19. Additional antimicrobial and coccidiostat drug dosages have been compiled (Menzies 2000; Navarre and Marley 2006), although some of the suggested dosages for goats are empirical. Pharmacokinetic data for numerous antibiotics administered to goats have also been summarized (Navarre and Marley 2006).

MEAT AND MILK WITHDRAWAL TIMES

Relatively few studies have been conducted to determine drug metabolism and excretion in goats. Label information specifically for goats also is rarely available, because few drugs are approved by the Food and Drug Administration Center for Veterinary Medicine for use in goats in the United States (Webb et al. 2004). In the United States, whenever a drug is administered in any way that differs from the label directions (to a different species, at a different dosage, by a different route) its use is said to be extralabel. Only a veterinarian can legally use a drug in an extralabel fashion, and then only in the presence of a carefully defined veterinarian-client-patient relationship (U.S. Department of Health and Human Services 2005). The

Appendix A Table 1.1. Drug dosages used in goats.

Drug	Dose	Indication	Chapter
Acepromazine	0.2 mg/kg IM	Tetanus	5
Acepromazine	0.05–0.10 mg/kg IV	Preanesthetic sedation	17
Acetic acid 5% (vinegar)	0.5–1 liter PO	Urea toxicity	19
Activated charcoal	0.75–2 g/kg PO	Ethylene glycol poisoning	12
Albendazole	20 mg/kg PO divided into 2 doses of 10 mg/kg at 12 h	Gastrointestinal strongyles	10
Albendazole	10–15 mg/kg PO	Tapeworms, liver flukes	10, 11
Ammonium chloride	200–300 mg/kg/day	Urinary acidification	12
Ammonium chloride	0.5–1% of diet DM	Urolithiasis prevention	12
Ammonium molybdate	100 mg PO SID for up to 3 weeks in conjunction with 1 g sodium sulfate PO SID	Copper toxicity	7
Amoxicillin	One commercial bovine mastitis tube every 12–24 h, 2 or 3 treatments	Mastitis	14
Ampicillin	5–10 mg/kg IM BID	Bacterial pneumonia	9
Ampicillin	15 mg/kg SC TID	Prevention of cystitis	12
Ampicillin sodium	10–50 mg/kg IV or IM QID	Meningo-encephalitis	5
Amprolium	25–50 mg/kg PO SID for 5 d	Coccidiosis	10
Aspirin	100 mg/kg PO BID	Joint pain (CAE)	4
		Meningitis adjunct	5
Atipamezole	0.08–0.1 mg/kg slowly IV	Reversal of medetomidine	17
Atropine sulfate	0.6–1 mg/kg SC or IM, repeat as needed	Organophosphate poisoning	5
Butorphanol	0.2 m/kg IM	Post-surgical analgesia	17
Calcium borogluconate 23%	50–100 ml SC	Oxalate poisoning	12
Calcium borogluconate 23%	60–100 ml SC or slowly IV	Milk fever (hypocalcemia)	13, 19
Ceftiofur	1.1–2.2 mg/kg/d IM	Bacterial pneumonia	9
Charcoal, activated	1 g/kg PO	Chlorinated hydrocarbon toxicity	5
Chloramphenicol	Do not use in USA	Forbidden in USA	
Cloprostenol	0.125–0.250 mg IM	Luteolysis, correction of hydrometra	13
Closantel	10–20 mg/kg PO (risk of blindness with overdose)	Liver flukes	11
Closantel	7.5 mg/kg	*Haemonchus*	10
Clorsulon	7 mg/kg PO	Liver flukes	11
Clostridium perfringens C and D antitoxin	5 ml SC	Prophylaxis of enterotoxemia	10
Clostridium perfringens C and D antitoxin	15–20 ml IV, repeat every 3–4 h	Treatment of enterotoxemia	10
Colostrum	20% of body weight PO over first 24 h	Passive transfer	19
Danofloxacin	Do not use in USA	Forbidden in USA	
Danofloxacin	6 mg/kg SC, repeated in 48 h	Mycoplasmosis	4
Decoquinate	0.5–1 mg/kg/d PO in feed, continuously	Coccidiosis prevention	10
Decoquinate	2.5 mg/kg/d PO	Cryptosporidiosis	10
Detomidine	0.01–0.02 mg/kg IM	Moderate sedation	17
Dexamethasone	0.1 mg/kg/d IV	Adjunct–listeriosis	5
Dexamethasone	1–2 mg/kg IM or IV	Cerebral edema from polio-encephalomalacia	5
Dexamethasone	20–25 mg SC or IM	Induction of parturition	13
Dextrose		See Glucose	
Diazepam	0.5–1.5 mg/kg IV	Convulsions, tetanus	5

