Guidelines are available for eradication of the disease initially from endemic areas and then worldwide in three stages.[6] The first stage is a **declaration of provisional freedom from disease**, which could be made by a veterinary officer based on clinical evidence. This is accompanied by increased surveillance including meat inspection and vaccination would cease. Two years later, a country could declare the second stage, **freedom from disease**, which would include no clinical disease, no vaccination, an adequate surveillance and disease-reporting system, and effective measures to prevent reintroduction of disease. Following another 2 years, a country could declare **freedom from infection**, which would be conferred by an expert panel based on continuation of criteria in the second stage. When **freedom from infection** has been established, the country would make a commitment to continue monitoring. All cases of disease would be reported and vaccination would not be allowed. Countries with no recent history of disease and which do not vaccinate would be able to declare '**freedom from infection**'.

In Europe, legislation exists to prevent the spread of CBPP. Any outbreak in a previously CBPP-free country must be reported to the Commission within 24 h of confirmation of the disease; the Commission will then inform other member states.[6] Unaffected regions may export only to other member states if cattle come from herds in which all animals over 12 months of age have been serologically negative in the previous 12 months. All animals for export must have been serologically tested negative 30 d before being loaded. No disease-free regions have been recognized in countries

in which the disease is endemic. Cattle from restricted areas must not be exported to other member states until all herds in the area have passed three clear herd tests on all animals over 12 months of age at intervals greater than 3 weeks apart.[6]

The return of the disease to southern Europe in the 1960s, its endemic nature in the Iberian Peninsula, and unconfirmed reports of its existence in eastern European countries considered to be free of the disease requires an increased awareness of its spread. The illegal transit of cattle between infected and non-infected regions combined with the political and economic considerations, such as delays in implementing both slaughter and payment of compensation to farmers are factors which delay the eradication of the disease from infected countries. Rules regulating intra-community trade are designed to prevent the movement of infected cattle in Europe but the insidious nature of the disease and the limitations of the tests mean that infected cattle are undetected. Effective control will require increased surveillance at abattoirs and the judicious use of diagnostic tests.

In Africa, there is a need to improve the control of livestock movements through regional and international cooperation.

CONTAGIOUS AGALACTIA IN GOATS AND SHEEP

Synopsis

Etiology *M. agalactiae* in sheep. *M. agalactiae*, *M. mycoides* subsp. *mycoides* large colony type and *M. capricolum* subsp. *capricolum* in goats
Epidemiology Occurs on very continent but outbreaks and severe disease occur in the Mediterranean area and Africa. Introduction of infected animals. Direct spread by infected milk and ocular discharge to sucking young and to adults by contamination of bedding, feed, and milking machine equipment
Clinical findings Triad of mastitis, arthritis and ocular disease. Sometimes accompanied with respiratory disease, abortion and diarrhea
Lesions Indurative mastitis with abscessation, polyarthritis
Diagnostic confirmation Culture, PCR, serology
Treatment Antimicrobials may mitigate disease severity but not achieve a bacteriological cure
Control Flock/herd biosecurity, milking-time hygiene. Test and slaughter eradication. Vaccines have poor efficacy

ETIOLOGY

Contagious agalactia is a disease of sheep and goats, particularly those used for milk production. *M. agalactiae* is the main causal agent in sheep and goats but *M. agalactiae*, *M. mycoides* subsp. *mycoides* large colony type and *M. capricolum* subsp. *capricolum* produce a similar if not identical clinical presentation. There is apparent variation in virulence between isolates from different countries and frequently, more than one of these agents can be isolated from the same outbreak.[1–4]

M. putrefaciens, first isolated from the joints of arthritic goats in California, has been isolated and implicated in some outbreaks of contagious agalactia but experimental challenge with this organism does not produce classical contagious agalactia.[1]

M. putrefaciens can cause septicemia, pneumonia and mastitis in small ruminants that are predisposed by other diseases but it should be considered an opportunist when isolated from cases of contagious agalactia.[5]

Epidemiology

Occurrence

Contagious agalactia is endemic in most European countries and Africa, and occurs in most other areas of the world including Asia and the Indian subcontinent, Australasia, the Middle-East and North America but with little documented occurrence in Britain or South America.[1,5] The disease is endemic in most Mediterranean countries and is particularly widespread in Spain.[3] An example of how it can become endemic is that it was recently reported for the first time in goats in the Canary Islands[4] but is now recognized as being endemic on all islands.[6]

Prevalence

In endemic areas the disease is cyclic in occurrence with periods of outbreaks of severe disease interspersed with periods of chronic or mild disease.[5]

Peak rates of clinical disease occur after parturition in both the dams and their young with another peak occurring in association with the onset of machine milking after the young are removed from sucking. The mortality rate can be high (10–30%) and many adult females are culled because the udder is permanently damaged.

Transmission

The organisms are present in the milk and ocular secretions of infected animals and in respiratory secretions where the pulmonary from of the disease is present. Transmission is by direct contact, aerosol transmission, ingestion and by contact with infected fomites. The young are infected through the ingestion of infection present in colostrums and milk. Infected

milk can also contaminate bedding, feed[7] and dairy equipment and spread occurs with machine milking.

The organisms are also resident in the ear canal of sheep and goats and transmission by ear mites is thought to occur.[8–10] The common practice of transhumance and communal grazing in endemic areas also promotes transmission between herds and flocks either from direct contact or grazing over infected pastures. Illegal importation of animals from an endemically infected area to countries free of disease has also resulted in introduction of disease.[11]

Experimental reproduction

The disease can be reproduced experimentally and reflects the natural disease with acute and chronic multifocal necrotizing mastitis, acute arthritis, conjunctivitis, and subacute enteritis. Shedding of the organism precedes the onset of clinical disease by 1 to 10 days.[1,5,8,12] The experimentally produced disease is much more severe in pregnant animals.[13]

Host risk factors

The relative severity of clinical disease in sheep versus goats depends on the infecting mycoplasmal and varies with region[1,5] and there are breed differences in susceptibility. Septicemia and acute disease more common in young lambs and kids and lactating females with less severe disease in adult males and non-lactating non-pregnant females

Pathogen risk factors

There is regional variation in the virulence of isolates, or in some regional environmental factor. *M. agalactiae*, *M. mycoides* subsp. *mycoides* large colony type, *M. capricolum* subsp. *capricolum* and *M. putrefaciens* have all been isolated from goats in Australia and the USA over several decades but clinical disease in these countries associated with these organisms is extremely rare.

CLINICAL FINDINGS

The classical signs of contagious agalactia include septicemia, arthritis, mastitis, conjunctivitis and localization in abscesses but these are not all consistently present in outbreaks.

In acute cases the onset is sudden with pyrexia, abrupt and complete agalactia, and unilateral or bilateral swelling of the udder with enlargement of the mammary lymph nodes and the development of multiple abscesses in the mammary gland. Induration of the udder may result in culling. In animals that survive mycoplasmal are excreted in the milk for several months[8,13] and will persist in the udder to subsequent lactations.

Arthritis may be manifest by lameness or recumbency and its presence detected in the carpal and tarsal joints by the occurrence of heat and palpable joint fluid, and confirmed by aspiration and examination of joint fluid. Conjunctivitis progresses to keratitis with corneal revascularization in one or both eyes. Some cases have diarrhea.

In less acute cases, there is a long period of illness of from one to several months. Abortion may also occur and genital disease with vulvovaginitis and metritis occurs in some outbreaks.[14]

CLINICAL PATHOLOGY

Herd diagnosis is possible by the isolation of the organism *M. agalactiae* from the bloodstream, joint fluid and mammary tissue. PCR can be used for identification.[15,16]

Herd diagnosis can also be made serologically by CFT which becomes positive soon after a clinical attack. There are also commercial ELISA tests available that have limitations in sensitivity and specificity but that can be used for serological diagnosis.[17]

NECROPSY FINDINGS

Lesions are of indurative mastitis with abscessation, lymphadenopathy, arthritis and ocular disease.

Samples for confirmation of diagnosis

- **Bacteriology** – milk, ocular fluid, joint fluid aspirate (AEROBIC CULT PCR)
- **Serology** – CFT, ELISA.

TREATMENT

Antimicrobial therapy is restricted to the reduction of the severity of the disease and mortality. The cost and practicality of therapy in many endemic areas is a consideration as is the concern that a bacteriological cure is unlikely with antimicrobials such as tetracycline. In vitro sensitivity testing of field isolates of *M. agalactia* found enrofloxin most effective followed by tylosin, tetracycline, lincomycin, and spectinomycin.[18]

High cure rates are reported with the use of lincomycin, spectinomycin, and tylosin.[19]

CONTROL

The majority of infections in healthy flocks come from introduction of carriers or contact with infected animals. Isolation from infected flocks and herds and a closed herd policy is important in the control of disease.

Where disease is restricted to a small number of flocks in a geographically isolated area slaughter of serologically or culturally positive flocks can be an effective method of control,[11] but in most affected areas the disease is endemic, slaughter eradication is not an option, and control rests with immunoprophylaxis.[6]

However, the efficacy and duration of immunity is poor. Vaccination of sheep and goats with either an attenuated live vaccine or a killed adjuvant vaccine of *M. agalactiae* gives mixed results; in late pregnant ewes the former is rather too virulent, and the latter insufficiently so unless it is used in ewes before mating, when efficiency is good. Early vaccination is recommended because of the susceptibility of young animals but should not be carried out before 10 weeks of age. Extensive use of both vaccines over a period of 13 years has resulted in almost complete disappearance of the disease from Romania but live attenuated vaccines are banned in many countries.

Comparison between commercial vaccines shows that a saponized vaccine gives better results than a live, egg-cultured vaccine and saponin and phenol inactivated vaccines show better efficacy against experimental disease than do vaccines killed by heat or formalin.[20] An *M. agalactiae* bacterin combined with a mineral oil adjuvant has given good results when three doses are given before, and one dose after each parturition, and the herd is kept isolated.[3] Intramammary vaccination provides the highest level of antibody.[21]

Autogenous vaccines prepared from milk brain and mammary gland homogenates from infected sheep have been used for many years in parts of Europe but have been linked to outbreaks of scrapie.[22]

In infected herds, milking-time hygiene is important in limiting the spread of disease.

CONTAGIOUS CAPRINE PLEUROPNEUMONIA

Synopsis

Etiology *Mycoplasma capricolum* subsp. *capripneumoniae*
Epidemiology Disease of goats. Highly contagious to susceptible goats
Clinical findings Pleuropneumonia.
Lesions Pleuropneumonia
Diagnostic confirmation Culture, PCR on pleural fluid. Latex agglutination tes.
Treatment Antimicrobials
Control Herd biosecurity, vaccination strong immunity but short duration

ETIOLOGY

Contagious caprine pleuropneumonia (CCPP) is a classical disease of goats, associated with *Mycoplasma capricolum* subsp. *capripneumoniae* and commonly confused with other serious pneumonias of goats and sheep. It presents primarily as a pleuropneumonia. The causative agent is previously known as mycoplasma strain F38.[1] This organism is difficult to grow which has led to poor differentiation of the disease from that induced by *M. mycoides* subsp. *mycoides* LC and *M. mycoides* subsp. *capri*.[2] There are different strains and one study established four different lineages of *M. capricolum* subsp. *capripneumoniae* based on nucleotide sequence.[3] These correlated relatively well to the geographic origin of the strains.

EPIDEMIOLOGY

Occurrence

CCPP is one of the most serious fatal diseases of goats.[4] The exact distribution of the disease is unknown but clinical disease has been reported from 38 countries, mostly from Africa and Asia. However, the causative organism has only been isolated from some of these due to the difficulty in growing it and the lack of mycoplasmal laboratories in many countries.[3,5,6] The disease is called Abu Nini in the Sudan.[7] CCPP has many similarities clinically and at necropsy to contagious bovine pleuropneumonia, but it is not transmissible to cattle. The incubation period is 6–10 d, infectivity is high with a morbidity of 100%, and the illness is acute and severe with a case–mortality rate of 60–100%. Morbidity and mortality rates in a recent outbreak in a herd in Eritria were 90 and 65% respectively.[8]

This represents the response to the introduction of infection into a susceptible flock. What the epidemiological picture would be in a naturally immunized flock receiving constant invasions of infected animals is not clear.

Transmission

The disease is readily transmitted by inhalation, but the organism does not survive for long outside the animal body and the infection is brought into the flock by a carrier or infected animal.

Experimental reproduction

The disease has been reproduced experimentally and in most reports mortality is high.[9,10] Spread to in-contact goats seen with experimental infections parallels this occurrence in natural cases in the field.[7]

CLINICAL FINDINGS

The following description does not fit most current descriptions of the disease. It is customary in them to include other serious pneumonias of goats associated with *M. mycoides* var. *capri* and *M. mycoides* which may manifest with disease in additional organ systems.

The clinical findings in contagious caprine pleuropneumonia are restricted to the respiratory system and include cough, dyspnea, lagging, lying down a lot (but the animal can stand and walk), fever (40.5–41.5°C; 104.5–106°F) and in the terminal stages, mouth-breathing, tongue protrusion and frothy salivation with death in two or more days. Under adverse climatic conditions the disease may occur in a septicemic form with little clinical or postmortem evidence of pneumonia.

CLINICAL PATHOLOGY

Antigen can be detected in lung tissue and pleural fluid by PCR.[2] Serological tests used to identify carrier animals include complement fixation, ELISA and a latex agglutination test. The latter is robust, available commercially and suitable for field use.[2] The F38 monoclonal antibody is used in serological tests to identify caprine F38-type isolates by the disc growth inhibition method, which will include *M. agalactiae*, *M. capricolum* subsp. *capricolum* and the other members of the *Mycoplasma mycoides* cluster associated with goats.[11] A blocking ELISA using monoclonal antibodies is highly specific for CCPP.[12]

NECROPSY FINDINGS

The more usual necropsy findings are similar to those of contagious bovine pleuropneumonia except that sequestra are not formed in the lungs. Lesions are restricted to the lungs and pleura with hepatization of parts of the lung and an increase in pleural fluid with a fibrinous pleuritis. Histologically, contagious caprine pleuropneumonia is characterized by an interstitial intralobular edema rather than a thickening of the interlobular septa seen with other mycoplasmal infections.[2] The lesions may be confined to one lung.

Samples for confirmation of diagnosis

- **Bacteriology.** These mycoplasmas are fragile and should be freeze dried if there is to be a significant transport time. More effective detection is by PCR performed on samples of pleural fluid dried on filter paper
- **Serology.** CFT or Latex agglutination.

DIFFERENTIAL DIAGNOSIS

The other pulmonary mycoplasmoses from which this disease needs to be differentiated are those associated with *Mycoplasma mycoides* subsp. capri, *M. mycoides* subsp. *mycoides* (large colony type) and *M. capricolum*.[8]

TREATMENT

Treatment of cases of CCPP with tylosin tartrate 10 mg/kg BW or oxytetracycline (15 mg/kg/d) is highly successful in limiting the severity of disease. The severity of the disease is reduced but treated animals are still sources of infection.

CONTROL

Herd biosecurity to prevent contact with infected animals is important. Vaccination with an inactivated mycoplasma F38 vaccine induces an immune response which is effective in reducing morbidity and mortality rates, and a booster dose 1 month after the first vaccination provides additional protection.[13,14] Immunity is generally short-lived. Maternal antibody may interfere with the development of immunity and kids born to does that have been vaccinated while pregnant should themselves not be vaccinated prior to 12 weeks of age.

MYCOPLASMAL ARTHRITIS IN CATTLE

Synopsis

Etiology *Mycoplasma bovis*
Epidemiology Occurs in association with pneumonia or lotitis in calves, mastitis in cows, but occasionally with no apparent inciting disease. Attack rates can be high and recovery slow
Clinical findings Moderate fever, lameness, pronounced swelling of the joints and tendon sheaths
Lesions Fibrinous synovitis
Diagnostic confirmation culture Detection by PCR
Treatment Refractory to treatment. Early treatment with tylosin may be effective
Control Herd biosecurity. Control of pneumonia. Pasteurization of milk fed to calves

ETIOLOGY

The cause is *Mycoplasma bovis*.[1] *Mycoplasma alkalescens* has also been isolated from 3-week-old calves affected with polyarthritis and a group 7 mycoplasma has been recovered from a calf with polyarthritis. *M. bovis* may be found in calves with polyarthritis and enzootic pneumonia, which may suggest a pneumonia–arthritis syndrome. *M. californicum*, usually isolated only from mammary disease, has also been isolated from the joints of cattle with arthritis in Germany.[2]

EPIDEMIOLOGY

Mycoplasma arthritis of cattle has been reported in a number of countries including Canada, the United States, Europe and the United Kingdom. The causal organism and its associated diseases appears to be spreading in association with animal movement and occurring in areas where it has not previously been recorded.[3–5] Commonly arthritis occurs in association with respiratory disease or otitis media in calves, or mastitis in adult cattle, and isolations from arthritis are much less common than isolations from these other diseases.[4,6]

Coincident with the geographic spread the age and type of animal affected is also changing, or expanding. Earlier reports suggested that it occurred most commonly in young feedlot cattle usually affecting many animals a few weeks after arrival and mingling in the lot. The morbidity ranged from 20–85% and the case-mortality rate from 3–50%. In Canada, the disease has been seen commonly in young cattle (6–8 months of age) following shipment from western rangelands to eastern feedlots, which suggests that long transportation and mixing of cattle of different origins may be important epidemiological characteristics. Calves affected with arthritis commonly have necropsy evidence of mycoplasma pneumonia and it is proposed that the pneumonia precedes the development of the arthritis. Calves sucking cows with experimental mastitis due to this organism may develop mycoplasmal arthritis, and a high incidence is recorded in calves in dairy herds where mycoplasmal mastitis was occurring.

In Ireland, infection has occurred in housed adult dairy cattle, without any evidence of pneumonia, producing severe polyarthritis with a clinical incidence in 12 farms that varied from 2 to 66%.[5]

In calves, the feeding of unpasteurized discard milk from cows with mycoplasmal mastitis is a risk factor.[7]

PATHOGENESIS

M. bovis arthritis is normally regarded as a sequel to pneumonia or mastitis and infection in the respiratory tract or in the mammary gland is believed to lead to bacteremia and localization in joints.[2,3] However, arthritis can suddenly occur in regions or countries where mycoplasmal pneumonia has been recognized for many years suggesting that a new strain with different virulence or tropism has been introduced. Also, clinical disease in individual herds commonly follows the introduction of new animals to the herd.

Adherence to host cells of isolates from different pathologies has been examined as a possible explanation for this but does not appear a determinant for differences in disease presentation.[8]

The intra-articular injection of *M. bovis* into calves causes severe fibrinosuppurative synovitis and tenosynovitis, erosion of cartilage and its replacement by polypoid granulation tissue. Erosion of the cartilage is accompanied by chronic osteomyelitis and formation of pannus tissue. Histologically, there is extensive ulceration of synovial membranes of leukocytic infiltration of the subsynovium, congestion, hyperemia and thrombosis of the subsynovial vessels. Intratracheal inoculation of the organism results in pneumonia and severe lameness, which suggests that *M. bovis* is involved in pneumonia–arthritis syndrome.

A combined infection of *M. bovis* and bovine virus diarrhea (BVD) has been found in the joints of feedlot cattle that had chronic unresponsive arthritis.[9]

CLINICAL FINDINGS

There is stiffness of gait, lameness, inappetence, moderate fever and progressive loss of weight. Swelling of the large movable limb joints and distension of tendon sheaths, associated with fibrinous synovitis and synovial fluid effusions, are characteristic.

Both forelimbs and hind limbs can be affected and commonly involvement of the carpal joints, the fetlocks and the proximal and distal interphalangeal joints can be clinically detected. In calves, pneumonia is a common finding in the affected group.

Some affected cattle spend considerable time in recumbency, lose weight and develop decubitus ulcers, and must be destroyed. Mildly affected cases recover spontaneously over a period of several weeks but severe cases become progressively worse, may develop discharging sinuses over affected joints, and must be culled.

CLINICAL PATHOLOGY

Culture methods for the detection of *M. bovis* are restricted to culture and serology but both methods are time consuming, laborious, difficult and expensive.

A DNA probe and PCR test are now available to detect the organism in milk samples[10] and may be applicable to samples from joint fluid and an ELISA can be used to detect the organism in lung tissue of animals with pneumonia.[11]

NECROPSY FINDINGS

At necropsy, the fibrinous synovitis is remarkable. There is severe thickening and edema of the synovial membranes and large quantities of fibrinopurulent synovial fluid. The tendon sheaths are similarly affected. Microscopically, large numbers of lymphocytes and plasma cells are found within the hypertrophic synovial villi. There can be multiple foci of coagulative necrosis within the joint capsule. *M. bovis* can often be recovered from pneumonic lungs and has been linked to pulmonary foci of coagulation necrosis.[2,12,13]

Immunohistochemical studies suggest that this organism may also briefly localize in the kidney and liver.[12] *M. bovis* has been associated with pleuritis and pericarditis and has been isolated from decubital ulcers of calves.[14]

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed lung, synovial membrane (LM, IHC)
- **Mycoplasmology** – lung, culture swab from joint cavity (MCULT).

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other causes of joint swelling and lameness in feedlot cattle. There are usually several animals affected in a short period of time, which serves to distinguish it from other sporadic causes of arthritis in feedlot cattle. A diagnosis of infection by *M. bovis* should be considered when pneumonia and arthritis and synovitis occur at about the same time. For a definitive diagnosis, joint fluid must be placed immediately into laboratory media specially prepared for *Mycoplasma* spp. The failure to isolate the mycoplasma from the fluid of joints which have been affected for more than 14 d does not preclude a diagnosis of mycoplasma arthritis because the organism may have been eliminated from the joint.

TREATMENT

Treatment is usually ineffective. Several antimicrobials, including tylosin, oxytetracycline, lincomycin and oleandomycin, have been used in natural, and experimental cases and while the organism is sensitive to these antibiotics in vitro, the response in affected animals has been unsatisfactory. The antimicrobial susceptibility of *M. bovis* strains, cultured from cases of pneumonia, arthritis, and mastitis of cattle, measured in vitro indicate that enrofloxacin was the only one which exhibited any measurable activity.[15] Administration of tylosin at the onset of clinical signs has been reported to arrest the progression of the disease.[5]

CONTROL

Effective control of the disease is not yet possible. A formalinized *M. bovis* vaccine provided protection against experimentally induced mycoplasmal arthritis but was unsuccessful under naturally occurring conditions. The disease usually disappears from an affected group, which suggests that herd immunity may develop.

OVINE AND CAPRINE CONTAGIOUS OPHTHALMIA (OVINE AND CAPRINE INFECTIOUS KERATOCONJUNCTIVITIS, CONTAGIOUS CONJUNCTIVO-KERATITIS, PINKEYE IN SHEEP AND GOATS)

Etiology *Mycoplasma conjunctivae* is a significant cause but many agents can produce clinically identical disease
Epidemiology Spread by contact or mediate infection from carrier animal. Usually occurs as outbreak in summer months and when conditions are dry and dusty. Disease in lambs is less severe than in adults, and most severe in weaned
Clinical findings Lacrimation, conjunctival hyperemia, pannus, neovascularization, iritis, keratitis in one or both eyes
Diagnostic confirmation Clinical examination of the flock, exfoliative cytology, culture
Treatment Topical or preferably parenteral tetracycline
Control Avoid confinement and movement in dusty conditions. Fly control

ETIOLOGY

A variety of organisms have been isolated from the eyes of animals affected with this disease. Some are primary pathogens and others secondary invaders. It is difficult to attribute a primary etiological cause to a single agent as all the putative causal organisms have also been isolated from the eyes of normal sheep. Many of the agents are demonstrable in the eyes of sheep in a single outbreak. The management circumstances that lead to flock outbreaks of disease with each of these agents, and the clinical syndromes that result, are not sufficiently distinct to allow the differentiation of the various etiologies on clinical or epidemiological grounds. There have been limited studies on the relative prevalence of flock outbreaks of disease associated with the various putative causes but there is a developing literature to incriminate *Mycoplasma* spp. as the major cause. For this edition the disease is described under this chapter heading.

Mycoplasma conjunctivae

Mycoplasma conjunctivae is a common isolate in outbreaks of the disease but it is not present in all affected sheep and it can also be isolated, with lesser frequency, from the eyes of clinically normal sheep.[1–4] Nevertheless the disease can be **reproduced experimentally** by the installation of pure cultures of this organism into the eye of sheep and the disease will spread to other sheep by contact transmission.[4–8] Consequently, it is believed to be a principal cause of pinkeye in sheep and goats. It has been further suggested that the inclusion bodies believed typical for rickettsial infection in ovine keratoconjunctivitis are in fact extracellular mycoplasmas.[5]

Other mycoplasma

Other *Mycoplasma* spp. are frequently identified in the eyes of sheep and goats with pinkeye.[1–3,5,9] *M. agalactiae* is considered a primary cause of an outbreak in Spain.[10] *M. arginini* and *Acholeplasma oculi* have been isolated from clinical cases of contagious ophthalmia but have not been implicated as causal agents.[2,11,12] Diseases reproduced by other mycoplasmas such as *M. capricolum*, *M. mycoides* subsp. *mycoides* can be accompanied by conjunctivitis but other manifestations predominate.

Chlamydophila pecorum

Chlamydophila pecorum (*Colesiota conjunctivae*) was initially incriminated as a cause of contagious ophthalmia in sheep and goats in South Africa and Australia and has also been isolated from outbreaks of keratoconjunctivitis in sheep in the United States and the United Kingdom and the disease has been reproduced experimentally.[7] Involved strains are related to those associated with polyarthritis in sheep and not to those associated with abortion.[5] A rickettsial agent, *Rupricapra rupricapae*, has been isolated from keratoconjunctivitis in chamois (*R. tragis*) and ibex (*Capra ibex*) in the French Alps.[13]

A number of bacteria including *Branhamella* (*Neisseria*) *ovis*, *Staphylococcus aureus* and *Escherichia coli* can be isolated from the eyes of animals with contagious ophthalmia and the rates of isolation from affected eyes are higher than that from normal sheep. They have not been shown capable of producing disease by experimental challenge and are considered to be secondary infections and not to have a causal role.[1,5,7,9] However, they may have a significant secondary role in the disease after resistance has been reduced by the primary inciting agent.[14] *B. ovis* is considered a cause of follicular conjunctivitis.[15] Similarly *Moraxella bovis* which is associated with contagious keratoconjunctivitis in cattle, has no apparent causal association with the disease in sheep or goats.[1,5] *Listeria monocytogenes* may be a primary cause of keratoconjunctivitis and iritis in sheep.

EPIDEMIOLOGY

Occurrence

The disease in sheep is widespread in most countries. All breeds of sheep are equally affected but the disease in lambs is less severe than in adults, and recently weaned animals are most severely affected.

Source of infection and transmission

Source of infection is infected or carrier animals. The disease is spread indirectly by flies, long grass and dust contaminated by the tears of infected sheep, or directly by means of exhaled droplets or immediate contact.[16] *M. conjunctivae* also infects wild small ruminant species and can transmit between domestic and wild animals.[16]

Risk factors

The **prevalence** is highest during the warm, summer months and when conditions are dry and dusty, and the fly population is heavy. The morbidity rate varies widely depending on seasonal conditions. It is usually about 10–15% but may be as high as 80%. Resistance to infection is reduced by concurrent disease, poor nutrition and adverse weather conditions. The disease occurs as **widespread outbreaks** in some years and in such circumstances may cause appreciable losses in weight gains for unexplained reasons. Outbreaks during the mating season can reduce the incidence of twinning.

In many flocks at pasture, the disease causes only minor inconvenience and weight loss by interfering with grazing for a few days, however, in some it becomes endemic. Clinical experience suggests that the incidence and the severity of the disease in an affected flock is increased by the stress, dust and close contact associated with gathering and yarding of the flock. Thus a decision to treat an outbreak can be associated with an apparent exacerbation of clinical disease.

PATHOGENESIS

Rapid onset of acute inflammation of the conjunctiva is followed by hyperemia of the sclera, pannus, and opacity of the cornea.

CLINICAL FINDINGS

Clinical findings are **similar with all agents** associated with the disease. There is conjunctivitis with lacrimation and blepharospasm followed by keratitis with cloudiness of the cornea and some increase in vascularity. There is profuse lacrimation and initial signs in the flock may be a brown discoloration below the eye associated with dust accumulation on lacrimal discharges.

Corneal opacity is initially most pronounced at the dorsal corneal–scleral junction and is followed by vascularization to produce a **horizontal zone of opacity** associated with an area of vertical-oriented vascularization in the upper area of the eye. In severe cases, the whole cornea is affected and there may be corneal ulceration. In some outbreaks there is severe corneal edema in affected sheep.

In most sheep in flocks experiencing an outbreak, the disease is mild providing there are no complicating circumstances; the initial watery discharge from the eye becomes purulent but **recovery** commences in 3–4 d and is complete at about 20 d. In some animals the cloudiness of the cornea may persist for several weeks or even permanently. Local ulceration of the cornea may cause collapse of the eyeball. One or both eyes may be affected but many sheep have both eyes affected in outbreaks and spread through the flock is rapid.

Conjunctivitis is followed by the development of granular lesions of **follicular conjunctivitis** on the palpebral conjunctiva and third eyelid, which are thought by some to be specific for infections involving *B. ovis*.

In **goats**, the disease is milder with little apparent ophthalmia or keratitis. A more severe keratoconjunctivitis than that associated with *M. conjunctivae*, and manifest with corneal edema, occurs in some outbreaks in goats but its cause has not been established.[11] All age groups are affected and although the morbidity is usually 12–20%, it may reach 50%. Direct contact between animals appears to be necessary for spread of the infection, but the disease has not been transmitted experimentally. Conjunctivitis, opacity, vascularization and sometimes ulceration of the cornea are accompanied by an ocular discharge and blepharospasm. In some goats there is severe corneal edema with intracorneal edema accumulating to a degree to produce corneal vesicles. In mildly affected goats, recovery begins in 4–7 d but in severe cases, healing may not be complete for 2–4 weeks or longer.

CLINICAL PATHOLOGY

Scrapings can be taken for **exfoliative cytology** from the palpebral conjunctiva following topical anesthesia. Samples should be collected from early clinical cases. *Mycoplasma*, *Branhamella* and *Chlamydia* have characteristic morphology and can be demonstrated in Giemsa-stained smears or by immunofluorescent staining.[12] Samples can also be submitted for cultural identification and paired serum samples can be submitted for examination for antibodies to *Chlamydia*. The determination of the etiological agent currently has limited significance to the subsequent approach to the control of the disease and is largely academic. However PCR can be used to detect *M. conjunctivae*[3,17] and PCR can be a better method of detection of infection than culture.[17] Indirect ELISA has been used to detect infected sheep flocks.[18]

TREATMENT

A decision for treatment needs to be taken with consideration of the adverse effects on the disease of the associated movement and close yarding of the flock. Repeated treatments of sheep pastured under extensive grazing are impractical and spontaneous recovery will occur within 3 weeks. Consequently, in extensive grazing conditions a decision for no treatment is often made.

A single intramuscular injection of long-acting tetracycline at 20 mg/kg halts further development of clinical conjunctivitis when given as clinical signs develop and results in rapid clinical cure in animals affected with keratoconjunctivitis produced by *M. conjunctivae*. However, neither parenteral or topical antibiotic treatment eliminates infection and relapse in individual animals and recurrence of outbreaks in flocks is common.[19–21] Where the etiology is not known and treatment is deemed desirable, tetracyclines administered either topically or parenterally or topical treatment with cloxacillin ophthalmic ointment have been shown to be of benefit.[19,22]

CONTROL

Complete eradication of the disease is not attempted but isolation of affected sheep, and removal to grassier, less dusty pasture may reduce the rate of spread. Confinement of affected sheep should also be avoided.

MYCOPLASMAL PNEUMONIA OF PIGS (FORMERLY ENZOOTIC PNEUMONIA, NOW ALSO A COMPONENT OF THE PORCINE RESPIRATORY DISEASE COMPLEX)

ETIOLOGY

Mycoplasma hyopneumoniae (once also called *Mycoplasma suipneumoniae*) is the primary causative agent and *Pasteurella multocida* is commonly a secondary invader.[1] *M. hyopneumoniae* (M.hyo) inhabits the respiratory tract of pigs, appears to be host specific and survives in the environment for only a very short period of time. The disease has been reproduced with pure cultures and the organism can be demonstrated directly or indirectly in pigs with enzootic pneumonia worldwide. The isolation of M.hyo is complicated by the presence of other mycoplasmas in the upper respiratory tract of pigs including *M. hyopharyngis*,[2] *M. hyorhinis*, *M. sualvi*, and *Acholeplasma* species. The agent is also a significant contributor to the Porcine Respiratory Disease Complex (PRDC) together with PRRS, PCV2, SIV, and secondary bacterial agents.[3] This complex is characterized by slow growth, decreased food conversion efficiency, anorexia, fever, cough and dyspnea in grow/finish pigs typically around 16–22 weeks of age.

EPIDEMIOLOGY

Occurrence and prevalence of infection

Enzootic pneumonia occurs in pigs worldwide and the incidence is high in intensive pig rearing enterprises. Lesions may be present in 40–80% of the lungs of pigs at abattoirs. The peak incidence of pneumonia occurs at 16–20 weeks of age, which is likely related to increased stocking density. In northern climates, the incidence of clinical disease and prevalence of lesions at slaughter are higher in the summer months.[4] The prevalence of lung lesions is often highest in pigs slaughtered in the winter months compared to autumn-slaughtered pigs.[5] In a survey of the gross lung lesions of 855 slaughter weight pigs from nine selected herds in Norway, pneumonic or pleuritic lesions were found in 84% of the lungs, ranging from 37% in the least affected herd to 97% in the one most affected.[6] Bronchopneumonia suggestive of a primary M.hyo infection was present in 70% of the lungs, ranging from 9–82% in the individual herds. The amount of bronchopneumonic lesions in individual lungs ranged from 0–69%, with an average of 7.8%. A 2002 survey in the USA showed that 82.3% of finishing sites had at least one animal positive on antibody testing and 94.4% of breeding sites.[7] Seroprevalences were higher in the clinically affected herds and most of the pigs were infected with M.hyo at a younger age.[8]

Morbidity and case fatality

In infected herds, the morbidity rate is high during the growing period but the case–fatality rate is low. There is however an increase in the number of treatments of sick pigs in comparison with herds free of the disease and secondary bacterial pneumonia can be a significant cause of mortality in the weaning-to-market period. The morbidity rate falls markedly with increasing age and there is a much lower incidence of pneumonic lesions in sows, even though they may still harbor the organism. However, when enzootic pneumonia gains entry into a herd which has been previously free of the disease, all ages of pigs are affected and mortality, even in adults, can occur.

Methods of transmission

The organism is an inhabitant of the respiratory tract of pigs and transmission occurs by direct pig-to-pig contact. This is the main source of transmission. Airborne transmission[9] and fomites are less important sources of transmission. Mycoplasma can be transmitted over 1, 75, and 150 meters.[10] Airborne transmission was suggested on 80% of farms where acute respiratory disease was present. No airborne organisms were found on farms without acute respiratory disease. There is no other known host for the organism although infection and breakdown of closed pneumonia-free herds has occurred without any pig introductions. The number of organisms required for infection is very small and the possibility of wind-borne infection has been suggested. Transmission is by the respiratory route and in infected herds occurs primarily from the sow to the suckling piglets. In a study of shedding of M.hyo in different parities: gilts were 73% positive, parity 2–4 sows were 42% positive, parity 6–7 sows 50% positive and parity 8–11 sows were 6% positive.[11] Generally, the nursery is considered the area where transmission occurs[12] and infection spreads slowly.[13] Within pen transmission measured by PCR is very slow.[14] Animals can be PCR positive and not infectious for long periods of time and then can become very infectious. There is therefore a nonlinear excretion of M.hyo.[14] It is thought that one infected nursery pig will infect on average one littermate.[15] Boars can also infect sows when they are kept together in service areas but in these areas the disease spreads slowly.[16] The disease is also transmitted and exacerbated during the grouping and stress of pigs that occurs at weaning. The highest clinical and pathological incidence occurs in the postweaning and growing period and in most herds this is maintained through the growing period to market age. The start of finishing is the critical point.[17] Direct exposure (nose-to-nose contact) of pigs at 9–11 weeks of age to seropositive gilts results in seroconversion to the organism by 21 d and is most frequent by about 11 weeks after exposure.[18] The presence of gross lesions of pneumonia correlated with the seroconversion.

Frequent coughing by infected, intensively reared pigs suggests that repeated aerosol exposure occurs and is an important natural mode of transmission of respiratory pathogens. There is general agreement that management and environmental conditions considerably influence the severity of the disease.

The reinfection of enzootic pneumonia-free herds, recurrences or so-called breakdowns, occurs at a rate of about 3% of herds every 6 months. In a study of swine herds which had participated in the Pig Health Control Association Scheme in the United Kingdom, the close proximity of the uninfected herds to infected herds appeared to be the most important risk factor which could explain the introduction of the infection. The size of the herd, the density of the pig population in the area, the distance to the next road regularly used for transportation of pigs and differences in topography were risk factors associated with reinfection.[19] There was little evidence to indicate that unexplained breakdowns occurred in association with long-term latent infection in other herds from which animals had been imported. Clinical signs of enzootic pneumonia in these herds commonly did not occur for several months after the introduction of infected pigs.

M. hyopneumoniae was not transmitted during a 20-week period when personnel weekly contacted susceptible pigs in a naïve herd after they had been in contact with pigs in an infected herd.[20]

Risk factors

The prevalence, incidence and severity of pneumonia in swine herds are determined by interactions among infectious agents, the host, the environment and management practices. This being said a large survey of the seroprevalence of M.hyo in 50 finishing herds showed[21] that there were no risk indicators. Each farm is an individual one with the farm itself exerting a great effect.[22]

Animal risk factors

Several factors such as breed, age, presence of diarrhea, the prevalence of atrophic rhinitis, birth weight, weaning weight, have been examined as animal risk factors. In some herds, the risk of coughing and pneumonic lesions increased

with increasing age of pigs within a herd. In a survey of two different groups of pigs slaughtered at different ages, the age-specific prevalence of pneumonic lesions was 2.7% in pigs less than 16 weeks of age at slaughter, but increased rapidly when pigs were between 16 and 22 weeks of age at slaughter.[23] Infection at an early age has a greater effect than infection later in life. Pigs coughing by 14 weeks of age were, on average, 6.2–6.9 kg lighter than those with onset of disease near market age.[24] The highest seroconversion rate occurs between 3–4 months of age.[25] In a recent experimental infection 77.7% of the infected animals were still positive 185 days later[26] and 100% of the naturally infected animals were still infected at the same time. There may be selective differences in the colonization rates between litters.[27] There may also be a sex effect on colonization as well.[27]

Atrophic rhinitis may also be present along with enzootic pneumonia and the two diseases in combination may have a greater economic effect than either disease alone. When outbreaks of respiratory disease in pigs occur, they are frequently the result of complex interactions between many agents. The importance of M.hyo is not only its effect as a primary pathogen but also its ability to act synergistically with other infecting agents to produce significant respiratory disease. *M. hyopneumoniae* causes a mild pneumonia, whereas *P. multocida* is not pathogenic alone but aggravates the pneumonia initiated by the former pathogen. The epidemiological associations between M. hyo and *Actinobacillus pleuropneumoniae* antibody titers and lung lesions in pigs at slaughter have been examined.[28] Only titers to the mycoplasma pneumonia were associated with lesions.[28]

Immune mechanisms

Pigs which recover from experimentally induced enzootic pneumonia are resistant to subsequent challenge. The nature of the immunity, whether serum or local antibody-mediated, T-cell mediated, or a combination of these factors, is not clear. Based on lymphocyte transformation tests of experimentally infected pigs, it is possible that cell-mediated immunity correlates with protective immunity. The median half-life of passively acquired antibodies to M.hyo is 16 d, the persistence of antibodies is related to the initial antibody concentration, and antibodies waned by 30–63 d after birth depending on initial concentration.[29] It has been detected as late as 155 days of age.[30] The titer of maternal antibodies is a major concern when pigs are vaccinated. The age of the piglet vaccinated is not the key factor.[31] The level of the sow's antibodies approximately 4 weeks prepartum are at their highest and similar to the levels in colostrums.[32] Immunity is not conferred through colostral immunoglobulins and thus piglets born from immune dams are susceptible to infection and clinical disease. No significant correlations have been found between the colostral antibody levels and the colonization status of the sows.[33] The level of immunoglobulins to M.hyo can be used to monitor infection in the herd.[34–36] Pigs usually seroconvert to APP and then M.hyo.[37]

Pigs raised under unfavorable conditions develop pneumonic lesions more frequently than pigs raised under better conditions, regardless of their immune status.[25] Pigs vaccinated with inactivated M.hyo organisms develop both a cell-mediated and humoral immune response, but they are not protected from challenge exposure by natural infection. Local immunity, particularly secretory IgA, is considered to be important in protection against mycoplasma infection. *M. hyopneumoniae* may suppress alveolar macrophage function, which may predispose the lung to secondary infection. The organism is very clever in evading the immune response probably by changing the nature of the immune response to one that is less effective. To do this it causes the production of cytokines IL-1 alpha and beta, IL-6, and TNF alpha by macrophages and monocytes and induces local inflammation.[38] This is essentially moving the immune response from a TH1 type response to a T-helper type 2 response.[39]

Pathogen risk factors

M. hyopneumoniae adheres to the tracheal and bronchial mucosae and causes an extensive loss of cilia.[40] An evaluation of the virulence factors of M.hyo field isolates has been made.[41] The extent of the lesions produced may be influenced by other contributing factors to account for the variations in severity of lesions. Concurrent infection with lungworm, migrating ascarids and an adenovirus has resulted in lesions of greater severity and secondary invasion of pneumonic lesions by pasteurellae, streptococci, mycoplasmas and *Bordetella bronchiseptica; Klebsiella pneumoniae* is very common and largely influences the outcome of the disease in individual pigs. In some abattoir surveys of lungs, *P. multocida* can be cultured from 16% of normal lungs and from 55% of lungs with lesions resembling those of enzootic pneumonia. *P. multocida* and *Haemophilus* spp. may also be found in conjunction with M.hyo in the lungs of slaughter weight swine affected with pneumonia and examined at the abattoir. Those lungs with both M.hyo and *P. multocida* had the most macroscopic pneumonia and those lungs with either of the agents alone had much less pneumonia. *M. hyopneumoniae* renders the lungs susceptible to *P. multocida* colonization and infection.[1]

Along with M.hyo, other mycoplasma species such as *M. hyorhinis, Acholeplasma granularum* and *Acholeplasma laidlawii* have been isolated from the lungs of pigs at slaughter, but their significance is unclear. *M. hyopneumoniae* and *Mycoplasma hyorhinis* have been isolated from 30% and 50% of pneumonic lungs, respectively, from pigs examined at slaughter. *M. hyopneumoniae* was also isolated from 12% of lungs with no gross lesions of pneumonia. In a survey in Norway, M.hyo, *P. multocida* and *M. hyorhinis* were detected in 83%, 43%, and 37% of the pneumonic lungs respectively.[42] Most of the macroscopic pneumonia – up to 25% – occurred in lungs with all three pathogens. *M. flocculare* was the most frequently isolated organism in the non-pneumonic lungs.

Mycoplasma hyopneumoniae potentiates the severity of PCV2 associated lung and lymphoid lesions, increases the amount and perhaps the presence of PCV2 antigen. It also increases the incidence of PMWS in pigs.[43]

Environmental and management risk factors

Several environmental and management factors are associated with a high prevalence of pneumonic lesions at slaughter. They include continuous vs all-in/all-out production, open herds, large temperature fluctuations, semisolid pen partitions, and large numbers of pigs in a common air space. These factors may operate individually or in combination synergistically. Housing pigs in a clean, isolated, disease free and low stress environment positively influences the health of pigs.[44]

The primary and secondary pathogens of the disease produce their most detrimental economic effects and the highest level of morbidity and mortality during the finishing period when the economics of production necessitate indoor housing and intensification.[45]

Four main groups of environmental factors which contribute to high levels of clinical disease and lesions at slaughter include:

1. Meteorological
2. Population and social
3. Management
4. Air-borne pollution.

Meterological factors include wide fluctuations in the temperature indoors, wide variations in relative humidity, irregular ventilation rates and winter

housing. However, experimentally, elevated concentrations of ammonia and fluctuating ambient temperature did not influence the severity of the pneumonia nor its effect growth rate.[46]

Population factors which contribute to an increased prevalence of pneumonia are increasing herd size, increased population density and decreased air space and floor space per pig. All management practices influence the microclimate, and the quality of housing and management influence the incidence of pneumonic lesions at slaughter. Larger-than-average swine farms milling their own feed and with characteristics of modern buildings (mechanized inlets, slatted floors) and in close proximity to other farms tend to have a higher risk of enzootic pneumonia.[47] Extensively housed pigs with above-average pen space and air volume have a reduced prevalence of enzootic pneumonia lesions.[48]

Management factors associated with enzootic pneumonia include family farms which feed pigs on the floor[47,48] and feeder barns which obtain pigs from multiple sources compared to those with good facilities and where the pigs originate directly from breeding units.[45] The disease is a particular problem in continuous-flow herds. In pigs reared in all-in all-out groups in the farrowing house, nursery, and growing-finishing unit, any mycoplasmas transmitted from sows to pigs or between pigs do not necessarily result in clinical signs or lesions of pneumonia. Pigs reared in all-in all-out systems do not have lesions or minimal lesions at slaughter and gained at a faster rate than littermate pigs reared in a continuous system.[46]

In small herds, the factors commonly associated with a high prevalence of enzootic pneumonia were larger numbers of pigs per pen section, larger group sizes and drafty farrowing and weaner accommodation.

Airborne pollution in pig houses is thought to contribute to an increased incidence of clinical disease and prevalence of lesions at slaughter but this has not been well documented. Toxic levels of ammonia, high concentrations of aerial dust, and high colony counts of aerial bacteria may contribute to an increased incidence and prevalence of pneumonia but these factors have not been quantified and are commonly based on subjective evaluations by the observer. A large study of 960 pigs has shown that there are no influences of ammonia or dust on the respiratory health of pigs.[49] Environmental air contaminants such as dust, ammonia, carbon dioxide and microbes in swine barns measured over a period of 12 months were associated with lesions of pneumonia and pleuritis at slaughter.

In large herds, factors associated with a high prevalence were higher pen stocking rate and air space stocking rate, and a trend toward higher atmospheric ammonia levels in the summer months. The trend to increased herd size has not been accompanied by the satisfactory control of pneumonia.

Combination and interaction of environmental risk factors

A computer-based guide can indicate how the prevalence of the disease can be influenced by the combined effect of risk factors.[50] The expected prevalence is estimated by consideration of 11 risk factors which include the following:

1. Number of pigs in the same room
2/3. All-in/all-out vs continuous flow of pigs
4. Type of partitions separating adjacent pens
5/6. Presence or absence of diarrhea as a clinical problem
7/8. Liquid vs solid manure disposal
9. Ascarid control efficiency
10/11. Presence or absence of active Aujeszky's disease.

The temperature and humidity influence the penetration into the lungs of both primary and secondary pathogens by influencing the size of infected aerosol particles and the protective mechanism in the respiratory tract. Temperature and humidity also influence the sedimentation of infected particles in the air, and the ventilation and stocking density. Pigs kept at high stocking densities and subjected to environmental temperature fluctuations, cold drafty conditions and poor nutrition are more likely to suffer greater adverse effects from this disease.