Appendix A Table 1.1. *Continued*

Drug	Dose	Indication	Chapter
Diazepam	0.1–0.5 mg/kg IV	Urolithiasis, to relax urethra	12
Diazepam	0.5 mg/kg IV	Preanesthetic sedation	17
Diethylcarbamazine	40–60 mg/kg/d PO 1–6 d	Setariasis	5
Diminazene aceturate	3.5 mg/kg IM	Trypanosomosis	7
Dioctyl sodium sulfosuccinate (DSS)	15–30 ml PO	Bloat	10
Doxopram HCl	1–1.5 mg/kg IV or sublingually	Resuscitation of neonate	13
Enrofloxacin	Do not use in USA	Forbidden in USA	
Epinephrine	0.03 mg/kg IV	Anaphylaxis	10
Epinephrine 1:1000	1 ml IM	Uterine relaxation for obstetrical manipulation	13
Eprinomectin	1 mg/kg topical	Sarcoptic mange	2
Eprinomectin	0.4 mg/kg PO	Gastrointestinal strongyles	10
Equine chorionic gonadotropin (PMSG)	400–750 IU IM 48 h before progestogen withdrawal	Induction of estrus out of season	13
Fenbendazole	10 mg/kg PO	*Dictyocaulus*	9
		Gastrointestinal strongyles	10
Fenbendazole	15 mg/kg	Tapeworms	10
Fenbendazole	15–30 mg/kg PO	*Muellerius*	9
Fenbendazole	50 mg/kg/d for 5 d PO	Cerebrospinal nematodiasis	5
Florfenicol	40 mg/kg SC every 1–2 d	Bacterial pneumonia	9
Flunixin meglumine	1 mg/kg/d IV, IM or PO	Laminitis	4
Flunixin meglumine	1.1 mg/kg IV BID	Anti-inflammatory	12, 17
Flunixin meglumine	1–2 mg/kg IV or IM BID	Meningo-encephalitis	5
Furosemide	1 mg/kg IV	Cerebral edema	5
Furosemide	50–100 mg IM or IV	Udder edema	14
Glucose	25–50 g IV as 5% or 10% solution	Pregnancy toxemia, ketosis	19
Glucose 20% solution	25–50 ml IP	Hypoglycemia in neonate	19
Griseofulvin	25 mg/kg/d PO for 3 weeks	Ringworm, rarely justified	2
Imidocarb diproprionate	1–2 mg/kg once	Babesiosis	7
Isometamidium chloride	0.5–1.0 mg/kg IM	Trypanosomosis prophylaxis	7
Ivermectin	0.5–20 mg/100 kg SC	Warbles	2
Ivermectin	0.2–0.4 mg/kg SC, repeat in 2 weeks	Sarcoptic mange	2
Ivermectin	0.2 mg/kg PO	Nose bots	9
Ivermectin	0.4 mg/kg PO	Gastrointestinal strongyles	10
Ivermectin, adjunct to fenbendazole	0.2 mg/kg/d SC for 5 d	Cerebrospinal nematodiasis	5
Ketamine	6 mg/kg IV or 11 mg/kg IM	General anesthesia	17
Ketoprofen	3 mg/kg IV or IM SID	Post-surgical analgesia	17
Lasalocid	20–30 g/ton of feed	Coccidiosis prevention	10
Levamisole	12 mg/kg PO	Gastrointestinal strongyles	10
Levamisole	7.5 mg/kg PO or SC	*Dictyocaulus*	9
Lidocaine	Up to 5 mg/kg IM or SC	Local analgesia	17
Lidocaine 2%	2–4 ml	Caudal epidural	17
Lincomycin/Spectinomycin	5 mg/kg/d Lincomycin + 10 mg/kg/d Spectinomycin IM for 3 d	Mycoplasmosis (Contagious agalactia)	4
Magnesium hydroxide	50 g PO (adult goat)	Rumen acidosis	19
Medetomidine	0.005 mg/kg IV or 0.015 mg/kg IM	Deep sedation	17
Melengestrol acetate (MGA)	0.125 mg/head BID PO for 10–14 d, followed by a prostaglandin IM	Estrus synchronization in season (not permitted in USA)	13

Appendix A Table 1.1. *Continued*

Drug	Dose	Indication	Chapter
Methocarbamol	22 mg/kg IV	Muscle relaxant (tetanus)	5
Methylene blue 1%	4–15 mg/kg IV	Nitrate poisoning	9
Midazolam	0.4 mg/kg IV	Preanesthetic sedation	17
Monensin	15–20 g/ton of feed	Coccidiosis prevention	10
Morantel tartrate	10 mg/kg PO	Gastrointestinal strongyles	10
Morantel citrate	6 mg base/kg PO	Paramphistomes	10
Moxidectin	0.4 mg/kg PO	Gastrointestinal strongyles	10
Niacin	1 g/animal/d IM or PO	Pregnancy toxemia prevention and treatment	19
Niclosamide	50 mg/kg	Tapeworms	10
Oxytetracycline	10 mg/kg IV BID at least 3 d	Listeriosis	5
Oxytetracycline	15 mg/kg/d IM at least 5 d	Mycoplasmosis	4
Oxytetracycline	5 mg/kg/d IV for 5 d (combined with intramammary therapy)	Gangrenous mastitis	14
Oxytetracycline, long-acting	20 mg/kg SC or IM once	Dermatophilosis	2
		Foot rot or foot scald	4
		Heartwater	8
Oxytetracycline, long-acting	20 mg/kg SC or IM every 3 d	Chlamydiosis, other abortion diseases	13
Oxytocin	5 IU IM BID–TID	Retained placenta, milk letdown	13
Oxytocin	50 IU IM BID for 4 d	Correction of hydrometra	13
Paromomycin	100 mg/kg/d PO	Cryptosporidiosis	10
Penicillamine	50 mg/kg/d PO	Copper toxicity	7
Penicillin G, procaine	20,000 IU/kg/d IM for 7–14 d	Staphylococcal dermatitis	2
Penicillin G, procaine	20,000–40,000 IU/kg/d IM	Bacterial pneumonia	9
Penicillin G, procaine	22,000 IU/kg IM BID	Prevention of cystitis	10
Penicillin G, procaine	25,000 IU/kg IM BID	Tetanus	5
Penicillin G, sodium	40,000 IU/kg IV QID followed by Penicillin G procaine 20,000 IU/kg IM BID	Listeriosis	5
Penicillin G, sodium	20,000–40,000 IU/kg IV or IM QID	Meningo-encephalitis	5
Pentobarbital	30 mg/kg IV	General anesthesia	17
Phenylbutazone	10 mg/kg/d PO	Joint pain (CAE), laminitis	4
Poloxalene	100 mg/kg PO	Bloat	10
Praziquantel	5–15 mg/kg PO	Tapeworms	10, 11
Praziquantel	25–60 mg/kg PO	Schistosomosis	8
Prednisone, prednisolone	1 mg/kg IM BID	Pemphigus foliaceus	2
Propofol	4–6 mg/kg IV	Anesthesia induction	17
Propylene glycol	60 ml PO BID or TID	Pregnancy toxemia, ketosis	19
Prostaglandin F2 alpha (Dinoprost)	5–10 mg IM	Luteolysis, correction of hydrometra	13
Pyrantel tartrate	25 mg/kg PO	Gastrointestinal strongyles	10
Selenite, sodium	1 mg/18 kg SC once (follow label for sheep on selenium-vitamin E product)	White muscle disease	4
Sodium bicarbonate	20 g PO (adult goat)	Rumen acidosis	19
Sodium bicarbonate 1.3%	125–200 ml IV	Floppy kid disease	19
Sodium bicarbonate (powder)	2.5–3.0 g PO (0.5 tsp mixed with cold water)	Floppy kid disease	19
Sodium iodide	20 mg/kg IV or SC, weekly 5–7 weeks	Actinobacillosis,	2
		Actinomycosis	3