Economic losses and importance

In annual surveys completed by the American Association of Swine Practitioners, pneumonia consistently ranks as the most economically important disease in finishing pigs.[51] The prime importance of enzootic pneumonia is in its economic effects on pig rearing. The disease adversely affects feed conversion efficiency and daily rate of gain under certain circumstances. However, the magnitude of these effects depends on the conditions in which the pigs are reared and has been a subject of much controversy. The complexity of pneumonia and its interactions with the environment make measuring the effect of pneumonia on performance very difficult.[51]

An accurate assessment of the biological and economic effects of enzootic pneumonia has been difficult because of the difficulty of conducting a controlled experiment in which pigs of equivalent genetic merit, both free of the disease and infected, are raised in an identical manner. In addition, studies on the association between performance parameters and the severity of lesions of the lungs have yielded widely variable results dependent on the management and environmental conditions and the different research design and techniques used. In general, there is a proportional relationship between severity of pneumonia and depression of performance[51] but in other observations, this relationship was not found.[52] Where pigs are raised under good management, infection of herds previously free of the disease has resulted in no adverse economic effect other than during the initial period of acute infection in the herd. However, in other situations adverse economic effects are associated with the disease. One study estimated a reduction of feed conversion efficiency as high as 22% and although the effect of the disease is probably not this severe in most piggeries, a significant economic reduction can occur even under good management conditions.[53]

Because there is no universally accepted method of measuring the extent or prevalence of pneumonia in pigs at slaughter, the results of studies of correlations between the lesions and performance have been difficult to compare. In general, the economic loss associated with respiratory disease ranges from a 2–25% reduction in average daily gains. Some methods have been compared and the most informative procedure is to assess the percentage of lung involved and calculate a mean value for the herd sample. The relationship between the weight of pneumonic lesions from pigs at slaughter and their performance indicated that within a range between 3.32 and 74.5% for the weight of a pneumonic lung, a 10% increase in the weight of pneumonic lung was associated with a decrease in mean daily gain of 31.4 g and a 13.2 d increase to slaughter at 104 kg liveweight.[54] There is a high correlation between rapid gross lung scores and detailed examination, which indicates that lungs can be visually scored accurately as they pass on a slaughter line.[55] On average, mean daily gain decreases from 23–37 g for every 10% of the lung affected by pneumonia.[56] However, the rapid subjective scoring of the lungs, adjusted for lung proportions, is considered adequate for estimating naturally occurring pneumonia and just as informative as detailed dissection of the lungs.[57]

Because the prevalence of pneumonia peaks at about 60–65 kg BW and then declines steadily to a very low level in pigs

that are 125 kg or more, the age and weight at slaughter must be considered when evaluating the effects of the lesions on performance and when comparing results between different observations. Weight losses are more substantial in pigs affected early in life.[18] In some studies, lung lesion scores detected at slaughter did not significantly correlate to growth indicators during any season.[52] The gross lesions of mycoplasmal pneumonia heal over a 2-month period, which may explain why significant correlations are not found between growth indicators and lung lesions scores.[52] The effects of the lesions on mean daily gains over an entire growth period may vary from one study to another because of the different times during growth when the lesions exerted their effects and in part to compensatory regrowth following recovery from the lesions.[58,59] Radiographic examination of the lungs of pigs from 21–150 d of age, and gross examination of the lungs at slaughter revealed that lesions progress and regress dynamically throughout the life of the animals and examination at slaughter is an inadequate indicator of lifetime pneumonia.[60]

PATHOGENESIS

Little is as yet known about the virulence factors of M.hyo. A wide variety of proteins are produced. Mycoplasmas have the smallest genomes of organisms capable of separate existence. This genome encodes for several immunogenic proteins including a cytosolic protein p36 (which may have lactic dehydrogenase activity), membrane proteins p46, p65, and p74 (can produce neutralizing antibodies) and an adhesin p97.[61] The p97 adhesin mediates adherence of M.hyo to swine cilia.[62] An adhesin-like protein (p110) composed of a p54 and 2 p28 units has also been found.[63] Attachment is a complex process involving many gene products. A recent study of the total protein profile, glycoprotein profile and size differences in the amplified PCR product of p97 adhesin genes suggests that there is an intraspecies variation in the M.hyo population in the USA.[64]

The mycoplasma penetrate the mucus layer and attach to cilia. They appear only to attach to the cilia.[65,66] They release calcium^{++} ions from the endoplasmic reticulum of the ciliated cells. As a result there is a clumping and a loss of cilia and excess production of mucus by goblet cells. As a result there is a dysfunction of mucociliary clearance. The secondary bacteria attach to the damaged epithelium.

In experimental infections of tracheal explants with M.hyo it was shown that IL-10 was produced, and this was a possible mechanism for the enhancement of the duration and severity of pneumonia with PRRSv and a mechanism to modulate the immune response.[67]

The experimental inoculation of the J strain of M.hyo into piglets causes gross pneumonic lesions which are detectable 7–10 d later. Moderately extensive pneumonia is present 6 weeks after inoculation, progressive recovery can be observed after 10 weeks and residual lung lesions are detectable in a few pigs up to 37 weeks after inoculation.

M. hyopneumoniae causes peribronchiolar lymphoreticular hyperplasia and mononuclear accumulation in the lamina propria, which causes obliteration of the bronchial lumina. There is also perivascular lymphoid hyperplasia. The bronchial mucous glands undergo hypertrophy; there are increased numbers of polymorphonuclear cells in the bronchial lumina and macrophages in the alveoli. Lymphocytes, together with plasma cells and macrophages are responsible for the increase in the thickness of the interlobular septa as the disease progresses. The hyperplastic BALT (bronchial and bronchiolar associated lymphoid tissue) in enzootic pneumonia cases consisted of macrophages, dendritic cells, T and B lymphocytes, and IgG$^+$ and IgA$^+$ cells. In these aggregates CD4$^+$ predominated over CD8$^+$ cells.[68] The cells in the BALT released IL-2, IL-4 TNF alpha and to a lesser extent IL-1 alpha and beta. IL-1 alpha and TNF alpha were also released in bronchoalveolar lavage fluids and IL-6 and IL-8 were found in the mononuclear cells of the alveolar septa.[68,69]

Hyperplasia of Type II alveolar epithelial cells is progressive as the disease becomes worse. Affected pigs cough persistently, show labored respiration and reduced exercise tolerance. The lesions are similar to those of chronic bronchitis. After infection, M.hyo multiplies in tracheal and bronchial mucosae, adheres to the ciliated cells and causes a cytopathic effect and exfoliation of epithelial cells.[70] There is a significant increase in the gland/wall ratio and a decrease in the ratio of respiratory to expiratory resistance.[45]

The effects of this chronic pulmonary lesion have been the subject of considerable investigation. It is thought that the presence of mycoplasmal lesions uncomplicated by secondary bacterial infections has minimal effect on the production of the pig if the environmental conditions are suitable. The lesions will heal and any loss in production from the initial infection will be regained by compensatory regrowth. Severe lesions or those accompanied by secondary bacterial bronchopneumonia and pleuritis will usually cause a significant decrease in average daily gain and feed efficiency. Secondary infection with *Pasteurella* spp. results in acute episodes of toxemic bronchopneumonia and pleuritis. Dual infections are usually more severe than single infections. For example SIV and M.hyo together are more severe.[71]

The pulmonary and hematological changes in experimental M.hyo pneumonia cause no significant changes in heart rate, respiratory rate and rectal temperature, even though at necropsy well-demarcated pulmonary lesions were present. There were several measurable changes in respiratory functions due to the atelectasis: partial occlusion of the bronchioles with exudate, localized pulmonary edema and a reduction in oxygen perfusion to the alveoli leading to a decrease in the partial pressure of oxygen in the arterial blood. There are no remarkable changes in the hematology. The body weight gains are decreased compared to the control animals.

The distribution of lesions is characteristic. They occur in the right middle lobe, the right cranial and left middle lobes, the left cranial and diaphragmatic lobes, in that order of frequency. It has been suggested that their distribution is in part due to the more commonly affected lobes.

CLINICAL FINDINGS

A natural incubation period of 10–16 d is shortened to 5–12 d by experimental transmission. Two forms of the disease are described. In the relatively rare acute form, a severe outbreak may occur in a susceptible herd when the infection is first introduced. In such herds pigs of all ages are susceptible and a morbidity of 100% may be experienced. Suckling piglets as young as 10 d of age have been infected. Acute respiratory distress with or without fever is characteristic and mortality may occur. The usual course of this form of the disease within a herd is usually about 3 months after which it subsides to the more common chronic form.

The chronic form of the disease is much more common and is the pattern seen in endemically infected herds. Young piglets are usually infected when they are 3–10 weeks of age and clinical signs may be seen in suckling piglets. More commonly, the disease shows greatest clinical manifestation after weaning and in the growing period. The onset of clinical abnormality is insidious and coughing is the major manifestation. Initially only a few pigs within the group may show clinical abnormality, but then the incidence generally increases until coughing may be elicited from most pigs. It may disappear in 2–3 weeks or persist throughout the growing period. In affected herds, individual pigs may be heard to cough at any time, but coughing is most obvious at initial activity in the morning and at

feeding time. Coughing may also be elicited by exercising the pigs around the pen and it occurs with greater frequency in the period immediately following the exercise. A dry or crackling, hacking cough, which is usually repetitive, is characteristic. Respiratory embarrassment is rare and there is no fever or obvious inappetence. Subsequently there is retardation of growth which varies in severity between individuals so that uneven group size is common. Some pigs affected with the chronic form of the disease may later develop acute pneumonia due to secondary invasion with *pasteurellae* or other organisms.

Clinical disease becomes less obvious with increasing age and is rarely detected in the sow herd, though gilts and young sows frequently harbor M.hyo.

Simultaneous occurrence of Aujesky's disease does increase the severity of acute mycoplasmal pneumonia.[72]

A series of investigations has shown that PRRSv does not predispose to M.hyo infection although lesions are more severe in those pigs that both infections. M.hyo does potentiate PRRSv induced disease and lesions.[73,74] There may be an association between the seroconversion to PRRS virus and the transmission of M.hyo.[75]

CLINICAL PATHOLOGY

Serological tests

Serological tests have included the CFT (low sensitivity), indirect hemagglutination test (good for early detection as it detects IgM) and the latex agglutination test. The unsatisfactory sensitivities and specificities of these tests led to the development of ELISA systems, DNA probe technology and polymerase chain reaction to accurately diagnose enzootic pneumonia. The ELISAs detect all classes of IgG, are very sensitive, but detect the onset of seroconversion not infection.

An ELISA using a commercially available antigen (Auspharm) is highly sensitive (95.6%) and specific (98.8%) for antibodies against M.hyo when pig sera from commercial herds of known infection status were evaluated.[76] An improved ELISA is also available and the two ELISAs are able to distinguish populations of gross pathology-negative pigs in endemic herds from pigs in true specific pathogen-free (SPF) herds.[77] Pigs from the former group have significantly higher ELISA activity with both tests and would represent recovered or exposed non-diseased pigs, or pigs with only histological lesions in endemic herds. The ELISA is ideal for diagnostic laboratories and should obviate much of the need for culture and immunofluorescent histopathology, reducing the cost of diagnosis. The ELISA can also detect antibodies in the colostrum of sows with a high specificity.[78,79] A recent study comparing three ELISAs has shown that the sensitivities of the tests were lower than previously reported especially for vaccinated animals. Animals within 21 days post-infection were also not easily detected.[80] The blocking ELISA was the most sensitive. All three were highly specific. There is also a blocking ELISA against a p40 protein.[81]

Detection of organism

The organism can be detected in lung tissues by culture, immunofluorescence, polymerase chain reaction and antigen-ELISA, and all have high sensitivity in the acute stages of pneumonia.[82] A polymerase chain reaction (PCR)-based assay can also differentiate *M. hyopneumoniae*, *M. flocculare*, and *M. hyorhinis* and also detect low numbers of organisms.[83–86] It can also be used on the bronchoalveolar lavage.[87] The identification of the p36 and p46 protein genes has enabled them to be used in a PCR for M.hyo with a sensitivity of 86.6% and a specificity of 96.7%.[88] Nested PCR is much better.[89] There is a good correlation between the results of nested-PCR and histology.[90] In situ hybridization shows M.hyo on the surface of the epithelial cells not in the cytoplasm with an occasional signal in the cytoplasm of the alveolar and interstitial macrophages.[91]

Herd certification

The determination of the presence or absence of enzootic pneumonia within a herd for certification purposes can be difficult and should be approached with caution. It should not be based on a single examination procedure. It requires a surveillance system which combines regular farm visits and serological, cultural and tissue examination of selected pigs and of those sent to slaughter. The herd should be examined clinically for evidence of the disease and the lungs from several shipments of pigs should be examined at the abattoir and subsequently histologically. There can be seasonal variation in the severity of lung lesions and at certain times market-age pigs may not have visible gross lesions, even though infection may be present in the herd. If doubt exists, the lungs of younger pigs, preferably clinically suspect pigs, or recently weaned pigs, should be examined after elective slaughter. The herd should also be examined for the presence of antibody to M.hyo.

NECROPSY FINDINGS

Except in severe cases, the damage is confined to the cranial and middle lobes, which are clearly demarcated from the normal lung tissue. The lesions are commonly more severe in the right than in the left lung. Plum-colored or grayish areas of lobular consolidation are evident. Enlarged, edematous bronchial lymph nodes are characteristic. In acute cases, there is intense edema and congestion of the lung and frothy exudate in the bronchi. When secondary invasion occurs, pleuritis and pericarditis are common and there may be severe hepatization and congestion with a suppurative bronchopneumonia.

Evaluation of the pneumonic lesions at slaughter has been used extensively for herd health monitoring. Scoring of the lesions is typically done on both lungs (the entire pluck). To overcome the logistical problems associated with examining entire plucks during the slaughtering procedure, an alternate system based on scoring the right lung only has been investigated.[92] The overall right lung relative sensitivities for the detection of catarrhal pneumonia or chronic pleuritis were 81% and 72%, respectively. It is suggested that an evaluation of the right lung pathology is a useful alternative when the purpose of the survey is to demonstrate the presence or absence of lesions, or when scoring the severity of the lesion is the objective.

The microscopic changes of enzootic pneumonia include lymphohistiocytic peribronchiolar cuffing with increased numbers of mononuclear leukocytes in the bronchial lamina propria. There is hyperplasia of the bronchiolar epithelium and filling of alveoli with macrophages, protein-rich fluid and small numbers of lymphocytes and plasma cells. Hyperplasia of Type II alveolar epithelial cells occurs as the disease progresses.

In one study, a definitive diagnosis of mycoplasmal pneumonia of swine was based on the demonstration of M.hyo in lung sections using specific antisera or successful culture of the organism. Utilizing these techniques, it was found that up to 19% of grossly normal lungs may be infected with M.hyo. Conversely, the organism could not be demonstrated in about 33% of the lungs of pigs from herds thought to be affected with mycoplasmal pneumonia, even though typical gross lesions were present. The sensitivity of these techniques may be surpassed by newer PCR methods. The organism can also be detected in formalin-fixed paraffin-embedded porcine lung by the indirect immunoperoxidase test. The results of immunofluorescence tests performed on piglets with experimentally induced pneumonia revealed that M.hyo organisms are located primarily on bronchial and bronchiolar epithelial surfaces of lungs with gross lesions of pneumonia. Fluorescence was most intense 4–6 weeks after infection and began to decrease at 8–12 weeks. This suggests a decrease in the number of M.hyo in the more advanced stages of

the disease. When assessing plucks at slaughter to determine the severity of pneumonia in a group, it must be remembered that in most instances the lesions observed represent a chronic, partially resolved disease process. Therefore the clinical effects of the infection may have caused a greater degree of respiratory compromise than is apparent at slaughter.

Samples for confirmation of diagnosis

- **Touch preparations** using Giemsa stained slides have been used
- **Histology –** formalin-fixed lung (LM, IHC). Simple histopathology may not always indicate mycoplasma infection. For example Aujesky's disease together with *P. multocida* may be difficult to differentiate from M.hyo. Lesions may be characteristic but not pathognonomic.[93] Indirect immunofluorescence (IF) and indirect immunoperoxidase (IHC) for M.hyo in tissues are extremely useful.[94] However IF has a lack of sensitivity and IHC is time consuming and expensive
- **Mycoplasmology** – lung (MCULT, FAT, PCR). Isolation of M.hyo is complicated by the overgrowth that occurs from *M. hyorhinis* and *M. flocculare*. The organism is fastidious. Many animals that are culture positive do not have gross or microscopic lesions. The PCR can be used as a one step test but is not good for nasal swabs. The nested PCR can be used for these but it does tend to produce some false positives. Correct samples give a better diagnosis. Samples from lavage and tracheobronchial sites were the best for nested PCR and lung tissue and nasal swabs are not the most reliable.[95]

TREATMENT

There is no effective treatment to eliminate infection with M.hyo, although the severity of the clinical disease may be reduced.

Isolates of the organism from the United States were susceptible to lincomycin-spectinomycin, tylosin and oxytetracycline.[96] Isolates from the United Kingdom were susceptible to doxycycline and oxytetracycline.[97] Doxycycline, a semi-synthetic tetracycline has a greater antimicrobial activity, is better absorbed orally and is more widely distributed in tissues than the first generation tetracyclines (oxytetracycline, tetracycline and chlortetracycline).

In some early studies, a mixture of tylosin tartrate at a dose of 50 mg/kg BW and tiamulin at 10 mg/kg BW orally daily for 10 d significantly reduced the pulmonary lesions associated with the experimental disease. However, the use of 60 mg, 120 mg or 180 mg of tiamulin per liter of drinking water for 10 d was not effective in suppressing the lesions of experimentally induced M.hyo pneumonia or infection in disease-free pigs.

The newer fluoroquinolones have good in vitro activity against M.hyo and exhibit superior activity to tylosin, tiamulin, oxytetracycline and gentamicin. Ciprofloxacin is particularly active against M.hyo.

Tilmicosin is particularly effective since it appears to prevent the attachment of M.hyo to the surface of the epithelial cells.[98]

Tetracyclines will either prevent transmission or suppress lesion formation in experimental pigs but the levels required are high and in an infected herd continuous administration would be necessary, which would be uneconomic. Treatment is generally restricted to individual pigs showing acute respiratory distress as a result of a severe infection or secondary invaders. Broad-spectrum antimicrobials are used, usually tetracyclines, but the response is only moderately good. The occurrence of severe signs within a group of pigs may necessitate treatment. Tetracyclines, tylosin or spiramycin fed at 200 mg/kg feed for 5–10 d are recommended. A combination of 300 g of oxytetracycline and 30 g of tiamulin per tonne of finished feed fed for 2–3 d/week over a 16-month period has been used to reduce the incidence of enzootic pneumonia in a large herd.[99] Lung lesions were reduced, average daily gain increased, and efficiency of feed conversion increased with an overall increase in profitability. Valnemulin may prove to be effective in the treatment of enzootic pneumonia.[100] There is a higher susceptibility to valnemulin and tiamulin when used in conjunction with doxycycline as a treatment.[101]

Tulathromycin administered as a single injection at a standard dosage of 2.5 mg/kg is effective in the treatment of swine pneumonia associated with mycoplasmosis.[102]

There is no evidence for resistance to lincomycin/spectinomycin, oxytetracycline, doxycycline, gentamicin, flufenicol, and tiamulin. There is evidence for some resistance to tylosin, tilmicosin, fluquinolone and enrofloxacin.[103]

CONTROL

M. hyopneumoniae infects only pigs and transmission requires close pig-to-pig contact. If transmission can be prevented it is possible to limit or even eradicate the disease from a herd. There are thus two levels at which control can be practised:

1. Complete eradication of the disease or
2. Controlling the disease and its effects at a low level.

The principles of control of enzootic pneumonia include the following strategies:

- Regular inspection of the herd for clinical evidence of disease and slaughter checks of lungs
- Rigorous biosecurity of animals being introduced into the herd and control of visitors
- Provision of adequate environmental conditions including air quality, ventilation, temperature control and stocking density
- The use of the all-in all-out system of production in which groups of pigs by age or stage of production are moved through the herd from the gestation barn, farrowing barn, nursery rooms and finishing units as groups and the pens previously occupied are cleaned, disinfected and left vacant for several days before animals are reintroduced. Since most infection is believed to occur between 4-12 weeks nursery depopulation has become an effective way of controlling the infection in nursery pigs.[12]

Control by eradication

This method of control is the most satisfactory and is probably mandatory for large breeding companies, and herds supplying replacement stock to other herds and for large intensive farrow-to-finish enterprises. It is based on the principle that the source of infection for the young pig is the gilt or the sow and this chain of infection must be interrupted to prevent infection. In the past the 10-month cutoff point has been used in eradication programs but in view of the colonization studies[26] this may be too soon. This is especially so in off-site production systems where the time of infection is delayed.

There are three different principles.[104] First, there is total depopulation followed by re-stocking with non infected stock (Danish SPF system). Second, test and removal of all positives and inconclusives. Third, eradication without total depopulation and restocking.

Eradication without restocking has been described[105] and here the secret was to wait until farrowing finished, then vaccinate all sows and treat with tiamulin at 6 mg/kg daily for 3 weeks and then monitor with blood tests.

Specific pathogen-free or minimal disease pigs

Several methods of eradication have been attempted but the most satisfactory is repopulation with specific pathogen-free (SPF) pigs. The principle underlying this method is that the piglet in utero is free of infection with M.hyo. If it is taken from the uterus at term by suitable sterile hysterectomy or hysterotomy techniques

and reared artificially in an environment free of pigs, it will remain free of this infection. In practice this has been carried out in special units and the piglets have been subsequently used to repopulate existing farms where all pigs have been removed 30 d prior to the introduction of the SPF pigs and a thorough cleaning program completed. This method was initially developed for the control of enzootic pneumonia and atrophic rhinitis. Moreover, if suitable precautions are taken and if the piglets are used to populate new units that have had no previous exposure to pigs, then freedom from other important diseases such as internal and external parasitism, leptospirosis, brucellosis, swine dysentery and others can be achieved. The progeny of these primary SPF herds can subsequently be used to repopulate other or secondary SPF herds known as minimal disease pigs. The details of these procedures are available in the textbook *Herd Health*.[106]

Because of the cost and technical difficulty of this method, other methods of eradicating enzootic pneumonia have been attempted but they are generally less satisfactory and have a higher failure rate. These include 'snatching' of pigs at birth and isolated farrowing. In the former the piglets are caught and removed from the sow immediately at birth and reared as previously described or foster-suckled on SPF sows in another environment. Although enzootic pneumonia may be eliminated by this method, fecal contamination during parturition of the vulva and vagina and consequently of the piglet is common and this method is less satisfactory for disease control than removal by hysterectomy.

Isolated farrowing

Isolated farrowing techniques have proved successful in small herds but have a high failure rate when practiced on a large scale. Older sows believed to be free of infection are farrowed in isolation in individual pens erected outside on pasture and each sow and litter is kept as a separate unit. The litter is inspected clinically at regular intervals and subsequently a proportion of the litter, usually excess males and gilts undesirable for breeding, are examined at slaughter for evidence of pneumonia. Any litters with clinical, pathological or laboratory evidence of pneumonia are eliminated from the program. Litters that pass inspection are kept for repopulation of the herd. Because of the difficulties in detecting carrier pigs without lesions, eradication by methods using these principles frequently fails.

Minimal disease herds

Minimal disease herds have been established in most countries with significant pig populations either by breeding companies or private purebred breeders. As a result there is, in most countries, a nucleus of enzootic pneumonia-free stock which is a major swine-producing enterprise worldwide. The establishment of primary SPF herds is technically difficult, very costly and should not be undertaken lightly. There is also a considerable delay in cash flow between the time of initial population and build-up of herd numbers to the time when significant numbers of pigs are available for sale. Because of this, if eradication by repopulation is intended, it is preferable to purchase pregnant gilts from established primary SPF herds unless the maintenance of existing genetic lines dictates otherwise. Before recommending eradication by this method it is essential that the pig owner understands the principles of this method of control and the restrictions that will need to apply if it is to be successful. Farrow-to-finish enterprises established by this method should be run as closed herds and if further genetic material is required it should be introduced by hysterectomy techniques or by purchase from the initial source herd. The use of artificial insemination is an alternate method; however, isolation of M.hyo from semen is recorded.

The problem of certifying and maintaining herds free of enzootic pneumonia is a major task.

Reinfection of herds

Reinfection of enzootic pneumonia-free pig herds occurs despite high standards of isolation and strict precautions whereby complete protective clothing and showering routines are required for all visitors entering the unit. All visitors are debarred entry if they have been to a possible source of infection during the previous 48 h and even up to 7 d. Also, the majority of breakdowns occur in herds which have not imported infected stock recently. In reinfected herds which imported stock there was no concurrent evidence of breakdown in the parent herds, which supported the contention that the importation of infected pigs was an unlikely source of the infection. An epidemiological investigation of these reinfections suggests that close proximity of uninfected herds to infected herds may be an important factor. The organism does not survive for more than a few days under dry conditions; however, it can survive in diluted tapwater and rainwater for 2–3 weeks and it has been suggested that the organism may be transported in moist air and that airborne infection between piggeries is a possible method of transmission. In Switzerland 107 farms were reinfected of 3983 that eradicated during the period 1996–1999 (2.6%).[107] The significance of known risk factors such as farm size, high density of pigs, and farm type was confirmed in this analysis.

Some preliminary estimates of risk indices based on the proximity of other pig units has indicated that the most important factor was the reciprocal of the square of distance to the nearest other unit. The crucial distance for maximum survival was about 3.2 km. A breakdown was described recently in which a whole variety of measures were included in an attempt to control the disease.[108]

Antimicrobial prophylaxis

Eradication has also been attempted by antimicrobial treatment of newborn piglets with oxytetracycline on days 1, 7 and 14, weaned on day 14 and moved to offsite nursery.[109] This is known as a low-cost modified medicated-early-weaning program. This can be followed by serological testing of the breeding herd and culling of positive reactors. Control by vaccination on the one hand and by the use of tilmicosin on the other produced similar results when measured by serological results and the prevalence of macroscopic lung lesions.[110] Lincocin with or without vaccination considerably improves the growth and performance.[111] Doxycycline in the feed at 11 mg/kg bodyweight is effective in controlling pneumonia due to *P. multocida* and M.hyo in feeder pigs.[112]

Low-level disease

The alternative to eradication is to limit the effects of the disease in those herds where eradication is either not desirable or feasible. The effects of the disease are generally less severe in non-intensive rearing situations, in small herds where individual litters are reared separately and where litters from older sows can be reared separately from other pigs. Where litters are grouped at weaning, a low stocking density with less than 25 pigs in initial pen groups and 100 pigs in a common air space may also reduce the severity of the disease.

Temperature, humidity and ventilation also have an important influence on the disease. It is possible to determine an optimal air temperature zone for growing-finishing pigs based on the measurement of behavioral and health-related problems. They are interrelated with stocking density and housing. The subject is too broad for treatment here and the requirements for pigs at different ages and under different housing situations may be found in standard texts on pig housing and production. The environmental risk factors associated with the incidence of enzootic pneumonia should be assessed in each circumstance. Some

important environmental variables which should be assessed and modified include:[45]

- Number of pigs per shed
- Number of pigs per pen
- Air space per pig
- Floor space per pig
- Cleaning and disinfection techniques used
- Number of air changes per hour
- Waste disposal system
- Number of temperature fluctuations in a 24-hour period
- Direction of the flow of air in the building
- Concentrations of ammonia and hydrogen sulfide in the building
- Dust levels
- Feeding and watering systems
- Whether or not the all-in/all-out system is being used effectively.

Medication of breeding stock

The original medicated early weaning program was based on medication of the sows with tiamulin at the time of farrowing and the early weaning of the piglets to an off site location. A variation of this method is to prevent the spread of infection by:[113]

- Isolation of the breeding stock
- Strategic antimicrobial medication of the breeding stock
- Reintroduction of the breeding stock to the original but empty and disinfected gestation barn
- Separate rearing of the piglets before and after initiating the program
- Regulation of flow of animals through the herd. Farrowing barns are emptied out when possible and cleaned, disinfected and left empty. After weaning their piglets, sows are transferred to the dry sow barns. Sows about to farrow are treated with tiamulin and moved to the farrowing barn.

Source of feeder pigs

Where possible the purchase of weaners or pigs for finishing units should be from herds free of the disease or from a single source. Purchase through saleyards or the purchase of coughing or uneven litters is not advisable. When pigs from infected herds are purchased it may be necessary to medicate the feed prophylactically with one of the tetracycline group of antibiotics or tylosin or spiramycin at 100–200 mg/kg of feed for a 2-week period after introduction. Medication of the feed of finishing pigs with tiamulin at 20 and 30 mg/kg of feed over an 8-week period on farms with histories of severe complicated enzootic pneumonia resulted in improved weight gains and feed efficiency, but the extent and severity of the lung lesions did not change.[114] The level of 30 mg/kg in the feed was superior to the level of 20 mg/kg. Tiamulin at 100 mg/kg combined with chlortetracycline at 300 mg/kg of feed for 7 d was effective in herds with a history of enzootic pneumonia complicated by the presence of *P. multocida* and *Actinobacillus pleuropneumoniae*.[115]

Introduced pigs should be isolated from the rest of the herd and preferably they should be reared as a batch through a house on the all-in/all-out system.[116] A high stocking density should be avoided and internal parasites should be controlled.

Vaccination

Mycoplasma hyopneumoniae vaccines are generally bacterins consisting of outer membrane proteins or whole organisms. The vaccines give little protection against initial infection and often incomplete protection against clinical pneumonia. The vaccines produce a TH1 response and also IgA and IgG in the lavage fluids. Natural maternal antibodies do not seem to inhibit vaccination but vaccination of sows may inhibit subsequent immunity.

Vaccination with killed M.hyo induces protection in pigs against experimental challenge exposure with the organism. A cost benefit analysis shows that the vaccination is economically beneficial.[21] The relationships between maternally derived antibodies, age and other factors in vaccine response have been discussed.[117–120]

A killed M.hyo vaccine evaluated in a single herd reduced the prevalence of pneumonic lesions in slaughter pigs from 69% to 36% and the prevalence of pleuritis from 20% to 13%.[121] There was a small decrease in the number of days to market. It usually results in a 2–8% increase in daily gain. The mortality rate is usually only better numerically. Feed conversion efficiency increases by about 2–3%.[122] Other limited studies indicate that vaccination can reduce the severity and prevalence of lung lesions detected at slaughter[123] (4–6% compared to 12% in controls). It improves feed efficiency and increases average daily gain during the finishing period.[124] In other studies the average daily gain was not improved.[125] Vaccination of sows against M.hyo reduced the prevalence of positive piglets at weaning and could be used to control M.hyo infections[126] as judged by a nested PCR. PRRS vaccination does not interfere with M.hyo vaccination.[127] Needle less intradermal vaccination has also been described.[128]

Both dual and single injection vaccines are available but the protection obtained is similar.[129,130] The single dose vaccine[131] gives protection for up to 23 weeks.[132] The level of protection will probably last 4 months.[133] Vaccination is economically attractive.[134]

DNA vaccination using a p42 heat stable protein gene has also been used and this induces rises in IL-2, IL-4, and IFN gamma which indicates that it induces both a TH1 and aTH2 response.[135] Vaccination for mycoplasma generally induces local mucosal immunity, humoral and cellular immunity.[136]

MYCOPLASMAL POLYSEROSITIS IN PIGS

Mycoplasmal arthritis occurs in suckling and growing pigs and is characterized clinically by dyspnea and lameness.

ETIOLOGY

M. hyorhinis causes arthritis and polyserositis in young pigs, and *M. hyosynoviae* causes arthritis in growing pigs. *M. hyorhinis* has also been isolated from pigs with otitis media.[1,2] *M. hyoarthrinosa* has been associated with a syndrome similar to that produced by *M. hyosynoviae* but they may be the same species. Other mycoplasmas including *M. flocculare* and *Acholeplasma* spp. have been isolated from pigs but appear to have no propensity to produce arthritis.

EPIDEMIOLOGY

M. hyorhinis is an inhabitant of the respiratory tract and conjunctivae[3,4] of pigs and is a common secondary infection in pre-existing respiratory disease.[5] It probably spreads pig to pig through nasal contact or by aerosol. It colonizes the mucosa of suckling piglets within the first few weeks of life and may spread with subsequent polyserositis and arthritis but more commonly does so following stress. Disease is essentially restricted to pigs between 3 and 10 weeks of age and occurs in older suckling pigs and following weaning, but may occur occasionally in older pigs. Disease occurs sporadically in most herds and is a significant cause of sporadic runting and general poor bodily condition in young pigs. There is some evidence to show that pigs with high and low immune responses differ in their cytokine response to *M. hyorhinis* but there is no characteristic cytokine response in association with the relative susceptibility to infection in high immune expression pigs.[6] In some cases there may be no external signs except bursitis and septic fluctuating joints. Affected pigs limp, shift weight, and are unable to rise. Outbreaks can occur with multiple cases within and between litters. Morbidity may reach 20–35% but mortality is rarely high. The case fatality rate seldom exceeds 10% but chronically affected pigs fail to grow and become runts. *M. hyorhinis* is also associated with otitis media in pigs.[1,2,7]

M. hyosynoviae is a causative organism with a very wide heterogeneity[8] and is resident on the pharyngeal mucosa and tonsil. Shedding is less frequent than with *M. hyorhinis* and the organism cannot usually be isolated from the pharynx of piglets prior to 7 weeks of age and is regarded as rare before 12 weeks by some authors.[9] This is true even when most of the sows in a herd are tonsillar carriers.[9,10] There is a very varied pattern of carriage. It appears that this transference is fairly rare but when it does occur can be the source of infection for the other littermates.[9] There is some variation in virulence between strains. With virulent strains, bacteremia with subsequent arthritis follows within a few days of minor stress such as vaccination, movement, regrouping or a change in weather. The overall prevalence of clinical disease appears to be low but it achieves significance in certain herds which experience a persistent problem. The reasons for this are still unclear.[11] These authors have shown that infection profiles between herds vary considerably.[9] In some herds in the UK the incidence may be higher with 21% of sows culled because of lameness primarily associated with *M. hyosynoviae*. In these herds the sows are nearly always culled for lameness before the 4th parity which constitutes a huge economic loss. Failure to treat leads to chronic lameness.[12,13] When gilts and sows are treated they do not appear to have a reduced overall survival time indicating that treatment is cost effective. Clinical disease occurs primarily in pigs over 3 months of age and in replacement stock brought into these problem herds. It appears that

there is a latent period between the tonsillar infection and the development of generalized infection and arthritis[9] which may be accounted for by the long persistence of maternal antibodies of 8–16 weeks. The active serological response possibly indicating immunity only seems to occur when there is the onset of arthritis[9] but others disagree[14,15] and not even when there is hematogenous spread. In only a few pigs was a rising OD ratio observed before the onset of generalized infection. It is more prevalent in heavily muscled pigs with straight-legged conformation and there is variation in breed susceptibility. Morbidity in problem herds is generally 5–15% but may reach 50%. Mortality is rare but 2–15% may become chronically affected.

Abattoir studies have suggested that 5–10% of pigs may be affected.[16] Transmission of infection is by direct contact or possibly by aerosol infection.

M. hyosynoviae can survive drying for up to 4 weeks and may be capable of survival in the environment for longer periods than most mycoplasmas. A further consideration of the importance of these diseases must be given to their possible contribution to the occurrence of carcass condemnation from arthritis.

PATHOGENESIS

The most important thing is that pigs can carry the infection in their tonsils and their synovial fluid without clinical signs of lameness and may therefore not be diagnosed as carriers and can act as a potential source of infection to others.[17,18]

Systemic infection by mycoplasma may occur following stress. Clinical disease is manifest if localization occurs but this is probably the exception rather than the rule. In the experimental disease the incubation period varies from 4–10 days. After experimental intranasal infection with *M. hyosynoviae* septicemia usually takes about 2–4 days. The reason for the variation in age susceptibility between the two diseases is unknown. *M. hyorhinis* produces a polyserositis in which fibrinous pericarditis, pleuritis and occasionally pneumonia, or polyarthritis, may be the predominant features. Acute eustachitis associated with *M. hyorhinis* occurs as early as 1 week of life and precedes inflammation of other sites of the ear. *M. hyosynoviae* produces synovitis with some arthritis, especially in the larger joints of the hindlimbs.

CLINICAL FINDINGS

Diagnosis of both infections is often difficult to make clinically and it is essential that a good clinical diagnostic test or tests are produced in the near future.

Pigs affected with *M. hyorhinis* are usually 3–10 weeks and show initial transient fever, depression and inappetence. Normally, however fever is absent. The first presenting sign may be just stiff legs. Dyspnea with abdominal breathing and a pleural friction rub may be present. There is polyarthritis with lameness, reluctance to rise and moderate swelling and heat in affected joints. Pigs may recover spontaneously in 1–2 weeks but more commonly become unthrifty. Acute outbreaks may occur in suckling pigs 3–8 weeks of age but more commonly the disease is more sporadic and insidious, producing moderate ill-thrift in a proportion of the sucklers which then show severe runting following weaning. With *M. hyosynoviae* infection there is a sudden onset of acute lameness in one or more limbs, usually without fever. Lameness may be referable to one or more joints and the stifle, hock and elbow joints are most commonly affected. In many cases the pigs may lie in sternal recumbency. The lameness is severe although clinical swelling of the affected joint may be minimal. In the majority of affected pigs clinical recovery occurs after 3–10 days but some may become permanently recumbent. Otitis media is characterized by anorexia, circling and tilting of the head and neck, leaning against the wall,[19] and eventually recumbency with the affected side down.

In the UK, the condition is often associated with delivery of high herd health gilts to more conventional farms, with the condition occurring 2–4 weeks after the delivery or with a change of housing. Other outbreaks have followed the introduction of pigs to straw yards whereas contemporary animals kept in fully slatted accommodation have been unaffected.[20] Both mycoplasma infections may require humane slaughter.

CLINICAL PATHOLOGY

Blood cell counts remain within the normal range but there is an increase in leukocytes and protein in synovial fluid. The organisms may be detected by immunofluorescent techniques, and complement fixing antibody develops following infection.

NECROPSY FINDINGS

A serofibrinous pleuritis, pericarditis and peritonitis are present with *M. hyorhinis* infections. Chronic cases show fibrous pleural and pleural–pericardial adhesions. Synovial hypertrophy with an increased amount of serosanguinous synovial fluid occurs in affected joints with both mycoplasmal species. Sometimes the amount of fluid is considerable. Chronic cases show thickening of the joint capsule with a varying degree of articular erosion and pannus formation.[12] Joint lesions are most likely to be found in the carpus, shoulder, stifle and tarsus. Quite often with *M. hyosynoviae* infections one joint usually the hock is affected.

Microscopically, there is usually edema, hyperemia, hyperplasia of synovial cells, and an increased density of subsynovial cells. Lymphocytes and plasma cells are present in the affected serosal and synovial membranes of subacute to chronic cases. There is often a significant villus hypertrophy of the synovial membrane. In the chronic phase there may be some fibrosis.[21] A full description of the phases of infection has recently been described.[22] With both infections, the organism is more easily demonstrated during the acute stage of the disease. A synergistic link between *M. hyorhinus* and PRRS virus has been suggested to contribute to some cases of pneumonia.[23] This species of mycoplasma may also play a role in porcine otitis media, possibly via ascension of the eustachian tubes.[23,24]

Samples for confirmation of diagnosis

- **Histology** – synovial membrane, liver, lung, heart. Sometimes the mycoplasmas can be seen between the synoviocytes on the tips of the villi of the synovial membrane
- **Mycoplasmology** – culture swabs from serosal surfaces, joints. Friis's medium suppresses the growth of *M. hyorhinis* in mixed cultures. It can be recovered from blood for 7–11 days from 1–4 days post-exposure. It can be recovered from the joints for 5–21 days and from the tonsils from 6–61 days[25,26]
- ***M. hyosynoviae* is best grown in anaerobic conditions** where it outgrows *M. hyorhinis*
- **Synovial fluid** has been taken from the hock joint under general anaesthesia and cultured. It was shown[27] that isolation from the joints of lame pigs was twice as high as from littermates that were not lame. About 8–9% of synovial fluid samples from non-patent arthritis samples from Danish slaughterhouse pigs were positive.[28] The same authors also showed that blood culture was also effective
- **Antigen detection.** An in situ hybridization technique for the differentiation of *M. hyosynoviae*, *M. hyorhinis* and *M. hyopneumoniae* has been described for use with formalin fixed tissues[29]
- **PCR** can be used to amplify a p36 or p46 gene to differentiate *M. hyorhinis* and *M. hyosynoviae* infections[30]
- **Serology.** It has been shown that herds with *M. hyosynoviae* arthritis had higher serological responses and more carriers amongst growers of

16 week old pigs than did the unaffected herds, but by the end of the finishing period the serological response and carrier prevalence were as high in herds with arthritis as without

- **An indirect ELISA** has been developed using membrane lipoprotein antigens.[31,32]

The differential diagnosis of mycoplasma infections must include *S. suis*, and *H. parasuis*.

TREATMENT

Treatment with tylosin at 1–2 mg up to 15 mg/kg BW IM or lincomycin at 2.5 mg/kg BW IM for three consecutive days has been recommended.[14,15] The lincomycin was effective in one outbreak but as soon as it was removed the outbreak flared up again.[20] Oxytetracycline also can be used.[33] Early treatment of *M. hyosynoviae* arthritis with 8 mg of betamethasone IM has been found to reduce the occurrence of chronic lameness. Tiamulin at both 10 and 15 mg/kg BW IM daily for 3 days is effective for treatment of pigs affected with arthritis associated with *M. hyosynoviae* and is as effective as lincomycin. Recently, enrofloxacin has been used at 2.1 mg/kg for 3 days. It is essential to treat the incontacts[34] and to isolate the treated animals until the clinical signs have disappeared. Valnemulin was highly active against *M. hyosynoviae*,[35] whereas tiamulin and enrofloxacin were much less active.

CONTROL

The control of both diseases rests largely in the avoidance of stress situations. The administration of tylosin or tetracyclines in the drinking water or feed during unavoidable stress such as weaning can reduce the incidence.[36] The use of tiamulin as a single im injection prior to moving pigs from one house to another was sufficient to prevent 50% of the cases of the disease.[15] Early weaning at 3–5 weeks of age has been recommended as a method of preventing infection of pigs with *M. hyosynoviae* and thus of reducing the occurrence of the disease in growing pigs. However, in a recent study[37] it was shown that *M. hyosynoviae* was not eliminated in herds where the piglets were commingled after 4 weeks and reared in herds using all in/all out management. In fact the herd had widespread infection when the herd was 4 months old. The authors concluded that elimination of *M. hyosynoviae* requires that the pigs are moved immediately from weaning at an age of no more than 4 weeks.

EPERYTHROZOONOSIS

Synopsis

Etiology Hemotrophic mycoplasmas (previously *Eperythrozoon* species)
Epidemiology Subclinical infection common and clinical disease precipitated by stress. Horizontal transmission by blood. Vertical transmission important in swine
Clinical findings Acute icteroanemia or chronic ill-thrift in sheep and swine. Reproductive inefficiency and neonatal anemia in swine. Syndromes in cattle less defined
Clinical pathology Anemia and bilirubinemia. Blood smear for parasite in early disease. Serology useful as flock/herd test. PCR
Treatment Tetracyclines, organic arsenicals
Control Non-specific. Prophylactic administration of tetracyclines

ETIOLOGY

The disease is associated with hemotrophic mycoplasmas that were, until recently, thought to be ricketsial parasites and were classified as *Eperythrozoon*. Species in farm livestock that have been associated with disease are *Mycoplasma* (*Eperythrozoon*) *ovis* in sheep, *M. haemosuis* in swine and *M. wenyonii* in cattle.[1,2] They cannot be grown in culture.

EPIDEMIOLOGY

Occurrence

Eperythrozoonosis occurs in sheep, swine, cattle, and llamas but has greater clinical occurrence in swine and sheep. Latent eperythrozoonosis also occurs in mule deer, elk and goats. The organisms appear species specific although *M. ovis* has been transmitted from sheep to goats. The distribution is as follows:

- **Sheep**. Eperythrozoonosis of lambs associated with *M. ovis* is recorded in Africa, Iran, the United States, Canada, Great Britain, France, Norway, Germany, Poland, Australia, and New Zealand
- **Pigs**. Disease is recorded mainly in the United States, Canada, Great Britain, and continental Europe
- **Cattle**. Eperythrozoonosis in cattle is apparently widely distributed with reports from North and South America, Africa, Australasia, the British Isles, western Europe, and the Middle East[1]
- **Llamas**. Infection with *Eperythrozoon* spp. is reported in llamas in the United States and apparently has widespread occurrence.[3] Infection has been detected in animals that also had other disease problems or as the result of specific survey studies, and it is likely that the organism acts primarily as a secondary opportunistic pathogen in llamas

Source and transmission

The reservoir of infection is the **persistently infected** animal and the disease can be transmitted by any mechanism that transfers infected blood. It is proposed that in sheep the minimal infective dose is one parasitized erythrocyte.[4] **Horizontal and vertical** transmission is possible.

Sheep

The method of natural spread of the infection in sheep is probably via biting insects. Serological studies in Australian sheep show that the prevalence of farms with infection is high and that spatial differences are probably due to differences in vector occurrence.[5] In an infected flock or herd the disease can also be spread by management practices that transfer infected blood. In sheep these include vaccination, ear-tagging, shearing and

mulesing, although these risk factors have not been associated with infection in flock epidemiologic studies.[5]

Pigs

Skin parasites and blood-contaminated needles and instruments have been shown to transmit disease in swine.[6] **Transplacental transmission** is also an important route in swine.

Host and pathogen risk factors

Seasonal differences in disease prevalence occur – it is more common in the summer and autumn. **Regional** differences in the clinical severity of the disease has led to postulations of differences in virulence between strains of the organism. There may also be **genetic** difference in host susceptibility and field observations are that the Merino is more susceptible to infection and disease.

Several studies suggest that subclinical infection is common and that the development of clinical disease requires the presence of some other debilitating factor or **stress** for manifestation. **Viral infections** with porcine reproductive and respiratory syndrome (PRRS) and swine influenza appear to predispose its occurrence in swine.[7]

PATHOGENESIS

Following experimental infection there is a variable prepatent period, usually 1–3 weeks, which is followed by a period of intense parasitemia. Ring form, coccoid and rod-shaped organisms are evident in stained blood smears. The organism is epicellular, infecting the surface and periphery of erythrocytes and is also found free in the plasma in blood examinations. There is a profound hypoglycemia during the parasitemic phase which is believed to be due to direct consumption of glucose by the parasite.[2,8,9] The period of intense parasitemia lasts for a period of 5–10 days following which visible organisms in the blood become much less frequent and anemia develops. Parasitized erythrocytes are removed from the circulation by the spleen. It is believed the parasite alters the erythrocyte membrane, exposing new antigenic determinants and stimulating the development of antierythrocyte antibodies. The severity and duration of the anemia varies between individuals but commonly lasts from 1–2 months. Upon recovery there may be further cycles of parasitemia and anemia which are less severe. Sheep that develop a high antibody titer tend to rapidly clear the parasitemia whereas sheep that have a poorer antibody response tend to show persistent parasitemia and recurrent episodes of anemia. Once an animal is infected it is probably infected for life.

CLINICAL FINDINGS

Sheep

Sudden death and deaths associated with exercise, accompanied by hemoglobinuria and icterus, may be a feature in some sheep and some outbreaks but, more commonly, the disease is manifest with fever and depression followed by the development of **anemia**, exercise intolerance and ill-thrift. In some areas it may be the principal cause of **ill-thrift** in lambs.[10] There is reduced **wool yield** and in the experimental disease in lambs at pasture a retardation of growth of up to 2 kg has been recorded 5 weeks after infection.[11] Lambs suckled by infected ewes are passively immunized via the colostrum until weaning.

Pigs

Acute icteroanemia is the classical syndrome and occurs in feeder pigs. It is characterized by weakness of the hind legs, mild fever (40°C, 104°F), increased pulse rate, pallor of the mucosae and emaciation. Jaundice is a frequent but inconstant feature of the disease. Case fatality is high and death occurs 1–5 days after the onset of clinical signs. Although once quite common, the prevalence of this form has decreased, possibly due to the use of feed additives containing arsenicals and to effective ectoparasite control.[12]

Anemia and weakness in neonatal pigs accompanied by low piglet viability and affecting several litters is another manifestation.[12,13] Affected pigs are pale and lethargic and there is marked variation in birthweight within affected litters. Low birthweight piglets die shortly after birth. The anemia increases in severity between birth and weaning age, the pigs have skin palor, exercise intolerance, and there is considerable variability in weaning weights. The syndrome may or may not be accompanied by reproductive inefficiency characterized by delayed estrus cycles and embryonic death. Anemia, jaundice and poor growth rate can also present primarily in weaner pigs.[14]

Subclinical infections associated with subclinical anemia are reported to result in reproductive failure, anestrus and delayed estrus, reduced sow body condition, increased susceptibility to enteric and respiratory disease, and failure of feeder pigs to gain weight at the expected rate.[12–14]

Cattle

Clinical disease has been considered uncommon and has largely been a problem in cattle that have been splenectomized for experimental use, disease occurring 1–4 weeks after the **splenectomy.** However, clinical disease is recorded in adult commercial dairy cattle[15] manifest with lassitude, stiffness, pyrexia, diarrhea, and a fall in milk production.

Eperythrozoonosis has also been associated with a syndrome occurring in heifers in early to mid-lactation during the late summer and early autumn in which there was fever, swelling of the teats and the hindlimbs, lymph node enlargement and a fall in milk production. Signs of infection resolved in 7–10 days regardless of treatment.[1] A similar transient disease occurring in the spring and summer months, and manifest with scrotal and hindlimb edema and infertility, has been recorded associated with eperythrozoonosis in young bulls.[16]

CLINICAL PATHOLOGY

Blood smears and hematology

The presence of the organism can be established by examination of a blood smear taken during a clinical episode and when the animal has fever. In countries where there is no serological test available this may be the only method of diagnosis. **Parasitemia** is most intense prior to the development of clinical anemia and appears as 0.5–1.0 mm, coccoid, rod- or ring-shaped basophilic particles on red cells or free in plasma. Parasitemia is difficult to detect once clinical signs of disease are evident and very difficult in chronic disease. It is recommended that blood samples from a number of animals in the group be examined if eperythrozoonosis is suspected.

Lowered values for hemoglobin and packed cell volume (PCV) are evident on hematological examination of clinically affected animals and there is marked red cell anisocytosis and polychromasia with basophilic stippling and the presence of many Howell–Jolly bodies in sheep. A profound hypoglycemia may be demonstrated and there are elevated concentrations of unconjugated and total bilirubin.