Appendix A Table 1.1. *Continued*

Drug	Dose	Indication	Chapter
Sodium nitrite	22 mg/kg IV	Cyanide poisoning	9
Sodium thiosulfate	660 mg/kg IV	Cyanide poisoning	9
Spiramycin	50 mg/kg IM then 25 mg/kg/d	Mycoplasmosis	4
Streptomycin	20 mg/kg/d 5–7 d	Actinobacillosis, Actinomycosis	2 3
Streptomycin	30 mg/kg/d IM at least 5 d	Mycoplasmosis	4
Sulfadimethoxine	75 mg/kg PO for 5 days	Coccidiosis	10
Tetanus antitoxin	10,000–15,000 units IV BID	Tetanus treatment	5
Tetanus antitoxin	250–300 IU SC/kid, 500 IU SC/adult	Tetanus prophylaxis	18
Tetracycline	5 mg/kg IM or SC SID or BID	Bacterial pneumonia	9
Tetracycline	0.5–1 g PO (single dose)	Adjunct–rumen acidosis treatment	19
Thiamine	10 mg/kg IV, IM, or SC QID	Polioencephalomalacia	5
Thiamine	300–500 mg IM or SC BID	Adjunct–rumen acidosis	19
Thiamylal sodium	10 mg/kg IV	Induction of anesthesia	17
Thiopental sodium	15–20 mg/kg IV	Induction of anesthesia	17
Tiamulin	20 mg/kg/d IM at least 5 d; severely irritating, toxic myopathy	Mycoplasmosis (CCPP)	4
Tiamulin	10 mg/kg IM BID	Mycoplasma mastitis	14
Tiletamine-zolazepam (Telazol®)	5.5 mg/kg IV	General anesthesia	17
Tilmicosin	Do not use	May be fatal	
Tolazoline	1.5 mg/kg IV	Xylazine reversal	17
Triclabendazole	10 mg/kg PO	Liver flukes	10
Trimethoprim-sulfonamide	16–24 mg/kg IV BID	Meningo-encephalitis	5
Trimethoprim-sulfonamide	15 mg/kg IV BID (trimepthoprim inactivated in rumen)	Salmonellosis	10
Tylosin	10–20 mg/kg IM SID or BID	Bacterial pneumonia	9
Tylosin	20 mg/kg/d IM at least 5 d	Mycoplasmosis	4
Vancomycin	Do not use in USA	Forbidden in USA	
Vitamin B$_{12}$	0.01–0.3 mg IM weekly	White liver disease	11
Xylazine	0.03–0.04 mg/kg IV	Light sedation	17
Xylazine	0.05 mg/kg IV or 0.1 mg/kg IM	Heavy sedation; combine with local anesthesia	17
Xylazine plus Ketamine	0.22 mg/kg IM Xylazine followed in 10 min by 11 mg/kg IM Ketamine	General anesthesia	17
Yohimbine	0.125 mg/kg IV	Xylazine reversal	17
Zinc sulfate	1 g/d/adult goat PO	Zinc deficiency dermatopathy	2

IU = international units
tsp = teaspoon

veterinarian is then responsible for specifying the time periods before meat or milk can be marketed, to ensure that no illegal drug residues occur. Practitioners working with goats are continually forced to extrapolate from other species (Lofstedt 1987; Riviere et al. 1997) or to select drug dosages or withdrawal periods on empirical bases.

A withdrawal time (WT) is the interval after dosing for all tissue concentrations of a drug or its metabolites to decrease to below a specific concentration established as safe for human consumption by the regulatory agency involved (Riviere et al. 1998). For labeled drugs in the United States, the meat WT is the time required for 99% of treated animals to achieve drug concentrations in muscle, liver, and kidney below the established tolerance concentration (Riviere et al. 1998). The labeled WT takes into account slight errors in dosing and individual differences in clearance rates. The WT must be increased if a drug is given at a higher dosage than is on the label or to a more severely diseased animal. Typically, the WT is approximately five to ten times the elimination half-life for the drug, and if the dose administered is doubled, the WT needs to be extended by one half-life, or 10% to 20%. If, on the other hand, the drug is given to an animal that is more severely compromised by its illness than those for which the drug is labeled, the elimination half-life increases and the WT becomes approximately ten times the new half-life. When the drug is given to an animal such as a goat, for which it is not labeled, the distribution and elimination parameters of the drug in that species must be taken into consideration when estimating a WT. Frequently, a smaller species (such as a goat) metabolizes and excretes a drug faster than a larger species of similar physiology (such as cattle), so a cattle WT is often adequate for goats if the same dose is administered (Riviere et al. 1997, 1998). Pharmacokinetic data from the world literature for goats and other species have been tabulated and published by FARAD (Craigmill et al. 2006).