PCR

The recent development of PCR-based assays has allowed a more precise and efficient method of detection and diagnosis and is much more sensitive than blood smear.[2,17,18]

Serology

Sheep

Complement fixation test and an indirect fluorescent antibody test (IFA) have been used. With the complement fixation test sera from affected animals give positive reactions on the 3rd day of clinical illness, remain positive for 2–3 weeks, and then gradually revert to negative. Chronic carriers of the disease are usually negative reactors. The IFA test or an ELISA test are more suitable for serological studies as infected animals remain seropositive for significantly longer periods.[5]

Pigs

The indirect hemagglutination test and ELISA test can be used in swine and are of value in herd diagnosis but may not detect infection in an individual pig, especially those under 3 months of age.[12,19] Experimental challenge of splenectomized piglets may be used to determine the presence of infection. PCR may resolve laboratory detection diagnostic problems.[20]

TREATMENT

A single intramuscular injection of tetracycline or oxytetracycline (3 mg/kg BW or more) is an effective treatment in sheep, with clinical improvement occurring in 24 hours in the early stages of the disease. Chronic infections are less responsive. Treatment of affected lambs with neoarsphenamine (30 mg/kg BW) or Antimosan (6 mg/kg BW antimony) is effective in relieving clinical illness, but does not completely eliminate the parasite. Imidocarb dipropionate also is effective in treatment but recrudescence at 2–4 weeks is common.

CONTROL

Control of disease in sows and neonates has been reported with the inclusion of chlortetracycline in the sow feed at 300 g/tonne, or by intramuscular administration of oxytetracycline to sows at 14 and 7 days before the expected farrowing date.[12] Tetracyclines can also be used in feed or by in-line water medication in feeder pigs. With large flocks of sheep in enzootic areas, reinfection or recrudescence occurs so quickly that control by treatment may be an unwarranted expenditure.

In confined swine operations, the detection carrier pigs by PCR, and their subsequent removal has been proposed as a possible control procedure.[17]

Diseases associated with viruses and *Chlamydia* – I

21

The comments made earlier about diseases associated with bacteria and their importance as infectious diseases to animal agriculture apply also to diseases associated with viral infections, which are presented in this chapter and Chapter 22. However, there are several factors that make viral diseases even more important.

Viruses have a much greater capability for surviving independently of their host. Spore-forming bacteria survive for long periods in the environment, but, in general terms, viruses are more viable at large than are bacteria. Because of their structure, viruses are much less susceptible to destruction by cleaning and disinfectant agents than are bacteria.

Viruses also have a greater capacity for living in relative harmony with the host, without destroying it. Some, such as the Lentivirus group, produce persistent infections with antigenic drift and the emergence of novel antigenic strains, with consequent relapsing disease. Many of the viruses are insect-borne and have reservoir hosts in other species, especially wildlife. These properties pose unique problems for the diagnosis, control and eradication of these viral infections, and in the development of suitable vaccines. In terms of exotic disease threats, viral diseases can represent a much more significant challenge than bacterial diseases. They have the capacity for escaping beyond standard prophylactic barriers and proceeding on a path of global disease. In recent times African swine fever, bluetongue and African horse sickness have made territorial gains in this way, while the vesicular diseases and the insect-borne encephalitides are constantly on the move into new territory. Perhaps the biggest threat, because of its zoonotic potential, is Rift Valley fever. The viral diseases with potential for severe economic effect and risk for spread to uninfected areas are listed in the table of List A diseases (Table 16.1).

The role of the field veterinarian is made very much more onerous by the presence of these diseases. Because of the speed with which they spread, for example when foot-and-mouth disease virus is airborne, or when ephemeral fever is carried by *Culicoides* sp., they can appear for the first time in an outbreak some distance from their point of entry and in places where an imported exotic disease would not be expected to appear for the first time. Field veterinarians must be on the alert at all times for the appearance of new diseases in their practice areas, and be aware of the implications of their presence, and the kinds of emergency action necessary when they are recognized.

There is no way to prepare oneself for an encounter with an exotic viral disease other than by becoming familiar with their clinical and clinico-pathological findings and their epidemiological behavior. This chapter and Chapter 22 attempt to fill that need.

Viral diseases with manifestations attributable to involvement of the body as a whole

HOG CHOLERA (CLASSIC SWINE FEVER)

Hog cholera, also known as classical swine fever (CSF), is a highly infectious pestivirus infection of pigs which causes acute, chronic or inapparent disease. At one time it was characterized clinically by an acute highly fatal disease and pathologically by lesions of a severe viremia. It is now known that chronic or inapparent disease also occurs, including persistent congenital infection in newborn pigs infected during fetal life. In many countries, where it is endemic, clinical ability will diagnose it more often than laboratory skills, as long as you remember that is a real diagnostic possibility.

Synopsis

Etiology Hog cholera virus, a pestivirus belonging to the genus *Flaviviridae* and related to the bovine virus diarrhea virus
Epidemiology Affects domestic pig of all ages; causes major economic losses interfering with trade when outbreaks occur in pig-raising countries. Occurs in Europe, South America and the Far East. Highly virulent virus causes high morbidity

high mortality; less virulent strains cause milder form. Transmitted by direct contact, feeding of uncooked pork products. Neutralizing antibodies provide protection
Signs Sudden onset of peracute deaths first indication in herd. Many pigs affected within days. Severe depression, fever, anorexia, purplish discoloration of skin, ocular discharge, nervous signs, and death in few days. Nervous form may predominate. Reproductive failure in pregnant sows (abortions, mummification, stillbirths, birth of persistently infected pigs)
Clinical pathology Leucopenia. Detection of virus in tissues and serological testing
Lesions Diffuse hemorrhages subcapsular of kidney, lymph nodes, bladder, larynx, swollen lymph nodes, splenic infarcts, congestion of liver and bone marrow, button ulcers in colon, non-suppurative encephalitis. Hydropic degeneration and proliferation of vascular endothelium
Diagnostic confirmation Detection of virus in tissues and serological tests
Differential diagnosis list
- African swine fever
- Erysipelas
- Salmonellosis

Treatment None
Control Eradication in hog cholera-free countries by slaughter of all in-contact and affected pigs. Use of vaccines in endemic areas. Eradication in countries where endemic by use of vaccination followed by test and slaughter, quarantine farms

ETIOLOGY

Hog cholera is associated with a virus of the family Flaviviridae, genus Pestiviridae. There is only one antigenic type but a number of strains of variable virulence and antigenicity.[1,2] Genetic typing has been described in detail[3,4] and is absolutely essential for following the world wide pattern of infection.[5] For example, there are at least 8 antigenic groups in Thailand. It is generally stable in vitro and in vivo.[6] The viruses have been grouped. In Europe they used to be mainly group 1 viruses but these have been replaced by group 2 viruses. Group 1 still survives in Russia and also Cuba. Group 3 appear to be found in Asia only.

The virus has an antigenic relationship to the bovine virus diarrhea virus (BVDV).[7] In Denmark, BVDV antibodies were found in 6.4% of the sera of pigs while all area were found to be free from antibodies to the hog cholera virus.

EPIDEMIOLOGY

Occurrence

The pig is the only domestic animal species naturally infected by the virus. All breeds and ages are susceptible and adults are more likely to survive an acute infection. The disease originated in the United States but is now almost worldwide in distribution. Canada, Australia, New Zealand and South Africa have not experienced the disease for many years. A mild form of the disease occurred in Australia in 1960–1961.[8] The disease was eradicated from the United Kingdom during the period 1963–1967 and the United States was declared free of the disease in 1978. Outbreaks of acute hog cholera have occurred occasionally in other countries but were quickly controlled by a rigorous policy of slaughter and quarantine. The disease occurred in the United Kingdom in 1986 in which three primary outbreaks were identified; all outbreaks were attributed to the feeding of unprocessed waste feed containing imported pig meat products. A similar origin was suspected for the outbreak in the UK in 2000.[9] In this outbreak an interesting feature was the transport of infected pig carcasses from a site where bodies were dumped for quite long distances by scavenging foxes, infecting new outside pig arks across fields as they went. Between 1982 and 1984 epidemics occurred in Germany, the Netherlands,[10] Belgium, France, Italy, Greece, and the Iberian peninsula. As of 1985, six countries in Europe were free of classic swine fever: Denmark, Ireland (including Northern Ireland), Norway, Sweden, Finland, and Switzerland.

The disease is currently endemic in most countries of South America and the Far East except Japan and Korea. In Asia the problem is the back-yard pig that is not vaccinated and is always a reservoir. Here extension services, appropriate vaccination schemes and regulatory control is difficult to implement but it may be time to try for world wide eradication. The costs are astronomical (the Belgian outbreak of 1997 cost an estimated 11 million euros,[11] and the Netherlands outbreak even more).[12] This 1997–1998 outbreak in the Netherlands was very serious.[13] The disease has also concentrated in certain parts of Europe where the pig populations are intense and live in close proximity to wild boar and feral pig populations. For instance outbreaks occurred regularly between 1997–2001 in Croatia, one source was imported pig meat and the other strains reaching domestic pigs from wild boar.[14] These areas include parts of Germany and Poland and probably most of Eastern Europe. The disease together with ASF is endemic in the central highlands of Sardinia. Many outbreaks of classical swine fever occurred in Germany between 1993 and 1995 and major outbreaks occurred in 1996–1997 in Germany and the Netherlands.[15] The risk factors for Germany have been described.[16] In these countries, over the past 25 years, the disease occurred as a series of epidemics in which many swine herds in a geographical area were affected within a few months. As pig production continues to become intensified the disease has been more difficult to control. In some areas of Western Europe, the pig population has more than doubled in the last 10 years. The hazards of introduction of the disease have increased considerably, due to the introduction of free movement of animals and the non-vaccination policy currently practiced in the European Union. Improvements in the Identification and Recording system which is supposed to identify all relevant animals in a particular population and record their movements and changes in inventory, are necessary to support the control of contagious diseases such as classical swine fever.[17] Most of the outbreaks of swine fever in Belgium in 1990 had to be classified (afterwards) as being due to 'area' and 'unknown' transmission.

In the Philippines, the disease is endemic on many large-scale swine farms.[18] In spite of vaccination of the sows and boars every 6 months and piglets at 6–8 weeks of age, the disease causes sub-optimal performance in 10–30% of pigs between 7–16 weeks of age.

Infection with the classical swine fever virus has also occurred in the wild boar population in Tuscany in Italy, Germany, France, Austria, and Czechoslovakia[19] and Croatia. Serological surveys of wild boar in Sardinia found an overall prevalence of 11%[20] and seropositive boars were found not only in areas where they share their habitat with free ranging domestic pigs but also in areas of the island where contacts between wild and domestic pigs are unlikely to occur. Thus there may be transmission and persistence of the virus within the wild boar population. This has occurred with the low virulence strain in Germany.[21] The persistence of infection in a wild boar population in the Brandenburg region of Germany provided optimum conditions for the establishment of a CSF epidemic in Germany.[22]

Morbidity and case fatality

The disease usually occurs in epidemics, often with a morbidity of 100% and a case–fatality rate approaching 100%, when a virulent strain of the virus infects a susceptible population. However, in recent years outbreaks of a relatively slowly spreading, mild form of the disease have caused great concern in many countries. The disease associated with strains of low virulence may be unnoticed in growing and adult pigs but the infection can be associated with perinatal mortality, abortions and mummified fetuses. In a recent outbreak a mild form given experimentally to sows only produced a mild viremia with widespread antigen distribution, but without clinical signs, except lesions of

hemorrhagic dermatitis. It did however produce an antibody response and transplacental infection.[23]

Methods of transmission

The source of virus is always an infected pig or its products and the infection is usually acquired by ingestion but inhalation is also a possible portal of entry. Direct animal to animal contact is the most important method of spread. Infected pigs shed a large amount of the virus in all normal secretions[24] – nasal, salivary, urinary, fecal and is important in transmission when there are clinical signs of the disease. It is excreted in the urine for some days before clinical illness appears and for 2–3 weeks after clinical recovery. Virus spread via excretions is more important in early stages of an outbreak.[25] Highly contagious by direct contact, it is likely to be transmitted by aerosol only when all the pigs in the same airspace are viremic[26] and even then only for a distance of 1 meter.[27] It has been spread experimentally by aerosol which followed the pattern of air currents.[28]

Sick pigs excrete virus until they die, and obviously even longer if they recover. The resistance and high infectivity of the virus make spread of the disease by inert materials, especially uncooked meat, a major problem. The UK virus in the 2000 outbreak probably came from an infected pork product, imported illegally and fed to an outdoor pig.[29] Outside pens, in warm weather and exposed to sunlight, lose their infectivity within 1–2 days. The ability of the virus to survive in the environment in more favorable situations is uncertain. However, it is probable that it can survive for considerable periods as the virus is quite resistant to chemical and physical influences. Transmission from neighboring units is very easy.[5] One of the major features of the recent Dutch outbreak was the proof that transmission from boar studs (AI) was possible as infected boars excreted virus in semen[30–32] and the virus probably infects spermatogonia.[33] It was shown that following insemination with semen containing CSF antibodies could occur as early as 7 days and all pigs were positive by 14 days.[34] The transmission rates in the Dutch outbreak have been calculated.[35]

In areas free of the disease, introduction is usually by the importation of infected pigs or the feeding of garbage containing uncooked pork scraps. Hopefully, in Europe the ban on swill feeding will prevent further cases of infected meat causing the problems.[5] Movement of pigs which are incubating the disease or are persistently infected is the most common method of spread. The infection usually originates directly from infected breeding farms. Birds and humans may also act as physical carriers of the virus. In endemic areas, transmission to new farms can occur in feeder pigs purchased for finishing, or indirectly by flies and mosquitoes, or on bedding, feed, boots, automobile tires or transport vehicles. Farmers, veterinarians and vaccination teams can transmit the virus by contaminated instruments and drugs[10] but recent evidence suggests that mechanical transmission may have been overestimated.[25] Farmers can spread the virus within a herd by treating sick animals or employing routine health management procedures such as iron injections of newborn pigs. The common practice of not changing syringes and needles between farm visits constitutes a major risk when viremic animals are present. The most common cause of dissemination occurs through the movement and sale of infected or carrier pigs through communal sale yards when there is ample opportunity for infection of primary and secondary contacts.

When the disease is introduced into a susceptible population, an epidemic usually develops rapidly because of the resistance of the virus and the short incubation period. In recent years outbreaks have been observed in which the rate of spread is much reduced and this has delayed field diagnosis. It is not spread by dogs, cats or rats[36] and bird transmission is unlikely.[37]

Risk factors

Following the 1997–1998 severe outbreak in the Netherlands analysis showed that there were five major increased risk factors identified.[38] These were: (i) presence of commercial poultry on the farm; (ii) visitors to the units not being provided with protective clothing; (iii) drivers of lorries using their own clothes not the premises they were visiting; (iv) larger size; and (v) aerosols produced by high pressure hosing. Reduced risk was associated with (i) over 30 years experience of farming; and (ii) additional lorry cleaning before being allowed on to the farm.

Animal risk factors

Historically, infection with the hog cholera virus rapidly resulted in severe clinical disease. It is now recognized that with less virulent strains, a carrier state can occur, at least for a period of time. Following exposure to these strains, pigs may become infected without showing overt signs of the disease and although they may eventually develop clinical disease, this latent period is of importance in dissemination of infection when such pigs are sold and come in contact with others. In recent outbreaks in high pig density areas in Belgium, the interval between the first occurrence of clinical signs and the report of a suspect herd was shorter when the disease was first diagnosed in finishing pigs rather than in sows, boars or nursing piglets.[39] The proportion of clinically affected animals was positively correlated with the proportion of serologically positive animals.

Susceptible pregnant sows, if exposed to less virulent strains of the virus, may remain clinically healthy but infection of the fetuses in utero is common and virus may be introduced into susceptible herds by way of these infected offspring. The sow with 'carrier sow syndrome' can give birth to normal healthy appearing piglets which are persistently infected and immunotolerant; these pigs along with those with chronic infections are responsible for the perpetuation of the virus in the pig population.[10] A fully virulent virus may also be transmitted in this manner if the sows are treated with inadequate amounts of antiserum at the time of exposure or if they are exposed following inadequate vaccination. Piglets infected in utero, if they survive, may support a viremia for long periods after birth.

During outbreaks of classical swine fever in Germany between 1993 and 1995, differing clinical courses were observed ranging from mild clinical signs to severe typical disease. The genotype of pigs may influence the outcome of hog cholera virus infection. In certain pig breeds the chronic form of the disease is more likely to occur and these pigs may excrete the virus over prolonged periods.[40] Experimental inoculation of purebred pigs resulted in acute fatal infections, while cross-bred pigs experienced acute, chronic and transient infections.[40]

Pathogen risk factors

Virulence characteristics

The most virulent strains produce clinical disease in pigs of all ages. But there are differences in the clinical and pathological features between strains of the virus[8] and in their virological characteristics.[41] The less virulent strains cause only mild clinical disease or disease restricted primarily to fetal and newborn piglets. It is probable that this variance has always occurred in field strains of the virus but the use of inadequately attenuated live virus vaccines is also a contributory factor. The occurrence of variation in virulence and antigenicity has been recognized as a cause of failure of vaccination and 'vaccine breakdowns'. It is equally important in causing problems with the diagnosis of hog cholera in eradication programs when infection is manifest in patterns not traditionally associated with this disease.

Genetic analysis of isolates of the virus for a series of epidemics of swine fever in Italy affecting both domestic pigs and wild boar has provided useful

epidemiological information.[42] The isolates were divided into three subgroups and it is suggested that there have been at least two separate introductions of classical swine fever over a 7-year period and that the virus has been transmitted between domestic pigs and wild boar. Molecular analysis can aid in tracing the transmission of the virus from domestic pigs to wild pigs and back to domestic pigs.

In the outbreaks of hog cholera in England in 1986, affected pigs in the first outbreak exhibited clinical signs and necropsy lesions indicative of a virulent strain of the virus. However, in subsequent outbreaks, clinical disease was much milder and case–fatality rates low. Experimental infection of pigs with a field isolate of the virus resulted in variations in clinical response, from acute illness to inapparent infection, including minimal changes visible at necropsy, all of which indicates that genotype may influence the pathogenesis of the disease. High titers of virus were found in several tissues of one experimental pig which was recovering, even in the presence of serum neutralizing antibodies. It is clear that some infected pigs may pass through an abattoir without detection because of the absence of lesions.

Resistance of virus. The virus is destroyed by boiling 5% cresol, or 3% sodium hydroxide and by sunlight, but it persists in meat which is preserved by salting, smoking and particularly by freezing. The virus can be inactivated in at least 80% of pork hams after exposure to a flash temperature of 71°C (159°F). It can survive in infected uncooked ham pork for at least 84 days and 140 days in diced ham or sausage[43]; bacon for 27 days after traditional curing processes and for at least 102 days in hams cured in salt concentrations of up to 17.4%, which is much higher than that normally used in curing bacon. The use of lower salt concentrations in curing solutions, and the decreased time between slaughter and consumption as a result of modern abattoir practices, increases the risk of disease transmission. It survives pH ranges from 3 to 11. Persistence in frozen meat has been observed after 4.5 years. The virus persists for 3–4 days in decomposing organs and for 15 days in decomposing blood and bone marrow.

Immune mechanisms

Maternal antibodies may interfere with the production of viral specific cell mediated immunity.[44] Neutralizing antibodies occur as early as 9 days after infection in recovering pigs and after 15 days in fatally infected pigs.[45] Neutralizing antibodies are the most important antibodies in terms of protection. The maximum antibody response occurs 3–4 weeks after infection and levels may persist indefinitely but last at least 6 months. In chronic hog cholera, neutralizing antibodies may be transiently detectable during the phase of partial recovery between 3 and 6 weeks after infection. Low virulent strains of hog cholera may cause inapparent infections and are described as poorly immunogenic but in some instances may induce considerable titers of neutralizing antibodies in immunocompetent pigs. Cellular immunity mechanisms are probably very important in that it has been shown that there is CSFv specific IFN-gamma formed early after antigen exposure.[46] These mechanisms produce a higher response after I/N or oral vaccination than after I/M vaccination and therefore vaccines should be looked at for their potential to induce higher T-cell responses.[47] Intra-uterine infection of piglets with the virus may induce a state of specific immunological unresponsiveness. The piglets are persistently viremic and may continue to live for several weeks or months but the majority die within the first 3 weeks of life. Piglets with PRRSv infections have been shown to produce a poorer response.[48]

Economic importance

Hog cholera has been responsible for large economic losses in the swine industry worldwide. It is considered to be the most important disease of pigs in the European Union and a common program of eradication in the member states is in effect. The magnitude of the economic importance of the disease is directly proportional to the size of the pig population and the standards of the swine industry. In countries with intensified systems of pig production, such as the Netherlands, it is estimated that the direct costs of transport and destruction of infected herds, disinfection of premises, indemnities to farmers, vaccination, and identification and registration of pigs on behalf of the control of the disease amounted to a large percentage of the gross slaughter value. The additional, indirect, damage as a result of loss of production on infected farms, standstill of pig movements in affected areas or regions and restrictions on export is difficult to evaluate. Losses due to the death of pigs are aggravated by the high cost of vaccination programs in enzootic areas and by the problem that vaccination may not be completely effective in controlling epidemics. Recovered or partially recovered pigs are very susceptible to secondary infections, and exacerbation of existing chronic infections such as enzootic pneumonia are likely to occur during the convalescent period. Between 1990 and 1994, outbreaks occurred in Belgium which resulted in the destruction of about 2 million pigs and the total cost of control by 1995 was $120 million.[49]

PATHOGENESIS

The tonsil is the primary site of virus invasion following oral exposure. Primary multiplication of the virus occurs in the tonsils, beginning within several hours after infection. The virus is first found in plasma before the mononuclear cell populations.[50] The primary cell in the peripheral blood to be infected is the mixed granulocyte.[51] The virus then moves through lymphatic vessels and enters blood capillaries, resulting in an initial viremia at approximately 24 hours. At this time the virus is present in the spleen and other sites such as peripheral and visceral lymph nodes, bone marrow and Peyer's patches. The virus exerts its pathogenetic effect on endothelial cells, lymphoreticular cells and macrophages, and epithelial cells.[52] A B-lymphocyte deficiency associated with viral destruction of germinal centers in lymphoid tissues is the most significant pathoimmunological consequence of acute hog cholera infection.[53] This lymphocyte apoptosis which is activation induced programmed cell death is one of the key features of CSF infections.[54]

Most of the lesions are produced by hydropic degeneration and proliferation of vascular endothelium, which results in the occlusion of blood vessels. This effect on the vascular system results in the characteristic lesions of congestion, hemorrhage and infarction from changes in arterioles, venules and capillaries. Thrombosis of small and medium-sized arteries is another feature. Vascular changes are most severe in the lymph nodes, spleen, kidneys and gastrointestinal tract. Lesions related to the effects on the endothelial cells also occur in the adrenals, central nervous system and eyes. Atrophy of the thymus, depletion of lymphocytes and germinal follicles in peripheral lymphoid tissues, renal glomerular changes and splenitis are characteristic. A leukopenia is common in the early stages, followed by a leukocytosis in some animals, and anemia and thrombocytopenia occur.[52] The thrombocytopenia may be caused by massive platelet activation and subsequent phagocytosis of platelets secondarily to the release of platelet activating factors by activated macrophages.[55] Disseminated intravascular coagulation is common with microthrombi in small vessels, particularly of the kidney, liver, spleen, lymph nodes, lung, intestine, and intestinal lymph nodes. The end stage of a lethal infection in the natural host is associated with a marked depletion preferentially of B-lymphocytes in the circulatory system as well as in the lymphoid tissues.[14] Macrophage activation and

subsequent release of pro-inflammatory cytokines, plays an important role in the development of the classical signs of CSF. This is particularly true for the pulmonary intravascular macrophages.[56]

It has been shown that there is a significant expression of TNFα in virus infected lymph nodes.[57] It may be that commitment to apoptosis may depend on the IFN production.[58] In these lymph nodes lymphocyte death occurred by apoptosis and some of the cells were positive on IHC for both TNFα and apoptosis. It may be that the release of the TNFα may induce the apoptosis in the uninfected bystander cells. Early immunosuppression is an important feature of the development of CSF[59] with the depression of $CD1^+$, $CD4^+$ and $CD8^+$ common thymocytes. It has recently been shown that CSF can replicate in the dendritic cells and control IFN type 1 responses without interfering with immune reactivity.[60] It is still not clear, even though it is known that there is clear targeting of macrophages and monocytes, how these cells produce this immunosuppression and account for the death of the T-lymphocytes.[61] It is known that the dendritic cells are the sentinels of the immune system[62] and respond to easy viral contact.[63] They then develop the effective immune responses by migrating into the lymphoid tissue to present the processed viral antigens to the T-lymphocytes.[64] However, in both CSF and BVD infections there is no activation of the dendritic cells[65] and this may be a feature of pestivirus infections and enable them to evade the immune response. At the same time there is no interference with the maturation of the dendritic cells. The virus induces pro-inflammatory cytokine production (IL-1, IL-6, and IL-8) by 3 hours and even further at 24 hours post-infection and also increases the coagulation factors, tissue factor and vascular endothelium cell growth factor.[66] Endothelial cells that were chronically infected were unable to produce IFN type 1 and these cells were also protected from apoptosis. This establishes a long-term infection of endothelial cells with virus replication and increasing levels of IL-1, IL-6, and IL-8. It shows that there has been long term interference with cellular antiviral defences[67] possibly by targeting interferon regulating factor 3 like BVDv does[68,69] or by increased binding of NF-κβ (kappa/beta) which modulates an apoptotic pathway controlling several anti-apoptotic genes.[70]

In many cases, secondary bacterial infection occurs and plays an important part in the development of lesions and clinical signs.

The experimental disease is characterized by a biphasic temperature elevation at the 2nd and 6th day after inoculation, a profound leukopenia and an appreciable anemia 24 hours after inoculation, diarrhea at the 7th day, and anorexia and death on the 4th to 15th day in slaughter pigs.[71] The anemia can be explained by the infection of 2–9% of the megakaryocytes 2–9 days after infection.[72]

The inoculation of pregnant sows with a low-virulent field strain of hog cholera virus at various stages of pregnancy results in prenatal mortality in litters from sows infected at pregnancy day 40 and postnatal death at 65 days. The later that infection occurs in pregnancy the greater the number of uninfected piglets born in infected litters. Transplacental infection of the porcine fetus with both field and vaccine strains of the virus may induce a spectrum of abnormalities including hypoplasia of the lungs, malformation of the pulmonary artery, micrognathia, arthrogryposis, fissures in the renal cortex, multiple septa in the gallbladder and malformations of the brain. Infection of the fetus at a critical stage of gestation (30 days) induces retardation in growth and maturation of the brain, resulting in microencephaly. The teratogenicity of the virus clearly depends on the stage of gestation. In general, the earlier the infection occurs the more severe the abnormalities are likely to be. The virus can be found in the ovaries because the blood vessels deliver peripheral macrophages to the ovaries through atretic follicles.[73]

One of the sequelae of transplacental hog cholera virus infection of the fetus is congenital persistent virus infection with the evolution of a runt-like syndrome during the first few months of life.[52] At birth, affected piglets appear normal, although they are viremic and the viremia persists throughout life of the animals. The first evidence of clinical disease may occur at about 10 weeks of age but it may be delayed until 4 months of age. Growth retardation, anorexia and depression, conjunctivitis, dermatitis, intermittent diarrhea, and locomotor disturbance with posterior paresis occur. At necropsy, the most remarkable lesion is atrophy of the thymus gland and lesions of classical hog cholera are not present. In experimental congenital persistent hog cholera infection, the earlier the infection occurs in pregnancy the greater the number of persistent infections in piglets born alive with immunological tolerance.[52] The immunological tolerance is specific to the virus because affected piglets respond to other selected antigens.

The experimental infection of pregnant goats with the hog cholera virus on days 64–84 of gestation can result in transplacental infection with the virus replicating and persisting in the fetuses for at least 40–61 days. The virus is highly pathogenic for goat fetuses and serum antibodies may be present in the pre-colostral sera of the kids.

CLINICAL FINDINGS

Diagnosis

Nearly always the detection is too late because it has been missed.[74,75] The clinical signs are often non-specific but the score system suggested by the Dutch may help to suggest it.[76] The differences in the four most recent German outbreaks in terms of clinical and pathological signs were minimal.[77] In former times most of the European outbreaks were associated with the virulent genotype 1 of the virus but now they are types 2:1, 2:2 or 2:3,[78,79] which are much less virulent and therefore produce a milder clinical course that is much more difficult to recognize over the first 14 days post-infection. In a recent set of experiments (with a strain of virus SF0277) all the pigs died but in other experiments[80] some of the pigs survived.

A recent report has suggested that the occurrence of PRRS does not appear to potentiate the clinical outcome of CSF in young pigs,[81] but this has been disputed.[48]

Simultaneous infection with *Trypanosoma evansi* does seem to produce a poor response to CSF vaccination.[82]

As a result of the recent outbreak in the Netherlands a quantitative retrospective analysis was made of the clinical signs[83] which suggested that the clinical inspection was the most important part of detection but was not very specific. Moderate virulence and low virulence strains cause a mild disease that may be so mild that clinical disease is not suspected.[84]

Differential diagnosis should include PRRS, PDNS,[85] ASF, salmonellosis, and coumarin poisoning.

Peracute and acute disease

Clinical signs usually appear 5–10 days after infection but incubation periods up to 35 days or more are recorded. At the beginning of an outbreak, young pigs may die peracutely without evidence of clinical signs having occurred. Acute cases are the most common. Affected pigs are depressed, do not eat, and stand in a drooped position with their tails hanging. They are disinclined to move and, when forced, do so with a swaying movement of the hindquarters. They tend to lie down and burrow into the bedding, often piled one on top of the other. Prior to the appearance of other signs, a high temperature (40.5-41.5°C; 105–107°F) is usual. In recent European outbreaks respiratory signs have not been common. Constipation followed by diarrhea and vomiting also occur. Later a diffuse purplish discoloration of the abdominal skin occurs. Small areas of necrosis are sometimes seen on the edges

of the ears, on the tail and lips of the vulva. A degree of conjunctivitis is usual and in some pigs the eyelids are stuck together by dried, purulent exudate. Nervous signs often occur in the early stages of illness and include circling, incoordination, muscle tremor and convulsions. Death can be expected 5–7 days after the commencement of illness. Infection with *Salmonella choleraesuis* may also be potentiated by hog cholera infection and the two diseases in combination can result in high mortality.

Nervous manifestations

A form of the disease in which nervous signs predominate is attributed to a variant strain of the virus. The incubation period is often shorter and the course of the disease more acute than usual. Pigs in lateral recumbency show a tetanic convulsion for 10–15 seconds followed by a clonic convulsion of 30–40 seconds. The convulsion may be accompanied by loud squealing and may occur constantly or at intervals of several hours, often being followed by a period of terminal coma. In some cases convulsions do not occur but nervous involvement is manifested by coarse tremor of the body and limb muscles. Apparent blindness, stumbling and allotriophagia have also been observed.

Chronic disease

Low virulence strains of virus result in less severe disease syndromes.[86] A chronic form occurs in field outbreaks and occasionally after serum–virus simultaneous vaccination. The incubation period is longer than normal and there is depression, anorexia, persistent mild fever, unthriftiness, the appearance of characteristic skin lesions including alopecia, dermatitis, blotching of the ears and a terminal, deep purple coloration of the abdominal skin. Pigs may apparently recover following a short period of illness but subsequently relapse and die if stressed.

Pigs infected with the low virulence strains of the virus appear more susceptible to intercurrent bacterial disease. The changeable nature of this combination is such that hog cholera should be suspected in a herd or area where there is an increase in mortality from any apparent infectious cause that either does not respond, or responds only temporarily, to therapeutic ploys that are usually effective.

Reproductive failure

Reproductive failure can be a significant feature and may occur without other clinical evidence of disease within the herd. It may occur when inadequately protected pregnant sows are exposed to virulent virus, or when susceptible pregnant sows are vaccinated with live attenuated vaccines or exposed to low-virulent field strains. Infection of the sow may result in no clinical signs other than a mild pyrexia, but it may be followed by a high incidence of abortion, low litter size, mummification, stillbirth and anomalies of piglets.[52] Liveborn pigs, although carriers, may be weak or clinically normal. Persistent congenital infection is characterized by persistent viremia, continuous virus excretion and late onset of disease, with death occurring 2–11 months after birth. No antibodies to the virus are present in spite of the persistent infection; affected pigs have a normal immune response to other antigens, but do not respond to the hog cholera virus.[52] Cell-mediated immunity appears to be normal. A high incidence of myoclonia congenita (congenital trembles) associated with cerebellar hypoplasia has been observed in some outbreaks where prenatal infection with hog cholera virus has occurred and this syndrome has been reproduced experimentally.[52] The prevalence of any one of these manifestations appears to vary with the strain of the virus and the stage of gestation at the time of infection.[52]

CLINICAL PATHOLOGY

Hematology

A valuable antemortem diagnostic test is the total and differential leukocyte count. In the early stages of the disease there is a marked leukopenia, the total count falling from a normal range of 14 000–24 000 µl to 4000–9000 µl.[35] This is specifically a granulocytopenia caused by a bone marrow atrophy.[54] It is a result of apoptosis or necrosis, from 1–3 days post-infection probably as a result of cytokine interaction. Depletion of the lymphocyte sub-populations occurs 1–4 days before the virus can be detected by RT PCR on serum. If a virulent form depletion is evident by 2 days.

B-lymphocytes, T-helper cells and cytotoxic T-cells are the most affected by the virus. The loss of the circulating B-lymphocytes was consistent with the failure to generate a circulating neutralizing antibody.[87] Virulent strains produce a more reduction in B-lymphocytes than do mild forms.[88] This can be of value in differentiation from bacterial septicemias but it should not be used as the sole method of differentiation. In the late stages of hog cholera, a leukocytosis due to secondary bacterial invasion may develop. Piglets less than 5 weeks of age normally have low leukocyte counts.

Diagnostic tests

A comparison of diagnostic tests shows that the best results are detected by RT-PCR (98.9%) which is earlier than VI on blood which gives only a result of 94.5%. RT-PCR is expensive and labor intensive. The antigen-ELISA gives a later detection and the worst results.[89] The leukocyte count gives the earliest pointer to CSF infection but of course does not confirm the disease.

The advent of eradication programs has resulted in the development of diagnostic tests for hog cholera. These tests must be accurate and rapid so that control measures can be rapidly instituted or lifted as required. Diagnosis by virus isolation is slow, cytopathic effect may be minimal and some strains have low infectivity and limited growth in tissue culture. This method is seldom used as a primary diagnostic method. Animal inoculation tests still provide an excellent method for the diagnosis of hog cholera and involve the challenge of susceptible and immune pigs with suspect material followed by subsequent challenge at a later date with fully virulent hog cholera virus. However, this test is time-consuming and costly and, although it is used for the final confirmatory test for the presence of hog cholera infection in various situations, it is not satisfactory for a rapid diagnostic test.

Detection of virus

The more rapid tests rely on the detection of antigen in infected pig tissues or the detection of antibody following infection.

Fluorescent antibody techniques

This technique allows the rapid detection of antigen in frozen sections of tissue or impression smears and in infected tissue cultures and these methods have been adopted as a primary test in the eradication program in the United States. Antigen can be detected up to 2 days after death and this method has been considered more reliable than the agar gel precipitation test. The method is capable of detecting virus carriers among vaccinated pigs.

Antigen-capture ELISA

The antigen-capture enzyme-linked immunosorbent assay (ELISA) can detect the virus antigens in blood and tissues from experimentally infected pigs at 4–6 days after infection with a moderate–high virulent strain (Weybridge virus) and 7–9 days after infection with a low-virulent strain (New South Wales virus).[90] The technique does not require tissue culture and takes less than 36 hours for a definitive result.

Agar gel precipitation test

This test detects antigen in tissue by means of a precipitin formed with immune sera. Usually pancreas from suspect pigs is tested. This test was used widely in the United Kingdom eradication program and is the standard primary test in many countries.

Differentiation of swine fever virus from other pestiviruses

PCR tests

A **polymerase chain reaction (PCR)** assay can be used to differentiate classical swine fever virus from ruminant

pestiviruses.[91] An international reference panel of monoclonal antibodies for the differentiation of hog cholera virus from other pestiviruses has been developed.[92] Restriction endonuclease cleavage of PCR amplicons can distinguish between vaccine strains and European field viruses.[93] The RT-PCR can also detect CSF in boar semen.[94] A RT-PCR was then described.[95] Rapid detection of CSF using a portable real time reverse transcriptase PCR (RT-PCR; TaqMan) has been described.[96] Further modifications have been described[97] so that the test can be performed in a single tube with all the ingredients. It can then be used as a pen-side test and detects virus in nasal and tonsil scrapings 2–4 days before the onset of clinical signs. A further modification of RT-PCR and ISH has been that they can be used on formalin fixed sections.[98] A multiplex PCR is available to separate BVD from CSF.[99]

Serological tests

Antibody can be detected by the fluorescent antibody neutralization test, tissue culture serum neutralization test or an indirect ELISA. Serological tests are less satisfactory for detection of hog cholera in the acute phase and are of limited value in vaccinated animals. They are of value in the detection in sows of the subclinical infection of hog cholera associated with reproductive failure and for survey studies to determine the prevalence of hog cholera infection. BVDV may infect pigs, especially those in close contact with cattle, and may give false-positive serological reactions. The incidence of these false-positive reactions may be high and they pose a problem for hog cholera identification in eradication programs. The neutralizing peroxidase-linked antibody assay is a highly sensitive and specific test for hog cholera and will distinguish between pigs infected with different strains of the hog cholera virus and BVDV. The complex, trapping, blocking ELISA is sensitive, specific and reliable for screening purposes for early identification of infected herds and their elimination in an eradication program.[100] A peroxidase-labeled antibody assay can be used to detect swine IgG antibodies to hog cholera and BVDVs.[101] Monoclonal antibodies to pestiviruses are also available to discriminate between both viruses.[102,151] A competitive ELISA using a truncated E2 recombinant protein has been described which can be used when a large number of samples are to be tested.[103]

Samples for laboratory

When hog cholera is suspected, tissues submitted for examination should include the brain and sections of intestine and other internal organs in formalin, and pancreas, lymph node and tonsil unpreserved in sealed containers. Local regulations and requirements should be followed. The viral antigens are densely distributed in the skin and tongue of infected pigs, and biopsies of ear may be useful for diagnosis on a herd basis.[104]

NECROPSY FINDINGS

In many cases the single most important diagnostic aid is the post-mortem examination although in the Dutch outbreaks it was thought that the contribution to the detection of CSF was limited.[105,106] The reason for this is that there is tremendous individual variation. In the outbreak in the UK in 2000 there were few lesions in fetuses or in neonates and in the sows lesions were often restricted to conjunctivitis and lesions in the hepatic and splenic lymph nodes even though 15 animals in each group were examined. The only group showing more consistent lesions were the growers and in these the lesions were similar to those that are reported in the classical outbreaks.

In peracute cases there may be no gross changes at necropsy. In the more common acute form, there are many submucosal and subserosal hemorrhages but these are inconstant and to find them it may be necessary to examine several carcasses from an outbreak. The hemorrhage results from erythrodiapedesis and increased vascular permeability, probably aided by mast cell degranulation.[107] The hemorrhages are most noticeable under the capsule of the kidney, about the ileocecal valve, in the cortical sinuses of the lymph nodes and in the bladder and larynx. The hemorrhages are usually petechial and rarely ecchymotic. The lymph nodes are enlarged and the spleen may contain marginal infarcts. Infarction in the mucosa of the gallbladder is a common but not constant finding and appears to be an almost pathognomonic lesion. There is congestion of the liver and bone marrow and often of the lungs. Circular, raised button ulcers in the colonic mucosa are usual but cannot be distinguished from those of salmonellosis. Although these gross necropsy findings are fairly typical in cases of hog cholera, they cannot be considered as diagnostic unless accompanied by the clinical and epizootological evidence of the disease. They can occur in other diseases, particularly salmonellosis. In a recent study[77] found that the lymph nodes had the highest score for lesions and that the least lesions were found in the spleen and tonsil because infection of these organs was also rare. The most common lesions were also in the lymph nodes, around the ileo-caeco-colic junction and around the blood vessels of the brain. Atypical bronchiolar cilia have been reported.[108]

There are characteristic microscopic lesions of a non-suppurative encephalitis in most cases and a presumptive diagnosis of hog cholera can be made if they are present. It is thought that the most common lesion in chronic CSF is the mononuclear cell cuff in the CNS. Here ISH is capable of detecting viral nucleic acid even when viral antigen is not detected.[94] Histologically, the main site of tissue injury is the reticuloendothelial system. There is always a progressive lymphoid depletion and mucosal necrosis. The depletion is probably caused by apoptosis but not by direct apoptosis. Atrophy of the thymic cortex and loss of thymocytes is also a feature and may be related to synthesis of the cytokines, TNFα and IL-1α in particular[109] which may increase the apoptosis of the thymocytes.

Fibrinoid necrosis of the tunica media combined with hydropic degeneration and proliferation of the vascular endothelium causes occlusion of blood vessels. The more virulent 'neurotropic' strains produce lesions of a similar nature but greater severity.

In the intestinal tract mucosa there are large, usually infected macrophages.[110] The GALT areas are lymphocyte depleted usually because of massive lymphocyte apoptosis particularly in the B-cell areas. These changes are possibly due to the large amounts of TNFα and IL-1α released from the infected macrophages.[111] They also showed that the macrophages in the splenic marginal zone were amongst the first cells to be infected. The infection, mobilization, and apoptosis of splenic macrophages plays a very important role in the course of the infection through cytokine release. An unusual manifestation of CSF infection is the onset of metaphyseal bone formation caused by the partly thrombosed vessels in the bone with strong CSF viral specific fluorescence.[112]

Histology, showed swelling and vacuolation of megakaryocytes in the bone marrow 2 days after infection and they were necrotic 4 days after infection.[113] Severe swelling and necrosis of endothelial cells in the vascular endothelium were observed 3 days after infection. It was concluded that the thrombocytopenia due to direct viral damage to MKC and endothelial damage can cause hemorrhagic diathesis whereas coagulation disorders are not involved in early stages of the disease.[114]

In the chronic form of the disease, ulceration of the mucosa of the large intestine is usual. Secondary pneumonia and enteritis commonly accompany the primary lesions of hog cholera.

Infection of the fetus produces a persistent immunologically tolerant non-cytolytic infection, often with little evidence of cell necrosis or inflammatory reaction to suggest the presence of a virus. Aborted fetuses show non-diagnostic

changes of petechial hemorrhage and ascites. Malformations such as microcephaly, cerebellar hypoplasia, pulmonary hypogenesis and joint deformity appear due to inhibition of cell division and function in these areas. Antibody is not detected in fetal blood when infection occurs early in fetal life. In pigs showing signs of myoclonia congenita, cerebellar hypoplasia is highly suggestive of hog cholera infection.

An immune complex glomerulonephritis has been described[115] in which there is macrophage infiltration of the mesangium with immune complex deposits of IgM, IgG, and Clq in mesangial, subepithelial and subendothelial areas from 10 days post-infection and by 14 days neutrophils had also congregated.[116]

This is a disease of major economic importance and confirmation of the diagnosis is usually performed in specialized governmental laboratories. Virus isolation and fluorescent antibody tests [104] are most commonly used but other techniques, including immunoperoxidase staining of cryostat sections.[92] The demonstration of viral antigen in the crypts of the tonsils, tubular epithelial cells of the kidney, bronchiolar mucosal gland cells and the pancreatic epithelial cells has been shown to be possible even after 18 years in formalin.[117]

Samples for confirmation of diagnosis

Fresh tonsil can be used for polyclonal direct fluorescent antibody which also detects BVD and BDV and can then use additional tests. The sensitivity of this test was shown to be only 78% so to give a 99% chance of infection being detected you had to postmortem five animals.[118]

- **Histology** – formalin-fixed brain, spleen, lymph nodes, colon, cecum, ileum, kidney, tonsil, skin, tongue (LM). Tissue sections can also be used for ISH and IHC[115]
- **Virology** – lymph nodes, tonsil, spleen, distal ileum, skin, tongue, brain (FAT, ISO, IHC, PCR). Heparinized blood.

TREATMENT

DIFFERENTIAL DIAGNOSIS

A positive diagnosis of hog cholera is difficult to make without laboratory confirmation. This is particularly true of the chronic, less dramatic forms of the disease. A highly infectious, fatal disease of pigs with a course of 5–7 d in a group of unvaccinated animals should arouse suspicion of hog cholera, especially if there are no signs indicative of localization in particular organs. Nervous signs are probably the one exception. The gross necropsy findings are also non-specific and reliance must be placed on the leukopenia in the early stages and the non-suppurative encephalitis visible on histological examination. Both of these bacterial infection, particularly salmonellosis, is present.

The major diseases which resemble hog cholera include:

- **Salmonellosis** usually accompanied by enteritis and dyspnea
- **Erysipelas** in which there are characteristic diamond skin lesions, and the subserous hemorrhages are likely to be ecchymotic rather than petechial;
- **Pasteurellosis** in which respiratory signs predominate and lesions of pleuropneumonia at necropsy are characteristic.

Epidemiological considerations and hematological and bacteriological examination will usually differentiate these conditions.

Other encephalitides, particularly **viral encephalomyelitis** and **salmonellosis** cause similar nervous signs.

African swine fever apart from its greater severity, is almost impossible to differentiate from hog cholera without laboratory testing.

Hyperimmune serum is the only available treatment and may be of value in the very early stages of the illness if given in doses of 50–150 mL. It has more general use in the protection of in-contact animals. A concentrated serum permitting the use of much smaller doses is now available.

CONTROL

The methods used in the control include **eradication** and control by **vaccination**. Both modeling and real time prediction have been described.[119] In areas where effective barriers to reintroduction of the disease can be established, eradication of the disease by slaughter methods is feasible and usually desirable. In contrast, in areas where the structure and economics of the pig industry require considerable within-country and across-border movement of pigs, it may not be practical or economically feasible to institute a slaughter eradication program. The establishment of a highly susceptible population in a high-risk area is unwise. If repeated breakdowns occur, the restriction of movement of pigs within the quarantine areas creates considerable managemental problems for pig owners and they may, as a result, eventually become non-cooperative in the program. In these areas, control and possibly even eradication by vaccination is the approach of choice and this method is used in some countries like the Phillipines.[18] The Commission for the European Communities has declared its policy, supported by appropriate community legislation, to eliminate hog cholera without vaccination.[17] A full discussion of the possibility of using vaccination in the future has been outlined.[120] A computerized framework for the risk assessment for CSF has been produced.[150] In Germany there are big risks with regard to the import of pigs, wild boars and the import of pig meat.[121] A retrospective spatial and statistic simulation to compare two vaccination techniques with the non-vaccination scenario in the Dutch 1997/1998 CSF outbreak showed that both emergency vaccination techniques would hardly have been more efficient.[122] General procedures are described first followed by a description of the immunizing products available.

Control of outbreaks in hog cholera-free areas

Modelling for the control of CSF in such areas has been described B.[123]

In areas where the disease does not normally occur, eradication by slaughter of all in-contact and infected pigs is possible and recommended. The pigs are slaughtered and disposed of, preferably by burning. All herds in the area should be quarantined and no movement of pigs permitted unless for immediate slaughter. In areas with high pig densities, control strategies depend on highly effective identification and recording systems which provide information on herd inventories and animal movements so that herd epidemics can be traced back to their origin.[17] Recent experiences with epidemics of swine fever in Belgium and the Netherlands found that, with the current ear tag with manual recording and use of documents system, most epidemics could not be traced back to their origin.[17] The tracing and removal of carrier herds prevents these herds from becoming infectious and prevents the spread of disease at an early stage.

All vehicles used for the transport of pigs, all pens and premises and utensils must be disinfected with strong chemical disinfectant such as 5% cresylic acid. Contaminated clothing should be boiled. Entry to and departure from infected premises must be carefully controlled to avoid spread of the disease on footwear, clothes and automobile tires. Legislation prohibiting the feeding of garbage or commanding the boiling of all garbage before feeding must be enforced. This eradication procedure has controlled outbreaks which have occurred in Canada and Australia and has served to maintain these countries as free from the disease.

Control where hog cholera is endemic

One of the major problems in Europe is the wild life reservoir in the wild boar population. In areas where there is little

risk there are few positive animals but where there is a high risk then many animals may be positive. In Switzerland 179 of 528 boars in a risk area were positive.[124] The oral vaccination of wild boars was described in Germany[125,126] has no risk for the establishment of a persistent wild boar CSF infection.[127] However it was shown that more than 50% of the wild boar did not feed on the vaccination baits and therefore did not become immune.[125] There is evidence from wild boar studies in Italy that the level of infection in the free population gradually reduces in any case.[129] Where you have wild pigs with maternal antibodies when they contract live CSF virus they have transient clinical signs but the disease is not lethal. Infected wild boars could therefore play a very big part in the transmission of a natural outbreak.[130] The vaccination studies in wild boar were reported recently and showed that after the 5th vaccination there was no viremia, no virus excretion, and no post mortem virus recovery.[131] Oral vaccination of wild boar usually reduces the presence of CSF but only a low rate of wild boar (30–35%) become seropositive.[132]

In endemic areas, control is mostly a problem of selecting the best vaccine and using it judiciously. In Asia almost all the control is vested in the use of vaccines and their proper use. Most problems are caused by policy failures, or changes in demographics whereas most of a vaccination policy should be determined by the epidemiology of the disease. Much can also be done to keep the incidence of the disease low by the education of farmers whose cooperation can be best assured by a demonstration that eradication is both desirable and practicable. Once farmers are motivated to act, the greatest stumbling block to control, **failure to notify outbreaks**, is eliminated. Education of the farmer should emphasize the highly contagious nature of the disease and the ease with which it can be spread by the feeding of uncooked garbage and the purchase and sale of infected or in-contact pigs. The common practice of sending pigs to market as soon as illness appears in a group is one of the major methods by which hog cholera is spread.

There are two sorts of vaccine:[133]

1. The first group is the classical live group containing attenuated virus and these are to be preferred. Live, virulent virus vaccines produce a solid immunity within just a few days and give lifelong protection but are capable of introducing the infection and of actually causing the disease when vaccination 'breaks' occur. The reaction to live virus vaccine may be severe and the susceptibility of pigs to other diseases may be increased. Eradication of the disease is impossible while the use of this type of vaccine is permitted.
2. There is a recently developed second group of live vaccines aimed as marker vaccines[134] based on the E2 protein[135] but these are still undergoing development. There appears to be no complete protection against congenital infection, they do reduce transmission of virus[136] and they seem to only last about 1 year.[137] They do have the potential to allow tests to be used to differentiate between naturally infected and vaccinated animals.[138] They may also fail in the face of natural infection.[139–141] Recent further developments of these marker vaccines[77] possibly include a chimeric vaccine where one of the genes has been replaced by a BVD gene and a second vaccine where a DNA vaccine expresses the E2 protein after entering the host cell and others with E2 peptides.[142–145]

When an outbreak occurs in a herd, the immediate need is to prevent infection from spreading further. This can be best achieved by removing the source of infection and increasing the resistance of in-contact animals by the administration of hyperimmune serum or one of the available vaccines. Removal of the source of infection necessitates:

- Isolation of infected animals. This was highlighted in the recent Dutch outbreak[146]
- Suitable hygienic precautions to prevent the spread of infections on boots, clothing and utensils
- Disposal of carcasses by burning
- Disinfection of pens. The pens should be scraped, hosed and sprayed with 5% cresylic acid solution or another suitable disinfectant. The choice of serum or vaccine may depend on local legislation and will depend upon circumstances. Pigs in the affected pen should receive serum (20–75 mL depending on size) and pigs in unaffected pens should be vaccinated. Pigs receiving serum only will require active vaccination at a later date if a strong immunity is to be achieved. Routine vaccination of all pigs is desirable.

Hog cholera eradication

The elimination of hog cholera from a country where it is well established presents a formidable problem. Before the final stage of eradication can be attempted, the incidence of the disease must be reduced to a low level by widespread use of vaccination and enforcement of garbage-cooking regulations.

One of the most important problems encountered in eradication programs is the clinically normal 'carrier' animal and steps need to be taken to avoid the sale of all pigs from infected premises. A procedure which has been particularly effective in the control of this and other diseases of pigs is the complete prohibition of all community sales of feeder pigs. There are obvious political difficulties in such a prohibition, but despite their usefulness as marketing agencies, community sales continue to be a major source of swine infections. When the occurrence of virulent hog cholera has been eliminated, further necessary steps include the prohibition of use of any vaccine and serological studies to detect low virulence carrier states.

The eradication of swine fever in the United Kingdom in 1986 was an important achievement. Control was radical in that all herds in which the disease was diagnosed were slaughtered and all carcasses burned or buried to avoid missing atypical cases and recurrence through the swill cycle. The two focal points which became apparent were the need to avoid vaccination and the need to diagnose accurately. Vaccination was not permitted because it was not completely effective, produced 'carriers', and encouraged the development of mild and chronic forms of the disease. The need to diagnose accurately led to changes in diagnostic procedure as the campaign progressed. As the proportion of classical epidemics declined, there was increasing dependence on serological and antigen-detection tests. The program in the United States, which currently appears complete, is an equivalent achievement.

IMMUNIZATION METHODS

Very few pigs possess natural immunity to hog cholera and, until the introduction of the serum–virus method of vaccination, an outbreak of the disease in a herd meant virtually that the herd would be eliminated. The situation changed rapidly thereafter and it can be safely claimed that the development of the swine industry in the United States would have been impossible without the protection which the serum and virus provided. On the other hand, the dangers inherent in the use of fully virulent or partially avirulent virus do not recommend their use and have led to a continuing search for safe methods of immunization. The ideal vaccine should retain strong immunogenicity but should be completely avirulent, even for pregnant sows, the fetus and young or stressed pigs. It should be stable in the degree of

attenuation and should not persist in the vaccinate nor transmit from the vaccinate to in-contact pigs. Killed vaccines are safe and do not directly spread virus, but in general, they engender only a limited immunity. Live vaccines provide a longer lasting immunity but frequently have not met the criteria listed above.

Serum–virus vaccination

The serum–virus vaccination produces an immediate, solid and lasting immunity when properly administered to healthy swine. The virus, produced by collecting blood 6–7 days after artificial infection, is injected SC in 2 mL doses followed immediately by serum in doses graduated to the size of the pigs and varying from 20 mL for suckling pigs to 75 mL for adults. Overdosing with serum will not prevent the development of immunity. Vaccination is performed at any age after 4 weeks. Because of the availability of safer vaccines this method is not recommended.

Attenuated vaccines

Attenuated vaccines include tissue culture vaccines attenuated by repeated passage through tissue culture of porcine or other origin, lapinized vaccines produced by repeated rabbit passage, and vaccines from mutant strains. Many of the early vaccines of this type were not stable and could cause disease when not used in conjunction with serum. Furthermore, transmission to in-contact pigs, especially with porcine origin vaccines, and fetal disease following vaccination of pregnant sows have been problems. Attenuated vaccines are in wide use in Europe and Asia and include the Chinese or LPC and GPE strains. Recently, a safe and efficacious CSF marker vaccine based on the E2 protein (major immunogen) of the virus has been developed. This protein has neutralizing antibodies and it is also conserved. It can be used where there is an endemic problem and also after the outbreak.[147] It also prevents or reduces drastically the problem of trans-placental infection.[148] Experimental, non-transmissible marker vaccines have also been developed.[149] Highly passaged preparations are antigenically stable and show no evidence of reversion. They produce a very limited viremia, or none, and no leukopenia or clinical illness. Protection is evident within 5–10 days of vaccination. Piglets from non-immune sows can be vaccinated within the first 2 weeks of life. Because the presence of maternal immunity can interfere with effective immunization, the vaccination of piglets from immune sows should be delayed until at least the second month. The French Thiverval strain is a cold mutant strain which has lost its virulence but retained good immunogenicity. Vaccination of piglets even with ten times the regular dose produced no clinical illness and virtually no viremia. A single IM vaccination will produce resistance to challenge by 5–10 days and immunity persists for 3 years. Colostral immunity will protect piglets for periods up to 2 months after birth. When given to pregnant sows, even the highly attenuated strains have the ability to cross the placenta and produce fetal infection even though no clinical evidence of this may be manifest. Consequently it is recommended that replacement gilts be vaccinated at least 2 weeks prior to mating and that recently vaccinated animals be kept separate from susceptible pregnant sows.

In the Netherlands, the control of swine fever has relied on a slaughter policy on affected farms plus an emergency vaccination program in which all pigs over 2 weeks of age in areas of risk are vaccinated. The mass vaccination program is followed by supplementary vaccination of pigs at 7–9 weeks of age and revaccination of breeding gilts when they reach when 6–7 months of age. The serological response of piglets born from vaccinated sows is best at 9–10 weeks of age rather than at 5–6 weeks of age. A vaccine-induced neutralizing antibody titer of <32 is adequate to provide protection against clinical disease and to prevent virus transmission.

Inactivated vaccines

These are usually prepared from the blood or tissues of infected pigs. Crystal violet vaccine has been the one most widely used of this type and was used in the United Kingdom prior to eradication but never gained full acceptance in the United States. It is completely safe but its immunogenicity is poor. Immunity does not develop until 12 days after vaccination. Its duration is short and booster injections are required for maintenance. Vaccinated sows may still develop fetal infection when exposed to virulent virus and there is a danger that the use of this vaccine in enzootic areas may in this way induce virus carriers. The production of immune antibodies to the blood components of the vaccine may result in the occurrence of isoimmune hemolytic anemia in some breeds. For these reasons inactivated vaccines are not in common use.

AFRICAN SWINE FEVER (AFRICAN PIG DISEASE, WART HOG DISEASE)

This is an OIE List A disease. It is indistinguishable in the field from classical swine fever as both are hemorrhagic diatheses and it is just as contagious. However, it is associated with a totally different virus.

Synopsis

Etiology Large icosahedral cytoplasmic DNA virus

Epidemiology Disease of major threat to pig-producing countries. Occurs in Africa, western European countries, Caribbean countries. High morbidity, high case-fatality rate in classic form; low virulence form less fatal. In Africa, transmitted by argasid tick from wild pigs to domestic pigs. In Europe transmitted by direct contact with infected pigs

Antibodies in colostrum of recovered sows provide passive protection to piglets

Signs High fever, purplish skin, depression, anorexia, huddling, disinclination to move, weakness, incoordination, nasal and ocular discharges, diarrhea, vomiting, abortions, death in a few days. Historically, highly virulent forms; recent decades subacute and chronic forms common with fever, depression, lethargic, recover in few weeks but remain persistently infected; chronic cases are intermittently pyrexic and become emaciated with soft edematous swelling over joints and mandible

Clinical pathology Severe leukopenia and lymphopenia. Detect antigen or serological tests

Lesions Marked petechiation of all serous surfaces, lymph nodes, epicardium and endocardium, renal cortex, bladder, edema and congestion of colon and lungs. Renal hemorrhages are considered pathognomonic

Diagnostic confirmation Identify virus in tissues

Differential diagnosis list

- Hog cholera
- Erysipelas.
- Salmonellosis.

Treatment None

Control Identification of affected pigs, slaughter and quarantine premises. Establish disease-free areas

ETIOLOGY

It is associated with a DNA virus which is the sole member of the Asfariviridae and as such is the only known DNA arbovirus.[1] It is a large icosahedral virus that contains a linear, double-stranded DNA genome (170–190 kbp). The viral genome may encode for 165 genes[2] and encodes for approximately 113 viral proteins, most with an as yet unknown function.[3] Morphologically, it is similar to the iridoviruses but resembles the pox viruses in genome construction and gene expression. There are different forms from highly lethal to sub-clinical with different field strains and tissue culture adapted strains.[4] These are recognized by restriction fragment length polymorphism (RFLP) and protein p72 recognizes all viral groups. Partial p72 gene characterization allows genotyping of field strains.[5]

EPIDEMIOLOGY

Occurrence

African swine fever is indigenous to the African continent where it affects wild pigs. These include wart hogs, bush pigs and escaped (feral) forest hogs which act as reservoirs of the virus which cycles between the pigs and the ticks. Wild pigs in some areas are free of infection and consequently the disease is not endemic in all areas. It was always considered to be a disease of Sub-Saharan Africa but over the years has reached new areas. The occurrence has recently been reviewed.[6] These include Mozambique in 1994, Kenya in 1994, Ivory Coast in 1996,[7] Benin in 1997 and also Togo and Nigeria in 2001.[8] The Kenyan outbreak seemed to be maintained in the domestic pigs without sylvatic hosts.[9] The Nigerian strain was 92–97% homologous to the strains from

Uganda, Dominican Republic, and Spain. The serious worry was the appearance of the virus in Madagascar in 1998.[10] Although studies showed only a seropositivity of 5.3%[11] Infection of wild pigs produces no clinical disease but with virulent strains, infection in the domestic pig is almost always fatal. Since its recognition, occurrence of the disease in South Africa has been cyclical with periods of 10–12 years of clinical disease and then an absence of disease. Until 1957, African Swine Fever (ASF) had not occurred outside the African continent. To the rest of the world it represented the most formidable of the exotic diseases of swine, a disease which had to be kept within its existing boundaries at all costs. However, ASF spread from Africa, appearing in the domestic pig population in Portugal in 1957 and Spain in 1960; and resulted in the death or slaughter of thousands of pigs. Subsequently the disease appeared in France and then Italy and in 1971 occurred in Cuba. It was successfully eradicated from these latter three countries by extensive slaughter and quarantine programs.

The exception in Europe is Sardinia where the disease is endemic in the Central Highlands although it has decreased from Oct 1994 to March 1996. In a survey in 1998, 45 of 82 municipalities in the province of Nuoro in Sardinia were found to have ASF. The principal reasons being the extensive pig farming and the occurrence of wild boar.[12] The partial confinement farms have less seropositivity than the free-range farms[13] and those in total confinement have only 20% of the level of the free-range farms. In 1978, outbreaks occurred in Malta,[14] Brazil, Dominican Republic and Haiti. In Malta, the disease resulted in the death or slaughter of the entire population of 80 000 pigs within 12 months of the diagnosis.[14] This is one of the few examples where a country had to slaughter an entire species of a domestic animal in order to eliminate a disease. An outbreak occurred in Belgium in March 1985. The source of infection was thought to be pork imported from Spain, which was fed to only one boar. Once the official diagnosis was made, all animals on affected farms were slaughtered. Animals which had direct commercial contact with infected herds were also slaughtered and the disease was declared eradicated in September 1985. In Spain, the disease had been present since 1960 but the implementation of regulations for eradication adopted in 1985 made it possible to divide the country into an African swine fever-free region and an infected region.[15] Since 1995 Spain and Portugal have been declared free from the disease although there was an isolated outbreak in Portugal in 1995. This has resulted in a marked change in the distribution and incidence of the disease.

Only pigs are affected; domestic pigs of all ages and breeds are highly susceptible, but the virus can be passed in tissue cultures of rabbits, goats and embryonated hen eggs.

Until recently, the occurrence of the disease in Africa was limited to explosive outbreaks in European pigs which came in contact with indigenous African pigs. These outbreaks tended to be self-limiting because all pigs in affected herds died or were destroyed, but after a number of years the disease became enzootic in domestic herds. Surveys of the disease in countries like Malawi illustrate the changing behavior of the disease over a period of years. The virus which was introduced to Europe in 1957, was capable of persisting in European pigs and after a period of several years in which the disease was epizootic, a change to an enzootic character occurred. The outbreak in Cuba was of a comparatively virulent form.

When the disease occurred in the Caribbean region, it posed a major threat to the large swine industry of the United States principally because of the possible spread of the virus to the feral swine population in Florida.[16] The feral swine population in Florida is the largest in the United States and is of major recreational and economic importance to hunters, trappers, taxidermists and dealers who sell feral swine to hunting clubs. The feral swine in Florida are descendants of domestic swine which were allowed to run wild. Experimental inoculation of these pigs with virulent isolates of the virus will cause fatal disease.

Morbidity and case fatality

Early in the history of African swine fever, the morbidity rate could be as high as 100% and the case–fatality rate was also often over 90%. However, a decrease in the virulence of the virus occurs with time in enzootic areas, and the case–fatality rate may now be as low as 2–3%.[17]

Methods of transmission

In **Africa**, the method of transmission of the disease from the reservoir in wild pigs to the domestic pig has been the subject of considerable interest. Infection is primarily transmitted to domestic pigs via the argasid tick *Ornithodoros moubata*. The viremic wart hog is a source of infection for the ticks. The virus can be maintained in wart hog-associated argasid ticks by a transstadial, transovarial and sexual (male to female, but usually not vice versa) transmission mechanism. It needs to replicate in the mid-gut epithelium of the tick for successful ASF infection of the tick.[18] The tick is relatively restricted in its habitat and if contact between domestic pigs and wild pigs and their burrows is prevented, transmission can be prevented.[14] The virus can be maintained in these ticks for long periods in the absence of fresh sources of infection, with a low level of viremia lasting a long time. The young wart hogs in the burrows are infected early on, so that they act as a reservoir as well as vectors of infection. Sporadic outbreaks may thus occur in endemic areas when the virus spreads from infected ticks or wart hogs to domestic pigs. In some areas where infected wart hogs are common but where *O. moubata* is apparently absent, *O. savignyi* may be a natural field vector of the virus. It is also found in *O. porcinus porcinus*.[19,20] The ASF virus replicates to a high titer in the developing cells of the egg of the tick.[21] Ticks infected with ASF virus also have a higher mortality than uninfected ticks.[22]

The long-held belief that the source of the virus in primary epidemics of African swine fever in southern and eastern Africa is the carrier, wild pig, is not tenable. It is postulated that infected ticks are transported to the vicinity of domestic pigs either by wart hogs or on the carcasses of wart hogs.

In Africa, the virus is maintained primarily by a cycle of infection between wart hogs and soft ticks (*Ornithodoros moubata*).[14] The virus does not have an apparent effect on either wart hogs or ticks and it is only when infection of domestic pigs occurs that the virus produces disease. Indeed most wart hogs are aviremic but seropositive. The tick has a wide distribution in Africa south of the Sahara, and its main habitat is in burrows which are inhabited by the wart hog. There is a good correlation between antibodies in wart hogs and the presence of ticks. Newborn wart hogs can become infected soon after birth if bitten by infected ticks and the consequent viremia would be high enough to infect previously uninfected ticks feeding on them. It is also found in the bush pig (*Potamochoerus porcus*)[23,24] which following infection may be viremic for 35–91 days, and these also transmit the infection to ticks.

In **Spain and Portugal**, the methods of spread are contact between neighboring farms and the introduction of infected pigs either during the incubation period or as persistently infected virus carriers. During the last 20 years, an increasing number of outbreaks occurred in which clinical disease was not readily recognized. The mortality rates decreased and a wide range of clinical disease occurred, ranging from acute to chronic and including apparent recovery to normal health. The major consequence of the emergence of these less virulent forms of the virus was the development of persistently viremic

carriers and a large population of pigs with inapparent infection. The African swine fever virus may persist in the pig population by persistent infection in recovered pigs for several months, during which time the virus must be reactivated before transmission can occur. The virus can also persist by reinfection of recovered pigs in which virus replicates without producing clinical disease and transmission occurs by excretion and by infected blood and tissues. Wild boars in Spain carry the virus without clinical signs.[25]

The **European vector** of the virus is the soft tick *O. erraticus*.[14] It can maintain and transmit the virus for at least 300 days. In various areas of Spain, *O. erraticus* was found in 42–64% of the pens occupied by pigs.[26] Following the outbreak of the disease in Spain, abandonment of these pig pens has resulted in the elimination of most soft ticks infected with the virus.[26] The adults and large nymphs can survive for about 5 years or longer in the soil of pig pens when animals occasionally enter them. There is a relationship between the persistence of the disease and the distribution of the tick in Spain.[27] Hungry tick populations may transmit the virus when feeding in the winter but populations that have continuous access to pigs do not feed until the pig pens reach a temperature of 13–15°C. The development from larva to adults takes 2–3 years. In a recent studied on the ticks (*O. erraticus*) from farms in Southern Portugal two types of ASF were isolated.[28] One produced the acute, 100% fatal disease, and the other just a low viremia in pigs.

In **Sardinia**, the major factors involved in the spread of the disease are related to the:

- Mountainous terrain in which pigs may range freely in previously infected areas
- Movement of pigs which may survive infection and mingle with other herds
- Introduction of infected pigs from unknown sources into healthy herds because of the uncontrolled movement of pigs
- Feeding of waste food containing meat from infected pigs.[14]

The virus has been experimentally transmitted to healthy swine by *O. coriaceus*, an argasid tick indigenous to the United States. The potential arthropod vectors of the virus in **North America and the Caribbean Basin** has been examined. Most *Ornithodoros* spp. of ticks that will feed on pigs may be capable of acting as vectors of the virus, and the possible existence of potential vectors among the other blood-sucking arthropods should not be ignored. The soft tick *O.* (*Alectorobius*) *puertoricensis* found on the Caribbean Island of Hispaniola (Haiti and Dominican Republic) where African swine fever was endemic from 1978 to 1984, was experimentally able to transmit the virus from infected to susceptible pigs.[29] The *O. coriaceus* tick is able to harbor and transmit the virus for more than 440 days, passing it transstadially from the first nymphal stage to the adult, sustaining it through at least four molts. *O. puertoricensis* has all of the prerequisites for becoming a true biological vector and reservoir of the virus.

Once established in domestic pigs the disease can spread rapidly. Virus is present in high titer in nasopharyngeal excretions at the onset of clinical signs and is present in all organs and excretions in acutely sick pigs. In experimentally inoculated domestic pigs, the virus is present in substantial amounts in secretions and excretions of acutely infected pigs for only 7–10 days after the onset of fever and is present in the greatest amount in the feces. The virus can persist in the blood of some recovered pigs for 8 weeks and in the lymphoid tissues for 12 weeks. Feces are the environmental contaminant most likely to spread the infection, but blood is also highly infective and transmission could occur by contamination of wounds created by fighting. Infection occurs via oral and nasal routes and with the short incubation period once the disease is established in a herd, it spreads rapidly by direct contact. Infection amongst domestic pigs can also reputedly be spread by:

- Indirect contact by infected pens
- Ingestion of contaminated feed and water
- Feeding uncooked garbage containing infected pig material. Transmission via the hog louse *Haematopinus suis* is also probable. An important source of infection is the recovered pig which may remain persistently infected and a carrier indefinitely. Pigs which have recovered from the western hemisphere isolates (Brazilian and Dominican Republic) may be persistently infected and are resistant to experimental challenge.

Risk factors

Pathogen factors

The African swine fever virus is a multiclonal population of viruses in which all combinations of at least four markers (hemabsorption, virulence, plaque size, and antigenicity) are found. This may explain the epidemiological observation that when the disease was confined to Africa and the Iberian peninsula in the early 1960s, the viruses isolated were highly virulent to swine, but in subsequent years mortality decreased and subacute and chronic infection became more common. Experimentally, moderately virulent African swine fever virus obtained from the Dominican Republic, when inoculated into pigs, results in an acute febrile illness along with viremia and a transient neutrophilia from which the pigs recover. The Malta 78 isolate of the virus experimentally produces a clinical syndrome similar to the African isolates of the virus.

A huge amount of research is continuing apace into the genes and the proteins produced from the expression of these genes but these are really beyond the scope of this text.[30] However, recent studies of ASF have suggested that the virulence may depend on their ability to regulate the expression of macrophage derived cytokines which in turn regulate Th1 and Th2 responses and control the host protective responses.[31] The less virulent cultures of ASF with macrophages produce more TNFalpha, IL-6, IL-12, and IL-15, i.e. virulent strains inhibit their production. It also affects chemotactic responses and phagocytic capacity[32,33] at the same time as a reduction in the release of toxic oxygen radicals.

The virus is highly resistant to putrefaction, heat (it will survive 2 h at 56°C and dryness and survives in chilled carcasses for up to 6 months[17] and at 4°C for 2 years. Probably 0.5–0.66 of all the genes of ASF are not connected with virus replication but are important for viral transmission and survival in the host.[34]

Immune mechanisms

Antibodies against the African swine fever virus occur in the colostrum of sows previously infected with the virus and are transferred passively to nursing pigs. Experimentally, passively transferred virus-specific immunoglobulins alone will protect swine against lethal infection with a highly virulent homologous strain of the virus.[35] The antibody-mediated protective effect is also an early event which effectively delays disease onset. The construction of blocking antibodies by some of the viral proteins probably prevents the complete neutralization of the virus by antibodies.[36]

Pigs infected with virulent or attenuated virus may recover and resist challenge exposure with virulent homologous and, under certain conditions, heterologous viruses. Although pigs develop antibodies which are detectable by different tests, virus-neutralizing antibodies have only recently been demonstrated against viral protein p72.[37] However it has recently been suggested that p30, p54, p72, and p22 proteins are not associated with neutralizing antibodies.[38] The sera from pigs which have been infected and are resistant will inhibit virus replication but the nature of the inhibition is not understood. Neutralization of virulent virus

isolates in both Vero cell cultures and swine macrophages using swine immune sera has been demonstrated.[39] Experimental exposure of pigs to a low-virulent field isolate of the virus results in a range of virus-induced specific cellular responses.

The virus induces strong in vitro blastogenesis of primed blood mononuclear cells, when less virulent, but live virus isolates are used. Pigs recovering from an acute infection with the virus have significant levels of virus-specific cytotoxic T-lymphocytes after in vitro stimulation. Viral protein p36 induces a helper T-cell response in mice.[40] Resistance to infection appears to be related to the level of antibody dependent cell mediated cytotoxicity. Virus-specific blastogenic and cytotoxic T-cells are prime candidates for the cells inducing and conferring protective immunity against challenge with the virus suggesting that cellular based mechanisms are highly important.[41,42]

PATHOGENESIS

The virus invades through the tonsils and respiratory tract and replicates in the lymphoid tissues of the nasopharynx prior to the occurrence of a generalized viremia, which can occur within 48–72 hours of infection.

Infectivity and contact transmission develops at this time and continues for at least 7 d. Pigs inoculated with field isolates of the virus from the western hemisphere develop thrombocytopenia with a characteristic pattern. Infected pigs become thrombocytopenic over a 48-hour period after 3–4 days of illness. After several days of thrombocytopenia, the platelet count returns to baseline level even with a continuing viremia. Experimentally, the virus causes hematopoiesis in bone marrow which coincides with macrophage activation and bone marrow function is not impaired.[43] Membrane proteins on the surface of permissive cells act as receptors for ASF and specific interactions take place at this site.[44]

The effects of ASF are primarily hemorrhages and apoptosis.[45,46] A new protein (p54) encoded by the virus has just been shown to be the first that directly induces apoptosis.[47] The disease is characterized by apoptosis with abundant lymphocyte particularly B-cell death.[24] Both T and B-cells, particularly in the spleen, are affected as early as 3 days after infection. The apoptosis being induced by cytokines or apoptotic mediators released from ASF infected macrophages. In all probability there is an intra-cellular pathway triggered at the same time as the process of virus encoding.[48] It is probable that the inducers of apoptosis are balanced by the inhibitors of apoptosis.[49]

Tissue necrosis and generalized endothelial cell infection are not features of the disease caused by isolates of moderate virulence.

The virus causes hemorrhages through its effect on hemostatic mechanisms[50] by affecting vascular endothelium.[46] After about 4–5 days the vascular damage extends to the basement membranes and death ensues usually because of the serious edema and hemorrhage. The mechanisms related to hemorrhage consist of the:

1. Activation and extensive destruction of monoctyes and macrophages. Serum TNFα[51] and IL-1β increase in the serum.[52] The lymphocytes also appear to have decreased activity.[53] Apoptosis of thymocytes has been reported[54]
2. Disseminated intravascular coagulation
3. Infection and necrosis of megakaryocytes. Many apoptotic and also pyknotic and karryorhetic megakaryocytes[55] can be seen which are induced either by cytokine damage or peripheral destruction of platelets.[56] Between 0.2–9.5% of cells may be affected. Early in the infection there is prolongation of coagulation times due to inhibition of fibrin formation and later thrombocytopenia develops. The thrombocytopenia and coagulation defects lead to the development of:
   - Hemorrhages
   - Serous exudates
   - Infarction
   - Local edema
   - Engorgement of tissues.

All clinical forms of the disease are characterized by extensive hemorrhages at necropsy and it is this feature which often establishes a presumptive diagnosis in the field. A highly virulent virus produces renal hemorrhages as a result of intense endothelial injury, facilitated by phagoctyic activity.[57] With strains of moderate virulence, hemorrhage is a consequence of an increase in vascular permeability with diapedesis of erythrocytes.[57] Activation of platelets by the virus may also contribute to increased permeability.

The virus mainly infects cells of the mononuclear phagocyte system and also impairs lymphocyte function. Pulmonary intravascular macrophages demonstrate intense TNFα and IL-1α activity which coincides with the pulmonary edema, neutrophil sequestration and fibrin microthrombi.[58] The lymphopenia which is so characteristic of the disease is due to a significant increase in lymphoctye death by apoptosis (programmed cell death).[59] In the experimental disease, there is marked apoptosis of lymph-node lymphocytes and this occurs in both compartments of cortical tissue, but is more intense in diffuse lymphoid tissue (T area). The peripheral lymphopenia is associated with T-lymphocyte depletion. There is no evidence of virus replication in lymphocytes in the lymph nodes but there is a high rate of viral replication in macrophages in diffuse lymphoid tissue compared to the low rate in lymphoid follicles.[60] In summary, there is lymphoid tissue impairment and programmed cell death of a high percentage of lymphoid and monocyte/macrophage cell populations. This accounts for the lymphopenia and the state of immunodeficiency. There are also a variety of proteins encoded by the virus that are apoptosis inhibiting proteins.[61] Experimentally, the virus also causes activation and degranulation of platelets from day 3 after inoculation onwards, coinciding with activation of the mononuclear phagocyte system and virus replication in monocyte/macrophages.[62] Virions of the virus also appear in the platelets, which suggests that platelets assist in disseminating the virus within the body, especially in subacute infections. Probably 95% of the infectivity of blood is in the form of virus adsorbed to the red blood cells.

The virus can cross the placenta, replicate in fetal tissues and cause abortion. However, the pregnancy failure is probably the result of the effects of the virus infection on the dam more than from direct viral damage to the placenta or fetus.[63]

CLINICAL FINDINGS

In the acute form of the disease the animals die in an acute state of shock characterized by a disseminated intravascular coagulation with multiple hemorrhages in all tissues.[64] The incubation period after contact exposure varies from 5–15 days. A high fever (40.5°C; 105°F); appears abruptly and persists, without other apparent signs, for about 4 days. The fever then subsides and the pigs show marked cyanotic blotching of the skin, depression, anorexia, huddling together, disinclination to move, weakness and incoordination. Extreme of the hindquarters with difficulty in walking is an early and characteristic signs. Coordination remains in the front legs and affected pigs may walk on them, dragging the hind legs. Tachycardia, and serous to mucopurulent nasal and ocular discharges occur and dyspnea and cough (sometimes up to 30%) are present in some pigs. Diarrhea, sometimes dysentery, and vomiting occur in some outbreaks and pregnant sows usually abort. Purple discoloration of the skin may be present on the limbs, snout, abdomen and ears.

Abortion may occur in all stages of gestation about 5–8 days after the infection commences or after 1–2 days of fever. Death usually occurs within a day or two after the appearance of obvious signs of illness, and is often preceded by convulsions.

Historically, African swine fever was an acute to peracute disease with a case-fatality rate of almost 100%. However later, subacute and chronic diseases were observed. More recently, an even less virulent form of the disease has evolved. High fever and varying degrees of depression and lethargy are observed during the acute phase but some pigs continue to eat, case-fatality rate is usually less than 5%, the fever subsides in 2–3 weeks and the pigs return to full feed and grow at a normal rate. Recovered pigs have no lesions suggestive of the disease but may be viremic for several weeks. These persistently infected pigs would pass routine antemortem inspection at slaughter and potentially infectious offal and carcass trimming could be fed unknowingly to other pigs. Chronic cases are intermittently febrile, become emaciated and develop soft edematous swellings over limb joints and under the mandible.

Diagnosis depends on clinical signs (which are not distinguishable in the field from acute PDNS or CSF), post-mortem examination (it is said that button ulcers and turkey egg kidney are more rare in ASF but this cannot and must not be relied upon) but most importantly on diagnostic tests to rule out CSF and confirm ASF.

CLINICAL PATHOLOGY

Hematology

As in hog cholera, there is a fall in the total leukocyte count to about 40–50% of normal by the fourth day of fever. There is a pronounced lymphopenia and an increase in immature neutrophils. In chronic cases there is hypergammaglobulinemia. Clotting times are increased from about 5 days post-infection. Thrombocytopenia is detectable from day 6.

Detection of virus

Antigen can be detected by the fluorescent antibody technique in tonsil and mandibular lymph node within 24–48 hours of infection and elsewhere once generalization has occurred. The indirect fluorescence antibody and direct fluorescence tests are commonly carried out on pooled visceral fluid samples.[15]

Serological tests

Antibody to the virus may be detected within 7 days of infection. The ELISA is highly sensitive and specific and can be automated for screening large numbers of sera. It has been developed for a variety of ASF proteins such as p73 or p30. More than 90% of infected pigs can be detected by the demonstration of specific antibodies against the virus. An immunoblotting assay is a highly specific and sensitive test which is easy to interpret, and provides an alternative to immunofluorescence and can be carried out in less than 90 min under field conditions.[65] Complement testing is also a possibility. The inadequate storage or transport of sera may lead to samples being kept at high temperatures for long periods and up to 20% of these may be false-negatives by ELISA. All blood samples should be held at 4°C before testing and if incorrectly stored or handled should be tested by immunoblotting.[66] A monoclonal antibody immunoperoxidase test is also useful for screening purposes.

NECROPSY FINDINGS

Gross changes at necropsy resemble closely those found in hog cholera except that in the acute ASF, the lesions are more severe. In many organs there is a hyperemia or edema, with fibrinous microthrombi.[67] The most common gross findings are swollen and hemorrhagic gastrohepatic and renal lymph nodes, often so badly affected that they may resemble the spleen, subcapsular petechiation of the kidneys, ecchymoses of the cardiac surfaces and various serosae, and pulmonary edema with hydrothorax.[50] There may be hemopericardium. The renal hemorrhages are considered almost pathognomonic and are a consistent lesion following inoculation of pigs with the virulent or moderately virulent virus.[57] Splenomegaly is usual but in contrast to hog cholera, splenic infarcts are rarely seen. The gallbladder is edematous and hemorrhagic but this is not as sometimes thought a pathognonomic lesion. In chronic cases the lesions are essentially the same but also include pericarditis, interstitial pneumonia and lymphadenitis. There is severe submucosal congestion in the colon, although button ulcers in the large intestine are less common than in hog cholera. Histologically the lesions are more diagnostic. The virus causes destruction of the mononuclear phagocyte system and then infects megakaryocytes, tonsillar crypt cells, renal cells, hepatocytes and endothelial cells. Postcapillary venules undergo hyalinization and endothelial swelling. Destruction of monocytes/macrophages is visible in the lymph nodes, the spleen and the bone marrow. In the liver, there is extensive destruction of hepatocytes. Marked karyorrhexis of lymphocytes is visible in both normal lymphoid tissues and in the infiltrating population of cells within parenchymatous organs. An encephalitis may be present with lymphoid infiltration of the leptomeninges, but is generally less severe than that of hog cholera. In recovered animals the presence of virus and antibody simultaneously (persistent infection) can cause the formation of immune glomerulonephritis.

As for hog cholera, the diagnostic testing to confirm ASF tends to be restricted to specialized laboratories.

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed spleen, lung, lymph nodes, kidney, liver, colon, cecum, brain (LM). The virus can be detected by IHC or ISH[24]
- **Virology** – spleen, kidney, submandibular and abdominal lymph nodes, tonsil (ISO (the virus grows well in bone marrow), FAT, PCR). A highly sensitive PCR has been developed.[68] A Taqman PCR has been developed for ASF.[69] A PCR has also been developed that can be used on a blood sample on filter paper[70] and also a plaque assay.[71] The PCR developed using the p72 protein will enable detection of ASF within 5 hours of clinical sample submission and full characterization of the virus within 48 hours.[5]

DIFFERENTIAL DIAGNOSIS

The disease is easily confused with hog cholera and very careful examination is required to differentiate the two. Clinically, the illness is much shorter (2 d as against 7 d) than in hog cholera. Gross necropsy changes are similar to but more severe than those of hog cholera. The marked karyorrhexis of lymphocytes characteristic of ASF is not observed in hog cholera. Differential diagnosis must rely on laboratory testing.In the past, differentiation has been achieved by the challenge of hog cholera-susceptible and immune pigs with suspect material. More recently, reliance has been placed on the demonstration of hemadsorbing activity with virus from suspected outbreaks grown on pig leukocyte tissue cultures. But hemadsorbing activity may be weak, delayed or even absent and there is sometimes difficulty in isolating virus from subacute or chronic cases in enzootic areas. Demonstration of antigen by fluorescent antibody staining will allow diagnosis of acute cases. For chronic cases, serological testing has been recommended and with the use of more than one test a high degree of accuracy can be achieved. Several sensitive laboratory tests for detection of the virus in tissues and serum antibody are now available. ELISA tests are highly sensitive. Radioimmunoassay tests are also sensitive and isolates of the virus may be titrated in swine monocyte cultures using a microtechnique. In the lymphocyte response test to virus infection, there is a cytolytic effect on the lymphocytes; the effect is greater on the B-lymphocytes than on the T-lymphocytes. Pigs with demonstrable antibody should be considerred as chronic carriers of the virus as it is doubtful that true recovery ever occurs.

TREATMENT

There is no treatment for ASF.

CONTROL

Slaughter affected pigs and their ticks as quickly as possible.

The control and eradication of ASF is difficult because of the:

- Lack of an effective vaccine
- Transmission of the virus in fresh meat and cured pork products
- Recognition of persistent infection in some pigs, particularly wild feral pigs, possibly warthogs and bush pigs
- Clinical similarity of hog cholera and African swine fever
- Recognition that in some parts of the world soft ticks of the genus *Ornithodoros* (*erraticus*, *moubata*, *porcinus porcinus*) are involved in the biological transmission of the disease and can remain carriers for long periods (possibly 5 years).

Prevention of introduction of the disease to free countries is based on the prohibition of importation of live pigs or pig products from countries where African swine fever occurs. Strict application of the prohibition has prevented the spread of the disease from enzootic areas within South Africa. If a breakdown does occur, control must consist of prevention of spread by quarantine, slaughter of infected and in-contact animals and suitable hygienic precautions. The need for close contact between pigs for the disease to spread and the ease with which this can be prevented by the erection of pig-proof fences facilitates control. Conversely, the disease is virtually uncontrollable when pigs from a number of farms have access to communal grazing.[14] The virus is highly resistant to external influences including chemical agents and the most practical disinfectant to use against the virus is a strong solution of caustic soda. Contaminated sties can remain infective for periods exceeding 3 months. These factors and the persistence of the virus in recovered pigs probably contributed to the difficulties encountered in the eradication program in Portugal, where the disease was stamped out but reappeared in 1960. However, the most important factor appears to have been the indiscriminate use of attenuated vaccines, which fostered the development of carrier pigs. In this outbreak so very little was seen in the form of clinical signs.

In Spain in 1985, a comprehensive nationally coordinated program for the eradication of the disease was begun and substantial progress had been made.[72,73] Prior to 1985, the only method of control of the disease in Spain was depopulation of herds with clinical disease. The current eradication program consists of the following:

- Depopulation of herds with clinical disease
- Serological surveillance of all sows and boars in every herd
- Improvement of sanitary conditions of housing
- Improved hygiene (safe disposal of manure, vehicle disinfection, insect and rodent extermination)
- Veterinary control of all swine livestock transfers (with individual identification of every animal moved for finishing or breeding purposes)
- Health certification of every animal used for herd replacement
- Destruction of every seropositive animal
- Formation of mobile veterinary field teams exclusively dedicated to support the program.

Following introduction of this program, it has been possible to divide Spain into a disease-free region (the criteria is a minimum of 2 years without the disease) and an infected region. Eradication of the disease in Spain occurred by 2001.[73] In 1991, the Spanish government claimed that 96% of the Spanish territory was free of ASF.[73] The calculated benefit–cost ratio is estimated to vary from 1.23 to 1.47, depending on the intensity of the program. A reduction in the funding for control would result in a benefit–cost ratio of 0.97, making the program unprofitable.

Vaccines

Several different vaccines have been used, including an ineffective inactivated virus vaccine and modified live virus vaccines. The modified live virus vaccines provide some protection but the results following their use have been neither satisfactory nor safe and they have the two disadvantages of confounding laboratory tests and producing 'carrier' pigs.

EQUINE INFECTIOUS ANEMIA (SWAMP FEVER)

SYNOPSIS

Etiology Equine infectious anemia virus, a retrovirus (lentivirus)
Epidemiology Worldwide distribution. Affects all species of Equidae. Transmission of disease by contaminated blood of clinically affected or inapparently infected horses during interrupted feeding of blood-feeding insects. Horses are infected for life
Clinical signs Fever, depression, edema, petechial hemorrhages, abortion, chronic weight loss, splenomegaly
Clinical pathology Anemia, thrombocytopenia, hypergammaglobulinemia, positive agar gel immunodiffusion (AGID) or competitive enzyme-linked immunoassay (CELISA) test
Diagnostic confirmation AGID or CELISA test
Differential diagnosis list:
- Acute disease
- Chronic disease

Treatment There is no specific treatment
Control Compulsory identification and testing with eradication of infected horses

ETIOLOGY

The virus causing equine infectious anemia (EIAV) is a retrovirus, a member of the subfamily **Lentivirinae** of the family **Retroviridae**. The virus is an RNA virus that uses a reverse transcriptase enzyme to generate proviral DNA which is spliced into the host's genome. The virus infects only Equidae and there is not evidence that it infects or causes disease in humans. EIAV shares antigenic cross-reactivity with human and feline immunodeficiency viruses but not with the viruses causing caprine arthritis–encephalitis or maedi–visna of sheep. The virus has **one major group-specific antigen**, p26, that is conserved and is the basis of the agar gel immunodiffusion (AGID) and competitive ELISA diagnostic tests. There is considerable **antigenic drift** in the surface glycoproteins (gp45, gp90) and the emergence of novel antigenic strains within an individual horse is associated with the relapsing febrile reactions characteristic of the disease. Examination of variations in the viral regulatory protein, Rev, and the transmembrane protein, gp90, demonstrates the existence of viral quasispecies such that genetically distinct viral subpopulations of differing phenotype exist within a chronically infected, often asymptomatic, animal.[1,2] Mutations in gp45 and gp90 are random and related to the lack of a proof reading capacity of the viral reverse transcriptase enzyme.[3]

EPIDEMIOLOGY

Occurrence

EIA has been diagnosed on all continents except Antarctica. In Europe it is most prevalent in the northern and central regions. It has appeared in most states of the United States and the provinces of Canada but the principal enzootic areas are the Gulf Coast region and the northern wooded sections of Canada.[4]

Extensive **serological surveys** using the AGID (Coggin's) test have shown rates of infection of 1.5–2.5% in the United States, 6% in Canada, a low level in France, 1.6% in West Germany and 15–25% in Argentina. Within a geographic area, the **prevalence of infection** (positive AGID) varies depending on the density of the population, the proportion of carrier animals and the density of the population of insect vectors. Under ideal conditions the incidence of infection can approach 100% over a period of weeks, but this rapid spread is unusual.[5]

The **morbidity** varies considerably and depends on the strain of the virus and the inoculum delivered by the biting insect. Some horses become acutely ill and die after infection, while in others the infection is clinically inapparent. Outbreaks of disease associated with EIAV in horses of developed countries are rare.

Animal risk factors

Horses and ponies are susceptible to infection by EIAV and characteristically develop signs of the disease within days to weeks of infection. **Mules** also become infected and develop clinical signs similar to that of horses and ponies when infected with strains of the virus pathogenic to horses, but **donkeys** do not subsequently develop signs of the disease despite persistent infection with the horse-derived virus.[6,7] The resistance of donkeys to horse-derived strains of EIAV is not definitive evidence that donkeys do not develop equine infectious anemia and there is suspicion that strains of the virus pathogenic to donkeys exist.[7]

Methods of transmission

The source of all new infections of EIAV is an infected horse, donkey or mule. Horses are persistently infected and clinically normal infected horses are a source of the virus.[8] The virus can also be spread from clinically affected animals which, because of the high concentration of virus in their blood, are a potent source of infection and important in the rapid spread of infection. Transmission of EIAV occurs almost exclusively through the transfer of contaminated blood or blood products. In field conditions this occurs through the mechanical transmission of contaminated blood from an infected horse to an uninfected horse by biting insects.

Insect vectors

The insect vectors responsible for the transmission of EIAV between horses are all large biting flies including *Stomoxys calcitrans* (stable fly), *Chrysops* sp. (deer fly), and *Tabanus* sp. (horse flies). Mosquitoes are not recognized as an important vector. **Transmission is mechanical** because the virus does not replicate in insects and is related to the large (10 nL) quantity of blood that the biting insects are capable of holding in their mouth.[9] Infection occurs only if the feeding of the insect is interrupted. If this occurs the insect may attempt to feed again on the initial host or may seek another host that is close by. If the initial host is infected, the insect can carry blood from this animal to the second host and spread the infection. Tabanid flies can travel over a distance of 6 km, but when feeding is interrupted, the flies usually attempt to complete the meal on the initial host or a nearby animal and rarely travel more than 200 m to complete the meal.[10]

Insect factors that influence the likelihood of spread include[11]:

- Climate and season (tabanids prefer hot and humid conditions for feeding and breeding and their activity is much reduced or absent in winter months)
- Attractiveness of the host (foals are less likely to be bitten)
- Proximity of hosts to woodlands (tabanids preferred treed or sheltered habitat)
- Host housing (tabanids do not enter closed shelters)
- Distance between horses (as noted earlier, tabanids prefer to complete an interrupted meal on the initial host or a nearby host).

Other means of transmission

Intrauterine infection can occur and result in abortion or the birth of infected foals that often die within 2 months.[11] Mares can be infected by insemination with semen containing the virus. Infection can be readily achieved by the use of **contaminated surgical instruments** or needles or by the injection of minute quantities of virus, and the use of a common needle when injecting groups of horses can cause an outbreak of the disease. In enzootic areas outbreaks have been caused by the use of untreated **biological preparations** of equine origin.

The virus is also capable of invasion through intact oral and nasal mucosae, wounds and even unbroken skin, but these portals are probably of minor importance in field outbreaks. Transmission of infection from horse to horse seems possible via swabbing instruments used to collect saliva for doping tests.

Economic importance

The difficulty of diagnosis and the persistence of the 'carrier' state for periods of many years have resulted in embargoes on the introduction of horses into countries with a low prevalence of the disease, causing economic embarrassment and interference with sporting events.

PATHOGENESIS

Viral multiplication

After infection, EIAV multiplies in tissues that have abundant macrophages with the spleen being the principal site of viral infection and propagation and accounting for over 90% of cellular viral burden.[12] Viral replication occurs only in **mature tissue macrophages** and circulating monocytes account for only 1% of the cellular viral burden.[12] The concentration of cell free virus in blood, which can be as high as 10^6 $TCID_{50\%}$ per mL, parallels the clinical course. Fever and other clinical signs develop within **2–7 d of infection** as the concentration of virus in the blood increases, and resolves as the viremia abates. There is a persistent but low level viremia that persists for the life of the horse. The level of viremia in horses without clinical signs of the disease is very low and undetectable using conventional virus culture techniques but evident using PCR.[13] The virus is detectable in low concentrations in most tissues of asymptomatic horses.[12] During periods of **relapse** of the clinical disease the degree of viremia increases. On these occasions, the virus isolated from the blood has antigenic characteristics different than that which originally infected the horse. **Antigenic drift** of the gp45 and gp90 antigens, which occurs constantly even in asymptomatic horses with low levels of viremia, allows mutations of the virus that then avoid immune surveillance, multiply and cause clinical disease.[2] The frequency of relapses of the clinical disease declines markedly after the first year of infection and horses that survive become asymptomatic carriers.

Immune reaction

The immune response to EIAV is responsible for controlling replication of the virus and also plays an important role in the pathogenesis of the disease. The major clinical signs and lesions of equine infection anemia are attributable to the host response to the virus and not direct viral damage to tissue.[3] Replication of EIAV stimulates a strong immune response that is detectable in horses and ponies within 7–10 d of infection. The initial infection is likely controlled by **cytotoxic T-lymphocytes** before the appearance of **neutralizing antibodies**.[13] Antibodies to the p26 core protein are detectable by AGID test in almost all horses 45 d after infection and by 60 d after infection antibodies to gp45 and gp90 are present. The neutralizing antibodies are specific to the phenotype of virus causing the viremia – this phenotype can change over time as discussed above. Hypergammaglobulinemia develops. The immune response includes the production of virus neutralizing antibodies, complement-fixing antibodies, and cytotoxic T-lymphocytes.[13] The immune responses are responsible for the termination of viremia although this effect is not mediated by antibody-dependent cellular cytotoxicity against EIAV-infected macrophages,[14] but rather by development of neutralizing antibody and cytotoxic T-lymphocytes.[13] The importance of neutralizing antibodies in control of the disease within an animal is indicated by the observation that viremia is never associated with a virus with a neutralizing phenotype already recognized by the horse.[13]

Most virus in viremic horses is a complex of virus and antibody. The **virus-antibody complex** is readily phagocytosed by cells of the reticuloendothelial system, including tissue macrophages, and is involved in the development of the fever, depression, thrombocytopenia, anemia and glomerulonephritis characteristic of the disease.[15]

Neurologic disease in horses with EIAV infection is attributable to viral infection of neural tissue but not necessarily neurons.[15]

Anemia and thrombocytopenia

The **anemia** characteristic of horses experiencing several febrile episodes of EIA is attributable to shortened life of red blood cells and decreased red cell production. Infection with EIAV shortens the lifespan of circulating red blood cells to about 38 d, compared with the normal value of 130 d.[16] The reduction in red blood cell lifespan is likely due to the presence of virus–antibody complexes on the surface of red blood cells with subsequent clearance of such cells by the reticuloendothelial system as evidenced by the presence of sideroleukocytes in peripheral blood of infected horses. EIAV also has a suppressive effect on erythroid series cells in bone marrow.[17] Anemia occurs in Arabian foals with severe combined immunodeficiency infected with EIAV, indicating that the anemia is not wholly due to the adaptive immune response of the host.[18] Anemia of chronic disease, which is due in part to limited availability of iron stores, likely contributes to the lack of bone marrow response.