American veterinarians should consult the Food Animal Residue Avoidance Database (FARAD, http://www.farad.org) if available, for estimated meat and milk withdrawal periods for drugs not labeled for goats in the United States. Several helpful guides to withdrawal periods have been published (Baynes et al. 1997, 2000; Craigmill et al. 1997; Damian et al. 1997; Martin-Jimenez et al. 1997; Haskell et al. 2003, 2005; Gehring et al. 2005; Kukanich et al. 2005; Payne et al. 2006). These and additional FARAD digests have also been made available at the FARAD Website. Some estimated withdrawal times from FARAD for tranquilizers and general anesthetic drugs are provided in Table 17.1.

In the United States, records must be kept for at least two years after extralabel drug use in goats (Anonymous 1998); some states require a longer period for maintaining records.

Alternative Medicine

Goats make especially charming pets while performing the useful function of supplying milk or fiber for the family. They have become popular with Americans who seek a return-to-nature or homesteading lifestyle or who believe in alternative or holistic therapies for themselves and their animals. In some other parts of the world, modern veterinary medicine is not available to the small farmer. Instead, traditional medicines and folkloric techniques are still used to treat and prevent illness in goats. This appendix is not meant to either teach or endorse the various methods discussed. Instead, it is included to make veterinarians better able to communicate with the goat owner who believes in or is experimenting with various forms of holistic medicine. A comprehensive veterinary textbook discusses many of these techniques in depth (Schoen and Wynn 1998). An annotated bibliography of traditional veterinary medical practices from around the world, nowadays referred to as ethnoveterinary medicine, is also available (Martin et al. 2001).

Some veterinarians may become curious about the topics discussed below and consult the references for further information. Others will not be convinced until double-blind clinical trials have demonstrated treatment efficacy (Angell and Kassirer 1998; Margolin et al. 1998). In many instances, alternative and conventional methods can be employed simultaneously. It is critical to perform a thorough physical examination with appropriate scientific diagnostic tests before offering complementary treatments. Maintaining an accepted professional standard of care avoids overlooking problems that endanger the patient or the rest of the herd. It also decreases the risk of a malpractice suit.

ACUPUNCTURE

As more veterinarians attend special workshops on the technique and physiologic mechanisms for its effects are demonstrated, acupuncture is gradually becoming accepted in the Western world as a valid means of treating pain and disease in animals. Numerous veterinary texts on the subject are now available (Klide and Kung 1977; Kothbauer 1999; Schoen 2001; Lindley and Cummings 2006; Xie and Preast 2007). Courses and certification in acupuncture in the United States can be acquired through the International Veterinary Acupuncture Society (http://www.ivas.org/), the Chi Institute (http://www.tcvm.com/), or the Medical Acupuncture for Veterinarians program at Colorado State University (http://scienceofacupuncture.com/), among others.

A discussion of either the Chinese philosophy of energy flow, on which acupuncture was originally based, or the functions of the central nervous system or peripheral nerves that might explain its actions is beyond the scope of this book. In fact, the discipline is so complex that it is presumptuous to suggest that competency can be gained in a few weekends or even a few months. However, veterinarians with acupuncture training for other species may have the occasion to treat goats. For them, information concerning the location of points and prescriptions (point selections) for caprine diseases would be helpful. Unfortunately, very little information specific to goats is available. In

addition, the beneficial effect of acupuncture remains unproven in the typical published case report (Pawde et al. 1998).

Acupuncture points (or stimulation points) can be located on the surface of the body using an electric point finder. At these points, the electrical resistance is much lower than in the surrounding skin, while the points have a higher millivolt potential. Mapping of these acupoints in goats according to electrical properties of the skin has been described (Wheeler et al. 1976; Pontus 1982), but without any attempt to relate the various points to disease conditions or therapy. The skin over these points is often slightly depressed.

Charts of traditional Chinese acupuncture points for goats have been translated into English and published, accompanied by indications for stimulation of each point (Klide and Kung 1977). Most schools of acupuncture in the United States teach the meridian theory for organizing and locating points. There are twelve regular meridians along which Qi energy and Blood are believed to circulate from the body to the extremities and return to the body. Two important meridians are located on the dorsal and ventral midlines. The meridians and the points along them are named for body organs or functions that they influence. The bladder meridian, on each side of the back, has been demonstrated as a low impedance line in goats as well as in other species (Yu et al. 1994). Points are identified by the name of the meridian and a number, such as ST36 (stomach 36).

Anatomic transposition of sites of clinical importance for humans has been used to create meridian charts for veterinary species, especially horses and dogs (Schoen 2001), but also cattle (Kothbauer 1999; Kothbauer and VanEngelenburg 2001). Most acupuncturists use one of these charts as a starting point when treating goats. Points for cattle might be chosen when attempting to influence internal organs, while points for dogs might be appropriate for treating arthritic conditions of proximal joints. Points on the lower limbs of goats and cattle are most problematic (Kothbauer 1999), because transposition from human charts is not possible.

Once specific points have been selected, whether to treat a local problem such as a wound or painful joint or to rectify an internal imbalance, they must be stimulated. The stimulation may be provided in various ways, including pressure, heat or cold, cold laser, or insertion of fine needles that may be twirled or stimulated electrically. Assorted drugs such as vitamin B_{12} have also been injected into acupuncture points for prolonged effect. Xie and Preast (2007) suggest treating goats as miniature cattle and using dilute vitamin B_{12} aquapuncture to avoid the need for prolonged restraint. Treatment might be repeated daily, weekly, or as needed. An important benefit of acupuncture, especially for treatment of chronic or painful conditions, is that there is no meat or milk withdrawal required as long as inappropriate drugs are not injected.

Acupuncture has also been used to provide analgesia and sedation for surgery. Although a study has been published on the use of electro-acupuncture for abdominal and udder surgery in goats (Jaiswal and Kumar 2005), the effectiveness of acupuncture for reducing the dosage of drugs required for surgery has been questioned by others (Skarda and Glowaski 2007). Stimulation of a specific point on the nasal philtrum (GV26) is widely recommended for cardiopulmonary resuscitation in humans and animals. Some benefit was shown in a study involving anesthetized sheep (Davies et al. 1984).

AURICULAR DIAGNOSIS AND THERAPY

A specialized branch of acupuncture involves the utilization of the ear for diagnosis and treatment of conditions elsewhere in the body (Still 2001). In human acupuncture, the shape of an inverted fetus describes the relationship of certain organs with parts of the external ear (Klide and Kung 1977). Thus, the lower ear lobe corresponds to the head and might be stimulated for relief of migraine headache. Limited work with dogs suggests that active ear points can be identified by increased pressure sensitivity or increased electrical skin conductivity. Selected points (usually those that are pressure sensitive) are then stimulated with dry needles, aquapuncture using saline or diluted local anesthetic, or laser (Still 2001).

A partial list of ear points in cattle has been developed by observing reddened or otherwise inflamed areas in the ears of animals with chronic clinical conditions (Kothbauer 1999; Kothbauer and VanEngelenburg 2001). It is recommended to clean encrusted cerumen from the inner surface of the ear with tissue paper and clip long hairs with scissors before gently stroking the entire surface with a blunt probe. Areas that become reddened or ooze fluid in five to fifteen seconds have diagnostic importance. Apparently the ear points of the goat have not been mapped. One acupuncture point is known to exist close to the tip of the goat's ear (concave surface) and is specified for the treatment of abdominal pain (Klide and Kung 1977).

ACUPRESSURE

Finger pressure applied to acupoints is important in Chinese and Japanese medicine and has a popular following in the United States as well (Krieger 1979; Gach 1990). The use of acupressure on goats has not been well described or evaluated, but a popular text for treating cats and dogs (Schwarz 1996) can supply curious owners with basic information on the theory

of Chinese medicine as well as location and stimulation of points. Clipping a little hair or making a circle on the skin with an indelible marker helps the owner to find the points to be stimulated.

TELLINGTON TTOUCH

Linda Tellington-Jones is a horse trainer who has developed and taught techniques for handling and training animals (Tellington-Jones and Bruns 1978). Her TTEAM approach (originally Tellington-Jones Equine Awareness Method, later Tellington-Jones Every Animal Method or Tellington Touch Every Animal Method) has been taught at clinics in North America, Europe, Africa, Australia, and New Zealand. It is also the subject of many subsequent books and videos and an international newsletter (Tellington-Jones and Hood). The specific touches (referred to as TTouches) used with this technique have been shown to relax people and animals, including horses, llamas, dogs, goats, and various zoo species. Anxiety and stress appear to be reduced. Local circulation and neural transmission are said to be improved. The relaxed animal is easier to treat and it is more apt to recover from illness or injury because of its improved sense of well-being. Animals that have been hard to handle become quiet, self-confident, and cooperative. Try this on small children before dismissing the technique out of hand!

TTouch bodywork does not involve petting. Instead, for the most basic touch a finger is placed on the skin and moved in a clockwise direction to complete more than a full circle (from 6 o'clock to 7 or 8 o'clock). The skin actually moves with the finger in the circle, and when the finger is lifted it is with a conscious effort to lift the skin also. Very light, quick circles over many parts of the body or around an injured area are done on nervous animals. The circles become slower and firmer as the animal relaxes.

The TTEAM approach also involves "working" the ears. This includes doing the basic touch on the base of the ears and gently pulling the ears. The tip of the ear (an acupuncture/acupressure point) is worked firmly between forefinger and thumb in cases of colic or shock. An additional facet of TTEAM is the use of ground exercises to improve balance and focus of the patient.

Some uses of TTEAM in equine and small animal practice have been reviewed (Harman 1998). There are several potential applications for TTEAM methods to goats, and case reports concerning goats appear occasionally in the newsletter. Both goats and their owners are apt to need the mutual relaxation afforded by the touch after traumatic experiences such as dog attacks. Hospitalized goats might eat better. First, fresheners might learn sooner and with less spilled milk to stay on their feet during milking.

CHIROPRACTIC

Chiropractic is based on the theory that health and disease are life processes related to the function of the nervous system. Practitioners use a holistic approach to identify and remove mechanical, chemical, or psychic factors that may have caused disease. Frequently, manipulation of the vertebral column is used to correct a slightly faulty alignment of the bones that might be applying pressure on nerves or other structures in the intervertebral foramen and thereby causing disease (Willoughby 1998).

People who visit a chiropractor for relief of their own aches and pains may seek treatment of their animals as well. The chiropractor may request the loan of a veterinary anatomy book before working on a goat or other domestic animal. The results are not usually reported, possibly due to fear of prosecution for unlicensed practice of veterinary medicine. The veterinarian can allay these fears by asking the chiropractor to consult on the case. Unfortunately, if owners do not discuss the animal's condition with a veterinarian, very serious neurologic diseases may go undiagnosed to the detriment of the animal. An increasing number of veterinarians have taken postgraduate courses in chiropractic through the American Veterinary Chiropractic Association (http://www.animalchiropractic.org/) and integrate the techniques into their routine case management.