Thrombocytopenia is a consistent feature of the acute, febrile episodes of EIA and has been attributed to the deposition of virus–antibody complexes on platelets with subsequent removal of affected platelets by tissue macrophages.[19] However, others have identified a primary production deficit due to an indirect, non-cytocidal suppressive effect of EIAV on megakaryocytes.[20] EIAV does not infect megakaryocytes and the suppressive effect of infection is due at least in part to tumor necrosis factors alpha and beta.[20,21] Another explanation for the thrombocytopenia is increased removal of platelets because of increased in vivo activation and formation of platelet aggregates, a form of non-immune mediated platelet destruction.[22] This was associated with increased thrombopoiesis and an increase in the proportion of young platelets in blood.[22] The precise mechanisms underlying the thrombocytopenia associated with acute EIAV infection of horses is unclear.

Platelets of EIAV infected horses with clinical signs of disease have diminished function in vitro.[22] Platelets from infected horses had greater amounts of fibrinogen bound to their surface, ultrastructural abnormalities consistent with activation, and diminished in vitro aggregation responses.[22]

Persistence of infection

The **cell reservoir of virus** in persistently infected horses is unknown, as are the mechanisms underlying latency. However, the ability of retroviruses to **splice a DNA copy of their genome** into the genome of the host is probably important in the persistence of viral infection. Viral genome is detectable in clinically normal but persistently infected horses.[6] Presence of viral DNA in host tissue is indicative of infection whereas the presence of viral RNA in blood is suggestive of viral replication.[6] This viral strategy allows the virus to escape immune surveillance of the host. Factors triggering a relapse of

virus production from the latent genome are unknown, but relapse is associated with antigenic drift.

Summary of pathogenesis

A likely scheme of pathogenetic events includes:

- Primary entry and infection of tissue macrophages, especially in the spleen
- Destruction of macrophages and release of virus and components
- Production of antibodies to antigenic components
- Formation of antigen–antibody complexes, which induce fever, glomerulitis, anemia, thrombocytopenia and complement depletion
- Hemolysis or phagocytosis caused by specific complexes activating the reticuloendothelial system
- Temporary iron-deficient erythropoiesis caused by delayed release of iron from macrophages
- Subsidence of pathological processes as virus-neutralizing antibody restrains viral multiplication in macrophages. The virus is incorporated into the host genome and becomes latent
- Appearance of a new antigenic variant of the virus and commencement of a new cycle of viral replication in macrophages and a new clinical episode. The antigenic variation is due to changes in the surface glycoprotein of the EIA virus
- Less frequent recurrence of these episodes and the horse becomes permanently asymptomatic. The animal can be said to have achieved an appropriate level of immune response sufficient to protect it against antigenic epitopes that are common to all EIA virus strains.

CLINICAL FINDINGS

An **incubation period** of 2–4 weeks is usual in natural outbreaks of equine infectious anemia. Outbreaks usually follow a pattern of slow spread to susceptible horses after the introduction of an infected animal. On first exposure to infection, horses manifest signs of varying degree, classified as acute or subacute. Occasionally the initial attack is mild to inapparent and may be followed by rapid clinical recovery. As a rule there is initial **anorexia, depression, profound weakness** and loss of condition. Ataxia, behavioral changes, hyperesthesia and blindness occur and in some horses is recorded as the only clinical abnormality.[18,23] There is intermittent fever (up to 41°C; 105°F) which may rise and fall rapidly, sometimes varying as much as 1°C within 1 h. Jaundice, edema of the ventral abdomen, the prepuce and legs, and petechial hemorrhages in the mucosae, especially under the tongue and in the conjunctivae, may be observed. Pallor of the mucosae does not occur in this early stage and they tend to be congested and edematous. There is a characteristic increase in rate and intensity of the heart sounds, which are greatly exacerbated by moderate exercise. Respiratory signs are not marked and there is no dyspnea until the terminal stages, but there may be a thin serosanguineous nasal discharge. There is considerable enlargement of the spleen which may be detectable per rectum. Pregnant mares may abort. Many animals recover from this acute stage after a course of 3 d to 3 weeks. Others become progressively weak, recumbent and die after a course of 10–14 d of illness.

Animals recovering from the acute disease may appear normal for 2–3 weeks and then **relapse** with similar but usually less severe signs. Death may occur during such a relapse. Relapses continue to occur at intervals of as little as 2 weeks but usually cease after about a year. If they recur, they are usually associated with periods of stress and characterized by fever, increasing emaciation, weakness, ventral edema, and the development of pallor of the mucosae, a late sign of this disease. In this chronic stage, the appetite is usually good, although allotriophagia may be observed. Some affected animals appear to make a complete recovery but they remain infected and may suffer relapses in later years. Prolonged therapy with corticosteroids can cause such a relapse. Even in the absence of clinical illness infected animals often perform less efficiently than the uninfected. Most deaths occur within a year of infection. Survivors persist as asymptomatic carriers.

CLINICAL PATHOLOGY

Hematological examination of horses with the acute disease reveals a moderate to marked **thrombocytopenia** and an **anemia** that may be severe. Thrombocytopenia occurs during relapses of the disease, is most severe during the febrile episodes, and may be sufficiently low that it allows petechial hemorrhages to develop. The anemia may become more severe with relapse (14–20%, 0.14–0.20 L/L) and is normocytic and normochromic. The presence of **sideroleukocytes** (leukocytes containing hemosiderin) are considered highly suggestive of EIA.[24] There are no characteristic changes in the white blood cell count.

Hypergammaglobulinemia may be present. Serum biochemical examination may reveal an increase in bilirubin concentration and a decrease in serum iron concentration.

DIAGNOSTIC CONFIRMATION

Diagnostic confirmation is achieved through detection of antibodies to the p26 core antigen of EIAV. Two tests are in general use: the AGID test (Coggin's test) and a number of ELISAs including a competitive ELISA (CELISA) test.[25,26] Results of AGID testing are available in 24 hours while those of ELISA testing can be available in as little as one hour. Two commercially available ELISA tests detect antibody to the p26 antigen whereas the other detects antibody to the gp45 transmembrane protein. The ELISA tests inherently have greater sensitivity (detect lower concentrations of antibody) than does the AGID but often the characteristics of the commercial ELISA assays are modified to decrease the sensitivity (increase the lowest concentration of antibody detected by the kit) so that results obtained with these kits are concordant with those obtained by AGID.[25] The ELISA for detection of antibodies to gp45 has a slightly lower sensitivity than do those that detect antibody to p26.[27] For practical purposes the tests may be considered to have equal sensitivity and specificity, and are very accurate in the diagnosis of EIA.[26] However, the CELISA test can detect lower concentrations of antibody than the AGID can, therefore suspected false-negative or equivocal tests based on the AGID can be repeated using the CELISA.[26] Conversely, the CELISA has a slightly higher false-positive rate than the does the AGID, and positive reactions on the CELISA should be verified by AGID. A positive AGID test is accepted as synonymous with being infected and infective.

An advantage of an ELISA that detects antibodies to gp45 antigen is that, when combined with testing for antibodies to p26, the ability to detect infected horses with equivocal test results on a single test is increased.[25] This is similar to the technique of using a **Western blot test** to demonstrate the presence of antibodies to more than one antigen, especially those against the gp45 and gp90 antigens, when equivocal AGID or ELISA results are obtained.

False-negative reactions for either test may occur because the horse lacks antibodies to the p26 antigen. The AGID and CELISA tests might not detect a **recently infected** horse that has yet to develop antibodies. Some horses do not develop anti-p26 antibodies for 45 d after infection. **False-positive reactions** may occur in foals born to infected mares. Colostral transfer of anti-p26 antibodies to the foal will be detectable up to 6 months after birth.

Positive reactions to ELISA testing (to the p26 antigen) in samples that are negative by AGID testing can be the result of

Table 21.1 Algorithm for testing horses for infection by equine infectious anemia virus when the prevalence rate is less than 1 in 1000.

Collect sample and separate serum from red cells as soon as possible.
Test sample using a p26-based ELISA.
If negative, report the results. (False-negatives with p26-based ELISA occur with lower frequency than with AGID).
If repeatedly positive, confirm with another p26-based ELISA, then a gp45-based ELISA.
If positive for both p26 and gp45-based ELISA then infection is confirmed and a report issued.
If negative on the second p26-based ELISA and/or the gp45-based ELISA, then perform an AGID.
If negative on all but the initial test, report as negative.
If positive on any two tests, then perform an immunoblot test to confirm reactions to both p26 and gp45. If only p26 is recognized then the horse is not considered infected with EIAV (interspecies determinants – see text). If gp90 and/or p26 and gp45 are recognized, then the horse is infected and a positive report issued.
If the prevalence is high (approximately 1 in 10 horses) then samples with equivocal results on ELISA testing should be examined by immunoblot. This additional testing is indicated because of the high risk of false-negative reactions when large numbers of horses from a population with a high prevalence of the disease are tested.
If equivocal test results are obtained, repeat testing on samples obtained from the horse approximately 2 weeks after the initial sample was collected.

interspecies determinants.[26] It is suspected that horses exposed to related lentivirus produce antibodies to structural proteins that cross react with the EIAV p26 antigen in ELISA, but not AGID, testing.

An algorithm for testing of equine samples for EIAV is provided in Table 21.1.

Tests to detect proviral DNA or viral RNA in blood and tissue have been developed and are useful in detecting the presence of virus when viral concentrations in blood and/or tissue are low.[28,29] The identification of proviral DNA in blood of infected horses is as specific and apparently more sensitive than the AGID in detecting infected horses.[29]

Experimental transmission of the disease to susceptible horses by the SC injection of 20 mL whole blood or Seitz-filtered plasma is also used as a diagnostic test and is a valuable, although expensive and archaic supplement to other tests. The donor blood should be collected during a febrile episode when the viremia is most pronounced, and the recipient animals are checked for increases in body temperature twice daily.

NECROPSY FINDINGS

In the acute stages, there may be subcutaneous edema, jaundice and petechial or ecchymotic subserosal hemorrhages. There is considerable enlargement of the liver and spleen, and local lymph nodes. The bone marrow is reddened due to increased amounts of hematopoietic tissue and may contain focal infarcts. In the chronic stages, emaciation and pallor of tissues are often the only gross findings. Histological examination is helpful in the diagnosis, even in asymptomatic chronic carriers. Characteristic lesions include hemosiderosis, perivascular infiltrates of round cells in many organs, and an extensive proliferation of the mononuclear phagocytic cells throughout the body. A glomerulitis, probably caused by the deposition of virus–antibody complexes on the glomerular epithelium, may be present. Lesions in the brain are a lymphohistiocytic periventricular leukoencephalitis.[15] Culture of this virus is time-consuming and the diagnosis is usually confirmed on the basis of a positive serologic test and typical microscopic lesions.

Samples for confirmation of diagnosis

- **Histology –** formalin-fixed spleen, liver, bone marrow, kidney, lung, heart
- **Serology –** heart blood or pericardial fluid (AGID, ELISA)
- **Virology (if desired) –** chilled spleen, liver, bone marrow and perihepatic lymph node (ISO).

DIFFERENTIAL DIAGNOSIS

Acute disease
- Purpura hemorrhagica
- Babesiosis
- Equine granulocytic ehrlichiosis
- Equine viral arteritis
- Autoimmune hemolytic anemia
- Leptospirosis
- Parasitism
- Idiopathic thrombocytopenia.

Chronic disease
- Internal abscessation (metastatic *Streptococcus equi* infection
- Chronic inflammatory disease, neoplasia and chronic hepatitis.

TREATMENT

No specific treatment is available. Supportive treatment including blood transfusions and hematinic drugs may facilitate clinical recovery but it is important to remember that recovered horses are persistently infected and infectious for life.

CONTROL

Control of EIA is based on **identification and eradication or life-long quarantine of infected animals**, quarantine and testing of new stock, compulsory testing of imported horses, and efforts to prevent spread of the virus by controlling insect access to horses and use of strict hygiene when vaccinating or collecting blood samples from horses.

The control of equine infectious anemia is still universally based on the eradication of the disease by identifying the infected, clinically normal animals with a serological test and then destroying them. Identification is by means of the AGID or CELISA tests. The ability of a program of test and eradication to eliminate the disease is evidenced by the eradication of EIA from Hong Kong. An effective control program is described for Kentucky in the United States that permits the maintenance of infected horses with indelible identification and prescribed restrictions on housing.[30]

Control programs based on this test-and-slaughter policy are under fire because of the view of horse owners that many asymptomatic horses, with very low infectivity, are being destroyed unnecessarily. A decision on the matter depends on whether the objective is eradication or containment, and if the latter, at what level. Until now the policy has been eradication and it is obvious that another attitude is possible. Some flexibility in official attitude is desirable because of the fallibility of the recommended control procedures and the devastating losses that can occur when the optimum environment for the spread of the disease is encountered.

Foals from infected mares can be raised free of infection.[31] Such foals have detectable antibodies to EIAV for up to 330 days on immunoblot and 260 days on ELISA testing because of transfer of maternal immunoglobulins in colostrum during the neonatal period. However, foals that are ultimately free of infection do not have detectable viral RNA in blood and have declining concentration of antibodies to EIAV.[31] Foals should be isolated from infected horses as soon as feasible after diagnosis of EIAV infection in the dam.

Restriction of introduction of infected horses into clean herds or areas is important to prevent introduction of the disease. Horses should be tested before introduction to the herd, and perhaps again in 1 to 2 months. If suspect horses are to be introduced, they should be kept under close surveillance for at least 6 months before being admitted. Horses known or suspected to be infected should be separated from all other uninfected horses, donkeys and mules by a distance of at least 200 m. This recommendation is based on observations of the feeding behavior of tabanids, which are very unlikely to fly more than 100 m after an interrupted feeding. **Suspect positive horses** should be retested after at least 1 month and probably at regular intervals thereafter. Operators of open stud farms, and rest farms can also insist on proof of a negative test before admitting each horse. One deficiency of this policy is the long period of 'incubation' of up to 45 d between infection and seroconversion to a positive test.

In countries where the incidence is high, it is usual to control horse movement by a system of permits and certificates of freedom from the disease, and to insist on skin branding or lip tattooing of all horses. AGID or ELISA test-positive horses should be allowed to move only under specified conditions.[26]

Draining of marshy areas and the **control of biting insects** may aid in limiting spread of the disease. A degree of protection may be obtained by the use of **insect repellents** and by stabling in screened stables. Great care must be taken to avoid transmission of the disease on **surgical instruments** and hypodermic needles, which can only be sterilized by boiling for 15 min or by autoclaving at 6.6 kg pressure for a similar period. Chemical disinfection of instruments and tattoo equipment requires their immersion for 10 min in one of the less corrosive phenolic disinfectants. All materials to be disinfected need to be cleaned of organic matter first. For personal disinfection sodium hypochlorite, ethanol or iodine compounds are safe, and for materials where organic matter is not removable, agents such as chlorhexidine or phenolic compounds combined with a detergent are satisfactory.

There are considerable problems associated with development of vaccines against EIA because only neutralizing antibodies are capable of causing sterile immunity and preventing infection.[13] Neutralizing antibodies are specific for the homologous virus, but the large variation in phenotypes of the wild virus means that it will be difficult to stimulate neutralizing antibodies protective against all of the possible infecting phenotypes.

Vaccines are available in parts of the world but are not in general use. Killed, whole virus vaccines are safe but subunit vaccines may actually enhance the occurrence of the disease.[32] An experimental live attenuated EIAV DNA proviral vaccine affords complete protection in experimentally infected horses but is not commercially available at the time of writing.[33]

BOVINE EPHEMERAL FEVER

Synopsis

Etiology Arthropod-borne rhabdovirus of the genus *Ephemerovirus*
Epidemiology Enzootic in tropical areas. Transmitted by insect vectors. Episodic epizootics in summer in incursive areas probably initiated by wind-borne transmission of insect vector. High morbidity but low case fatality
Clinical findings Disease of cattle with fever, respiratory distress, muscular shivering, stiffness, lameness and enlargement of the peripheral lymph nodes
Generally spontaneous recovery in three days and low case–fatality rate
Clinical pathology Leukocytosis, hyperfibrinogenemia, hypocalcemia, elevated creatine kinase. Blocking ELISA for serology
Necropsy findings Serofibrinous polyserositis
Diagnostic confirmation Demonstration of specific bovine ephemeral fever (BEF) viral antigen by immunofluorescence or by isolation in mice
Treatment Non-steroidal anti-inflammatory drugs cause remission of clinical signs
Control Vaccination and supportive treatment

ETIOLOGY

Ephemeral fever is associated with an arthropod-borne rhabdovirus which is the type species of the genus *Ephemerovirus*. There are a number of strains that vary antigenically.[1,2] Other antigenically related but non-pathogenic species of *Ephemerovirus* occur in the same environment in Australia. The BEF virus is closely associated with the leukocyte–platelet fraction of the blood, and can be maintained deep frozen or on tissue culture and chick embryos.

EPIDEMIOLOGY

Occurrence

A disease of cattle, ephemeral fever is enzootic in the tropical areas of Africa, in most of Asia, the Middle East, the East Indies, and in much of Australia with extensions into the subtropics and some temperate regions. In these areas the disease presents as episodic epidemics. Area outbreaks can last several months, with the spread of infection following prevailing winds, and during this period most herds within a region will be infected. The proportion of herds affected in outbreaks in the Jordan Valley in Israel in 1990 and 1999 were 78.5% and 97.7% respectively.[3]

The morbidity rate in outbreaks is usually between 25% and 45%, but if the population is highly susceptible or the infecting strain virulent, the morbidity rate may reach 100%. In enzootic areas, only 5–10% will be affected. A case–fatality and loss from involuntary culling rate of 1% is usual with low virulence strains but can approach 10%.[4,5]

Source of infection

The source of infection is the animal affected with the clinical disease and biological vectors.

Method of transmission

A great deal of work in recent years has not clearly defined the **vector** list which probably includes the mosquitoes *Aedes* spp., *Culex annulirostris*, *Anopheles bancroftii* and *A. annulipes*, and the biting midge *Culicoides brevitarsis*.[6,7] *Culex annulirostris* has been identified as a biological vector in Australia.[8,9] This mosquito can transmit

infection within a week of feeding on an infected animal and the epidemiology of the disease in Australia supports transmission by mosquitoes rather than *Culicoides* spp.[10]

The **reservoir** host, other than cattle, has not been identified. This is of particular importance when the epidemiological pattern of occurrence of the disease changes as it has done in Australia. The disease now occurs annually in areas where it used to occur only once each decade, probably because of establishment of the virus in indigenous vectors.[11]

Spread by **wind-borne carriage** of vectors is suspected.[12, 13] Epidemiological studies suggest that outbreaks in Japan originate from Korea.[13] Spread is largely **independent of cattle movement**, and transmission does not occur through contact with infected animals or their saliva or ocular discharge. The disease is not spread through semen, nor is intrauterine administration of the virus a suitable route of transmission.

Experimental reproduction

The disease can be transmitted by the injection of whole blood or the leukocyte fraction of it. Experimental reproduction in cattle requires intravenous administration and viremia lasts 3 days with a maximum of 2 weeks. There is no carrier state.

Environment risk factors

The disease occurs in the **summer** months, outbreaks are **clustered** and relatively **short lived**,[13] and spread depends largely on the insect vector population and the force and direction of prevailing winds.[3] The disease tends to disappear for long periods to return in epizootic form when the resistance of the population is diminished.

Recurrence depends primarily on suitable environmental conditions for increase and dissemination of the insect vector.[6] During periods of quiescence the disease is still present but the morbidity is reputed to be very low. However, in many enzootic areas the degree of surveillance is less than intense and clinical cases may occur without being observed. Temporary protection against infection is provided by subclinical infections by other unrelated arboviruses, e.g. Akabane, Aino, and others.[11]

Animal risk factors

Among domestic animals, only **cattle** are known to be naturally affected but antibodies can be found in African ruminant wildlife. All **age groups** of cattle are susceptible but calves less than 3 to 6 months old are not affected by the natural disease. With experimental infections calves as young as 3 months old are as susceptible as adults to experimental infection but do not show clinical disease.

In dairy cattle, higher producing cows are at greater risk and clinical disease may be minimal in cows under 2 years of age. A recent Israeli study in 10 beef herds found an average morbidity and mortality rate of 46.2% and 4.8% respectively with higher rates in bulls than cows and a higher morbidity in cows 2 to 5 years of age than in heifers less than 2 years of age.[14] In natural outbreaks there is no breed susceptibility.[12]

In Africa, based on serological results, the virus is thought to be cycling in populations of wild ruminants between epidemics in domestic cattle. Buffalo (*Bubalus bubalis*) are susceptible to experimental infection, but it is unlikely that they play any part as a reservoir host.[15] After experimental infection of cattle there is solid immunity against homologous strains for up to 2 years. Immunity against heterologous strains is much less durable which probably accounts for the apparent variations in immunity following field exposure.

Economic importance

Although the case–fatality rate is very low, considerable loss occurs in **dairy herds** due to the depression of milk flow – up to 80% in cows in late lactation. In an Israeli study of eight infected dairy herds, the decline in milk yield from preinfection levels varied between cows and ranged from 30% to 70% with the highest yielding cows having the greatest drop. Following recovery from disease, milk production was still less than that of preinfection levels.[4]

There is also a lowered resistance to mastitis. Reproductive inefficiency is associated with a significant delay in the occurrence of estrus, abortion in cows and temporary sterility in bulls. Occasional animals die of intercurrent infection, usually pneumonia, or prolonged recumbency. BEF can have a serious effect on the agricultural economy in countries where cattle are used as **draught animals**. For cattle-exporting countries such as Australia, BEF causes interference with movement of cattle when receiving countries insist on evidence of freedom from the disease.

PATHOGENESIS

Experimental production of the disease requires the IV route of transmission. Virus multiplication probably occurs primarily within the **vascular system**.[8] After an incubation period of 2–10 days, there is a biphasic fever with peaks 12–24 h apart.[16] The fever lasts 2 d and increased respiratory rate, dyspnea, muscle trembling, limb stiffness and pain are characteristic at this time.[17]

There is **generalized inflammation** with vasculitis and thrombosis, serofibrinous inflammation in serous and synovial cavities, and increased endothelial permeability at the same sites.[18] The virus can be detected in circulating neutrophils and plasma, the serosal and synovial fluids, the mesothelial cells of synovial membrane and epicardium, and in neutrophils in the fluids.[8] Clinical signs are believed caused by the expression of mediators of inflammation coupled with a secondary hypocalcemia.[14]

CLINICAL FINDINGS

Calves are least affected, those less than 3 to 6 months of age showing no clinical signs. Overweight cows, high producing cows, and bulls are affected the most.

In most cases the disease is acute. After an incubation period of 2–4 d, sometimes as long as 10 d, there is a sudden onset of **fever** (40.5–41°C; 105–106°F), which may be biphasic or have morning remissions. **Anorexia** and a sharp **fall in milk yield** occur. There is severe constipation in some animals and diarrhea in others. Respiratory and cardiac rates are increased, and stringy nasal and watery ocular discharges are evident. The animals shake their heads constantly and muscle shivering and weakness are observed. There may be swellings about the shoulders, neck and back.

Muscular signs become more evident on the second day with severe **stiffness**, clonic muscle movements and weakness in one or more limbs. A **posture** similar to that of acute laminitis, with all four feet bunched under the body, is often adopted. On about the third day, the animal begins eating and ruminating, and the febrile reaction disappears, but lameness and weakness may persist for 2–3 more days.

Some animals remain standing during the acute stages, but the majority go down and assume a position reminiscent of parturient paresis, associated with **hypocalcemia**, with the hindlegs sticking out and the head turned into the flank. Occasionally, animals adopt a posture of lateral recumbency. Some develop clinically detectable pulmonary and SC emphysema, possibly related to a nutritional deficiency of selenium.[19] In most cases recovery is rapid and complete after an illness of 3–5 d unless there is exposure to severe weather, or unless aspiration of a misdirected drench or ruminal contents occurs. Some cases have a second episode of clinical disease 2 to 3 weeks after recovery.

Occasional cases show persistent recumbency and have to be destroyed and abortion occurs in a small proportion of cases. Affected bulls are temporarily sterile. Milder cases, with clinical signs restricted to pyrexia and lack of appetite, may occur at the end of an epizootic.

CLINICAL PATHOLOGY

Blood taken from cattle in the febrile stage clots poorly.[20] A marked **leukocytosis** with a relative increase in neutrophils occurs

during the acute stage of the disease. There is a shift to the left and a lymphopenia. Plasma fibrinogen levels are elevated for about 7 d[17] and there is a marked increase in **creatine kinase**. In natural cases, but not experimentally produced ones, a significant **hypocalcemia** occurs.[17,21,22] Available serological tests include a complement fixation test, serum neutralization, fluorescent antibody test, agar gel immunodiffusion (AGID) test,[19] and a **blocking ELISA**, which is reported to be simple and the preferred test.[23]

NECROPSY FINDINGS

Postmortem lesions are not dramatic. The most consistent lesions are a **serofibrinous polyserositis**, involving synovial, pericardial, pleural and peritoneal cavities, with a characteristic accumulation of neutrophils in these fluids and surrounding tissues. Hemorrhage may also be observed in the periarticular tissues, and there may be foci of necrosis in the musculature of the limbs and back. All lymph nodes are usually enlarged and edematous. **Pulmonary emphysema** and fibrinous bronchiolitis are standard findings and subcutaneous emphysema along the dorsum may be observed. Characteristic microscopic findings consist of a mild vasculitis of small vessels, with perivascular neutrophils and edema fluid plus intravascular fibrin thrombi.

Necropsy examinations of animals that develop persistent recumbency have shown severe degenerative changes in the spinal cord similar to those produced by physical compression but the pathogenesis of these lesions remains uncertain. Although nucleic acid sequences of the agent are known, PCR tests are not yet widely utilized.

Antigen in reticuloendothelial cells can be detected by immunoperoxidase and immunofluorescent techniques [24]

Samples for confirmation of diagnosis

- **Virology** – chilled lung, spleen, synovial membrane, pericardium (ISO)
- **Serology** – pericardial fluid (ELISA)
- **Histology** – formalin-fixed samples of above tissues.

DIFFERENTIAL DIAGNOSIS

The diagnosis of ephemeral fever in a cattle population is not difficult on the basis of its epidemiology and clinical presentation. It can produce difficulties in individual animals where differentials include:

- Botulism
- Parturient paresis
- Pneumonia
- Traumatic reticulitis.

TREATMENT

Palliative intramuscular treatment with the **non-steroidal anti-inflammatory** drugs phenylbutazone (8 mg/kg at 8-hour intervals) or flunixin meglumine (2.2 mg/kg/d) or with ketoprofen (3 mg/kg/d) result in **remission** of signs without in any way influencing the development of the disease.[21,22,25,26] There is little effect on the respiratory manifestations of the disease but a major effect on stiffness, lameness and anorexia. All treatments are continued for 3 days. Phenylbutazone may be most effective but the injection frequency is less practical. Parenteral treatment with **calcium borogluconate** should be given to cows that show signs of hypocalcemia and field observations are that parenteral treatment with calcium solutions often helps to get a recumbent cow to her feet. Proper nursing of the recumbent animal is required.

CONTROL

Restriction of movement from infected areas is practiced but **vaccination** is the only effective method of control. Vaccines prepared from **attenuated** tissue culture virus or in mouse brain and adjuvanated in Freund's incomplete or Quil A adjuvants are commercially available in Australia, Japan, Taiwan and South Africa. Two vaccinations are required and are effective in preventing disease in natural outbreaks for periods up to 12 months.[27] The use of vaccination in Japan is credited with preventing further major outbreaks.[13] Attenuated vaccines are expensive to produce, have a short shelf-life, and breakdowns are recorded after their use. Formalin **killed** vaccines are used, with and without adjuvants, and give protection for approximately 6 months, requiring frequent boosting for effect.[2,5] Vaccines prepared from the envelope glycoprotein (G protein) protect against experimental challenge.[21] Immunity is positively correlated with the level of specific antibody measured with a blocking ELISA or as virus neutralizing antibody.

AFRICAN HORSE SICKNESS

Synopsis

Etiology African horse sickness virus
Epidemiology Infectious, non-contagious, arthropod-borne disease of horses, donkeys and mules endemic to sub-Saharan Africa. Epizootics occur in the Iberian peninsula, Mediterranean coasts, Middle East and Indian subcontinent
Clinical signs *Pulmonary form*: fever, respiratory distress, frothy nasal discharge, death. *Cardiac form*: fever, edema of the head and ventral chest, hydropericardium. *Mixed form* has characteristics of both pulmonary and cardiac forms. *Horse fever*: mild fever, often inapparent infection
Clinical pathology Leukopenia, disseminated intravascular coagulation. Serology often negative in horses that die acutely
Lesions Pulmonary edema, hydropericardium, ascites, edema of the gastrointestinal tract
Diagnostic confirmation Histopathology. Detection of virus by cultivation or reverse transcriptase-polymerase chain reaction (RT–PCR) in blood or tissues
Differential diagnosis list:
- Pulmonary form
- Cardiac form

Treatment None Supportive care
Control specific *Enzootic area*: vaccination, reduce exposure to biting insects. Quarantine and eradication in non-enzootic areas

African horse sickness is an important disease of horses and mules in southern and central Africa and, during epizootics, in northern Africa and the Arabian and Iberian peninsulas. The disease in southern Africa occurs as frequent, intermittent small outbreaks and as periodic epidemics that kill large numbers of horses. An epidemic during 1854–55 killed over 17 000 horses, 40% of the horse population, in the Western Cape region. During pre-mechanized exploration and development of southern and central Africa and

during the Boer war the disease had a major economic and military impact. For example, during a single campaign in the Boer War, of 1732 British horses involved 323 died of African Horse Sickness within a 17 day period in late April, 1901.[1]

ETIOLOGY

African horse sickness (AHS) is associated with a viscerotropic orbivirus (family Reoviridae) of which nine antigenic strains (serotypes) are recognized. The serotypic differences are due to variations in the capsid proteins, predominantly VP2 and to a lesser extent VP5. VP2 contains the predominant neutralizing epitopes although antibodies to VP5 are one of the earliest serologic markers of infection and have neutralizing activity.[2] Lineages are also evident within serotypes and the resultant clades are grouped geographically, at least for the serotypes studied.[3] Identification of clades facilitates epidemiologic studies.[3] There are also variants of each serotype with attenuated virulence.[4] No new serotypes have been identified since 1960 and all virtually all epidemics outside of southern Africa, with the exception of that in the Iberian peninsula in 1987–90 (serotype 4), were caused by serotype 9.[5] The virus is similar to other animal orbiviruses including bluetongue virus, enzootic hemorrhagic disease virus, and equine encephalosis virus. The host range includes equids (horses, donkeys, mules, zebra), elephants, camels, sheep, goats, and predatory or scavenging carnivores.[4] Infection produces disease in horses and mules, and less commonly African donkeys, but rarely in the other herbivorous hosts.

The virus is inactivated by heating at 50°C for 3 hours or 60°C for 15 minutes, is stable at 4°C, and survives for 37 days at 37°C. It remains viable at pH of 6–12, but is inactivated by acid and in 48 hours by 0.1% formalin or phenol, sodium hypochlorite, and iodophores.[6,7]

Disease associated with African horse sickness virus is on List A of the Office International des Epizooties.[6]

EPIDEMIOLOGY

African horse sickness is an **infectious but not contagious** disease of Equidae. It is spread by the bite of blood-feeding insects.

Occurrence

The disease is **enzootic in sub-Saharan Africa**, causing clinical disease in horses, donkeys, mules and dogs, and infecting zebras, elephants and perhaps other wildlife.[8] The disease occurs from Senegal through sub-Saharan Africa to Somalia.[5] The disease makes occasional incursions into Iran, Pakistan, India, Turkey and the eastern Mediterranean and Cyprus. The virus occurs in the Middle East, including Saudi Arabia and the Yemen. It does not appear to be enzootic to Saudi Arabia[9] although the long-term status of this region is uncertain. In 1987 the disease recurred in Spain through introduction of infected zebras into a game park. By 1990 the disease had spread throughout Spain and Portugal but was eliminated by 1991.

South Africa

The disease has been recognized in South Africa since shortly after introduction of domesticated horses in the 1600s. The disease occurred throughout what is now South Africa in the 19th and early 20th centuries, but as an enzootic disease became restricted to the north east of the country in the middle and later part of the 20th century. The geographic contraction of disease was associated with elimination of large herds of wild zebra from all except the game parks of the north east of the country. Elimination of zebra, the reservoir of infection, reduced the occurrence of the disease dramatically.[10] Outbreaks of disease outside of the endemic areas in the north east of South Africa are associated with introductions of virus from endemic areas at times of high abundance of *Culicoides* spp., the vector. The disease does not overwinter in the essentially zebra-free non-endemic areas. Serotype 9 causes enzootic disease in central Africa in the absence of zebra – the wildlife host has not been identified.

African horse sickness occurred in 1999 in the surveillance zone of the Cape Province of South Africa surrounding the disease-free area of Cape Town. The virus (serotype 7) was of a clade identical to that found in Kwazulu Natal Province[13] and its introduction was by the movement of infected horses from that region into the Cape Province.

Transmission of infection

African horse sickness virus (AHSV) is transmitted by the **bite of hematophagous insects** including midges (*Culicoides* spp.), ticks (*Hyalomma dromadarii* and the brown dog tick, *Rhipicephalus sanguineus*), and mosquitoes (various species in laboratory studies).[11] **Midges** are by far the most important vector in the spread of the spontaneous disease. The source of virus for midges is blood of infected horses, donkeys, mules and zebra. Horses and mules have clinical signs of disease while viremic, but donkeys are often and, most importantly, zebra are always, inapparently infected. Zebras may remain viremic for 6 weeks, donkeys for 12 d, and horses for 18–21 d.[10,12,13] Dogs are infected by eating infected animals, although transmission to and from dogs by ticks can occur.

Transmission of the virus to areas where it does not usually exist occurs both by movement of infected animals, such as zebras and horses, and by transportation of midges by wind. Mechanical transmission of the virus on contaminated surgical instruments and needles should be considered a possibility.

Zebra

In areas in which the disease is enzootic, the virus persists by cycling between the mammalian host, the zebra, and vectors year round.[10,12] Zebra in enzootic areas can seroconvert during any month of the year, indicating that persistence of the virus is associated with sequential infection of zebra within a herd or region. Persistence of the virus in a region is attributable to the long period of viremia in zebra and the presence of a herd of sufficient size to support cycling of infection among animals. The minimum size of a zebra population to maintain an enzootic infection is unknown.[10] However, in areas in which the disease is not enzootic, the virus does not persist over the cooler winter months when viremic animals recover and the vectors die. Concern exists that reintroduction of zebra to areas of the country currently free of enzootic AHS might permit reestablishment of the virus and disease in horses.[5,10]

Midges

Midges are infected with AHSV, that is they are not mechanical vectors but rather the virus infects and replicates in the midge, although transovarial transmission of infection between generations of midges does not occur. *C. imicola* is the vector responsible for the transmission of AHSV within its enzootic area, and during epizootics. C. *bolitinos* is also a vector of AHSV in southern Africa[14] while a number of other *Culicoides* spp. are unlikely to be vectors as they are unable to maintain infection with virus 10 days after ingesting a meal of infected blood.[15] However, *C. varipenis*, *C. pulicaris*, and *C. obsoletus* are competent and likely important vectors because of their ability to maintain infection over winter, as demonstrated in Portugal.[16]

The abundance of midges can be predicted from measures of soil moisture content and land surface temperature.[4] Midges breed in damp soils that are rich in organic material, such as irrigated pastures, that provide soil moisture adequate for completion of the life cycle (at least 7 to 10 days).[5] Higher temperatures increase the rates of infection of midges, virogenesis within midges, and transmission rate but decrease midge longevity.[5] Replication of AHSV in midges does not occur at temperatures <15°C although midges continue to be active at 12°C. Midges can be transported by winds for up to 700 km.[17]

Risk factors

Environment factors

The incidence of the disease is often **seasonal** because of the seasonal variations in the number of *Culicoides* spp. present and possibly other weather related factors such as host (zebra) behavior. Vector activity is favored by temperatures between 12.5 and 29°C and it is likely that several cool or cold episodes, rather than one 'killing frost', are necessary to kill all or most vectors.[12] Local factors, including topography, influence the distribution of midges within their overall range and therefore the disease has a geographical distribution: the areas most severely affected are low lying and swampy.

Epizootics of AHS occur in southern Africa in association with variations in the El Nino/southern oscillation.[18] Epizootics of the disease occur in years in which the oscillation produces drought followed by heavy rains. The reason for this association, which was first anecdotally reported in the 1800s, is unknown but could be related to congregation of zebra around water holes during the drought. Congregation of large numbers of zebra might increase the infection rate among midges which then disseminate the infection when rains produce widespread conditions favorable to their reproduction.[18]

Animal factors

Natural infection occurs in Equidae, the most severe disease occurring in horses, with mules, donkeys and zebras showing lesser degrees of susceptibility in that order. The virus causes severe disease in dogs.[19] Elephants seroconvert when exposed to infection, but are probably not an important reservoir.[20] The case fatality rate varies depending on the severity of disease (see under 'Clinical signs') but can be as high as 90% in susceptible horses, but is lower in mules and donkeys.

After natural infection or vaccination immunity to that strain, but not to heterologous strains, is solid. The development of immunity is slow and may require 3 weeks to be appreciable: titers may continue to rise for 6 months after infection. Foals from immune dams derive passive immunity from the colostrum and are immune until 5–6 months of age.

Economic importance

The disease was of tremendous economic concern in southern Africa when horses were important for transportation and as draft animals. The disease is currently an economic concern because of the costs associated with preventive measures in enzootic areas, monitoring for introduction of disease in neighboring unaffected areas, and restrictions on importation of horses from countries in which the disease is enzootic. The high case fatality rate and morbidity of the disease in outbreaks is another source of loss. The cost of disease epizootics can be large, as demonstrated by the outbreak in the Iberian Peninsula where control of the disease in Portugal in 1990–1991 was achieved at a cost of US$2 000 000.[21]

Zoonotic disease

African horse sickness caused encephalitis and chorioretinitis in eight workers in an AHS vaccine factory. Infection was likely be inhalation of freeze-dried virus.[22]

PATHOGENESIS

AHSV affects vascular endothelium and monocytes/macrophages.[23,24] The tissue tropism of the infecting serotype determines which organs are most severely affected, with virus serotypes affecting endothelium in different organs, resulting in a variety of 'forms' or clinical presentations of the disease. After infection, the virus multiplies in local lymph nodes and a primary viremia ensues with dissemination of infection to endothelial cells and intravascular macrophages of lung, spleen and lymphoid tissues. Viral multiplication then results in a secondary cell-associated (red cell and white cell) viremia in horses of up to 9 days duration.[5] Fever and viremia occur at the same time and resolution of the viremia is associated with defervescence. Localization of antigen depends on the form of the disease – horses with horse sickness have most of the antigen in the spleen whereas horses with the more severe cardiopulmonary form have abundant antigen in cardiovascular and lymphatic systems.[5]

Infection of endothelial cells results in degenerative changes, increases in vascular permeability, impaired intercellular junctions, loss of endothelium, subendothelial deposition of cell debris and fibrin, and evidence of vascular repair.[23] Edema, hemorrhage, and microthrombi are associated with the vascular lesions. Abnormalities in the lungs include development of alveolar and interstitial edema, sequestration of neutrophils and platelet aggregates and formation of fibrinous microthrombi.[24] Combined these changes likely result in a coagulopathy, systemic inflammatory response syndrome, edema, impaired cardiovascular and pulmonary function and hypovolemia.

CLINICAL FINDINGS

The **incubation period** in natural infections is about 5–7 d. Three or four clinical forms of the disease occur, an acute or pulmonary form, a cardiac or subacute form, a mixed form, and a mild form known as 'horse sickness fever'. An intermittent fever of 40–41°C (105–106°F) is characteristic of all forms.

Acute (pulmonary) horse sickness (dunkop)

This is the most common form in epizootics and has a case fatality rate of 95%. Fever is followed by labored breathing, severe paroxysms of coughing and a **profuse nasal discharge** of yellowish serous fluid and froth. Profuse sweating, profound weakness and a staggery gait progress to recumbency. Death usually occurs after a total course of 4–5 d although it can be so acute as to be without observed premonitory signs in some horses. Severe respiratory distress persists for many weeks in surviving animals. This is the form of the disease that occurs naturally in dogs.

Subacute (cardiac) horse sickness (dikkop)

Subacute (cardiac) horse sickness is most common in horses in enzootic areas and has a case fatality rate of 50%. The incubation period may be up to 3 weeks, and the disease has a more protracted course than does the acute, pulmonary form. There is **edema** in the head, particularly in the temporal fossa, the eyelids and the lips, and the chest which may not develop until the horse has been febrile for a week. The oral mucosa is bluish in color and petechiae may develop under the tongue. Examination of the heart and lungs reveals evidence of **hydropericardium**, endocarditis and pulmonary edema. Restlessness and mild abdominal pain and paralysis of the esophagus, with inability to swallow and regurgitation of food and water through the nose, is not uncommon. Recovery is prolonged. A fatal course may last as long as 2 weeks.

A **mixed form** of the disease, with both pulmonary and cardiac signs, is evident as an initial subacute cardiac form that suddenly develops acute pulmonary signs. Also, a primary pulmonary syndrome may subside but cardiac involvement causes death. This mixed form is not common in field outbreaks.

Horse sickness fever

A mild form of horse sickness fever that may be easily overlooked, and is common in enzootic areas. The disease occurs in horses with some immunity or infection by serotypes of low virulence. This is the only form of the disease that occurs in zebras. The temperature rises to 40.5°C (105°F) over a period of 1–3 d but returns to normal about 3 d later. The appetite is poor, there is slight conjunctivitis and moderate respiratory distress.

CLINICAL PATHOLOGY

Leukopenia, with lymphopenia, neutropenia and a left shift, mild thrombocytopenia and hemoconcentration are characteristic of the acute forms of AHS.[25] **Serum biochemical abnormalities** include increases

in creatine kinase, lactate dehydrogenase, and alkaline phosphatase activities and creatinine and bilirubin concentrations.[25] There is evidence of activation of coagulation cascade and fibrinolysis although disseminated intravascular coagulation is unusual.[25]

Serological diagnosis of the acute disease may be difficult because many horses die before they mount a detectable antibody response.[26] In horses that survive for at least 10 d, agar gel immunodiffusion (AGID), indirect fluorescent antibody (IFA), complement fixation (CF), virus neutralization (VN) and ELISA tests are all effective in detecting antibody to the virus.[27,28] An indirect ELISA (I-ELISA) is more sensitive in detecting early immunological responses to vaccination or infection and the declining immunity in foals.[29] However, in outbreaks of disease early and accurate diagnosis of disease and identification of the serotype involved is important to guide selection of vaccine and thereby control spread of the disease. Diagnosis early in the course of the disease can be achieved by demonstration of **viral antigen or nucleic acid** in blood or tissue samples by any of a number of ELISA tests. A recent RT-PCR test enables rapid identification and differentiation of viral serotype from both live and formalin inactivated virus.[30] This test has utility in the early diagnosis of outbreaks of AHS. Viral isolation can be achieved in suckling mice or cell culture. Suitable samples are blood collected into heparin during the febrile stage of the disease or lung, spleen or lymphoid tissue collected at necropsy.

Tests approved for testing horses for international trade include a complement fixation test and an indirect sandwich ELISA.[31]

DIFFERENTIAL DIAGNOSIS

The fulminant disease in groups of horses is characteristic, although acute intoxication by monensin, salinomycin, or similar compounds can produce similar signs. Individual horses affected with purpura hemorrhagica and groups of horses affected with equine viral arteritis can have signs similar to horses with AHS. Piroplasmosis (*B. caballi* or *T. equi*) and trypanosomiasis cause fever and depression. Anthrax can cause acute deaths in solitary horses or groups of horses.

NECROPSY FINDINGS

Gross findings in acute cases include **severe hydrothorax and pulmonary edema** and moderate ascites. The liver is acutely congested and there is edema of the bowel wall. The pharynx, trachea and bronchi are filled with yellow serous fluid and froth. In cases of cardiac horse sickness there is marked hydropericardium, endocardial hemorrhage and myocardial degeneration. Edema of the head and neck is common, especially of the supraorbital fossa and nuchal ligament. Microscopic lesions are minimal in the acute form; pulmonary edema but no obvious vascular injury. Myocardial damage, including foci of necrosis, hemorrhage, and mild leukocytic infiltrates, may be seen during histologic examination of many cardiac (subacute) cases.

Samples for confirmation of diagnosis

- **Virology** – chilled spleen, lung, lymph node (PCR, VI)
- **Histology** – fixed lung, heart.

TREATMENT

There is no specific treatment for AHS. Supportive care and treatment of complication of the disease should be provided.

CONTROL

The **principles of control** in enzootic areas are **vaccination** and **reduction of exposure** of horses to biting insects, whereas in **non-enzootic** areas the aim is to **prevent introduction** of the disease, and **eradication** if it is introduced. The objectives of a control program for African horse sickness are:[5]

- Prevention of introduction of infection by clinically ill or inapparently infected animals
- Slaughter of viremic animals where animal welfare and economic considerations permit this course of action
- Management changes to reduce exposure to midges
- Vector control
- Induction of active immunity in animals at risk of disease.

Prevention of introduction

Infection can be introduced into an area free of AHSV by infected animals or midges. Control of midges is discussed below. Infected animals can be horses incubating the disease, clinically ill animals, or animals, including donkeys and zebras, that have no clinical signs of illness but are infected and viremic, as was the case of the Portuguese epizootic. Appropriate control measures to prevent movement of animals at risk of being infected should be instituted and include[32]: completion of a vaccination protocol effective against all important serotypes at least 42–60 days before introduction of the horse, positive identification of all horses by microchipping and passport documenting vaccination status, and a veterinary certificate confirming health and issued no more than 48 hours before introduction. Equids imported from areas in which the disease is enzootic, or from neighboring regions, should be housed in isolation in insect proof enclosures for 60 days. Recommendations that call for vaccination of all equids within 10 miles (16 km) of imported horses are not appropriate for most countries to which the disease is exotic.

Slaughter of sick or viremic animals

This extreme measure is appropriate in controlling infection recently introduced into areas previously free of the disease. It is an effective adjunct in control of spread of infection, as demonstrated in Portugal.[21] There are obvious economic, animal welfare and public relations aspects to this practice, especially in areas where horses have high intrinsic worth or are companion animals.

Reduce exposure to biting midges

Horses should be housed in insect proof buildings or, at a minimum, buildings that limit exposure of horses to midges by closure of doors and covering of windows with gauze.[33] Impregnation of gauze with an insecticide further reduces biting rates.[5] Stables should be situated in areas such as on hill tops or well-drained sites, that have minimal midge populations. Midge numbers on individual farms should be reduced by habitat alteration, so that areas of damp, organically enriched soils are eliminated. Widespread use of insecticides is unlikely to be environmentally acceptable.[5]

The feeding pattern of midges is such that housing of horses during the crepuscular periods and at night will significantly reduce biting rates and likelihood of infection.[5] Horses kept at pasture should have insect repellents applied regularly and especially to provide protection during periods of high insect biting activity. DEET (N,N-diethy-meta-toluamide) is the only commercially available repellent with documented activity against *Culicoides* spp.[34]

Vaccination

Vaccination is used in two circumstances – in areas in which the disease is endemic and in regions with an epizootic of the disease. Vaccination can be used in enzootic or neighboring regions to provide active immunity of all resident equids because of the continual risk of the disease in these areas. Vaccination in this instance is initiated as soon as foals no longer have passive immunity to the virus, and continues annually throughout the horse's life. Alternatively, vaccination may be used in the face of an epizootic to induce active immunity in horses in contact or in regions surrounding the outbreak. In this instance, vaccination is stopped when the infection is eradicated from the area.