KINESIOLOGY

Applied kinesiology is a technique of identifying dysfunction within the human body by testing the strength of the patient's muscles; it is promoted by the International College of Applied Kinesiology (http://www.icak.com/). The manual muscle test is commonly used by chiropractors and other health practitioners, and the literature on its scientific validity has been reviewed recently (Cuthbert and Goodheart 2007). This review was followed by publication of another, negative interpretation (Haas et al. 2007), that the validity of standard orthopedic muscle strength testing does not afford credibility to the applied kinesiologist's use of the test to identify subclinical disease conditions or the need for treatment of organic or metabolic conditions.

When kinesiology is applied to veterinary medicine, a surrogate is used during the diagnostic process (Tiekert 1981). The surrogate (such as a veterinary technician) holds one arm extended straight out from the shoulder while placing the index finger of the other, free hand on the part of the animal's body to be evaluated. Another person applies downward pressure on the surrogate's arm while the surrogate resists the pressure. The surrogate's arm is expected to drop (become weak) when contact is made with an area of the patient where normal energy has been disrupted

by disease or injury. The technique has been used to select portions of the body to radiograph or to choose which conditions are most important when the patient appears to have several problems.

HERBAL REMEDIES

Through the centuries, herbalists in almost every society have collected plants to be used as treatments for human or animal ailments. The medicinal lore of these sages was passed from generation to generation by oral tradition and eventually was compiled into books. Veterinary uses for both Western and Chinese herbs have been summarized (Schoen and Wynn 1998; Karreman 2007; Wynn and Fougère 2007; Xie 2008) and numerous courses are available on the subject of herbal medicine.

That many plants contain pharmacologically active compounds is disputed by none. That all of the plants espoused in the popular press, including what is written for goats (Levy 1976), have the beneficial actions ascribed to them is, however, frequently questioned. This is partly because many of the conditions for which herbal treatments are recommended are poorly characterized or are themselves self-limiting. For example, without sophisticated double-blind trials, it would be difficult to prove that raw cucumber juice squeezed into the eyes is excellent for keratoconjunctivitis or that celandine (*Chelidonium majus*) juice cures warts on the udder.

Herbs as Supplemental Therapy

Practitioners treating vague or chronic diseases of goats that belong to people who are intrigued by herbal medicine may be in a position to monitor the effects of various "natural" remedies on their patients, while at the same time supplying essential modern drugs. For instance, there are testimonials that yucca relieves the swelling of CAE arthritis (Padilla 1986), and an owner who had been told that nothing more could be done for an affected goat might choose to try the herbal remedy in addition to or in place of nonsteroidal anti-inflammatory drugs. Even if the pharmacological effects of these plants remain unproven, the confident attitude of the owner who is doing "everything possible" may have a very positive effect on a sensitive goat.

Possible Problems with Herbs

Many opponents to old herbal cures stress the uncertainty in the dosage of drug administered. Would it not be better to give just the right amount rather than deal with nature's variability? Experienced herbalists not only agree that the efficacy of a remedy varies, but specify a stage in the life cycle or time of day at which each plant should be collected in order to maximize potency. It has also been pointed out that modern allopathic drugs, because they have been developed to be very potent, often cause multiple, serious side effects that might be avoided by using a natural mixture of compounds (Thomson 1976).

Currently, the U.S. Food and Drug Administration (FDA) classifies herbal products as food supplements and they can only be marketed as such (de Guzman 1998). Because there is no proof of efficacy required for these products, there also is no information provided on safety, potency, or quality. When a product is purchased, it should at the very least be labeled with the genus and species, harvest date, and expiration date. Herbal remedies of toxicologic concern have been summarized recently (Poppenga 2007).

Foxglove

Foxglove (*Digitalis* spp.) may well be the first plant that comes to mind when discussing the dangers of self-treatment with herbs. Foxglove contains a variety of cardioactive glycosides known collectively as digitalis. The plant has been used for several centuries for treating heart disease in people. Although most physicians and veterinarians now prescribe synthetic forms (digoxin), toxicity is very common during the process of establishing an appropriate dosage for the patient. It has been claimed that the plant preparation has fewer undesirable side effects. However, overdosage or giving foxglove when another plant, such as comfrey, was intended may be fatal. It is inappropriate to encourage goat owners to administer foxglove internally to their animals. Besides, heart disease requiring digitalis therapy is very rare in goats. A lay person's faith in natural cures might lead to the death of the goat because an unrecognized selenium deficiency was the cause of the heart disease or "dropsy" was actually due to hypoproteinemia from endoparasitism.

Comfrey

Comfrey (*Symphytum officinale*) has been cultivated as both a fodder plant and a medicinal plant. Reported uses include controlling hemorrhage, healing fractures, treating pulmonary diseases and arthritis, and as a poultice (Levy 1976). It is now known that comfrey contains toxic pyrrolizidine alkaloids (Duke et al. 1998). Goats are considered to be relatively resistant to these toxins (Hooper 1978), but it is conceivable that chronic consumption of comfrey might lead to toxic changes in liver, kidney, or other organs. Herbal remedies containing comfrey have caused serious liver damage in people (Weston et al. 1987). The milk from goats consuming comfrey or other pyrrolizidine alkaloid-containing species may be toxic (Panter and James 1990).

Anthelmintics

Anthelmintic treatments comprise another area where herbal treatment may be disadvantageous

because a more effective remedy is withheld. Both garlic and tobacco have been used to treat worms. Controlled studies in small ruminants have failed to show a beneficial effect of garlic juice or a commercial herbal dewormer mixture containing garlic on intestinal worms (Allen et al. 1998; Burke et al. 2009a, 2009b). The nicotine from tobacco does paralyze worms but has a narrow margin of safety. Diatomaceous earth, a nonherbal substitute for modern anthelmintics, is not effective for worm control in concentrations at which it is included in feed for this purpose (Allen et al. 1998; Stromberg and Gasbarre 2006). In instances in which an owner sincerely believes that modern drugs would be harmful to his animals or organic farming techniques (see Chapter 20) are used to access a niche market, veterinarians should stress the use of nutrition, sanitation, and pasture rotation to control parasites. Tannin rich forages, as discussed in Chapter 10, may also be of value.

Some plants may appear to have an anthelmintic effect because they act as purgatives and goats may pass visible tapeworm segments, suggesting to the owner that the plant is an effective dewormer. However, at least in the case of kamala *(Mallotus philippinensis)*, it was demonstrated in a controlled study that while tapeworms were passed after treatment, the plant had no effect on clearing the more dangerous nematode parasites present in the goat's digestive system (Jost et al. 1996).

Fecal examinations should be performed several times a year to verify that the goats and their parasites are in balance. In large herds on small wet pastures or when nutrition and management are suboptimal, herbs alone do not control parasites. Only if the owner envisions generations of natural selection for resistance would this be a rational approach. Even then, it would be more humane to treat the susceptible goat but remove it from the breeding population.

Several plant-derived chemicals have been scientifically evaluated as anthelmintics for goats (Akhtar et al. 2000; Ketzis 2006). Goals have included finding plants that poor farmers could grow to aid in parasite control and isolating active plant compounds that might be synthesized and marketed commercially. When a potential plant has been identified though ethnoveterinary or traditional medicine information or by seeing a parasitized animal self-medicate with it, a crude extract is prepared and analyzed for compounds of potential interest. *In vitro* screens for bioactivity, such as *Haemonchus contortus* egg hatch tests, are then followed by *in vivo* studies to evaluate the plant-derived compound for efficacy, safety, and food residues. When this process was followed to test *Chenopodium ambrosioides* in goats, chenopodium oil caused death of some kids and milk contamination (Ketzis 2006).

BACH FLOWER REMEDIES

In England and the United States, flower essences have been used to treat both human and animal illnesses (Howard 1990; Chancellor 1991). Edward Bach, a physician in England, developed a system of thirty-eight remedies prepared from flowers and trees for negative states of mind such as fear, uncertainty, insufficient interest in present circumstances, loneliness, oversensitivity, despondency, and over-care for the welfare of others. Bach flower remedies are frequently available at health food or homeopathic medicine stores or can be purchased via the Internet.

"Rescue remedy" is a versatile treatment for shock and terror. It is actually a combination of five flowers (cherry plum, clematis, impatiens, rock rose, star of Bethlehem) (Goldstein 2008) that is given orally when the goat undergoes pain or stress, as with accidental injuries, disbudding, surgery, parturition, or a move to a new home. The owner may not mention the prior or ongoing treatment of an animal unless there is confidence that the veterinarian will not ridicule the practice. If the veterinarian offers a poor prognosis for an animal, to avoid disappointing an owner, the owner will naturally conclude that rescue remedy was instrumental in a subsequent recovery.

HOMEOPATHY

This controversial system of therapy traces back to the work of Samuel Hahnemann (1755–1843). It is based in part on two major beliefs (Kruger 1974; Vithoulkas 1980; Weiner and Goss 1989; Saxton and Gregory 2005). First, diseased people or animals are best treated with compounds that have properties similar to the signs shown by the patient (law of similars). Rather than suppress the signs of illness, which are in part results of the body's effort to rid itself of the disease process, these same signs should be amplified by the treatment. This is in contrast to allopathic medicine, which generally strives to suppress or alleviate a patient's symptoms. Thus, for example, "a little fever is good," because elevated temperature often is detrimental to pathogenic organisms. To always administer drugs that suppress fever may hinder the body's natural defense mechanisms. The second belief is that substances become more potent with greater dilution. In fact, the most "potent" remedies have been serially diluted by succussion (vigorous shaking of soluble compounds) or trituration (grinding in lactose with mortar and pestle for insoluble compounds) until there may be no molecules of the original compound left in the final preparation (Wynn 1998). In principle, only a single dose of the "dynamized remedy" is needed to activate the body's own vital forces.

In some countries, both human and veterinary homeopathy are quite popular, and specific remedies

are readily available. Homeopathy may be chosen by the owner on an ideological basis, trying to avoid using chemical substances such as antibiotics, or on an economic basis. Homeopathic remedies are relatively inexpensive and can be administered by the owner. They do not come with restrictions on the sale of meat or milk and are allowed on organic farms (Hektoen 2005).

Recommendations relative to the treatment of goats are available in French (Anonymous) and in English (Macleod 1991; Hunter 2004). A list of homeopathic remedies suggested for dairy cows on organic farms (Karreman 2007) could also be consulted. The possibilities for evaluating veterinary homeopathic treatment by means of placebo-controlled randomized clinical trials and the potential involvement of placebo effects and natural resolution of disease in the perceived response to treatment have been reviewed (Hektoen 2005). Such clinical trials are lacking in goats.

In classic homeopathy, a single remedy is used and antibiotics or other allopathic medications are seen as undesirable because they interfere with diagnosis from the symptomatology. Homotoxicology was founded by Dr. Hans-Heinrich Reckeweg in 1952 to combine classical homeopathy with conventional medicine (Goldstein 2008). Disease patterns in each organ system, known as homotoxicoses, are arranged in a six phase table that begins with the excretion phase, then progress to the inflammation phase and the deposition phase. As the disease worsens, the biological divide is crossed and the organism is unlikely to be able to recover on its own. The following more serious and chronic phases are impregnation, degeneration, and finally dedifferentiation (development of neoplasia). Homotoxicology uses very small doses (nanopharmacology) of combinations of remedies to detoxify or reverse the progression of the disease, back through the inflammation phase to healing. It is believed that conventional anti-inflammatory drugs may retard the healing process. Various formulas are available to manage symptoms such as arthritis, traumatic injuries, cardiac disease, or viral infections, and extensive treatment protocols have been published for small animals (Goldstein 2008).