Early attenuated virus vaccines, while effective in preventing AHS, were associated with significant side-effects, such as encephalitis. More recent vaccines of virus attenuated by passage through tissue culture are effective in preventing disease but do not prevent viremia. They were used to control the most recent outbreak in Spain and Portugal. Currently available vaccines are polyvalent or monovalent preparations containing attenuated strains of the virus. Protection against heterologous serotypes is usually weak and most vaccines are polyvalent. The polyvalent vaccines contain serotypes 1, 3, and 4 or serotypes 2, 6, 7, and 8, respectively.[35] AHSV-9 is not included as serotype 6 is cross protective.[5] A monovalent vaccine containing attenuated serotype 9 is used in western Africa where this is the only serotype present.[5] Inactivated vaccines are effective in preventing viremia in most animals and disease without side-effects.[27] Inactivated vaccines are no longer available and vaccination with sub-unit vaccines and DNA vaccination are experimental at the time of writing.

The recommended vaccination program for horses in South Africa is:[36]

- The primary vaccination consists of Horse Sickness Vaccine I (AHS I) and Horse Sickness Vaccine II (AHS II) administered at least 3 weeks apart to foals between 1 February and 31 July
- The primary vaccination should preferably not be administered before foals are 6 months of age to avoid the effect of maternally derived passive immunity on vaccine efficacy
- Revaccination with AHS I and AHS II at least 3 weeks apart to yearlings between 1 August and 31 January
- Subsequent revaccination with AHS I and AHS II either at intervals not exceeding 12 months, or every year between 1 July and 31 December.

Immunity after vaccination is protective for at least 1 year but annual revaccination of all horses, mules and donkeys is recommended.

There is concern over the use of attenuated virus vaccines in epizootic situations, that is in regions where AHSV is not enzootic. These reasons include the lack of vaccines approved for use in the European Community, the availability of only two types of polyvalent vaccines and one type of monovalent vaccine, delays in availability of vaccine for emergency vaccination, introduction of virus, even attenuated virus, into regions in which it is not present, attenuated virus viremia in some vaccinated horses, and reversion of vaccine strains to virulence.[5] These concerns have heightened the need for availability of inactivated virus or subunit vaccines.

ENCEPHALOMYOCARDITIS VIRUS DISEASE IN PIGS

Encephalomyocarditis is a viral infection of rodents, transmissible to domestic animals and man but it is only a significant pathogen in pigs and elephants. It is postulated as a risk in xenotransplantation.[1]

ETIOLOGY

The cause is a cardiovirus (family Picornaviridae) that is primarily a pathogen of rodents but which has the ability to produce disease in domestic animals, wild and zoo animals (particularly elephants), primates, and artiodactyls and man. It is found worldwide but its seriousness as a pathogen varies from probably inconsequential in the USA to important in Belgium.[2]

EPIDEMIOLOGY

It was first described as a cause of neonatal mortality in 1975.[3] When the disease was first described, pigs from 3–6 weeks were affected with myocarditis and encephalitis.[4] It is now known that the virus may cause reproductive failure in gilts and sows characterized by stillbirths and mummified fetuses.[5] The prevalence of inapparent infection in the swine population is high.

Outbreaks of the disease or serological evidence of the virus have been reported from the United States,[6–8] Canada,[9] Australia,[4,10] Italy,[11] Greece,[12] and many other countries including central America and now Venezuela.[13] Most work appears to have been carried out in Belgium[14,15] where there were major outbreaks in 1995–96 due to a new virus.[16] Serological studies of pigs in the United Kingdom, where the disease has not yet been recorded, found approximately 30% possess antibody to the virus. It is extraordinary that there never has been an outbreak that could be described clinically, pathologically or histologically as EMCV considering the close proximity of the UK to Belgium where the disease is widely reported. First reported in 1991 in Belgium, between 1995 and 1996 the disease was diagnosed 154 times in Belgium[16] either as a cause of myocardial failure with sudden death in finishing pigs and suckling piglets or as a cause of reproductive failure in sows. Their experience suggests that each isolate is specific for one age category and that the spread of the virus is limited. This recent finding suggests that rodents do play a part in the transmission of the virus but that pig to pig transmission is equally important as a source of infection.

In Iowa,[17] infection is widespread in swine herds; the true prevalence of infection in breeding stock is estimated at 13.8% and 8.5% in finishing animals.[8] About 90% of the herds surveyed in Iowa had one or more seropositive animals and seroprevalence increased with age. In Italy, most herds and 70% of pigs are seropositive for the virus. Clinical disease has been observed in very young suckling pigs to grower pigs up to 4 months of age but not in adults. It may occur as a sporadic disease or as an outbreak involving several litters of pigs, or pigs within a group. In outbreaks in Greece, in one herd of 100 breeding sows, 200 pigs aged 8–16 weeks of age died from the disease within 2 months.[12] Population mortality in a group of young pigs is variable but it may approach 50% in younger pigs. Transmission is usually believed to be oral

and spread amongst pigs is said to be limited[18] although because of the presence of virus clones there may be the occasional large outbreak as well.

The role of rodents, especially the genus *Rattus*, always supposed to be the main reservoir of the virus for domestic pigs has been suspected but not documented as the source of spread of the infection to pigs.[19] No pig to pig transmission has been shown and the pig is probably not a risk to man. Serological surveys of free-living animal species in Iowa in the United States have failed to find evidence of infection in these species and it is suggested that swine themselves are the main reservoir of infection. In an Australian outbreak, a plague of rats in the piggery may have been the source of the virus.[4] The virus is relatively resistant to heat and chemical influences and a wide variety of pH but is sensitive to desiccation. Outbreaks are frequently associated with rodent plagues in the piggery or area, or with rodent infestation of feed stores. An epidemic in Australia was associated with a plague of mice which were present in all piggeries reporting the disease.[20]

The virus is now considered a major cause of reproductive failure in swine herds.[21] The virus has been recovered from fetuses, antibodies to the virus have been demonstrated in fetal fluids, and histological lesions supporting a diagnosis of the viral infection have been observed.[21]

The economic losses associated with reproductive and neonatal losses associated with the virus have been estimated at US$100 per inventoried sow.[21] Investigations of outbreaks on two Minnesota (United States) swine farms indicated that the monthly averages for the numbers of piglets born dead per litter reached 4.6 and 3.6, the pre-weaning mortalities 50% and 31%, and the farrowing rates 52% and 63%, respectively.

Isolates of the virus from different countries have different clinical characteristics and differences in pathogenicity, molecular and antigenic properties.[22] A possible pneumotropic strain was identified in Quebec, Canada and this caused interstitial pneumonia.[9] Strain differences between isolates are manifested in differences in virulence. The Belgian isolate is classified as a reproductive strain and the Greek isolate as a myocardial strain. Both strains are able to cause reproductive failure in sows in gestation and to cause myocardial lesions in piglets but a difference in virulence between both isolates is evident.[22]

The effects of different experimental doses and ages in experimental infections of pigs are described in a paper from Greece.[23] The pathogenesis of these Greek viruses has been described[24] and in most cases there is a viremia with the lymphoid tissues containing the virus and they are probably the main source of the virus replication. Inoculation of a suspension of heart, spleen and lymph node tissues from affected pigs can result in sudden deaths of experimental pigs within 3 days.[12] The highest titers of the virus are found in the areas of damaged heart muscle. The virus can cause fetal death if the pregnant sow is infected in late pregnancy. The experimental inoculation of the virus into pregnant sows at 46–50 d of gestation results in transplacental infection and fetal deaths.[21] On the other hand experimental infections of 4–6 week old conventional pigs with a USA isolate produced no overt clinical disease.[25]

CLINICAL FINDINGS

Rarely is there clinical disease as most cases are seen as sudden death without clinical signs. Sub-clinical infection is the normal event and particularly in older or adult animals but even here, occasionally, death may occur.

The clinical course in young and growing pigs is short and manifested by inappetence, depression, trembling, incoordination and dyspnea. It has been described as being associated with respiratory disease in the USA.[26] There may be cyanosis of the extremities. Most frequently, pigs are found dead or die suddenly while feeding or when excited. Death appears to result from cardiac failure and clinical signs referable to encephalitis are rare. The reproductive form of the disease is characterized clinically by inappetence and fever, possibly to 41°C followed by farrowing at 109–111 days of gestation in affected sows.[6] There are numbers of mid to term abortions. The numbers increase for stillborn piglets, mummified fetuses and weak piglets, which are more susceptible to crushing and starvation and other common neonatal diseases. The course of the outbreak will usually last several weeks and possibly as long as 2–3 months with continuing reproductive failure with persistence of the virus.[23,27] Animals with cardiac failure should be killed humanely because the heart damage does not resolve.

CLINICAL PATHOLOGY

Neutralizing antibodies to the virus are present in sows and healthy in-contact pigs of affected farms.[12] In outbreaks of reproductive failure, specific antibody to the virus can be found in both fetal and neonatal sera collected from abnormal litters.[6] The hemagglutination inhibition and AGID tests are comparable for the detection of antibodies to encephalomyocarditis virus in fetal thoracic fluids.[22] A microtiter serum-neutralization test is a relatively specific and sensitive test for the diagnosis.[28] Antibodies of above eight are suspicious, and titers ≥16 are positive. Serum-neutralizing antibodies persist for several months and it is necessary to examine paired samples. A nucleic-acid probe can detect the presence of the virus in infected cell lysates.[29] Enzymes such as serum creatine kinase-MS and lactic dehydrogenase isoenzyme are also elevated.[30]

NECROPSY FINDINGS

At necropsy, there is reddening of the skin, excess peritoneal, pleural and pericardial fluid – frequently with fibrinous strands and edema of the omentum and mesentery. Sometimes there is pulmonary edema and liver enlargement. Characteristically, the heart appears pale and soft and there is diffuse or focal myocardial pallor involving the ventricles and associated with myocardial necrosis.[12] These may appear as distinct white foci or streaks[31] from 2–15 mm in diameter and these are most commonly on the right ventricular epicardium. Histologically, there is diffuse or focal myocarditis, with infiltration by histiocytes, lymphocytes, plasma cells and degeneration of cardiac muscle cells.[12] The virus can be identified in the cytoplasm of cardiac muscle cells[32] and virus particles are also seen in the protrusions from the cell surface of the Purkinje fibers and endothelial cells of the capillaries and intranuclearly in the cardiac muscle fibers. In chronic cases these have healed in the only way possible as fibrous plaques. In acute cases virus may be isolated from the heart muscle and also from the brain, spleen and other tissues. Neutralizing antibody becomes detectable 5–7 days after infection.

The predominant histopathological lesion in stillborn fetuses is myocarditis consisting of myocyte degeneration and necrosis with focal or diffuse mononuclear cell infiltration. In nursing piglets with the disease, histologically there are lesions of multifocal interstitial pneumonia, myocarditis, and mild multifocal nonsuppurative meningoencephalitis.[14] The immunohistochemistry is usually positive in the nuclei of the cardiac muscle cells, Purkinje cells, the endothelial cells of the capillaries and in the macrophages.[33]

Samples for confirmation

- Serological samples for neutralizing antibodies[34] which is widely available and is specific or HI antibodies may be helpful
- The virus can be isolated from stillborn pigs.[35] It can also be demonstrated by PCR, RT-PCR and one step PCR.[36] The RT-PCR can be followed by genetic typing using sequence analysis and this is useful in molecular epidemiology.[37] It has also been demonstrated by in situ hybridization (ISH)[38]

- Histopathology on heart muscle also useful with immunohistochemistry to follow to confirm. In the neonate, the brain histology may show a non-suppurative meningo-encephalitis which can be confirmed by immunohistochemistry.

Diagnosis

The diagnosis is from the history, clinical signs, gross and microscopic pathology and from isolation of the virus or demonstration of the antigen by immunohistochemistry. In some cases it may be necessary to consider vitamin E deficiency (Mulberry heart disease). The reproductive form of the infection may need to be differentiated from porcine parvovirus infection.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from bowel edema and mulberry heart disease in growing pigs and the per-acute bacterial diseases in suckling pigs. The myocardial lesions in suckling pigs have similarities to those produced by foot and mouth disease virus in this age group of pigs – the so-called 'Tiger Heart'.

TREATMENT AND CONTROL

There is no treatment and the control of the disease currently rests with rodent control and eradication in the piggery. There is now an inactivated vaccine available, which is an oil adjuvanted vaccine developed to protect elephants. It has been shown to work in mice and pigs[39] and is believed to produce high antibody titers in both domestic and wild animals.

POST-WEANING MULTISYSTEMIC WASTING SYNDROME (PMWS) AND PORCINE DERMATITIS AND NEPHROPATHY SYNDROME (PDNS) AND PORCINE CIRCOVIRUS-ASSOCIATED DISEASES

This disease (PMWS) was first described in weaned pigs possessing unique macroscopic and microscopic features[1] It was first recognized in Western Canada[2–5] and then Europe[6] and finally Asia and the United States. PDNS was originally thought to be a separate condition when it occurred as sporadic PDNS but now it is seen as an important component of PMWS.

A good definition of the disease was provided by Steve Sorden.[7] For a diagnosis you must have: (i) wasting, poor growth rate, often dyspnea, and swollen inguinal lymph nodes; (ii) lymphocyte depletion and granulomatous inflammation in lymph nodes; and (iii) detection of PCV2 in the lesions in the lymph nodes. The study of PCV2 and PMWS is still in its infancy.

ETIOLOGY

Porcine circovirus 2 (PCV2) is not a new agent but it is newly discovered as a pathogen. It has been found in 30 year old serum.[8–10] It does not appear to be found in horses or cattle.[11]

PCV2 is the essential infectious cause of the condition [5,12] but it is not the primary pathogen in the accepted sense of the word. Some authorities and many practitioners would still the see the cause as unknown. The reason for thinking this is that there are only three things that could have changed so that an infection which has obviously been present for a long time could suddenly become infectious. One is that the agent has itself changed but there is no evidence that this is so. The second is that the environment of the pig has changed and this is so in the sense of weaning and nutritional changes. The third thought is that the host is different and this may be so because of genetic engineering and breeding developments. Compare the growth rate and feed efficiency of pigs in the 21st century with those of the 1960s. The agent PCV2 is best viewed as a ubiquitous primary pathogen that can cause disease with the help of adequate co-factors and susceptible hosts.[13] The problem is that we do not know all these factors and neither do we know what the determinants of the host susceptibility are.[14]

PCV2 has been found in the tissues from pigs with PDNS.[15] The discussion goes on. The triggering of PMWS in herds could not be linked to coinfection with either PRRSV or PPV or to the use of specific immunostimulants such as vaccines or to particular genomic differences between the PCV2 strains.[16]

The Danish case study and the geographical spread in Denmark suggests that PMWS is an infectious disease. These studies also show that there may be a case for thinking that there is still an agent X out there that has not yet been discovered.[17]

The agent

The group of viruses known as circoviruses is an odd assortment of viruses. They are an important group of plant viruses and avian viruses including chicken anemia virus, psittacine beak and feather virus and pigeon circovirus. Initially Porcine Circovirus, now known as PCV1, was discovered in tissue culture[18,19] and it is now widely distributed in pigs worldwide. It is non-pathogenic[20] and has no place in the etiology of PMWS. There is only about 70–80% homology between PCV1 and PCV2.

In some cases PPV has been seen in the PMWS cases in the field. In gnotobiotes it may be essential for the full expression of the disease. Where it does occur the lesions of PMWS may be more severe.[21–23] Neither PCV2 or PPV on their own were pathogenic for gnotobiotes and produce a disease which is not the same as that seen in the field.

Porcine circovirus 2 (PCV2) is classified in the Circoviridae, which are single stranded circular genomic DNA viruses. Protein and viral nucleic acid has been found in the tissues of pigs with PMWS. The fulfillment of Koch's postulates with PCV2 in both gnotobiotic and conventional colostrum deprived pigs has been carried out.[6]

The genetic work so far carried out on PCV2 shows that the virus is quite stable

with 94% nucleotide identity. It is a very small virus with little of its own genetic makeup coding for proteins. It has only two open reading frames (ORF1 codes a replicase protein; ORF2 encodes a 30 kDa capsid protein).[24]

PCV2-associated diseases

PCV1 is non-pathogenic. The pathogenic porcine circovirus type 2 (PCV2) is implicated in the occurrence of PMWS. No pig with PMWS has been found without evidence of infection with PCV2.

PCV2 is also implicated in the causation of epizootic (acute) PDNS.[15,25]

It has been suggested as a cause of congenital tremor AII,[26] but other authors could find no evidence for this but could neither prove or disprove it.[27] It was shown (using indirect fluorescent assay, ISH and PCR) that there was an association between PCV2 in neonatal pigs and congenital tremor in pigs from 4 farms in the mid west of the USA.[26]

It may be a cause of neonatal cardiomyopathy. Myocarditis and abortion were seen in intra uterine infections of sows.[28]

It may be a cause of reproductive failure. Transplacental infection does occur in the field and stillbirths in pigs may be associated with the PCV2 infections.[29] Multiple abortions were seen in a multisite system.[30]

It is also a significant contributor to porcine respiratory disease complex (PRDC).[31–33]

In the mid 1980s in the UK it was a contributor to granulomatous enteritis although this was only detected retrospectively.

EPIDEMIOLOGY

Distribution

Worldwide distribution now includes the original areas like Canada, the USA and widely in Europe notably France,[34] Spain,[35] the British Isles,[36] and Ireland.[37] It occurred in Taiwan in 1995,[38] Japan in 1995[39] and Korea.[40] Not very significantly in the southern hemisphere until recently when it occurred in New Zealand in 2004.[41] Now been found in the Australian pig herd[42] and also from South Africa[43] and Brazil in 2005.[44]

Occurrence

Evidence was found of the virus as early as 1973 in Ireland[8] and from 1985 in Canada[45] and Belgium[46] and 1986 in Switzerland when archived tissue was looked at.[47]

In the USA proven occurrences in the field are described as rare.[28,48]

As well as the countries documented above it has also occurred in Korea,[49] Japan,[50] Switzerland since 1986,[51] and Germany since 1999.[52]

Wild boar have been found to have both PCV1 and PCV2 not only in the young pigs but also in the pigs of 1–2 years.[53] Also found in the feral pigs in Germany.[54] PCV2 occurs in wild boar in Spain with 3/656 being positive and one had PMWS.[55]

PRRS occurs before PCV2 in the life of the pig as it is either born with the infection or picks up the infection in the nursery. Only a few pigs have serological evidence of PPV varying from perhaps over 50% in the USA, to 25% in Korea, and 13% in Canada.

One of the first studies on the epidemiology of PCV2 was carried out in Ontario.[56] Data sheets were sent to 21 practitioners covering 922 herds and they said 15 herds had evidence of PMWS. The authors investigated 15 farms of which 13 turned out to be negative for PMWS. Of the other 12 some had PCV2 but were PMWS negative. 5/25 farms had epidemic disease and 7/25 endemic disease. The other 12 had either higher than average mortality or low grade PMWS. You can have a 95–100% prevalence of infection but this is rare. Most typically PMWS affects 4–33% of pigs with 70–80% case mortality.[57,58]

Nobody knows where it replicates although the supposition is rapidly dividing cells but it is able to infect macrophages and express its two viral proteins.[59]

The virus is probably found in all secretions[60] including the nasal, fecal and urinary secretions.[61] It is certainly shed in feces from pigs that have no enteritis and this suggests that fecal/oral/fecal route is the common method of spread.[60]

It is readily transmitted from inoculated to sentinel pigs and can be found in the tissues for at least 125 days and shed in all secretions.[62] It is secreted intermittently in semen[63,64] and it could be that it only occurs there because it is contained within macrophages which are extruded into the semen via the local lymphoid tissues particularly the bulbourethral glands.

Risk factors

The slow spread of the syndrome PMWS through Sweden appears not to be related to the spread of a new contagious microbe and it has not been spread through the semen [62]

Herds that vaccinate for *Mycoplasma hyopneumoniae* (M.hyo) had a lower mortality. In Denmark the case study showed that the use of M.hyo vaccines in PMWS positive herds reduced the mortality rate.[17]

It has been found in wild boar in Germany and Spain so they may potentially act as a reservoir.[62]

Clinical history

Risk factors for PMWS show that infected farms had more nursery pig diseases and lower biosecurity scores than non-infected farms.[65]

Genetic

In a study of Duroc, Landrace and Large White pigs only the Landrace had PMWS cases which suggests that there may be a predisposition in this breed.[66] In a study in Denmark, albeit only in one herd, Duroc boar progeny had a higher survival rate.[17] This author also made the point that 80% of Danish stock are supplied by the same breeding company and therefore nationwide the genetics are similar but the occurrence of PMWS is still very variable.

There may be a significant litter effect.[67] This litter effect may in part be explained by the sow's humoral immune state at farrowing. Measures to reduce the sow viremia and increase the colostral antibody provision at farrowing would increase the chances of piglet survival. Most farmers in the UK are convinced that there is a considerable repeatable maternal or litter effect on PMWS mortality., however the mechanism underlying this is unknown. One possible explanation is that these pigs may have extremely low levels of vitamin E.[68] It may be that castrated males are more affected.[69]

A recent study of 1063 piglets using PCR tests concluded that there was a significant effect of genetics on the expression of PMWS. It was not possible to say whether this effect was due to breed or particular boar lines.[70]

In an experiment involving the transfer of passive immunity maternal antibodies to PMWS it was shown that none of 36 piglets born to sows with PCV2 serum antibody levels >1/1250 developed PMWS. Piglets from sows with levels of 1/50 and four piglets with 1/250–1/500 also developed the disease.[71]

The agent

Phylogenetic analysis of the entire genomic sequence of PCV2 isolates has been determined with a >95% nucleotide homogeneity amongst all the tested strains.[72,73] The strains of PCV2 from PMWS subjected to genomic analysis [74] had a 99% nt sequence identity with other isolated PMWS strains had a 95% homology with associated strains from around the world. The strains from congenital tremor cases (2 PCV2 and 1PCV1) had only 72% sequence identity with each other. The PCV1 strain from the neonatal pig in the 1960s did cause congenital tremor when inoculated into the sow as an experimental infection.[74]

Pigs with PMWS have more PCV2 compared to the pigs on the same farm that are not clinically affected.[75,76] We are not as yet able to answer the question as to whether the severity of PCV2 associated disease is related to the virulence of the strain as in a recent study 94–100% shared the same nucleotide sequence and

91–100% shared the same amino acid sequence.[77]

The quantitative TaqMan-based real time PCR[78] allows the determination of viral load. No healthy pig had in excess of 10^6 PCV2 genomes per mL of serum or 500 ng of tissue sample. On the other hand all the clinically sick PMWS pigs had above 10^7 in both the serum and the tissues. Also the estimated viral load in the tissues of the PMWS pigs was related to the IHC findings with the LN, ileum and tonsil giving both a high viral load and high IHC staining. There is increasing evidence that the viral load in the affected pig is the crucial factor in the conversion of a latently infected animal to clinical PMWS.[79] PCV2 may be associated with different tissues of the reproductive tract but it is unlikely that it is associated with the uterine stage embryo.[80] It was found that 13.1% of 350 aborted fetuses[46] were positive for PCV2 by PCR and the virus was detected at all stages of gestation.[81]

The virus that causes PDNS is the same virus that is found in the cases of sow abortion.[82]

The agent can persist in the dendritic cells in the absence of viral replication.[83]

Environmental influences

The virus is very stable. It is not affected by heat, dryness, humidity, or common disinfectants.[84]

Clinically healthy pigs from PMWS affected farms developed the disease when transported and commingled with clinically affected pigs.[85]

Co-infections

The Danish view is that the higher the standard of health care the lower the losses.[17] It may be that co-infection is necessary to further the replication of PCV2. The more coinfections the more PCV2 material and it may be that it is this increased viral load that is the key to overcoming the host defenses. It would certainly explain why SPF and high health herds appear to be less severely affected by PMWS although they have PCV2. It would also explain that in some cases the extra antigens provided by vaccines may also be a triggering factor as the vaccine antigens or adjuvants may cause more replication of PCV2.

There is no doubt that PCV2 is associated with PMWS. No cases of PMWS have been described without the presence of PCV2.

Infections with porcine parvovirus (PPV) may be an important factor in the pathogenesis of some but not all PMWS cases.[86]

A study in Germany described the pathogens found in PMWS cases other than PCV2. PRRSv was found in 75%, *H. parasuis* in 13.4%, *E. coli* in 7.7%, *S. suis* in 7.2%, coronavirus in 7.2%, swine influenza in 4.4% and brachyspira in 4.2%.

The most common of the coinfections is M.hyo, which is a common agent in the respiratory component of PMWS. It increases the severity and duration of PCV2 induced lesions in lung and lymphoid tissues, the PCV2 replication in the tissues and the incidence of PMWS in conventional pigs.[87,88]

It was thought that PRRSv was the necessary sole catalytic agent for the conversion to the clinical case.[89–91] In a series of Spanish cases the PRRSv was found in only 23% of cases.[92] However, it seems that PRRSv infection occurs some time before PCV2 infection.[76]

The epidemiology of PPV suggests that the simultaneous co-infection with PPV and PCV2 is unlikely in the 6–12 -week-old period of life when pigs have PMWS.[93] On the other hand[94] in a study of 138 farrow to finish farms in France a strong association was suggested between PRRS and PPV in a herd with PMWS.

Simultaneous coinfection with salmonella has also been described. Here the pigs with salmonella had severe lymphoid depletion.[95] Infection resulted in more severe clinical disease and an increased mortality up to 80%.

- *Pneumocystis carinii* has been described in PCV2 infected pigs[96]
- *Cryptosporidium parvum* has also been found in association[97]
- *Chlamydia* has been found in association with the PMWS[98]
- It has also been associated with pulmonary aspergillosis[99]
- PCV2 and PEDv infections were described in the same animal.[100]

Immunology

Experimental studies and field observation confirm that the transfer of passive immunity maternal antibodies to PCV2 does confer protection against the development of PMWS.[71]

Immediately after birth the immune system of the pig is programmed to a sequence of actions that down regulate the responses of the immune system particularly in the gastrointestinal tract. In PMWS there appears to be the opposite up regulation of the immune response. Immunostimulation is not important[101] so it may be a failure of down regulation. Whatever happens, and it is not yet clear, the immune system is impaired.[102]

Maternal antibodies can prevent PMWS but they only limit virus circulation and shedding to some extent[103] and certainly not PCV2 infection.[104] Active antibody production occurs during the early grower period[69] at about 6–10 weeks and earlier if there is a heavy infection.[105–107]

It may be that conventionally raised pigs can establish protective immunity and not develop PMWS if animals at the age of 4–10 weeks are exposed to the viral proteins (virus or vaccine) but not exposed to any major immunostimulants or co-infected with any other viral infections.

Suppression of cell mediated immunity may play a part in the etiology of PMWS.[108]

Cytometric analysis shows that leukocyte subsets change after PCV2 infection with the increase in monocytes, reduction in T-cells (mainly $CD4^+$), and B-lymphocytes and the presence of low density immature granulocytes. This suggests an inability to mount an effective immune response.[109] Serum antibodies occur but PCV2 persists.

Serological profiles of affected and non affected herds have been described in France.[94] PCV2 antibodies have a high prevalence in all countries. Convalescent sera from pigs with the clinical disease will also induce antibodies to PCV2. In the UK titers seldom exceed 1:640 but those that received serotherapy responded with serum antibody levels possibly as high as 1:32 000.

Vaccinations

There has been a considerable controversy over the effect of vaccination on the conversion of sub clinical infection to clinical disease. The basis of this thinking was that vaccines are essentially no different to any other antigen and if other agents were important in the production of clinical PMWS why not vaccine antigens. In one study approximately 215 of the vaccinated pigs developed clinical signs and histopathological changes typical of PMWS.[110,111] The vaccines particularly suggested as culprits were those for APP and more importantly M.hyo. This latter was regarded as particularly important as the use of M.hyo occurred much at the same time as the epidemic of PMWS. Vaccines may help the pathogenesis of PCV2 diseases.[23,110,112,113] In an on farm trial in the UK when half the pigs were vaccinated and the other half were not there were no significant differences in overall death rates between the two groups.[114] It is possible that the timing of vaccination may not be important. There are no or minimal PCV2 associated lesions when pigs are vaccinated at 2–4 weeks prior to expected PCV2 exposure.[115] There is also the possibility that the adjuvants may be involved in the up regulation of the immune response. All the adjuvants at an early stage of infection increased the severity of lymphoid depletion associated with PCV2. In the later stages of infection (post 35 days) the oil/water adjuvants increased the length of viremia, the amount of PCV2 in serum

and tissue and the severity of lymphoid depletion.[116] It has been shown that local immunostimulation with a vaccine adjuvant is not sufficient to induce PMWS in conventional pigs and also not to increase the PCV2 load.[117]

PATHOGENESIS

PRRS may complicate PMWS. PPV is often present in the affected pigs but is not essential for PMWS. However the worst clinical signs and often the most severe lesions are seen in pigs that also have PPV infection and where the serological titers for PPV in these pigs are their highest point of seroconversion.

The role of the PPV is to enhance the PCV2 replication and thereby to exceed the threshold for the development of PMWS. How this is done is not known. There is some evidence that PMWS affected pigs seroconvert to PCV2 earlier than non affected pigs and this may suggest that they are infected earlier.[118] Both are non-enveloped DNA viruses and both probably use the DNA synthesis and protein synthesis of the host cell. Where joint infections occur the number of cells that are positive for PPV is much less than those that are positive for PCV2. It may facilitate high levels of replication of PCV2 during the preclinical phase of co-infection by promoting monocyte proliferation. It is possible that both viruses have similar tissue tropisms.[119] The primary target in vivo is probably not the monocytic series of cells,[120] although other authors suggest that the target cell changes from cardiomyocyte, hepatocyte, and macrophages of the fetal pig to just the macrophage/monocyte series in the neonatal pig[121] and possibly the nephrogenic zone of the kidney.

It is possible that the PPV may induce immunosuppression or macrophage activation. Death in these experimental infections may be due to liver failure.

Destruction of thymic lymphocytes has a central role in the pathogenesis of PMWS infections. Pigs with PMWS have altered cytokine responses to mitogens and other antigens.[122]

PCV2 in PMWS causes a reduction or loss in the T and B-cells, increased numbers of macrophages and partial loss and redistribution of antigen presenting cells throughout all the lymphoid tissues compared with control cases.[123]

The loss of B-cells is the earliest characteristic. There is also a loss of T-cells and in particular the memory T-cells although naive T-helper, cytotoxic T-lymphocytes, natural killer cells and mature granulocytes were also depleted but not the monocytes. There appears to be no direct PCV2 effect on lymphocytes and how this lymphopenia is caused is unknown. It does not cause apoptosis either[124,125] Positive PCV2 macrophages can in fact phagocytose apoptotic cells.[126] The PCV2 remains detectable at all stages of the infection. This suggests that it somehow does not trigger the degradation systems of macrophages and dendritic cells and the virus remains silent. Perhaps a novel thought is that the virus does not replicate in cells but can replicate free in the serum. PCV2 does not appear to harm macrophages but persistent PCV2 infection is a problem for dendritic cells. They are the most potent antigen presenting cells and are also mobile and may therefore spread through the body system. They are particularly adept at capturing antigens and migrating to lymph nodes and lymphoid tissues where they act directly with B and T-lymphocytes. The dendritic cells accumulate large quantities of PCV2 antigen by endocytosis not replication and retain this for several days if not longer. All that happens is that there appears to be no transmission of messages to the T-lymphocytes and therefore no further triggering of immune or cellular responses occurs.

The PCV2 may contain a sequence that has a marked inhibitory effect on interferon α production by porcine leukocytes.[127]

Co-infected pigs always have more severe microscopic lesions than pigs infected with PCV2 alone.

It may be an early or inappropriate immune stimulation which is the most likely event that triggers the PMWS in the PCV2 infected pigs. In situ hybridization shows that PPV can be visualized in the same animals that have PCV2[128] but on the other hand PCV2 can induce PMWS lesions in weaned pigs in the absence of PPV.[129,130]

Fetuses inoculated with PCV2 in the first two-thirds of the gestation are likely to be resorbed or die with severe heart congestion whilst fetuses infected in late gestation are minimally infected.

The PCV2 capsular protein is first detected in the cytoplasm of infected cells in a perinuclear position. After 18 hours the proteins are detected in the nucleus. Later protein is found in both the nucleus and cytoplasm of the infected cells. Sometimes immense amounts of viral protein and viral DNA are produced.[131]

The antigen is widely distributed. The cell most usually infected is the macrophage/histiocyte and also the dendritic cells of lymphoid tissues. Kupffer cells in the liver show considerable positivity. Virus can also be identified in cardiac myofibers, isolated myofibers in the intestinal tract and also hepatocytes. Lymphocytes do not contain virus.

PCV2 increased the levels of IL-10 and IFN-γ mRNA levels in the thymus and tonsils and were thought to be indicative of a T-cell immunosuppression.[132] There were no differences in the IL-6 levels between clinically and subclinically affected animals.[133] However the IFN-γ levels were lower in the PMWS animals which suggests a down regulation.[134]

In a similar study IL-1 β, IL-2 and IL-6 were expressed to a higher degree in PMWS pigs whereas IL-4 and IFN-γ were reduced.[135] In experiments with PCV2 and PPV there were no changes in the cellular response but in a joint experiment $CD2^+CD4^+$ cells decreased significantly in 21 and 35 day post-infection samples compare with 10DPI. There was also a strong influx of NK cells into the LN and peripheral blood monocytes.[136] There is a collapse over time in both T and B-cell populations. All T-cells are affected but the memory activated T-helper cells may be the worst affected.[137] The PMWS affected pig is depleted of $CD8^+$ and $CD4^+$ cells (both T and B-cells).

In the field, secondary infections are the most common presentation.[90] The chief of these is often Glasser's disease (*H. parasuis* infection).

Secondary infections with opportunistic organisms are common.[122] Co-infection with PPV, PRRSv, or mycoplasma will trigger PMWS.[21] Since these different pathogens have different targets and pathogenicity, a common aggravating factor can indeed be found in the immune stimulation.

A marked granulomatous inflammation takes place in the lymph nodes and this spreads to the parenchymatous organs. This is manifested as LN hyperplasia and macrophage infiltration of the cortex and medulla with syncytia and inclusions.[22] The virus load generated is enormous and the organs are all loaded with virus. There is an extremely dysfunctional immune system.[122]

Experimental infections

There is no really reliable method to produce PMWS in all experimental pigs with the characteristic clinical signs, gross lesions and microscopic lesions. PCV2 infections can be produced easily but PMWS is much more difficult.

In all experimental models of PMWS, replication of PCV2 is enhanced and concentrations of PCV2 are higher in animals that develop PMWS. It may simply be that these animals have more dividing cells to provide a replication site than those that do not develop PMWS.

Conventional pigs

One of the most interesting experiments was the clinical disease produced using a virus that had been present in the Swedish population since 1993 without causing problems but when injected into pigs did produce PMWS.[138]

PMWS has been completely reproduced with typical PMWS clinical signs, gross lesions, and microscopic lesions by use of CD/CD pigs with only PCV2.[62,139] They also produced the disease with dual inoculation with both PPV and PCV2.[21–23]

In another study with PCV2 and keyhole limpet hemocyanin (KLH) emulsified in Freund's incomplete adjuvant a total PMWS and enhanced replication of PCV2 was seen only in pigs receiving both PCV2 and the KLH.

Adjuvant and antigen resulted in immunostimulation that enhanced PCV2 replication.[101] The PCV2 is present in lesions in proportion to the severity of the PMWS and it can be said that the PCV2 plays an important part in the occurrence of PMWS. Only in some pigs will co-infection evolve into PMWS between 6–10 weeks of age.[140]

The only piglet infection group which developed clinical evidence of PMWS were those piglets which received combined inocula as either infected lymph node homogenates or dually infected pigs with both PCV2 and PPV propagated in PK-15 cell lines.[141] PCV2 was isolated or antigen recovered (IHC or ISH) from tissues in all the pigs that were given the dual inocula. An unusual dose dependent relationship has been identified. Low titer PPV/PCV2 produced a milder but still active form of the disease. A 100-fold higher titer produced fulminant and fatal disease. The liver is the primary target organ followed by the kidneys, gastrointestinal tract and pulmonary tissues.

PRRS together with PCV2 will also produce PMWS.[142] Again the PRRS seems to increase the replication of PCV2 and thereby exceed the threshold for PMWS.[143,144]

A Swedish virus isolated before PMWS was described in Sweden was given to the workers in N. Ireland and given to pigs. These pigs went on to show PMWS.[145]

Experimental infection of fetuses produced mummified, stillborn or weak piglets in 13 pigs and 24 were normal.[146] This shows that PCV2 can infect late term fetuses.[146] It was shown that PCV2 spreads amongst fetuses in utero. Four of six sows inoculated with PCV2 aborted 7–21 days post-infection. Three of four litters had 85–100% of stillborn piglets.[146]

Infections in gnotobiotes

If PCV2 is inoculated into gnotobiotes, CD/CD pigs or conventional pigs then you get typical microscopic lesions but few to moderate gross lesions whilst the clinical disease is mild or absent.[21–23,129] A novel study in germfree pigs confirmed PCV2 as the sole essential infectious cause of PMWS, fulfilling Koch's postulates.[147]

Experimental infections in gnotobiotic pigs have been described.[119,140] They reproduced PCV2 infections but most animals failed to reproduce any pathological changes and/or clinical signs similar to those observed in PMWS in the field. Most of the animals had the virus or viral antigens in the tissues such as trachea, lung, liver, kidney, pancreas, lymph nodes, spleen, thymus, ileum, colon, cecum, salivary gland heart, brain, and testis. This experiment did not fulfil Koch's postulates. Pigs with clinical signs consistent with PMWS were only seen in pigs with PCV2/PPV co-infected animals, PPV vaccinated and non-vaccinated. Mild to severe lymphoid depletion was seen and lymphoplasmocytic interstitial nephritis and hepatitis.

An infectious molecular clone has been developed and produced PMWS[148] and two chimeric infectious DNA clones also were effective[149] in producing PMWS.

CLINICAL FINDINGS

It should always be remembered that there are at least 25 other causes of failure to thrive and loss of weight and wasting. These should be examined first. A wasting pig does not always equal PMWS.

Diagnosis of PMWS is made on the basis is made on the basis of three criteria: clinical signs consistent with PMWS; secondly histopathologic changes; and detection of PCV2 in the microscopic lesions.

The initial clinical findings were described in Canada[2,3] and a full account of the clinical side of PMWS in Spain has also been described.[150] It was often found in high health herds in Canada an observation that has also been made throughout Europe. All sizes of herd have been affected.[151] Things usually return to normal in the period of 10–20 months. The cynics would suggest that that is because the susceptible population of pigs has died out over this period.

Sick pigs may exist alongside fit and healthy pigs. The major sign is not thriving.

There is a progressive weight loss. The ribs of the pigs are usually visible often with a severe abdominal distension. There may also be signs of heart failure with pericardial effusions and myocardial dysfunction.

There may be evidence of respiratory disease in the form of cough, dyspnea, and or tachypnea. There may be slight fever, pallor, diarrhea and less commonly there is icterus or jaundice.

The most characteristic clinical feature is the presence of swollen inguinal lymph nodes which in Europe is the first time that this has been described as a clinical sign. This may not be so in North America where some of the strains of PRRSv have been capable of causing this gross lesion.

Unless there is a susceptible coinfection there is no response to antibiotics.

Mortality is variable, but usually low, 5–15%[7,151] although the case mortality rate may reach 80-90%.[151] 65% of the deaths are males and 34% females. The morbidity is 10–30%.

The peak of PMWS mortality typically coincides with seroconversion to PCV2. Sub clinical infection is the most common presentation. It can be very mild and transient.[152] Often the records of production may be the only method of detecting that there is a problem of PMWS or PCV2 infection. Sometimes this is only appreciated by a higher return of condemnations from the slaughterhouse. There is a reduced average daily weight gain, increased time to slaughter, more severe lung lesions, and higher amount of antigen.

There was an association between the levels of infectious PCV2 and/or PCV2 DNA load and the severity of the clinical signs as described for PMWS.[153]

The occurrence of PRDC is a major manifestation and both PCV2 and M.hyo are common in respiratory disease. In growing and finishing pigs PCV2 associated PRDC is characterized by slow growth, prolonged growth, and dyspnea that is refractory to antibiotic therapy. There is also a marked increase in mortality from single and multiple concurrent bacterial infections.[31,154–156]

There are four criteria for a diagnosis of PCV2 associated PRDC: (i) respiratory signs; (ii) microscopic characteristic lung lesions; (iii) IHC or other demonstration of PCV2 in the lesion; and (iv) the absence of characteristic microscopic lesions of PMWS in lymphoid tissues.

PCV2 associated PRDC should be differentiated from PMWS clinically and histopathologically.

The condition of Porcine Necrotizing Pneumonia (PNP) is a result of coinfection with PRRSv and PCV2.[25]

In the past there have been wasting problems in pigs with loss of weight and watery diarrhea in which there is a granulomatous inflammation in the intestines with characteristic lesions with giant cells and possibly inclusions affecting the Peyer's patches.[157]

The common differential diagnosis of PMWS is PIA.[158]

Reproductive problems associated with PCV2 infection are uncommon.[159] In a recent survey in Spain it was shown that PRRSv was an important cause of reproductive failure but that the PCV2 was not a common cause of a problem.[160] Elevated abortion, stillbirths, and fetal mummification are a feature. Midgestation abortion, mummified fetuses, and early embryonic death were also observed in a recent Korean study.[142] *In utero* infection may produce fetal deaths and abortions.[48,161–163] Abortion is typically

sporadic and characterized by increased numbers of mummified fetuses. Multiple PCV2 associated abortion and reproductive failure in a **multisite** production system has been described.[164] Transplacental infection with PCV2 was associated with reproductive failure in a gilt.[165]

Reproductive failure associated with PCV2 is uncommon in the USA[166] and the UK. There are no characteristic lesions in the PCV2 affected fetuses. PCV2 is associated with reproductive failure at all stages of gestation.[167] The replication kinetics of these reproductive strains are different from those from pigs with PMWS or PDNS.[168]

CLINICAL PATHOLOGY

The early changes in PMWS are anemia. This may be related to the sub acute/chronic nephritis, gastric ulceration or *M. suis* infections.

Monocytic hyperchromic regenerative anemia is the most common type with anisocytosis and polychromasia and later monocytic normochromic non-regenerative anemia. Significant differences (lower levels) were observed in RBC counts and hemoglobin levels, between healthy and naturally and experimentally infected pigs.[169] Most of the pigs seem to have *M. suis* (*Eperythrozoon suis*).

Neutrophilia and lymphopenia were recorded. Animals which will subsequently become PMWS cases show a lymphopenia,[102,126,170,171] very early on in their history,[172] and certainly before they show clinical signs. Many of the pigs showed increased levels of blood urea and creatinine with persistent leucopenia or sporadic leukocytosis both with neutrophilia and lymphopenia.[173] Wasting pigs with high blood urea, low albumin, and hemoglobin with lymphopenia provides further evidence of PMWS infection.

The risk of dying is related to the increasing titers against PCV2 from weaning until 4 weeks after weaning.[174] Pigs suffering from PDNS usually show high blood levels of creatinine and urea.

NECROPSY FINDINGS

The carcass is wasted. The skin is pale and rarely jaundiced except in the USA and Canada where it may be more common. The relationship between PCV2 and hepatitis E has probably not been examined. The abdomen is distended. The lesions were classically described in Canada.[2,3,175] The most common manifestation of PCV2 infection is often pneumonia. Analysis of the submissions to the diagnostic laboratory at Iowa State University shows that the PCV2 antigen is often associated with the characteristic lung lesions.[177,178] The second most common manifestation of PCV2 infection (in the records of the Iowa diagnostic laboratory) is PMWS.

The third manifestation is the systemic infection and PCV2 associated enteric infection is relatively uncommon but where it does occur often resembles regional ileitis.

The examination of the carcass generally reveals a lymphadenopathy in the form of enlarged lymph nodes.[179] Lymphoid organs are always affected. These gross lesions occur before other gross and histopathological lesions occur. The subcutaneous lymph nodes and in particular the superficial inguinals are the most severely affected. Other swollen lymph nodes include the tracheobronchial and mesenteric lymph nodes which is a reflection of the antigenic strain that the respiratory and alimentary systems are under all of the time in PCV2 affected pigs. The lymph nodes in cross section appear homogeneous, often pale and in many cases also edematous.

The lungs are swollen, often rubbery and may be edematous and these lungs do not collapse.

The other early change is the presence of fluid in the body cavities (peritonitis, pleurisy, pericarditis). These occasionally have fibrin tags which may or may not be associated with the presence of *H. parasuis* which is the most commonly isolated secondary bacterium from these cases.

Stomach ulcers (*pars esophagea*) are a common feature and in many of these there is also an edema of the gastric wall. There may also be cecal edema.

Sometimes the liver is atrophic or yellow. The spleen may be enlarged.

The kidneys may be very swollen but may have petechiae or even white stripes. Reproductive pathology is uncommon. Occasionally, we can find lymphohistiocytic myocarditis and/or myocardial fibrosis.[160] One of the manifestations is PDNS where there is both PRRSv and PCV2 in the same tissues.[180]

Microscopy

The overall histological changes in PMWS are granulomatous inflammation with inflammatory cell exudates. The lesions form angiocentric granulomatous formations and often include eosinophils, neutrophils, and lymphocytes. There are often multinucleate giant cells but not always. The granulomas may coalesce and then the LN appears as a solid mass of cells. The follicular architecture is lost and the germinal centers become obscured. Paracortical T-cell areas become less cellular and eventually there is a marked lymphocyte depletion. Often there are massive inclusions which may be distinct intracytoplasmic inclusions or intranuclear basophilic inclusions. These inclusions are not sites of active viral protein and DNA synthesis but are aggregations of ingested virions.

These occur in the lymph nodes[2] and also in lymphocytic aggregates such as BALT or GALT (Peyer's patches). Lymphoid depletion and histiocytic infiltration are highly specific for the disease.[7] Necrotizing vasculitis is also a feature in some instances.[181]

The PCV2 antigen is associated with characteristic lung lesions, with necrotizing and ulcerative laryngitis, ulcerative bronchiolitis , bronchiolitis obliterans, fibroplasias of the lamina propria, and granulomatous inflammation of the alveolar septae. For this reason the tracheobronchial LN often show the most characteristic lesions of PMWS probably as these are the ones most affected by the continual inhalation of antigens. In many pigs the lung lesions are mild and consist only of an interstitial pneumonia.

Hepatic histiocytic infiltration is a feature and sometimes necrotizing hepatitis.[21]

The kidney has lesions which are very similar to some of the lesions described in mycotoxicosis which are essentially a pyelitis with a multifocal interstitial plasmacytic cellular infiltration extending through the cortex with focal lymphoid aggregates forming at the corticomedullary junction. Myocarditis is a common feature particularly in the younger pig.

Diffuse hepatic necrosis has been described associated with PCV2 infection in a piglet.[182] Immunohistochemistry reveals the presence of antigen in the cytoplasm of macrophages and dendritic cells but noT-lymphocytes.[120] No replicating proteins have been found in the macrophages.[183] This suggests that the virus is being endocytosed by the macrophages and not produced by them. Infectious PCV2 remains associated with these cells for several days, possibly even weeks, without impairing their functions or losing its own infectivity. The IHC characterization of the LN reaction in pigs has been described.[184] In the initial and intermediate stages there is an absence of follicles and depletion of lymphocytes. There is also a reduction of interfollicular dendritic cells and interdigitating cells and a reduction/absence of B-cells and in particular $CD4^+$ T-cells.

After the evaluation of histopathology and IHC and/or ISH and the conclusion is that the pig has only mild lesions then it is possible to say that the pig may have (a) subclinical PCV2; (b) early PCV2 leading subsequently to PMWS; or (c) are recovering from PCV2 infection. If there are moderate to severe lesions then there is no problem it is ether PMWS or PRDC or granulomatous enteritis or any combination thereof.

Samples for confirmation of diagnosis

- **Blood** – The virus may be present in the serum before or after the virus can replicate in the tissues so therefore blood may be useful and PCR is more sensitive than ISH[185]
- **Tissues – Microscopy and antigen detection.** The best tissues are lymphoid organs particularly tonsil, lymph nodes especially the inguinal, mesenteric and tracheobronchial as these will also give you comment on the general systemic state, lung and alimentary tract. Also ileum (which has Peyer's patches), and spleen. Other tissues may have lesions (kidney, liver, and lung).

DIAGNOSIS

Techniques such as virus isolation, neutralization tests and indirect immunofluorescence have been used primarily by research workers and are not normally part of the diagnostic methods used. Virus isolation has also been described.[5]

Serology

PCV1 and PCV2 can be distinguished by PCR and monoclonal antibody techniques. Several serological tests have been developed for PCV2[8,69] and these showed that nearly all pigs become seropositive during the growing phases. Since most pigs are seropositive there is little point in carrying out serology.

Antigen detection

A PCV2 specific antigen capture ELISA has been described.[186] The double ISH technique has been used for the demonstration of both PCV1 and PCV2 in tissues.[187,188]

The original PCR was developed[189] and superseded by a multiplex PCR that will detect both PCV1 and PCV.[190,191] One that can be used for boar semen[192] was then developed. A positive PCR result confirms the presence of PCV2 only[193] and does make a diagnosis of PMWS.[194] When the PCR detects PCV2 in lesions in histologically identified lesions then it is positive for PMWS.[195] Quantitative PCR is a molecular technique that can allow you to assess the viral load.[73,142]

Immunohistochemistry was shown to be useful for the detection of PCV2 in tissues.[12,40,196] IHC was shown to be better than ISH.[197]

TREATMENT

The only treatment is for secondary bacterial diseases. These require an accurate diagnosis and probably bacterial sensitivity testing for effective results. The results of antibiotic therapy are not good.