The homeopathic approach to vaccination warrants special mention, because practitioners may be frustrated by the unwillingness of an owner to use conventional vaccines. A nosode is a potentized homeopathic remedy prepared from diseased tissue or an infected discharge (Hunter 2004). Nosodes have not been documented to provide protection, but users believe that the nosodes are free of the side effects, including chronic ill health or vaccinosis, that homeopaths ascribe to conventional vaccines. Some authors stress the importance of using certain conventional vaccines, as

for tetanus or rabies, while avoiding vaccination of young animals when possible (Hunter 2004, Saxton and Gregory 2005). Nosodes are given orally to "protect" without vaccination. When conventional vaccination is performed or when disease has occurred, the nosode is given to mitigate the effects. Autogenous nosodes can be prepared from any secretion or body fluid, or even from a bacterial culture of a pathogenic organism, derived, for example, from an animal with mastitis (Sheaffer 1998; Wynn 1998). In a placebo-controlled double-blind study with dairy cattle, a nosode prepared from six common mastitis pathogens had no effect on new intramammary infections in the eleven participating herds containing more than 1,000 lactating cows (McCrory and Barlow 2006).

Fluorine	19.00	ppm or µg/ml	µmol/l	52.64
Glucose	180.16	mg/dl	mmol/1	0.0555
Iodine, protein bound	126.904	µg/dl	µmol/l	0.079
Iron	55.847	µg/dl	µmol/l	0.179
Ketones (acetoacetic acid)	102.1	mg/dl	mmol/l	0.098 (0.1)
Lactate	89.07	mg/dl	mmol/l	0.112
Lactic acid	90.08	mg/dl	mmol/l	0.111
Lead	207.2	ppm or µg/ml	µmol/l	4.83
Lead	207.2	µg/dl	µmol/l	0.0483
Magnesium	24.305	mg/dl	mmol/1	0.411
Magnesium	24.305	mEq/l	mmol/l	0.5
Molybdenum	95.94	ppm or µg/ml	µmol/l	10.42
Phosphate, inorganic (as P)	30.974	mg/dl	mmol/l	0.323
Phosphorus, inorganic	30.974	mg/dl	mmol/l	0.323

Component	Formula Weight	Other Units	S.I. Units	Factor
Phosphorus, inorganic	30.974	mEq/1	mmol/l	no change
Potassium	39.098	mEq/l	mmol/l	no change
Progesterone	314.47	ng/ml	nmol/l	3.18
Protein–total	—	g/dl	g/1	10
Selenium	78.96	ppm or µg/ml	µmol/l	12.66
Selenium	78.96	µg/dl	µmol/l	0.1266
Sodium	22.990	mEq/1	mmol/l	no change
T_3 Tri-iodothyronine	646	ng/dl	nmol/l	0.0155
T_4 Thyroxine	773	µg/dl	nmol/l	12.9
T_4 Thyroxine	773	ng/ml	nmol/l	1.29
Urea	60.06	mg/dl	mmol/l	0.166
Urea nitrogen (2N/molecule)	28.014	mg/dl	mmol/l	0.357
Vitamin A	286.44	µg/dl	µmol/l	.0349
Vitamin B_{12}	1355.42	ng/dl	pmol/l	7.38
Vitamin B_{12}	1355.42	pg/dl	pmol/l	0.00738
Vitamin E	430.69	µg/ml	µmol/l	2.32
Zinc	65.38	mg/dl	µmol/l	152.95
Zinc	65.38	ppm or µg/dl	µmol/l	15.295
Bone calcium	40.08	% of Ash	mol/kg of Ash	0.25
Bone magnesium	24.305	% of Ash	mol/kg of Ash	0.41
Thyroid iodine	126.904	µg/100 g	µmol/kg	0.079
Tissue copper	63.546	ppm or µg/g	µmol/kg	15.74
Tissue fluorine	19.00	ppm or µg/g	µmol/kg	52.63
Tissue lead	207.2	ppm or µg/g	µmol/kg	4.826
Tissue manganese	54.938	ppm or µg/g	µmol/kg	18.20
Tissue molybdenum	95.94	ppm or µg/g	µmol/kg	10.42
Tissue selenium	78.96	ppm or µg/g	nmol/kg	12660
Tissue selenium	78.96	ppm or µg/g	µmol/kg	12.66
Tissue zinc	65.38	ppm or µg/g	µmol/kg	15.30
Liver vitamin A	286.44	ppm or µg/g	µmol/kg	3.49
Liver vitamin B_{12}	1355.42	pg/g	pmol/kg	0.74
Hemoglobin		g per 100 ml	g/dl	no change
P.C.V. (packed cell volume)		%	1/l	0.01
R.B.C. (red blood cells)		10^6/cu. mm	10^{12}/l	no change
R.B.C. (red blood cells)		10^6/µl	10^{12}/l	no change
W.B.C. (white blood cells)		10^3/cu. mm	10^9/l	no change
M.C.H. (mean corpuscular hemoglobin)		µµg	pg	no change
M.C.H.C. (mean corpuscular hemoglobin concentration)		%	g/dl	no change
M.C.V. (mean corpuscular volume)		$µ^3$	fl	no change
Platelets		10^3/cu. mm	10^9/l	no change

dl = 100 ml; cu. mm = mm^3 = µl