Serotherapy has received publicity as an effective treatment but the effects are very variable. It will work for some batches but not others and is not without risk of other diseases been transmitted as well as the prospect of dirty conditions causing outbreaks of clostridial disease.[198]

The use of aspirin for the sows may be of use[150] and the administration of corticosteroids may reduce stress and therefore help in the reduction of death losses.

CONTROL

The first attempt at control was the 20-point plan of Madec[199] who said that you had to get 16/20 points adopted by the farmer to get the plan to work. In most cases certainly in the UK it was difficult to persuade the farmer to do 4–5.[200] The core of the plan was to use all in/all out production, feed pigs with multivitamins, minimize stress, and handle pigs with extra care. In some cases the high mortality rates were still observed even after implementing good management practices.[201] In many ways the plan was no different to those proposed 20 years earlier for the control of respiratory disease or alimentary disease. Many of the UK farmers simply tried to limit pig to pig contact, to remove stress from the system, to introduce better hygiene and improve nutrition. Batch farrowing helped to allow all in/all out production, and others tried partial or total depopulation. One of the major controls is to reduce stress.[67]

A considerable effort was put into the provision of an improved diet. Many increased the amounts of vitamin E and selenium believing that there was an element of antioxidant deficiency in the rations when the pigs were being bombarded with toxic oxygen radicals. Many farmers were also convinced that part of the problem related to a high wheat content in the diet and tried to reduce it and replace it with barley. This may be one of the key differences between the low prevalence of PMWS in the USA (where maize is used) and the high occurrence of PMWS in Europe where diets are used in which wheat and barley figure highly. Reduction of wheat was often associated with a reduction in the level of PMWS.

Many producers said that ad libitum feeding was associated with an increase in the problem. In many ways the methods of control were summarized by a study on a farm in East Anglia in the United Kingdom.[202] He described the control as requiring attention to six main features: (i) keep the population closed; (ii) not mixing pigs of different ages; (iii) reducing the amount of mixing and moving between pigs of the same batch; (iv) reducing the number of moves that the piglets made; (v) clean and disinfect the buildings before the next batch; (vi) visit the pigs in situ, pull out the ill and cull immediately. One group of UK farmers said that the best way of controlling this disease was to go organic and what that means in practice is that the weaning age has to be raised to a minimum of 8 weeks.

Control of secondary infections is an essential control.[31,142,144,203] The second point is the removal of the factors that may promote immune stimulation.[87,88,115,204,205] The main measures in the control of the disease are as follows.[150]

1. **Maintain the balance of health.** These include the reduction of stocking density (the only measure that does reduce environmental and microbiological challenge), all in/all out management of the rooms of buildings with cleaning and disinfection and time to dry out before the next batch. No moving of animals back to clear a room. Reduction of entry of new stock to large batches i.e. 3-monthly not each month for replacement gilts. Depopulation of flat decks. Try and use a 3-site production system.
2. **Avoid contagion between animals.** Change weekly production to 3-weekly production. Avoid any form of fostering if possible and under no circumstances have 25% adopted piglets Avoid piglet handling and therefore stress. Increase the hygiene in the farrowing quarters. Do not use needles on more than one litter.
3. **Favor the natural immune response.** Make sure that the piglets have an adequate colostrums intake. Make sure that they are a good weight at weaning. Avoid stress. Avoid vaccinating piglets too early. Generate the right environmental conditions particularly for temperature and humidity and regulate with the stage of growth. Avoid overcrowding. Administer high quality feed. Avoid vaccination coinciding with the movement of pigs. Control parasites particularly if production is outside.

Segregated early weaning has limited success because (i) most pigs are weaned negative and get exposed to the PCV2 during growing;[206] (ii) adult animals with antibodies are not susceptible to PCV2; [207] (iii) PMWS is most common at 4–6 weeks of age or 2–3 weeks post-weaning.[4]

With the escalating prevalence in Denmark it has been found that rapid removal of the clinically affected animals (massive sources of virus) to hospital accommodation followed by plenty of fresh air and highly palatable food has been helpful in recovery.[208]

A recent paper from Denmark has described the control of PMWS simply through the use of depopulation and

repopulation.[209] Only one herd of the group examined was reinfected after 3 months and that was supplied by the original source of pigs to that farm.

The use of other vaccines and their role in the onset of the condition was discussed[210] and recent information from Denmark suggests that in the cases in the epidemic in Denmark vaccination for M.hyo has played no part.[211] In the USA there have been similar recommendations for control.[212] These include the diagnosis of the specific infections that are contributing to the disease picture. If it is possible to vaccinate for these then do so (PRRS, SIV, PPV, M.hyo, APP, HPS). If there is a vaccine problem, then re evaluate. Treat the bacterial infections and consider the use of anti inflammatory drugs. Remove pigs that are not responding to treatment. Strictly adhere to all in/all out policies and the rules of pig flow. Minimize the moving and mixing of pigs. Decrease the density of stocking. Use disinfectants. Change source of pigs. By the use of segregated early weaning it is possible to produce PCV2 virus-free pigs from PCV2-positive sows.[213]

Vaccines

A tremendous amount of effort has gone into the search for an effective vaccine for PCV2 associated conditions.

Chimeric PCV1 live virus and a chimeric infectious DNA clone induce strong immune responses against PCV2 in pigs, at least experimentally, and protect pigs against PCV2 challenge.[214]

An inactivated PCV2 vaccine has also been described.[215] Recently the use of PCV2 vaccination in France and Spain has, it is believed, been a great success.

PDNS

The case definition is relatively simple.[216–218] These animals are generally older than the animals affected with PMWS but the conditions usually occur in the same herd.[219] There are two main features. Firstly, there is the presence of necrotizing skin lesions particularly over the hind limbs, perineum, and extending forward along the abdomen. Secondly there is a systemic necrotizing vasculitis and necrotizing and fibrinous glomerulonephritis.

The condition in terms of either gross or histological features has not been reproduced experimentally.

The probable first case of the endemic from was reported from Chile in 1976.[220]

It was reported in the UK as a sporadic problem[221,222] and subsequently as part of the PMWS/PDNS outbreaks.[223] This has been reported worldwide including recently from Hungary[224] and Canada[225] and the rest of the world.[226]

The acute form is probably associated with PCV2 infection.[15] The major point is that it is indistinguishable from classical or African swine fever. The disease occurs at the end of the nursery stage and the beginning of the grower stage. It is also found occasionally in finishing pigs and replacement gilts. The skin lesions are multifocal, well-circumscribed, slightly raised, dark red, circular to irregular and 1 mm to 2 cm in diameter. They may coalesce. Other times they may heal. They are particularly severe over the hind legs, pelvis and perineum.

The lymph nodes are usually swollen as in PMWS but may also be dark red and hemorrhagic. The pigs affected are usually still eating but may be febrile and if so are usually anorectic. The lower limbs may be edematous and joints may also have excess or blood stained joint fluid. There are severe renal lesions which often include red focal lesions up to several millimeters in diameter, that correspond to congested of hemorrhagic glomeruli on the cortex of the kidney. These kidneys are often enlarged and the associated renal lymph nodes are very hemorrhagic. Many of these cases are detected in the abattoir as the kidneys are declared unfit for human consumption. The kidney failure is quite severe with a very elevated blood urea nitrogen and creatinine. Many cases also have a pneumonia and a gastric ulceration.

Histologically, the major lesion is a severe, fibrinoid, necrotizing vasculitis in the small vessels affecting the subcutis and dermis of the skin and renal pelvis and medulla. There is also a multifocal severe acute necrotizing glomerulonephritis. The lesions of the acute PDNS often mask the underlying PMWS. The target cells for the PCV2 in PDNS were cells of the macrophage/monocyte series.[15] The sporadic cases which occurred before PMWS in the UK were often associated with the occurrence of *P. multocida* of one electrophoretic type.[227,228] The cases occurring simultaneously with PMWS or after as these animals are slightly older do not show the same pattern of bacterial isolation. The condition is probably caused by an immune complex reaction occurring in the small blood vessels.

The subject has been described in detail.[229]

PORCINE REPRODUCTIVE AND RESPIRATORY SYNDROME (PRRS; BLUE-EARED PIG DISEASE; MYSTERY SWINE DISEASE; SWINE INFERTILITY AND RESPIRATORY SYNDROME (SIRS))

Synopsis

Etiology Porcine reproductive and respiratory syndrome virus (PRRSV) belonging to Arteriviridae family
Epidemiology Highly contagious disease of swine manifested by reproductive failure, and respiratory disease in young pigs. Worldwide occurrence; spread rapidly in swine-raising areas during last 15 years. Subclinical infection endemic in most swine herds; incidence of clinical disease lower but causes severe economic losses. Pigs become infected in nursery from older infected pigs; persistent infection for several months is common. Different antigenic strains with variable virulence. Natural infection or vaccination results in immunity, but viremia still common. Infection with virus may predispose to secondary infections of respiratory tract. Transmitted by direct contact, feces and discharges, importation of infected pigs into herds, aerosol infection and semen
Signs Highly variable clinical syndrome
Reproductive failure Outbreaks of late gestation abortions, stillbirths, mummified fetuses, weak neonates, high rate of return to estrus. Problem may persist and recur for many months
Respiratory form Anorexia, fever, dyspnea, polypnea, coughing, unthriftiness, high mortality in young pigs and low in older pigs and breeding stock. Deaths occur in acute phase
Lesions Interstitial pneumonia with reduction in alveolar macrophages. Aborted and mummified fetuses, stillbirths, weak neonates with pulmonary lesions
Diagnostic confirmation Serological testing for viral antibody titers. Detection of virus in tissues and alveolar macrophages using immunofluorescent microscopy
Differential diagnosis list:
Respiratory disease: Pneumonia due to:
- *Mycoplasma hyopneumoniae*
- *Actinobacillus pleuropneumoniae*
- *Pasteurella multocida*
- Glasser's disease (*Haemophilus parasuis*)
- *Streptococcus suis*

Reproductive failure
- Leptospirosis
- Parvovirus
- Brucellosis
- Aujeszky's disease
- Hog cholera virus

Treatment Must clinically manage outbreak to minimize mortality in young pigs
Control Segregation and off-site rearing of recently weaned pigs. Nursery depopulation and clean up protocol. Import only virus-free breeding stock into breeding herds. Vaccines available but insufficient information on efficacy

ETIOLOGY

Porcine reproductive and respiratory syndrome (PRRS) is associated with an RNA virus morphologically, structurally, and genomically similar to members of the genus arterivirus of the family **Arteriviridae** belonging to the Order Nidovirales. The virus was first isolated in Lelystad, The Netherlands in 1991 and called the Lelystad virus[1,2] it is closely related to the equine virus arteritis virus. The Mystery swine disease of the USA was then shown to be a similar virus.[3,4] These two strains are considered to be one virus but the European and North American strains are genetically[5,6] and antigenically different.[7] The US and European strains are only 55–70% identical at the nucleotide level.[8] The current theory of its origin is that Lactic Dehydrogenase Virus of Mice infected wild boar in Central Europe and became adapted. It then went to North Carolina in the USA in wild boars.[9] It is thought that the most likely date for a common isolate of the European strains is before 1981.[10] The two species of PRRSv then developed separately on the two continents.[11] Some evidence of this comes from a study of the number of nucleotides in ORF7 of the virus[12] from the USA (372 nucleotides), EU (Lelystad types) had 387 nucleotides but the Lithuanian strains that were collected had 378 nucleotides. In tissue culture it was suggested that a recombination between US and European isolates was 10 000 times less likely to occur than between diverse European isolates.[13]

EPIDEMIOLOGY

Occurrence

PRRS was first reported as a new disease in swine-raising areas in North America in 1986–1987,[14] and in 1991 was recognized in, and spread rapidly across, western European countries.[15] The disease was first recognized in Germany in 1990 and in The Netherlands in 1991, and occurs in Spain, France, Belgium, Denmark, Taiwan, and other countries. The rapid spread of the disease initially to the southwest of Europe and then to the north, paralleled the direction of the wind. Airborne spread was also suspected because even well-managed and isolated herds became infected.

Based on serological surveys, there is no evidence of infection in swine herds in Switzerland[16] and Australia.[17]

The introduction of legislation in some countries to restrict the movement of pigs from affected farms slowed the spread of the disease, but airborne spread over distances of a few km continued to occur, particularly in areas of high pig population density.[18]

The terms **'mystery pig disease'** and **'blue-eared pig disease'** were used because the etiology was unknown and the skin of the ears of affected pigs commonly appeared blue. The disease affects pregnant gilts and sows, unweaned and recently weaned pigs, and growing–finishing pigs. Outbreaks of late-term abortions, high numbers of stillbirths and mummified or weak newborn piglets, and respiratory disease in young unweaned and weaned pigs are common. After ten or more years of acceptance and relief that the European virus was not so pathogenic as the North American virus it is now accepted in Europe that the recent evolution of the virus may now be causing as many problems as the USA virus always has done.

Prevalence of infection

In endemic herds 30–70% of pigs may be seropositive to the virus and about 60% of herds have some seropositive pigs.[19] While the seroprevalence may be high in herds in some regions, the incidence of clinical disease is lower and variable.[20] Although the number of herds with the acute form of the disease has been decreasing, the infection is now **endemic** in many herds, characterized by increased mortality and suboptimal performance in nursery pigs, with active spreading of the virus mainly in nurseries. In endemically infected herds, **subpopulations of infected animals** may exist consisting of a low prevalence (<10%) of seropositive animals in the breeding animals and a high prevalence (>50%) of seropositive nursery piglets.[21] The elimination of these susceptible subpopulations by exposing all members of a population to the virus is used as a control strategy in large herds in which there may be subpopulations of highly susceptible breeding females. The virus can persist in non-pregnant sows and be transmitted to naïve in contact sows.[22] A PRRSv strain may persist in a herd for up to 3.5 years displaying as little as 2% variation in ORF5 during this period. In 78% of herds with multiple submissions genetically different strains were identified within 1 year of the original identification.[23] Virulent PRRSv isolates exhibit longer viremias but of no more elevated levels but they induce higher death rates and cause more severe clinical signs in a respiratory disease model. More virulent strains grew to significantly higher levels in pigs than did cell culture adapted isolates. Pathogenic consequences and immunological responses of pigs to PRRSv are closely related to viral load in acute infections as reflected in viral titers in blood.[24]

Morbidity and mortality

The morbidity rate in young pigs may be up to 50% and mortality in nursery piglets can reach 25%. Death is usually

associated with secondary bacterial infections such as *Salmonella choleraesuis, Streptococcus suis, Actinobacillus pleuropneumoniae, Haemophilus parasuis*. Major losses occur in reproductive failure but figures for the magnitude of reproductive losses during an outbreak are not readily available. In general, the reproductive performance of positive herds is significantly lower than negative herds.[25]

Risk factors

The severity and duration of outbreaks following infection are variable. Some herds may be devastated by high production losses, whereas other herds may have almost no losses. Differences in morbidity and mortality may be due to dose of virus at exposure, differences in host susceptibility, differences in strain virulence, environmental or housing differences, or the production practices in the herd.

Animal risk factors

Nursing piglets lacking maternal immunity, and young growing and finishing pigs and sows lacking acquired immunity from natural infection or vaccination are highly susceptible to infection and clinical disease. Severe disease appears to be more likely in large herds that have a large turnover of pigs, purchase replacements from other herds, and do not use a quarantine system. Introduction of the virus to previously virus-naive herds may cause severe economic losses. In the recent outbreaks in Denmark the study of 107 herds showed that a variety of hazards were identified including close neighboring herds, increasing herd size, purchase of semen from infected AI studs.[26]

Immune mechanisms. The immune responses that are generated by PRRSV are not understood and the control of the disease by immune mechanisms is not understood. The core effect of the virus is to infect and cause abnormalities in the macrophages. Disturbed macrophages may fail to present antigen successfully. More importantly whatever cytokines are present in the pig or are induced by the PRRS in that particular host may determine the outcome). It was shown that PRRSv is slow to produce both neutralizing antibodies and a cell mediated immunity.[27] It does produce an IFN response in PRRSv infected lymphoid tissue.

Following natural infection, most pigs are resistant to subsequent infection but the mechanisms of protective immunity are not understood. It has been suggested that the immune response to PRRSv has some degree of strain specificity.[28] Indeed it has also been suggested that the ability to cross the placenta is also strain specific and that although maternal immunity may not prevent transplacental infection it may exert additional selection pressure.[29] Circulating antibodies to the virus are detectable within 14–21 days after infection based on indirect immunofluorescence test or ELISA,[30,31] and 15-kDa protein is the most immunogenic of the viral proteins and may provide the antigenic basis for the development of improved diagnostic tests.[32] However, this response is not of neutralizing antibodies. These may take a long time to develop. At the same time the occurrence of interferon gamma producing cells is initially weak but this becomes much stronger from 3–6 months after infection. This response may be enhanced by the use of IL-12.[33] Several structural, functionally distinct, and specific antibodies to the virus are generated following infection or vaccination. Cell-mediated immune responses specific to the virus also occur.[34] The relative role of humoral and cell-mediated immunity in providing protection against disease is unknown.

A unique feature of infection is that viremia and circulating antibodies may exist together; the antibodies protect pigs from re-infection and reduce or eliminate shedding of the virus in the semen of boars. Sows are immune to further disease associated with the virus following recovery from acute infection. Following an outbreak of reproductive disease the level of performance will return to normal, suggesting that immunity develops following natural exposure.[35] Protection against subsequent reproductive losses is of long duration in individual animals. However, cross-protection to different strains may not occur. Experimentally infected sows are protected against reproductive losses when challenged with homologous virus over 300 days after initial exposure.[36] Extended studies against homologous infection found that the duration of protection was at least 604 days, which is essentially lifelong protection.[37] Protective immunity was based on two criteria: the absence of transplacental transfer of challenge virus, and the apparent lack of virus replication in the dam 21 days following inoculation.[38]

Piglets born from seropositive sows acquire **colostral antibodies** which decline at highly variable rates from 3 to 8 weeks after birth.[39] Passive immunity provides effective immunity for the piglets,[40] but loss of passive immunity at various ages results in susceptible pigs and infection that results in persistence of the virus in pigs 6–9 weeks of age, which are considered as the major reservoir of the virus in farrow-finish herds.[40] In the absence of natural infection, maternal antibodies become undetectable between 6 and 10 weeks of age.[39] Some litters do not have maternal antibodies and may not have detectable antibodies until 4 weeks of age, and clinical disease may occur at 2 weeks of age.[31] By 8 weeks of age, antibodies are usually detectable in all pigs and they persist for several months. However, there may be a large variation in the levels of antibodies in piglets at 10–12 weeks of age when they are moved to the finishing units.[39] In longitudinal surveys, the seroprevalence of the virus in the 4- to 5-week-old pigs were higher than in the 8- to 9-week-old pigs, and most pigs were negative when they entered the finishing units.[41] In herds where the virus persists, sows did not suffer repeated reproductive losses, indicating that some form of protective immunity develops.

The virus has a predilection for immune cells and disease manifestations can be linked directly to changes in the immune system.[34] The replication of the virus in the cells of the immune lineage, especially macrophages, may lead to immunosuppression and predispose to secondary infections. Thus immunity to the virus may be a double-edged sword; the virus attacks the immune system, which may cause immunosuppression, while at the same time inducing protective antibodies.

Antibody-dependent enhancement of infection may also occur since low levels of antibody enhance the ability of the virus to enter the pulmonary alveolar macrophage cells and replicate and destroy the cells. This may be important in sucking and nursery pigs exposed to the virus during a period of declining maternal antibody.

Environmental and management risk factors

Housing of all age groups in one building, introduction of new animals, housing on slatted floors, storage of slurry under floors, exposure to transport vehicles, and lack of disinfection procedures have been suggested as factors that increase the probability of herd infection. Lack of quarantine facilities for recently imported pigs is a major risk factor. There appears to be infrequent spread during warm weather compared to cold weather.[42]

Pathogen risk factors

PPRS virus strains have many identical properties but some antigenic differences. Strains of the virus from the United States and Canada are antigenically similar, and different from the European Lelystad virus isolate.[14,43] All the strains appear to be highly infectious.[44] There are serological differences between the European and American strains,[45] and the antigenic and genomic differences between the North American and European isolates suggests the existence of two genotypes.[46] There are different genotypes and at least three minor genotypes within the major US genotype.[47] The simultaneous

coexistence of the strains has been shown but the significance of the observation is not understood.[48] Genetic variations exist not only between European and US strains but among the US isolates, indicating the heterogeneous nature of the virus. Antigenic variation may affect the accuracy of diagnostic tests and the efficacy of vaccines.[49] The North American strains have been called type 2 virus. They are continuously varying. The European type 1 virus was thought to be less virulent and less likely to change but this may not be so, as recent isolations show that it is also continuing to change.

Infection with the virus does not always result in clinical disease and the detection of high levels of serum antibody in many herds without history of clinical disease suggests that the consequences of natural and experimental infection depend on a complex of factors associated with host susceptibility and virus virulence. In 2000–2001 there were severe outbreaks in the USA associated with new isolates.[50] There are now both European and US strains originating from viral vaccines in Poland.[51] The effects of the virus on reproductive performance are strain-dependent.[52] Strains of the virus cross the placenta when given to pregnant sows and most sows will remain clinically normal and farrow normally. However, depending on the strain used, the number of late-term dead fetuses from gilts infected experimentally at 90 days gestation may vary widely, and all gilts become viremic and develop antibody.[52] There are also marked differences in pathogenicity for the respiratory tract between US strains of the virus compared to the Lelystad virus when inoculated experimentally into 4-week-old cesarean-derived colostrum-deprived pigs.[53,54] Some strains cause severe lesions of the lymphoid and respiratory systems, which appear to be the major sites of viral replication.[55] The difference in pathogenicity may explain the variation in severity of clinical disease observed in field outbreaks.

Field observations have suggested that the presence of the virus in a herd may increase the susceptibility of animals to other infections. However, studies with sequential infection of the virus followed by experimental inoculation with *H. parasuis*, *Pasteurella multocida*, or *A. pleuropneumoniae* have failed to demonstrate increased severity of disease.[56] There is however strong evidence to say that PRRSv predisposes to *S. suis*.[57–60] It may also predispose to *Salmonella choleraesuis*,[61] *Bordetellae bronchiseptica*,[62] or *M. hyopneumoniae*.[63] This view is not universal in that infection with the virus did not increase the severity of experimental *Mycoplasma hyopneumoniae* infection in young piglets.[64] However, in the laboratory investigation of PRDC the most potent combination of agents is PRRSv and *M. hyopneumoniae*.[65,66] A model of the dual infection has recently been described in which M.hyo was shown to predispose to PRRSv infection.[67] Based on diagnostic submissions, however, concurrent pulmonary bacterial infections may occur in up to 58% of cases in which the virus was also isolated.[68]

There is also the possibility that many strains may be found in the same herd, e.g. three strains were found in one herd.[69] Several viruses have been found in the same pig and one great authority has expressed the view that each virus in each pig may be different from every other virus.[70]

A syndrome was described in neonatal pigs marked by neurovirulence. Replication in the brain was verified by IHC in brain sections. Meningoencephalitis induced by the virus was unusually severe.[71]

Methods of transmission

Virus is produced rapidly after infection probably within 12 hours.[72] The virus was shown to evolve continuously in infected pigs, with different genes of the viral genome undergoing various degrees of change.[73]

There are unlikely to be any wildlife reservoirs (except for feral and wild pigs)[61] although infected mallard can still excrete the virus 39 days later.[74] Most pigs clear PRRSV within 3–4 months but some may remain persistently infected for several months.[75,76] The antibody response does not reflect the carrier status. It is possible that cytokines can switch the balance from a sub-clinical infection to disease manifestation.[77] There is no evidence that PRRSv is found in the tonsils as a representative tissue.[78]

The virus spreads rapidly within herds when infected pigs are housed in confinement. Up to 90% of sows may seroconvert within 3 months of the virus being introduced into a closed breeding herd. The mode of spread is presumed to be by direct contact probably nose to nose. The virus generally requires close pig to pig contact to achieve an exposure dose. The virus is present in a variety of biological fluids,[74] nasal discharge (positive 21 days later), oropharyngeal scrapings (158 days later), possibly mammary secretions although this probably uncommon especially as previous vaccination does appear to prevent shedding,[79] urine (28 days) and feces (28 days), and intranasal inoculation has been used to reproduce the disease experimentally. The feces may be an intermittent source, a usual source, or not a source.[80] The virus is present in saliva and, considered in the context of the **social behavior** of pigs, may play an important role in transmission.[81]

The virus may persist in, and circulate between, different age groups and locations in a herd for several months despite the absence of clinical disease and may be transmitted by contact to replacement animals or to uninfected farms.[82] Infected pigs may remain carriers of the virus for up to 15 weeks.[31] Persistent and contact infection can be maintained in a nursery if uninfected pigs are continuously exposed to infected pigs.[19] Pigs in the nursery become infected through contact with older infected pigs and not by in utero or postpartum exposure to infected sows.[83] Long-term surveys of farrow-finish herds reveal that isolation rates of the virus reach highest level of 70–100% of pigs 6–8 weeks of age, which coincided with the lowest level of maternal immunity.[40] If you rely on infected nursery pigs to transmit infection to incoming gilts in acclimatization studies then nursery pigs may only be viremic for a maximum of 60 days.[84] There is no association between lymphadenopathy and PRRS viremia in nursery pigs 4 and 6 weeks post-weaning. Viremia cannot be predicted solely on the basis of clinical signs.[85] Large finishing enterprises purchasing pigs of variable infection and immune status provide ideal conditions for persistent virus circulation. Breeding herd subpopulations of infected pigs may exist, and perpetuate and enhance the infection in a herd. The inability to control such subpopulations may reduce opportunities for successfully controlling the disease.[21]

Infection may **persist** for an extended period of time because of:

- Incomplete infection of the susceptible population during the acute phase
- Introduction of susceptible breeding stock
- A persistent viral infection in individual pigs with the potential of shedding virus under certain conditions, such as grouping for weaning or farrowing
- A rapid decline in passive immunity in young pigs; and variable periods of active immunity.

Genetic randomness of isolates does not correlate with geographical distance. Movement on to the farm of PRRSv does not generally occur by distance limited processes such as the usual wildlife vectors but more typically occurs because of long distance transport of animals or semen.[86]

Spread between herds is associated with the introduction of infected carrier pigs. Infected boars may shed the virus in their semen for up to 40 days after experimental infection. In boars the virus can be found in semen by PCR for much longer

periods than can be found in the blood by virus isolation or antigen detection and the likelihood is that monocytes enter the bulbourethral glands which then contaminate the semen.[87] Following experimental infection of sexually mature boars the virus was present in the semen 3–5 days after infection, and on days 13, 25, 27, and 43.[88] Using a PCR assay the virus can be detected in semen for up to 92 days after experimental infection.[89] The insemination of gilts with semen from experimentally infected boars resulted in clinical signs of disease and failure to conceive.[90] Following artificial insemination of gilts with semen from experimentally infected boars, the gilts will seroconvert.[91] The use of the modified-live PRRS virus vaccine in boars is controversial because some boars may still shed wild-type virus in semen after challenge exposure 50 days after vaccination.[92] The inoculation of PRRSv negative replacement gilts with serum from nursery pigs presumed to be viremic resulted in seroconversion of all 50 gilts tested.[93]

Exposure of pregnant gilts to either attenuated (vaccine) or virulent (field) strains of the virus can result in **congenital infection**.[94] Congenitally infected pigs can support virus replication for a long period of time during which the viral replication is confined to the tonsils and lymph nodes.[95] After 260 days there were no serum antibodies and between 63–132 days there was no evidence of virus in the lung.[95] Vaccine and field strains can be transmitted postnatally from infected to non-infected littermates. Pigs infected with field strains have an inferior rate of survival and growth than do non-infected pigs. This suggests that use of attenuated virus vaccine during gestation is questionable.

The disease has occurred in PRRS-seropositive herds in Denmark with no previous clinical evidence of PRRS virus. These herds were then vaccinated with a modified live virus vaccine licensed for use in pigs 3–18 weeks of age.[96] Boars entering artificial insemination units were also vaccinated. Following vaccination, a large number of herds experienced an increased number of abortions and stillborn piglets, and an increasing mortality in the nursing period. The problems occurred mainly in herds without clinical signs among sows, and with sows with low antibody titers in the period immediately before vaccination. The PRRS virus was isolated from fetuses and identified as the vaccine virus. The evidence suggested that the vaccine virus had spread to non-vaccinated sows followed by transplacental infection of the fetuses. Spread of the vaccine virus was also demonstrated in a non-vaccinated and previously virus-free breeding herd.

Possible routes of transmission include:

- Introduction of vaccinated animals
- Use of semen from vaccinated artificial insemination boars
- **Aerosol transmission.** Although an experiment failed to transmit infection from pigs to pigs in a trailer parked 30 meters away[97] there is a suggestion that it is transmitted for a short distance but this possibly only occurs intermittently[98]
- **Others.** Fomites and infected personnel were shown to be capable of transmitting the virus following contact with infected material.
  Infected hands, boots and protective clothing can do it[99]
  Needles will transmit the virus[100]
  People do not usually act as vectors[101]
  Mosquitoes were not seen in one study to be a likely vector for PRRSv[102,103]
  Houseflies. The intestinal tract of houseflies will support infectious PRRSv for up to 12 hours following feeding on an infected pig but only for a short period of time on the surface of the fly.[104] Houseflies may transmit PRRSv within a herd of pigs and potentially between pig farms.[105]

Airborne spread across regions and between countries is suspected. In Europe, during the winter of 1990/91, the infection appeared to spread by the airborne route from Germany, across The Netherlands and into Belgium. Low temperatures, low sunlight, and high humidity may have facilitated airborne spread. Airborne spread up to 20 km has been suggested but most airborne spread is probably limited to less than 2 km. Usually it is difficult to transmit the agent one meter.[106,107] One author thinks that it may be capable of being transmitted 150 meters.[108]

A study in France of a series of outbreaks showed that 56% of the herds were infected through pigs, 20% through semen, 21% through fomites and the source was unknown in 3% of cases.[109] Epidemiological investigations in Belgium attribute 70% of herd infections to local spread, 9% to purchase of infected pigs, 4% to other contacts, and in 18% of cases the source of infection could not be determined. There is no evidence that rodents are susceptible to infection with the virus and are probably not a reservoir for the virus.[110]

Most spread between herds occurs by the introduction of unknown **infected breeding stock** into herds previously uninfected. Primary infections are common in multiplying herds which supply unknown infected replacement gilts to other farms.

The PRRS virus is fairly labile and does not survive for more than 1 day on solid fomites, but for several days in well and city water.[111] It may survive for several years in deep frozen tissues, but only 1 month at 4°C, 48 hours at 37°C and less than 45 minutes at 56°C. There appears to be a low risk from contaminated lagoon water and the viability of PRRSv in swine effluent is relatively short (1–8 days) although this is very temperature dependent.[112]

Pig meat does not retain detectable amounts of the virus and it is unlikely that the transmission through meat occurs.[113]

It is likely that piglets born with infection from in utero infection probably may remain viremic for ever even in the face of antibody formation. Neonatal infection is probably cleared slowly but infection in the older animal may be cleared much more quickly.

Economic importance

The export market for pork from a country can be seriously affected when a disease such as PRRS occurs. When the disease was recognized in the United States, countries such as Mexico, Japan, Canada, and South Korea banned the importation of pork from the United States, or required certification that the swine originated from premises where, within the 30 days prior to the issuance of the health certificate, no swine were introduced from a municipality in which a premises infected with the virus is located.

The economic losses may be very high because of stillbirths, abortions, small litter sizes, birth of weak pigs, which increases preweaning mortality, and increased non-productive days. In weaned pigs, losses are associated with respiratory disease. In addition, there are the costs of control which may be high, dependent on the control strategies undertaken. Typically, about 20% loss in annual production can be expected from a severe outbreak.

Negative weaned pigs had an increased margin per pig of $2.12 over the pigs minimally affected by PRRSv in the nursery but which seroconverted in the finishing herd, and $7.07 over the pigs with persistently circulating PRRSv in the nursery.[114]

PATHOGENESIS

Many piglets are probably infected in utero. This infection modulates the leukocyte subpopulations in peripheral blood and bronchoalveolar fluids.[115,116] Following infection the number of $CD8^+$ cells increased in systemic lymphoid tissue whereas numbers of B-cells increased in mucosal associated lymphoid tissue.[117] Virus infection induces a simultaneous polyclonal activation of B-cells mainly in

the tonsils and an exaggerated and prolonged specific humoral immune response due to persistent viral infection in lymphoid organs.[118] Piglets surviving in utero infections have a high count of $CD8^+$, $CD2^+$, $CD4^+CD8^+$, SLA-class II cells in the peripheral blood.[119] The cytokine changes have been described.[120–122] Persistent infection occurs in these pigs.[123] Virus appears to persist in the lymphatic organs and particularly the tonsils and the lungs.[124] Lymphoid tissue tropism occurs during persistent infection when the piglets have been exposed in utero.[125] There may be a PRRSv ligand for a cell surface heparin-like receptor on pulmonary alveolar macrophages.[126] It has been shown that PRRSv entry into the alveolar macrophage involves attachment to a specific virus receptor followed by a process of endocytosis, by which virions are taken into the cell within vesicles by a clathrin dependent pathway.[127] The alveolar macrophages when infected round up, show bleb formation and eventually rupture.[128] TNF α released from damaged macrophages after PRRSv infection may induce apoptosis in uninfected lymphoid cells.[129] In a study of cells in the lungs it was found in both non-infected and infected cells. The majority of the apoptotic cells were non-infected. The peak of apoptosis was at 14 days and was preceded by a peak of IL-1 and IL-10 production at 9 days post-infection.[130] The PRRSv infection directly interferes with type 1 IFN transcriptional activation.[131]

Neonatal or nursery infection is probably through the virus reaching the nasopharyngeal epithelium following inhalation from the nose to nose contact with other pigs. It is then probably removed to the tonsils where they are internalized into cells of the macrophage/monocyte series.

As few as 10 or even fewer virus particles inoculated into the nose or given intramuscularly will infect a pig.[132] The virus may enter the cell through an endocytic pathway[133] or through a virus receptor.[134] A third possibility is that the virus may enter the cell through an antibody-dependent enhancement with virus-antibody complexes entering the cell through Fc receptors on the cell surface.[135]

Initially, a viremia occurs, with subsequent distribution and multiplication of the virus in multiple body systems and organs causing interstitial pneumonia, vasculitis, lymphadenopathy, myocarditis, and encephalitis.[136] Alveolar macrophages are primary targets for virus multiplication but this does not fully explain the pathogenesis.[34] Multiple glycoproteins appear to be involved in infection of pulmonary alveolar macrophages.[137] Possibly up to 40% of alveolar macrophages are destroyed.[138] Whether it is a particular group that is damaged or not or all the alveolar macrophages is not known but after about 28 days there is a resumption of normal alveolar macrophage function. PRRSv causes the apoptosis of alveolar macrophages and pulmonary intravascular macrophages.[139] The increase in IFN gamma positive cells correlated well with the severity of the lung lesions which may be because of the presence of PRRSv in the lung.[140] IFN gamma markedly inhibits the replication of PRRSv in macrophages.[141] The effects of the virus on the immune system may explain the suspected immunosuppression and secondary infections, which are recognized clinically but have not been reproduced experimentally. The cytokines IL-10 and IL-12 are expressed in inflammatory lesions in the lung and play an important role in the defense against PRRSv.[142] In utero infected pigs showed significantly increased IL-6, IL-10 and IFN gamma mRNA expression (IL-2, IL-4 and IL-12 remained the same) and this was concurrent with a significant decrease in the number of $CD4^+CD8^+$ T-cells.[121] The cell mediated and cytokine message profiles returned to normal levels similar to those of control pigs by about 10 weeks of age. The induction of the IL-10 response may be one of the strategies used by PRRSv to modulate the host immune responses.[143] Increases in IL-4, gamma IFN and TNF α were found in the lymphocytes of infected piglets but IL-8 showed a decrease.[120] Other authors have the opposite views[144] who showed that T-cells showed an increase in $CD8^+CD4^+$ and $CD4^-CD8^+$ subsets within activated cells, whereas $CD4^+CD8^-$ cells decreased with time. T-cells responding to the virus showed a Th1 type cytokine production pattern.[145] These authors also reported a decrease in TNF-α and a decrease of IL-1-α and macrophage inflammatory protein which are contrary results to the above. Perhaps this is the key to PRRSv infections in that all pigs may respond differently. There may be either depressive or stimulatory effects.[146,147] The imbalance of IL-12 and IL-10 produced in PRRSv infected pigs may favor the humoral responses and suppress cell mediated immune responses for the first 2 weeks of life.[148]

There was also a temporary immunosuppression in piglets at about 4 weeks post-infection. Vascular lesions associated with PRRS virus infection are analogous to those observed in horses with equine arteritis virus, also a member of the Arteriviridae family,[149] and the renal lesions of equine viral arteritis infection correspond to those of PRRS. Inflammatory infiltrates are seen at the junction of the renal cortex and medulla, with vascular changes associated with the muscular tunics of small arterioles.

The characteristic lesions can be reproduced in conventional pigs at 1, 4, or 10 weeks of age, and the variation in severity of clinical disease can be attributed to differences in strain virulence.[54,150] The effects of the virus on reproductive performance are also strain-dependent.[52] There is no evidence that virus will grow in the ovarian tissues but may be taken into them by circulating macrophages. PRRS virus can replicate in the testicular germ cells[151] but there is no evidence that there is any PRRSv in ova indicating that the female gonad is resistant to persistent infection.[152] Some strains are of low pathogenicity, while others are highly pathogenic.[153] The reproductive disease has been reproduced experimentally and the effects on the fetus are dependent on the stage of gestation. Aerosol exposure of non-immune pregnant gilts to the Lelystad virus in late gestations (84 days) results in clinical disease.[154] After an incubation period of 4–7 days, all sows are inappetent and listless for 6–9 days. Some sows develop blue-colored ears accompanied by abdominal respirations. Sows may farrow at days 116 and 117 of gestation, giving birth to dead, mummified, and live piglets. Many of the live-born piglets are pale, listless, and weak, and some are in respiratory distress and exhibit varying degrees of splayleg or muscular tremors. The virus may be isolated from stillborn piglets or those born alive. Antibody is present in precolostral serum samples or ascitic fluids of piglets, which demonstrates transplacental passage of the virus.

The gross and microscopic lesions in the fetuses from sows experimentally infected oronasally with the virus at 90 days of gestation consist of hemorrhage of the umbilicus and necrotizing umbilical arteritis with periarterial hemorrhage.[155] Severe pulmonary lesions are present in fetuses inoculated in utero with the virus between 45 and 49 days of gestation.[156] Even the lowest PRRSv exposure dose[102] caused reproductive failure in naïve, unvaccinated animals.[157] When sows are inoculated oronasally with the virus in mid-gestation the virus does not readily cross the placenta, but replicates in fetuses that are inoculated directly in mid-gestation.[158] It is suggested in prenatal piglets that PRRS replicates primarily in lymphoid tissues, having gained access to the them from the placenta via the bloodstream.[159] Thus the fetuses are more susceptible in late gestation than earlier in mid-gestation,[160] or there is greater likelihood of transplacental infection during late gestation.[161] Experimentally, the intrauterine inoculation of the virus

into gilts on the day after natural breeding may have little or no effect on their reproductive performance.[162] There appears to be no direct or indirect effect on luteal function contributing to PRRSv induced abortion.[163] The virus may cause cell death directly such as the alveolar macrophages, or in lymphoid tissues. PRRSv affects Marc 145 cells which undergo necrosis at a much higher rate than apoptosis, and increases with virus levels used to infect the cells.[164] Apoptosis does occur in PRRSv infected cells but it is a late event during PRRSv replication and rapidly results in a necrotic-like death.[165] Lesions have been seen in the placenta and in the vessels of the umbilical cord but these are rarely reported with European strains although they may be more common with the USA strains.

The original descriptions of porcine necrotizing pneumonia (PNP) were associated with swine influenza but more recent research has shown that PRRSv is consistently and predominantly associated with PNP and should be considered the key etiologic agent for PNP together with PCV2.[166]

CLINICAL FINDINGS

The main feature of clinical disease associated with this virus was the extreme variability of the clinical signs. In general signs associated with PRRSv appear to result from a combination of genetic factors and herd management characteristics. The relative influences of these two factors differ depending on the specific clinical signs in question.[167] These may vary from inapparent infection to sudden death and abortion storms (the sow abortion and mortality syndrome). Its synergism with PCV2 is in doubt. It does not seem to be potentiated by the other great pig pathogen PCV2 virus[168] on one hand but on the other hand, others think it increases the severity of PRRSv induced interstitial pneumonia.[169] It may be that PRRS infection enhances PCV2 replication.[170] It is predisposed by *M. hyopneumoniae* and this can be reduced by vaccination for *M. hyopneumoniae*.[171] In turn PRRS predisposes to *Bordetella bronchicseptica*.[172,173] Both may interact to reduce the efficiency of lung defense mechanisms and facilitate infection with *P. multocida*. There is little effect on *H. parasuis* secondary infection with a slight increase in macrophage uptake of HPS during the early infection which is reduced after 7 days.[174] There is evidence that concurrent infection with TGEv and PRRSv is likely to have little or no effect on subsequent shedding or persistence of infection.[70] Infection with PRRS is common in pigs with PMWS but there is no evidence that PRRS is necessary for the development of PMWS.[175] PRRS has been seen in a swine herd with PCMV.[176] Synergism between PRRSv and *Salmonella choleraesuis* has been described with unthriftiness, rough hair coats, dyspnea, and diarrhea. Pigs that received dexamethasone were the most severely affected and half died but they also shed significantly more organisms in feces and also had significantly higher PRRSv titers.[177] Simultaneous infection between PRRSv and *S. suis* is much more severe than with either agent on its own.[178] PRRSv induced suppression of pulmonary intravascular macrophage function may in part explain PRRSv associated susceptibility to *S. suis* infection.[179]

There is also a clear synergism between PRRSv and LPS in the exhibition of respiratory signs in conventional pigs.[180,181] In these joint infections the rise in TNF-α, IL-1, and IL-6 were 10–100 times higher than in the single infections.[181] Reproductive failure and respiratory disease are the major clinical findings which are also highly variable between herds. All age groups in a herd may be affected within a short period of time.

Pigs infected with both PRRSv and *M. hyopneumoniae* had a greater percentage of pneumonic lung, increased clinical disease and lower viral clearance[182] than pigs with single infections. There were also increased levels of IL-β, IL-8, IL-10, and TNF-α in lung lavage fluid and this may be the way that the joint infection increases the pulmonary response.

Reproductive failure

If 90-day gestational gilts are given vaccine or field strains of PRRSv then some pigs are born dead, most pigs survive and some pigs were infected in utero. Vaccine strains did not affect postnatal growth but field strains reduced growth.[94] It may be that the virus entered the reproductive tract through the viremia and then the seeded tissues may release the virus back into the serum at low levels.[183]

Anorexia, lethargy, depression, and mild fever in pregnant gilts and sows are common initial clinical findings affecting 5–50% of animals. This is commonly followed by a sudden increase in early farrowings at 108–112 days of gestation, late-term abortions, stillborn and mummified fetuses, partially autolyzed fetuses, weak neonates with high mortality within a few hours or days after birth, late returns to estrus, and repeat breeders. This is generally followed by mid-gestation abortions, and marked increases in the percentage of mummified fetuses, early embryonic death, and infertility. In large herds, successive groups of 10–20% of gilts and sows may become anorexic over a period of 2–3 weeks. Cyanosis of ears, tails, vulvas, abdomens, and snouts may occur in a small number of sows, and occurs more commonly in European outbreaks and is uncommon in North America. Following the initial outbreak, a 'storm' of reproductive failure may occur consisting of premature farrowings, late-term abortions, an increase in stillbirths, mummified fetuses, and weak neonates. This second phase of reproductive failure may last 8–12 weeks. Stillbirths may reach 35–40%. Weakborn piglets die within 1 week and contribute to a high preweaning mortality.

In subsequent times with the European strains there may be just outbreaks of rolling inappetence or occasional early farrowings. However, there are serious clinical outbreaks in Italy, Poland and outbreaks associated with new variants in the UK.[184]

Reproductive disease may be preceded by, or follow, respiratory disease in the breeding herd, the finishing pigs, or younger pigs. The reproductive aspect of the disease typically lasts from 4–5 months, occupying an entire reproductive cycle within a herd. This is followed by a return to normal performance. Repeated incidents of reproductive failure in individual gilts and sows are unusual but recurrent episodes may occur in herds purchasing replacement gilts that do not have sufficient immunity.[185]

Outbreaks of the disease are characterized by a period of severe reproductive problems in the breeding herd, followed by a return to near normal reproductive performance, punctuated by recurrent episodes of reproductive failure.[186] Most herds eventually return to pre-outbreak levels of reproductive performance but some herds never achieve pre-outbreak performance levels.

Boars may also be affected with anorexia, fever, coughing, lack of libido, and temporary reduction in semen quality.[184]

Respiratory disease

The most important problem facing many of the larger pig industries in the world is porcine respiratory disease complex (PRDC). The most important contributor to this syndrome is PRRS virus. The generation of immunity capable of protecting pigs by mediating virus inhibition through virus neutralizing antibodies or interferon takes time.[187]

Disease occurs in pigs of any age, but especially in nursing and weaned pigs, and is characterized by anorexia, fever, dyspnea, polypnea, coughing, and subnormal growth rates. A bluish discoloration of the ears, abdomen, or vulva may also occur – 'blue-eared disease'. Death may occur in the acute phase. In some herds up to 50% of pigs are anorexic, up to 10%

may have a fever, up to 5% are cyanotic, and up to 30% have respiratory distress. In weanling pigs the morbidity may be as high as 30%, with a mortality of 5–10%. Nursery pigs exhibit respiratory distress and growth retardation. Conjunctivitis, sneezing, and diarrhea are common. All of these signs may appear to move through the various age groups in the herd over several days and a few weeks. The course of the disease in a herd may last 6–12 weeks. In gilts and sows of any parity, anorexia and fever, lasting for several days, are noted initially. The acute-phase respiratory disease may last several months but is often followed by a long period of postweaning respiratory disease which may last up to 2 years. This long course is often accompanied by secondary infections in successive batches of weaned pigs. Unthriftiness may persist throughout the finishing period with an ineffective response to antibiotics and vaccines.

Preweaning morbidity and mortality is a major feature of the disease. Litters are often unthrifty, and many deaths occur within the first week of age.

CLINICAL PATHOLOGY

PRRSv infection significantly increases the number of alveolar macrophages in bronchoalveolar lavage fluid approximately 10-fold between day 10 and day 21 of infection.[188] Approximately 63% of the cells were cytotoxic T-cells and natural killer cells. Serum haptoglobin levels were increased from 7–21 days.[189]

Piglets also become anemic in PRRSv infections and the most highly pneumovirulent strains induced the more severe anemia. This is probably due to a direct or indirect effect on the erythroid precursor cells of the bone marrow.[190]

A definitive diagnosis requires detection of virus in infected animals, detection of antibodies in fetal fluid, or in precolostral blood of stillborn and weak-born piglets.[191] Detection of antibodies in sera of groups of pigs of different ages is also necessary. The most suitable body fluid and tissue samples and diagnostic tests for the etiologic diagnosis of PRRS are dependent on several variables including:

- Age of pigs from which samples are collected
- Stage of infection (acute or persistent)
- Available complement of diagnostic reagents
- Urgency of obtaining results.[192]

When congenitally or neonatal pigs are affected, both serum and alveolar macrophages are reliable samples. For older pigs, alveolar macrophages are more reliable than serum.

Detection or isolation of virus

The virus can be demonstrated by isolation using cell cultures, by direct detection of viral antigen in tissue sections, or by the detection of virus-specific RNA.[191]

Samples used for virus isolation include serum, thoracic fluid, spleen, and lung. Porcine pulmonary alveolar macrophages are used for isolation of virus. Alveolar macrophages using immunofluorescence microscopy can be used for detection of virus during acute infections.[193] The PCR assay is a reliable, sensitive, and rapid test for the detection of virus in boar semen.[194] It can also be used to determine whether suckling piglets are infected with PRRSv before vaccination and for determining the relationship between parity and shedding of virus.[195] It can also be used to obtain PRRSv piglets.[196] PCR followed by RFLP analysis using several restriction enzymes provides a good genetic estimate for isolate differentiation.[197] A reverse transcription and PCR, coupled with a microplate colormetric assay, is an automated system that is a reliable and easy test for the routine detection of the virus in semen samples from seropositive boars.[198] Multiplex RT nested PCR can be applied to formalin-fixed tissues.[199]

A nested PCR has been described that is 100–1000 times more sensitive than the usual PCR.[200]

An assessment of the viral load can possibly be made by using the quantitative competitive RT-PCR.[201] A quantitative Taqman RT PCR is time saving, easy to handle, less likely to be cross contaminated and highly sensitive and specific.[202] Immunohistochemical techniques are available for the detection of virus in formalin-fixed tissues.[203,204] The virus was detected in 11–23% of animals with interstitial pneumonia. It was found in 21–31% of animals less than 3 months of age but in only 6–17% of those more than 4 months of age.[205] The immunogold silver staining is superior to the immunoperoxidase staining systems for detection of virus in formalin-fixed tissues.[206,207] Reverse transcription-polymerase chain reaction (RT-PCR) is also available and can distinguish between North American and European strains.

A double ISH technique has been developed[208] which can show both PRRSv and PCV2 and a small number of alveolar macrophages stain for both antigens.

Serology

Serological tests have good sensitivity and specificity for diagnosis on a herd level and less so on the individual animal. The tests in common usage are described below. One of the problems is that the serological response to a nonvirulent strain is the same as it is to a virulent strain.[204] It is also important to realize that although a positive result for antibody indicates exposure to virus, a negative test does not necessarily mean that the pig is free from PRRSv or has not been in contact with the virus.[209]

Immunoperoxidase monolayer assay test

The immunoperoxidase monolayer assay (IPMA) is often the first test used. Approximately 75% of sows infected with the virus seroconvert to the Lelystad virus. However, the IPMA does not allow for large scale surveys.

Indirect enzyme-linked immunosorbent assay

Indirect ELISA is used for the routine serodiagnosis; it is simple, inexpensive, effective, and a better alternative to the indirect immunofluorescent assay or the immunoperoxidase assay.[210] It is suitable for the screening of large numbers of samples and is best used as a herd test.[211] Because of marked differences between and within North American and European virus isolates, serological tests using only one antigenic type of the virus may potentially yield false-negative results with antisera against diverse antigenic types of the virus. A mixture of ELISA antigens from North American and European strains gives superior results when both types of viruses are known to exist.[212]

A meat juice ELISA has been developed which gives complete agreement with the serum ELISAs.[213,214]

Indirect fluorescent antibody assay

Immunofluorescent antibody (IFA) is a highly sensitive test. Antibody titers are detectable in infected pigs 8 days after inoculation. The IgM IFA test is also a rapid and simple test for diagnosing recent infection as early as 5–28 days after infection in 3-week-old piglets, and 7–21 days in sows.[215]

Modified serum neutralization test

This test is useful for the detection of later and higher levels of antibody when the conventional methods cannot detect antibody. The test can differentiate between strains.[216] The serum neutralization test is not used for routine diagnosis[191] because neutralizing antibodies do not appear early on in the infection.[217]

Herd diagnosis

The serological diagnosis must be used and applied on a herd basis, and acute and convalescent sera submitted for optimal results. A baseline herd sampling is necessary to evaluate the status of a herd and to determine if and in which groups the virus is circulating. In large herds of over 500 sows, samples are taken from 30 animals in each breeding, gestation, and farrowing group, with representation from all parities. In

addition, 10 nursery pigs (5 weeks old), 10 pigs at the end of the nursery period, and 10 pigs in late finishing stage constitute a **herd profile**. Thus, serological monitoring can be used to monitor the circulation of virus within a closed herd and to determine infection status of breeding animals which are to be introduced into seronegative herds.[218] Results from the sow sera indicate if the sow herd is virus-negative, stable, or has an active virus circulation. Comparison of the early and late nursery pigs indicates if the virus is circulating in the nursery. Comparing the nursery results with the end of the finishing period indicates if the virus is circulating in the finishing groups of pigs. IFA titers in pigs range from 1:256 to 1:1024 by 2–3 weeks after infection. Titers decline over 3–4 months unless reinduced by exposure to circulating virus. Uninfected nursing pigs are negative or have maternal antibody. Seropositive 9 to 10-week-old pigs leaving the nursery indicate virus circulation in the nursery. If pigs leaving the nursery are negative, and positive later in the finishing unit, virus circulation is occurring in the finishing unit.

Sera from outbreaks of the disease in the United States, Canada, and Europe have been compared, and although the isolates from both continents are closely related, the strains isolated in the United States and Canada are more closely related serologically than they are to the European strains.

NECROPSY FINDINGS

A series of postmortem examinations of different aged pigs obviously from different stages of production will tell you what is going on over time. A series of such examinations will probably tell you more than any other investigations.

No characteristic gross lesions are present in sows, aborted fetuses or stillborn piglets. Microscopic lesions which may be present in aborted fetuses include vasculitis of the umbilical cord (not recorded in European strain infections) and other large arteries, myocarditis, and encephalitis.[219,220] Unfortunately, none of these changes is present consistently, and the majority of fetuses and placentas are histologically normal. These lesions are all more common in the North American virus infections.

In suckling and grower pigs, infection with the PRRS virus is usually characterized by an interstitial pneumonia. The PRRSv affects both pulmonary intravascular macrophages which may be important as a replication site and alveolar macrophages.[221] Loss of bactericidal function in pulmonary intravascular macrophages may facilitate hematogenous bacterial infections. When Danish isolates were injected into piglets, PRRSV was isolated from the lungs and/or tonsillar tissues from both dead and culled piglets under 14 days of age.[222] Tracheobronchial and mediastinal lymph nodes are usually enlarged and firm. The gross pulmonary changes vary from lungs that appear normal but fail to collapse, to lungs that are diffusely red, meaty, and edematous. Porcine proliferative and necrotizing pneumonia has been linked to infection with PRRS virus, although the involvement of an unidentified co-pathogen cannot yet be discounted. Grossly, this form of pneumonia appears as confluent consolidation of the cranial, middle, and accessory lobes, together with the lower half of the caudal lobe. Affected lobes are red-gray, moist, and firm (meaty) in consistency. On cross-section, the affected lobes are bulging and dry, and the pulmonary parenchyma appears similar to thymic tissue.

In general histological lesions in piglets are focal non-suppurative inflammatory conditions particularly in the lung and heart.[222] Most of the cells undergoing apoptosis do not have markers for PRRSv which suggests that there is an indirect mechanism for the induction of apoptosis.[223]

Histologically, in addition to marked proliferation of type II pneumocytes in alveoli, there is severe necrosis of bronchiolar epithelium, with necrotic cellular debris plugging the airway lumina.

In the less severe and more common forms of PRRS pneumonia, the alveoli contain protein-rich fluid and large macrophages, some of which may appear degenerate. There is patchy thickening of the alveolar septa, due to infiltrating mononuclear leukocytes and mild, type II pneumocyte hyperplasia. Lymphoplasmacytic cuffing of arterioles is common and syncytial cells are occasionally seen. In field outbreaks, it is usual for the lung pathology to be complicated by concurrent respiratory pathogens.

Microscopic lesions may be found in many other tissues and include multinucleate cell formation within lymph nodes, infiltrates of lymphocytes and plasma cells in the heart, the brain, and the turbinates, plus a lymphocytic perivasculitis in various sites.[18,224] Thymic lesions include severe cortical depletion of thymocytes.[225] An in situ hybridization technique is a rapid, highly specific, and sensitive detection method for the diagnosis of PRRS virus in routinely fixed and processed tissues.[226] Immunohistochemical techniques can also be used to detect the virus in neurovascular lesions.[227] PRRSv and reovirus 2 have been found in brain, lung and tonsil by inoculation into Marc 145 and CPK cells.[228] Immunohistochemistry on one section would give a positive in 48% of cases, but if five sections were studied then there are positives in >90% of PRRSv infected pigs. If the animals are vaccinated then the positives fall to 14%.[229]

Samples for confirmation of diagnosis

- **Histology** – lung, tonsil thymus, thoracic lymph node, brain, kidney, heart, (umbilicus from fetus) (LM, IHC)
- **Virology** – lung, thoracic lymph node, tonsil (ISO, FAT, PCR).

DIFFERENTIAL DIAGNOSIS

Respiratory disease must be differentiated from:

- Swine influenza
- Porcine respiratory coronavirus
- Enzootic pneumonia (*Mycoplasma hyopneumoniae*)
- *Actinobacillus pleuropneumoniae*
- *Pasteurella multocida*
- Glasser's disease (*Haemophilus parasuis*)
- *Streptococcus suis*.

Reproductive disease must be differentiated from other causes of abortion, stillbirths, and weak neonates in pigs:

- Leptospirosis
- Encephalomyocarditis virus
- Hog cholera virus
- Pseudorabies virus
- Parvovirus
- Fumonisin, a recently identified mycotoxin produced by *Fusarium moniliforme*, has been associated with the appearance of PRRS in swine herds in the United States.

A definitive diagnosis requires a detailed epidemiological investigation of the epidemic including a detailed analysis of the breeding and production records for the previous several months, and the submission of tissue and serum samples for laboratory investigation.

TREATMENT

There is no specific treatment against the virus. In outbreaks of respiratory disease, mortality can be reduced by insuring that the environmental conditions in the barns and pens are adequate, the stocking density is kept low, and the feeds and feeding program are monitored. Routine procedures such as tail docking, iron injections, castrations, teeth clipping, and cross-fostering should be delayed or not done during the acute phase of the disease. Supplemental heat for neonatal pigs should be provided if necessary. Sows that have aborted their litters should not be bred until the normal time of weaning. This will reduce the incidence of infertility common at the first estrus after the abortion or premature farrowing. Culling of

sows should be minimized and weekly breedings increased by 10–15%. Replacement gilts may be introduced into the premises for exposure to infection before breeding. The consequences of boar infertility and low libido may be minimized by use of artificial insemination or by using multiple sires on each sow. Recurrent illness and secondary infections in weaner and growing pigs can be continuing problems for a few months after an acute outbreak. Reducing the stocking density and an all-in all-out strategy have been successful to reduce the chronic problem. If there is the possibility of treating secondary infections then this should be undertaken. Serum inoculation of naïve gilts has been described and this was shown to be capable of stabilizing sow herds and as shown by the production of negative weaned pigs.[230]

CONTROL

Control of PRRS is difficult, unreliable, and frustrating because of the complexity of the disease; the uncertainty of some aspects such as immunity, persistence, diagnosis, and the lack of published information based on control programs which have been evaluated under naturally-occurring field conditions. Much of the information available on control is anecdotal and not based on well-designed control programs that can be compared and evaluated. A major problem is the difficulty of obtaining a definitive etiological diagnosis when presented with young growing pigs with respiratory disease and the possibility that other pathogens could be involved. The diagnosis of reproductive failure in gilts and sows is also commonly uncertain.

Some characteristics of the disease are important in planning control programs for individual herds:

- Infection is highly contagious and is transmitted by direct contact. Non-immune pregnant gilts and sows, and young pigs, are highly susceptible to infection resulting in large economic losses
- Infection of breeding stock results in immunity. The efficacy of vaccination is not well-established
- Maternal immunity is present in piglets born from seropositive sows
- Infection can persist for many weeks and months in individuals and in subpopulations of animals
- Infections are usually introduced into a herd by the introduction of infected pigs.

There are two main options for control: **eradication of the virus from individual swine herds**; and **controlling the disease in individual herds to create a stable positive system that allows you to live with the disease.** Controlling the disease requires developing strategies to make pigs immune to the infection by controlling infection pressure in the herd and inducing naturally acquired immunity in the herd, or inducing acquired immunity through vaccination. The recommendations for control set out here are guidelines that can be applied and modified to meet different circumstances.

Table 21.2 Nursery depopulation and clean-up protocol for elimination of PRRS.

Day	Procedure
1	Empty all nurseries, off-site wearing, pump out slurry pits, clean and wash rooms with hot water (>95°C), and disinfect with formaldehyde-based product. Allow disinfectant water to remain in pits overnight
2	Pump out pits, repeat washing procedure, and disinfect in phenol-based product. Allow disinfectant to remain in pits
3–11	Allow facility to remain vacant
12	Pump out slurry pits, repeat washing procedure, and disinfect with formaldehyde-based product
13	Allow facility to remain vacant
14	Resume conventional flow of pigs into clean nurseries

Eradication of the virus from the herd

Depopulation and repopulation

Eradication of the virus from the herd by depopulation of the entire herd followed by repopulation with virus-free breeding stock is biologically possible, but in most cases is impractical and too expensive. Obtaining virus-free breeding stock is usually not possible and, if possible, the herd is highly susceptible to accidental reinfection.

Control in infected herds

Nursery depopulation

Control within a breeding herd is based on the observation that pigs commonly seroconvert to the virus during the nursery period. Pigs are seronegative shortly after weaning, but 80–100% are seropositive at 8–10 weeks of age.[83] A control program based on a **nursery depopulation** consists of emptying the nurseries and moving **all of the pigs** to off-site finishing facilities or selling them as feeder pigs.[231] Test and removal has been described.[232] This is combined with batch farrowing and weaning at intervals of at least 3 weeks.[19] The nurseries are completely emptied, cleaned three times with hot water and disinfectant, the slurry pits are pumped out after each cleaning, and the facilities are kept empty for 14 days, during which time all pigs weaned are moved to off-site nurseries, and after which the conventional flow of pigs into the cleaned facilities are resumed. The control program can result in significant improvements in both average daily gain and percentage mortality but it will not eliminate the virus from the herd.[231] Using a partial budget model to measure the profitability of nursery depopulation, the financial consequences indicate that it is a profitable strategy to improve pig performance in herds affected with the virus.[233] Additional income is generated by the increased number and weight of marketable pigs, as a result of their increased growth rate and decreased mortality. Lower treatment costs reduce overall expenses but there are additional costs due to extra feed necessary to raise the additional pigs and the costs required to house the depopulated pigs. However, it is possible that the economic benefits are due to the control of other pathogens and not merely the PRRS virus.

The details for a nursery depopulation and clean-up protocol for the elimination of the virus are shown in Table 21.2.[234]

Management of gilt pool

Management of the gilt pool is the single most important strategy for long-term effective control. Controlling the infection in the breeding herd is a prerequisite to controlling infection in the nursery and finishing pig groups. Strategies like partial depopulation and piglet vaccination are ineffective unless the breeding herd is first stabilized, preventing piglets from being infected before weaning. Replacements are a major source of introduction of the virus and activating existing virus in the breeding herd. They also initiate the formation and maintenance of breeding herd replacements.

Subpopulations are subsets of naive or recently infected gilts or sows which co-exist within chronically infected herds. These subpopulations perpetuate viral transmission in the breeding herd and farrowing units, which ultimately produces successions of infected piglets prior to weaning. Modifications in gilt management that may minimize subpopulations include ceasing introduction of replacement animals for a 4-month period, beginning to select replacements from the finishing unit, or introducing a 4-month allotment of gilts at one time.

Exposure to the virus in the breeding herd can be controlled by managing the gilt pool using two strategies.[235] In one strategy, herds may be closed to outside replacements, and replacement males and females are raised on the farm. In the other strategy, replacement gilts are held in an off-site holding facility from 9 to 12 weeks of age until breeding age at 7–7.5 months, or even much earlier. This is combined with nursery depopulation as described above. Prior to entry of the gilts into the herd they are serologically tested for evidence of seronegativity or a declining titer, which is required for entry into the herd. The gilts are isolated and quarantined for acclimatization for 45–60 days. This may be combined with two vaccinations, 30 days apart, after entering quarantine. This method reduces the risk of introducing potentially viremic animals into the existing population. The method selected will depend on the production system, management capabilities, and facilities available on each farm. The introduction of younger gilts, in larger groups, less frequently throughout the year, is being recognized as the most effective method for introducing replacement stock to virus-infected herds and long-term control of the disease.

Controlled infection of breeding herd

The presence of subpopulations of highly susceptible breeding animals in the herd can be a major risk factor for maintaining viral transmission within problem herds and may explain recurrent outbreaks of reproductive failure. By intentionally exposing all members of a population to the virus it may be possible to eliminate subpopulations and produce consistent herd immunity.[21] In endemic herds, exposure of gilts to the virus prior to breeding is critical for prevention of reproductive failure. Seronegative replacement gilts can be introduced into seropositive herds at 3–4 months of age to allow for viral exposure before breeding. If the status is uncertain, quarantine and exposure to nursery pigs of the importing unit is a suitable policy if replacement gilts are bought in before they are bred. It is possible to convert a PRRS positive unit to a negative herd by managing the gilt pool and regulating the pig flow. It appears that PRRSv infection eventually either disappears or becomes inactive in the donor gilt population.[236] Similarly serum from nursery pigs (thought to be PRRSv viremic) given to negative replacement gilts resulted in seroconversion of all 50 gilts receiving the serum.[237]

Control of secondary infections

When outbreaks of the disease occur in nursing piglets, and virus circulation is occurring continuously in the farrowing facility, the following are recommended:

- Cross-foster piglets only during the first 24 hours of life
- Prevent movement of pigs and sows between rooms
- Eliminate the use of nurse sows
- Euthanize piglets with low viability
- Minimize injections of suckling pigs
- Stop all feedback of pig and placental tissues
- Follow strict all-in all-out pig flow in the farrowing and nursery rooms.

These are similar to the system developed in the USA called the McRebel system. This was a method of control which showed that cross fostering of piglets should be minimal within the first 24 hours and banned after this time.[238]

Feedback has been tried although there are a lot of reasons not to do so. Minced whole piglets were fed to sows and the herd then closed for 23 weeks. No clinical signs were observed. One third of the sows present at the time of the outbreak were still seropositive 20 months after the deliberate infection.[239] Disinfection at cold temperatures was described.[240]

Biosecurity

Standard methods, such as quarantining and serological screening of imported breeding stock and restrictions on visitors are recommended to keep units free of infection. Control of infection between herds depends on restricting the movement of pigs from infected herds to uninfected herds. If pigs have to be bought in, then seropositive animals should be imported into seropositive herds. Only seronegative boars should be allowed entry into artificial-insemination units.

Vaccine and vaccination

Vaccination is an aid to management in developing effective immunity. The goal is to produce a constant level of immunity across a defined population. This effectively immunizes the entire population and eliminates the non-immune, susceptible subpopulations. Vaccination is most effective when used in replacement gilts combined with adequate isolation and acclimatization, and in sows after farrowing and prebreeding. The routine vaccination of sows is not economically viable in herds affected with PRRS virus.[241] The vaccine is best suited for stabilizing the herd and is a necessity prior to nursery depopulation or commingling segregated early weaning piglets from virus-positive herds. Vaccination is also intended to produce protective immunity in weaned and growing pigs. The PRRS virus exists in many forms and therefore the closer the genetic make up between the immunizing virus and the challenge virus the better.[159]

Both inactivated and modified live virus vaccines are available. Killed vaccines may not produce a measurable antibody response stimulation and activation of lymphocytes does occur and any subsequent exposure with vaccine or field virus increases that response. There is no possibility of producing a viremia and no chance of producing shedding and there are no detrimental effects on the host. However there is no evidence that killed vaccines protect against heterologous challenge.

A killed, oil-adjuvanted vaccine based on a Spanish isolate of the virus is intended for protection against reproductive disease in gilts and sows. Initial vaccination involves two vaccinations, 21 days apart, with the second vaccination at least 3 weeks before breeding and with booster vaccinations recommended during subsequent lactations. Experimental challenge provides 70% protection based on pigs born alive and surviving to 7 days.

Modified live vaccines do give a safe and efficacious protection against a wide variety of heterologous challenge strains.[242] The vaccine virus can be transmitted from vaccinated to naïve pigs.[94,96,243] and to naïve herds. Vaccination of boars causes the virus to be shed[244] but if they have been previously exposed and then are vaccinated then there is no release of virus.[245]

The live vaccine given to finishing pigs will protect against respiratory infections [246]

A modified live virus vaccine given once is safe for use in pregnant sows, and vaccine virus is not transmitted to susceptible contact pigs. In growing pigs, vaccinated at 3–18 weeks of age, the vaccine elicits protective immunity within 7 days which lasts 16 weeks. Compared to controls, vaccinated animals have a reduced level of viremia, their growth rates are superior, and they have a reduced number of lung lesions. Field trials suggest that the vaccine provides protection to nursery pigs in units with endemic infection. Live viral vaccines in sows may or may not be a good idea[247] as they demonstrated that reduced numbers of pigs were born alive and there were increased numbers of stillborn piglets to vaccinated sows irrespective of stage of vaccination. Both single strain and multistrain vaccines can be attenuated and be useful immunogens but additional studies are needed to make sure that the multistrain vaccines can be recommended for routine field use.[248]

In Denmark in 1996, the use of a modified live virus vaccine licensed for use in pigs 3–18 weeks of age was used in a large number of PRRS virus-seropositive herds.[96] Following vaccination, a large number of herds experienced an increased incidence of abortions, stillbirths, and

poor performance during the nursery period. The vaccine virus was isolated from fetuses and it was concluded that the virus was transmitted to seronegative non-vaccinated pregnant gilts and sows (see Methods of transmission). The viruses were collected and sequenced[204,249] and shown to have a 60% homology to Lelystad but a 98.5% homology to the USA strain ATC-2332 the USA reference strain. It was therefore thought that the vaccine viruses were reverting to their natural antecedents and their virulence.[250–252] Describing the vaccine virus it was shown that given to piglets it could infect non vaccinated sows. Given to sows it can produce congenital infection, fetal death, and an increased pre-weaning mortality.[252]

The vaccine virus can be maintained in the population where it may undergo considerable genetic change and then lead to the establishment new variants. Vaccination with the US type vaccine produces little effect on viremia with EU PRRSv. Vaccination with EU type vaccines produced complete suppression of EU PRRSv isolates.[253]

A modified live virus vaccine has been evaluated in pigs vaccinated at 3 weeks of age and challenged at 7 weeks of age.[254] Efficacy was evaluated using homologous and heterologous strains of virus known to cause respiratory and reproductive disease. The vaccine controlled respiratory disease but did not prevent infection and viremia. There are no published reports of randomized clinical trials evaluating the vaccines under naturally occurring conditions. In many cases of PRDC vaccination fails simply because it was given too late or because there was no cross protection to heterologous strains.

DNA vaccination is said to produce both humoral and cellular responses and neutralization epitopes on the viral envelope glycoproteins encoded by ORF4.[255] Possibly recombinants can be used as vaccines.[256]

Vaccination of boars

The use of an attenuated virus vaccine in boars results in a marked reduction in viremia and shedding of the virus in semen compared to non-vaccinated control animals.[257] Introducing a vaccination program using the live virus vaccine may be considered as a potential method to reduce the risk of transmission of virus by artificial insemination. In contrast, no changes in onset, level, and duration of viremia, and shedding of virus in semen were observed using the inactivated virus vaccine.

RIFT VALLEY FEVER

Synopsis

Etiology Rift Valley fever virus, a member of the family Bunyaviridae
Epidemiology Enzootic in sub-Saharan Africa and Egypt and recently the Arabian peninsular. Virus maintained in flood water mosquitoes and transmitted by hematophagous insects. Ruminants are amplifying hosts. Epizootics in high rainfall periods
Clinical findings Acute, febrile disease characterized in lambs and calves by hepatitis and high mortality, in adult sheep and in cattle by abortion, and in humans by influenza-like disease or hemorrhagic fever
Necropsy findings Hepatic necrosis
Diagnostic confirmation Immunohistochemical localization of viral antigens in tissues
Treatment None other than supportive
Control Vaccination, vector control, quarantine

ETIOLOGY

Rift Valley fever virus, a member of the family Bunyaviridae, genus *Phlebovirus*. Isolates from outbreaks in different countries are antigenically similar and there is only minor genetic variation between isolates.[1,2]

EPIDEMIOLOGY

Occurrence

Rift Valley fever was initially reported in the Rift Valley in Kenya but now exists and occurs as epizootics throughout sub-Saharan Africa with recent extensions into Egypt and Madagascar, Mauritania and most recently expansion to the Arabian peninsula.[3,4] It has great potential for spread to other countries. The pattern of occurrence is cyclical epidemics with periods of quiescence between, with the majority of cattle in enzootic areas remaining seronegative for periods of 5 years. A Rift Valley fever-like disease is reported in sheep in India.

Source of infection

The virus is believed to be maintained through a cycle involving mosquito vectors, wildlife and domestic livestock and by **transovarial** transmission in certain

floodwater *Aedes* mosquitoes which have drought-resistant eggs that survive several years without hatching. These **interepizootic vectors** belong to the *Aedes* subgenus *Neomelaniconion* in East Africa and the subgenus *Aedimorphus* in West Africa.[5] Epizootics occur in enzootic areas when wet and flood conditions promote the expansion of the vector population in the presence of susceptible livestock. Ruminants are highly susceptible and serve as the main amplifying hosts.[5] A pronounced, but short, viremia occurs in infected animals and facilitates the spread of the disease by biting insects. Virus is also present in milk, feces and aborted fetuses. An unidentified wildlife reservoir host may also exist.

Method of transmission

A wide variety of mosquitoes from several genera have been identified as vectors, or possible vectors, including species on continents such as Australia and North America. Sandflies and culicoides have also been identified as vectors but are not maintenance hosts.[2,5,6]

Experimental reproduction

The disease can be transmitted by most routes including inoculation and the inhalation of aerosols. Following inoculation of sheep and cattle the incubation period is 1 to 2 days and high virus titers are found in blood. Virus persists in the body for approximately 3 weeks but long-term carriage has not been observed. Pregnant animal abort but infection may be clinically mild in non-pregnant animals. IgM antibody can be detected as early as 4 days after infection and persists for 2 to 6 months.[2,7–9]

Environment risk factors

The incidence of the disease varies with the size of the vector population. It is greatest in seasons of **heavy rainfall** which allows the vector population to increase and expand from permanent water sites to breed in surface waters in normally dry areas.[10,11] Expanding irrigation schemes may also enlarge areas at risk.

Animal risk factors

Losses are due mainly to deaths in young lambs and calves, although there may be a high incidence of abortions and some deaths in adult sheep and cattle.

Mortality is higher in lambs than in calves. Indigenous breeds may have inapparent infections. Camels, domestic buffalo, monkeys, humans, mice, rats, ferrets, and hamsters are susceptible to infection and goats moderately so, but pigs, rabbits, guinea pigs, and poultry are not. A large number of different African wildlife species also have seropositivity in endemic areas.[12,13] Trade animals are suspect as the source of infection to previously free areas.

Zoonotic implications

The disease in humans is usually a transient illness but complications of hemorrhagic fever, retinal disease and encephalitis occur. Traditionally the groups exposed to greatest risk are laboratory workers handling the virus and those working amongst infected animals or their products, including veterinarians. However cases were not limited to these groups in the large outbreaks in Egypt in 1977 and 1978 and the more recent outbreaks in the Arabian peninsular and the occurrence rate in humans was very high in Egypt (more than 20 000 cases in 1977 with 600 deaths). In Saudi Arabia the case fatality was 14% in one cohort of 886 human cases.[14] The agent is identified as one for potential bioterrorism.[15]

PATHOGENESIS

Hepatocytes are the primary site of viral replication in lambs and calves and **age** is a determining factor in the progression and outcome of infection.[16,17] In very young animals, hepatic lesions progress from degeneration and necrosis of individual hepatocytes to extensive necrosis throughout the liver resulting in hepatic insufficiency and failure. In young animals, encephalomyelitis may also occur.[16]

CLINICAL FINDINGS

The major presentation is a regional outbreak of abortion and neonatal mortality. In lambs and calves, after an incubation period of about 12 h there is a sudden onset of high fever and incoordination followed by collapse and death within 36 h in 95–100% of affected lambs and 70% of young calves.

In adult sheep and cattle, abortion is the outstanding sign but the mortality rate in adult sheep may be as high as 20–30% and 10% in cattle. In less severe cases in cattle there is febrile disease and dysgalactia and some animals develop emaciation with jaundice. In fatal cases, sudden death is preceded by a high fever for 1–2 d. Goats show a febrile reaction but few other clinical signs.

CLINICAL PATHOLOGY

Severe leukopenia is a common finding. Antibodies appear in the serum about 1 week after infection and persistence depends on antibody type. Sera are usually screened using hemagglutination-nhibition or ELISA tests and positives confirmed with plaque reduction neutralization tests.[13,18] Transmission tests to white Swiss mice and sheep are also used.

ELISA tests that meet the desire for an accurate and safe test and that use inactivated antigen and that can meet international validation requirements are described.[19,20]

NECROPSY FINDINGS

Extensive hepatic necrosis is the characteristic lesion in Rift Valley fever. Other non-specific lesions include congestion and petechiation in the heart, lymph nodes, gallbladder, and alimentary tract. Abomasal and intestinal content may be dark brown to red due to hemorrhage. Microscopically there is focal or diffuse necrosis of the liver and there may be acidophilic intranuclear inclusion bodies in hepatic cells. The lesions are much more extensive in newborn lambs and calves than in older animals.[16,17,21] Immunohistochemical localization of viral antigens in tissues provides a specific diagnosis.[22]

Samples for confirmation of diagnosis

- **Virology** – liver, spleen, brain (VI, FAT, PCR)
- **Histology** – liver, spleen, brain (LM, IHC).

Note the zoonotic potential of this disease when handling these specimens.

DIFFERENTIAL DIAGNOSIS

In regions where this disease has not occurred it should be suspect when there is an area outbreak of abortion and neonatal mortality in sheep and cattle coupled with an area outbreak of flu-like disease in humans

- Wesselsbron disease
- Bluetongue
- Ephemeral fever
- Brodifacoum poisoning has been mistaken for Rift Valley fever.[21]

TREATMENT

Little attention has been given to the aspect of treatment of the disease and no known treatment is of any value.

CONTROL

Vector control and quarantine may aid in protection of livestock and humans in enzootic areas but vaccination is the single most practical and economic control measure. Killed-virus and living attenuated virus vaccines are available.

Live attenuated vaccines and mutagenized live virus vaccines provide good protection which lasts for at least 28 months but are not recommended for pregnant animals because they are abortigenic, causing fetal death and some teratogenic anomalies. The recorded problems include hydrops amnii, arthrogryposis, hydranencephaly, and microencephaly. There is also a concern for reversion to virulence.

Killed-virus vaccines require repeat administration for good immunity and annual vaccination of all dairy cattle is recommended as a cost-effective control program in endemic countries. They are also recommended for pregnant and young animals.

A mutagen attenuated vaccine protects against challenge in both sheep and cattle.[23,24] Viremia following vaccination is minimal and thought not to be a risk for infection of susceptible mosquitoes.[24] Mutagenic vaccines were initially thought to have no deleterious effect on the fetus but abortion and teratogenicity has been observed in the lambs of sheep vaccinated early in pregnancy.[25]

Prevention of the introduction of Rift Valley fever into countries free of the disease requires the prohibition of the importation of all susceptible species from Africa. All necessary steps to prevent the introduction of infective insects and infected biological materials should be taken. The possibility of humans carrying the infection from country to country is very real.

CONGENITAL ARTHROGRYPOSIS AND HYDRANENCEPHALY; AKABANE DISEASE; CACHE VALLEY VIRUS DISEASE

Synopsis

Etiology Akabane virus in the Simbu serogroup of *Bunyavirus*: Cache Valley virus in the Bunyamwera serogroup of *Bunyavirus*

Epidemiology Transmission by hematophagous insects. Outbreaks when cattle or sheep are infected in early pregnancy
Clinical findings Abortions, stillbirths and birth of calves with skeletal deformities and neurological disorders
Necropsy findings Necrotizing non-suppurative encephalomyelitis and polymyositis. Arthrogryposis and hydranencephaly
Control Vaccination

ETIOLOGY

Akabane virus and Cache valley viruses are both members of the genus *Bunyavirus* in the family Bunyaviridae with Akabane virus a member of the Simbu serogroup of the genus *Bunyavirus* and Cache Valley virus a member of the Bunyamwera serogroup of the genus *Bunyavirus*. There are a large number of members of the *Bunyavirus* genus and several can produce clinically inapparent infections in ruminants but Akabane virus and Cache Valley virus produce fetal disease when they infect the dam in early pregnancy.[1–3] There are subtypes of these viruses.[4]

Other *Bunyavirus* that have been associated with natural or experimentally produced fetal disease in ruminants include:

- Simbu serogroup. Aino and Peaton viruses[2,5,8]
- Bunyamwera serogroup. Main Drain viruses[6,7]
- California serogroup. LaCrosse and San Angelo viruses.[7]

Antibodies to the related, but as far as is known non-pathogenic, viruses Douglas and Tinaroo have been detected in cattle, sheep, goat, buffalo and deer.[1,2]

EPIDEMIOLOGY

Occurrence

Akabane

Serologic studies suggest that infection occurs in cattle, sheep, goats, horses, donkeys, camels, pigs, and buffaloes but disease occurs only in calves, lambs, and goat kids.[9]

The disease is most common in calves and has been recorded as the cause of epizootics of abortion, stillbirths and congenital malformation in calves in Australia, Israel, Iran, Kenya, Japan, Korea, and Taiwan with high attack rates in affected herds. Congenital disease in lambs is less common but is recorded in Israel and Australia.[5] The virus has also been isolated from insect vectors in Africa and is the probable cause of the 'rigid lamb syndrome' in Zimbabwe. Serological surveys suggest widespread distribution of the virus in the Middle East, Asia and southeast Asia, and in parts of Africa.[2,10,11] Whereas infection in adult cattle is common in endemic areas, reports of clinical disease are rare but neurological disease associated with infection in cattle 2 to 7 years of age has been observed.[12]

Cache Valley

There is serologic evidence that infection occurs in sheep, goats, horses, cattle, pigs and in several wildlife species but disease is recorded only in sheep. The disease in sheep is recorded as an occasional epizootic in flocks in North America.[4,7,13] Cache Valley virus is one of the more common *Bunyaviruses* in North America and has been isolated from mosquito pools collected in 22 states and several provinces in Canada and Mexico and also in Central and South America.[4,7]

Aino

Aino virus is present and believed a cause of disease in Australia, Japan and Israel.[8,14] Serological studies in Australia show a similar distribution in cattle to Akabane but at a lower prevalence[7,15] and clinical disease is much less common than with Akabane.

Source of infection

The viruses are maintained through a cycle involving vectors, in which there is probably transovarial transmission, and a susceptible vertebrate population. Replication occurs in both vertebrate and insect populations.

Akabane

Viremia in cattle is short-lived, lasting 1–9 d and long-term carriers are not believed to occur. Herbivores appear essential to the vector–virus–host cycle [16] and there is serological evidence of infection in cattle, sheep, goats, camels, horses, and buffaloes.[2,15,17]

In Australia, transmission is by the bites of *Culicoides brevitarsis* and *C. nebeculosus*.[18] Virus has been isolated from *C. brevitarsis* and this is probably the major vector as serological data in Australia shows that most identified infections are within the known habitat of *C. brevitarsis*. Introduction of the virus into the bovine uterus in semen causes no developmental defects.

The vector(s) for Akabane disease in Japan and Korea are *C. brevitarsis, Culicoides oxystoma* and *Aedes vexans* and *Culex tritaeniorhynchus*.[3,9]

Cache Valley

The virus has been isolated from mosquitoes and *Culicoides* spp.[4,7] Mosquitoes are the believed vector but the species involved and the natural history of the disease are not known.

Aino

The virus has been isolated from mosquitoes and midges including *C. brevitarsis*.[2] Serological studies show antibody in cattle, sheep, goats, and buffalo but not camels, dogs or horses.

Host and environmental risk factors

The seasonal and geographic pattern of epizootics of abortions and premature births are determined by the distribution of vectors and the availability of susceptible ruminant populations in early pregnancy.

Akabane

In the north of Australia, *C. brevitarsis* is active throughout the year and cattle are infected with Akabane virus before their first pregnancy and disease does not occur. Epizootics occur in southern Australia when *C. brevitarsis* extends its range of distribution,[19] probably by wind-borne spread from the north, to infect immunologically naive herds. Abortions and premature births commence in the autumn, with clinical cases of arthrogryposis, and hydranencephaly occurring in mid-winter.

Wind-borne introduction of *Culicoides* spp. is also postulated as the means of introduction of infection in Israel.[20] The movement of immunologically naive pregnant cattle into an enzootic area can be the result in severe outbreaks in those herds.[21]

The disease is likely to disappear for intervals of 5–10 years, until there is combination of a susceptible population and a heavy vector population. Occurrences of the disease are also dependent on the presence of susceptible, early pregnant females at the time that the vectors are plentiful. These conditions are provided by a series of years of drought in an enzootic area, so that there are no insect vectors, no infection, and no immunization activity of prepubescent females, followed by a wet season when the vectors are plentiful.

Cache Valley

Outbreaks occur after a long period of drought and winter frosts reducing the population of mosquito vectors and resulting in populations of seronegative ewes. Mating in the summer appears a major risk factor allowing sheep to be in the susceptible stage of pregnancy during the vector season.[22] Many outbreaks are in areas that interface between suburban and rural environments.[7]

Experimental reproduction

Disease has been reproduced by inoculation into early pregnant cattle, sheep and goats.[2,6,8,15,16,23,24]

Zoonotic implications

Bunyavirus infections occur in man from bites from infected insect vectors.

PATHOGENESIS

Akabane

Viremia occurs in the dam for 2–4 d, with an antibody peak 4–5 d after the viremia and a subsequent secondary rise. The dam is unaffected but there is a focal viral persistence in cotyledons and subsequent viremia in the fetus.

Inflammatory and degenerative lesions occur in the central nervous system but tissue tropism and damage is determined by the age of the fetus and its ability to mount an immune response. Three forms, or principal manifestations, of the disease in an affected herd are described. The first is arthrogryposis occurring in calves infected at an older age than others (fetus infected at 105–174 d of pregnancy). The second is arthrogryposis accompanied by hydranencephaly. The third is hydranencephaly only (infected between days 76 and 104 of pregnancy).

With arthrogryposis, there is almost complete absence of ventral horn cells in the spinal cord and an accompanying neurotropic failure of muscle development. Contracture of the joints results. The hydranencephaly is manifested by a partial or complete failure of development of the cerebral cortex. The brainstem and cerebellum are usually normal.

Several other manifestations have been described. They include pre-arthrogryposis groups of calves with incoordination and a mild to moderate non-suppurative encephalitis, and other calves with flaccid paralysis and active secondary demyelination in motor areas of the spinal cord. Some calves are unable to stand and have thickened dorsal cranial bones and hydranencephaly involving anterior and midbrainstem, and a diminutive cerebellum. The infection with Akabane virus is also credited with causing abortion, stillbirth and premature birth.

Lesions produced in **lambs** by experimental inoculation of the ewes during early pregnancy (days 32–36) include skeletal muscle atrophy and degeneration, and inflammatory and degenerative lesions in the cerebrum; the lesions in the central nervous system vary from porencephaly to hydranencephaly. There are also brachygnathism, scoliosis, hypoplasia of the lungs, agenesis or hypoplasia of the spinal cord, and arthrogryposis.[25] Lesions are also present in fetuses of ewes inoculated between 29 and 45 days of gestation.[15]

Cache Valley

Ovine fetuses are susceptible to the teratogenic effects between 28 and 48 days of gestation.[13] Destructive lesions occur in the central nervous system but infection of fetal membranes with a reduction in the volume of amniotic fluid and constriction by membranes around the fetus are believed to contribute to the occurrence of arthrogryposis.[7]

CLINICAL FINDINGS

Akabane

Infection in adult cattle is most commonly clinically inapparent, unless there is dystocia, but neurological disease manifest with hypersensitivity, tremor and ataxia is recorded.[12] In calves, the two syndromes, arthrogryposis and hydranencephaly, occur separately; arthrogryposis in the early stages of the outbreak and hydranencephaly at the end. Calves with both defects occur in the middle of the outbreak. In some outbreaks only one of the manifestations of the disease is seen.[26,27]

Calves with arthrogryposis almost always are the subjects of difficult birth requiring physical assistance. They are small and significantly underweight but they are fully mature in terms of teeth eruption and hair coat and hoof development. They are unable to rise, stand or walk. One or more limbs is fixed at the joints: there is a congenital articular rigidity. The limb is usually fixed in flexion but it may be in extension. The joint becomes freely movable if the tendons around it are severed, that is, there is no abnormality of the articular surface. The muscles of affected limbs are severely wasted. Kyphosis or scoliosis are common.

Calves with hydranencephaly have no difficulty rising and walking. The major defects are a lack of intelligence and blindness. They will suck if put onto the teat but if this is not done, they stand and bleat and have no apparent dam-seeking reflex. A few calves have microencephaly and are more severely affected. They are dummies, very uncoordinated in gait, unable to stand properly and move erratically when stimulated. These calves appear at the very end of the outbreak.

As well as the skeletal and neurological diseases, cases of abortion, stillbirth and premature birth are also regarded as being associated with Akabane virus infection in cows. They are usually recorded at the beginning of the outbreak before the neurological defects occur.

Cache Valley

Affected flocks have a higher rate of stillbirth and mummified fetuses. Congenital malformations in liveborn lambs include arthrogryposis of one or more limbs, scoliosis, torticollis, and neurological signs are similar to those seen in calves with Akabane disease.

CLINICAL PATHOLOGY

The presence of specific antibody in fetal sera or the precolostral sera of neonates is diagnostic but its absence does not exclude the diagnosis if infection precedes the development of immunological competence. Precolostral sera from several animals should be tested and most cases are positive at high titer.[2,24] A rising titer with paired samples from the dam, or a high titer in the serum of surviving

neonates is suggestive of recent infection but not confirmatory for disease. Serological tests include microneutralization, hemagglutination inhibition, agar gel immunodiffusion (AGID) and an (ELISA) test.[2,28,29]

NECROPSY FINDINGS

The primary lesions with both Akabane and Cache Valley infections in the fetus are a **necrotizing non-suppurative encephalomyelitis and polymyositis**.[2]

In calves and lambs with arthrogryposis there is severe muscle atrophy, fixation of joints by tendon contracture and normal articular surfaces. The joints are easily released by cutting the surrounding tendons. Histologically, there may be almost complete absence of ventral horn cells in the spinal cord. This lesion may be localized to one segment of the cord and viral antigen may be demonstrated via immunohistochemistry.[25]

In calves and lambs with hydranencephaly the cerebral hemispheres are completely absent and the vacant space is filled with fluid enclosed by the normal meninges. In a few cases the lesions will be limited to porencephaly. In most, the brainstem and cerebellum lack cavitations but diminution of their size may be recorded.

Samples for confirmation of diagnosis

- **Virology** – 2 mL fetal thoracic fluid and maternal serum for serology
- **Histology** – brain, spinal cord, muscle (LM, IHC).

DIFFERENTIAL DIAGNOSIS

Akabane virus disease and Cache Valley virus disease in sheep, as they are manifest epidemiologically, are well-defined and easily recognizable entities. Differentials include:

- Lupine-induced arthrogryposis in calves
- Manganese deficiency in calves
- Heritable forms of arthrogryposis and/or micrencephaly
- Fetal infection with bluetongue virus, rift valley fever virus, or pestivirus

Cattle in Japan may also produce hydranencaphalic calves, which are recumbent, opisthotonic and unable to suckle at birth, when infected during pregnancy by the Chuzan virus.[30,31] The virus, a member of the Polyam subgroup of orbiviruses, is transmitted by *Culicoides oxystoma*.

In Africa infection with flaviviruses including West Nile, Banzi and AR5189 also cause abortion, stillbirth and congenital brain malformations.[32]

TREATMENT AND CONTROL

No treatment would be contemplated because affected calves are not viable nor humanely kept alive.

Vector control is not possible with current knowledge and vaccination is the only effective method of control. Killed vaccines for Akabane virus have proved very effective against natural exposure and are available in Japan and Australia.[2,15] They require two inoculations prior to pregnancy and an annual booster. The economics of their annual use is dictated by the risk of disease in regions subject to periodic outbreaks of disease.

Enzootic bovine leukosis (bovine lymphosarcoma)

Synopsis

Etiology Bovine leukemia virus (BLV), the causative agent of enzootic bovine leucosis (EBL), is an exogenous C-type oncovirus in the Retroviridae family

Epidemiology Occurs worldwide, prevalence of infection varies between countries. Persistent infection is most common, followed by persistent lymphocytosis (PL) in 30% of infected animals, and less than 5% of infected animals develop lymphosarcoma. Clinical disease most common in mature cattle. Infected animal is only source of virus which is transmitted horizontally by infected lymphocytes in blood from parturition, contaminated surgical instruments, rectal palpation, blood-sucking insects. Congenital infection in 4–8% of calves born to infected cows. Genetic makeup of animal determines if becomes infected and develop disease. Economic losses due to loss in milk production traits and premature culling

Is not a zoonosis

Signs No clinical signs during stage of infection and persistent lymphocytosis. Lymphosarcomas characterized by loss of body weight, inappetence, pallor, weakness, and loss of milk production. Enlargement of all lymph nodes. Abomasal ulceration. Congestive heart failure. Paresis and paralyis due to neural involvement. Stertor due to enlargement of retropharyngeal lymph nodes. Eventually weak and recumbent. Sporadic bovine leukosis consists of juvenile lymphosarcoma, thymic lymphosarcoma, and cutaneous forms of tumors which may resemble enzootic bovine leukosis but are BLV-negative serologically

Clinical pathology Serology for BLV virus using AGID or ELISA
Detect virus by PCR or sheep bioassay

Lesions Multicentric lymphoid tumors affecting all body systems especially heart, digestive tract, nervous system, reproductive tract

Diagnostic confirmation Serology and detection of virus by PCR

Differential diagnosis list
Sporadic bovine leukosis
Congestive heart failure due to traumatic pericarditis
Lymphadenitis due to tuberculosis and actinobacillosis
Compression of spinal cord
Fat necrosis

Treatment None

Control Test and slaughter seropositive animals in herds and areas with low prevalence of infection. Use bulk tank milk ELISA as screening test. Establish virus free herds and certify by retesting. Control disease in herds and countries with high prevalence of infection by limitation of spread within herds and prevent introduction of infection

ETIOLOGY

Enzootic bovine leukosis and persistent lymphocytosis

The causative agent is bovine leukemia virus (BLV), an exogenous C-type oncovirus in the Retroviridae family. The complete genomic sequence of BLV strain from a cow has been described.[1] Infection occurs by iatrogenic transfer of infected lymphocytes from one individual to another and is followed by a permanent antibody response and, less frequently, development of persistent lymphocytosis or lymphosarcoma.[2] The virus causes a chronic B-cell proliferative disease in cattle and is an important model for human T-cell leukemia virus type 1 infection because of many shared molecular and biological features. However, EBL is not a zoonosis. It has leukemogenic activity, can be grown in tissue culture and produces specific antibodies in calves[2] and sheep.

Sporadic bovine leukosis

Sporadic bovine leukosis affects animals under 3 years of age including:

- Juvenile form in calves less than 6 months old, characterized by multiple lymph node enlargement
- Thymic form in yearlings less than 2 years old, characterized by a swelling in the neck causing bloat and edema
- Cutaneous form in cattle 1–3 years old, characterized by the development of nodes and plaques in the skin
- Cutaneous T-cell lymphoma in two Friesian cows in Azores has been described.[3]

The bovine leukemia virus cannot be cultured from nor antibodies to the virus be detected in animals affected with sporadic bovine leukosis. There is no evidence that these forms of sporadic bovine leukosis are associated with an infectious agent.[4]

EPIDEMIOLOGY

Prevalence of infection and occurrence of clinical disease

Leukosis in cattle was originally described in Germany in 1871.[2] Reports of the disease in cattle became common following World War II and most countries which raise cattle have reported the occurrence of the disease. The infection is now common in cattle in Canada, the United States, and many countries in Europe and South America.[2]

Serological surveys in cattle in the United States indicate prevalence rates within herds ranging from 0–100%. The disease does not spread rapidly and the number of herds containing positive reactors to the agar gel immunodiffusion (AGID) test is usually small. However, in infected herds the number of seropositive animals may be as high as 80%. Infection with the virus is estimated to be at least 20% in the adult dairy cow population of the United States, 6–11% in Canada, 27% in France, 37% in Venezuela; in the United Kingdom the prevalence of infection is low. In New Zealand, it is estimated that about 6.5% of the dairy herds have infected cattle, with an estimated within herd prevalence of 3.7%.[5] The prevalence of infection in beef cattle in Australia is 0.22%. In a national survey in Canada, 40% of the herds contained BLV-infected cows. In Prince Edward Island in Canada, 49.2% of the herds tested had at least one positive reactor, and 5.5% of all the cows tested were positive. In maritime Canadian dairy cattle, the individual cow prevalence was 21% and the herd prevalence 70%.[6]

The seroprevalence of BLV infection in breeding beed bulls under 2 years of age offered for sale in Kansas was 8.5%.[7] This indicates that young bulls purchased for entry into recipient herds could be infected with the virus.

In Argentina the individual seroprevalence is 33%, while the percentage of infected herds with one or more infected animals is 84%.[8] The infection occurs in water buffalo in Brazil[9] and in draught animals in Cambodia.[10]

An outbreak of enzootic bovine leukosis in Egypt was associated with the importation of Holstein Friesian heifers and bulls from Minnesota in 1989 to form a closed dairy herd in Upper Egypt.[11] In 1996, clinical evidence of enzootic leukosis occurred and ELISA testing revealed a BLV seroprevalence of 37.7% in cattle under 2 years of age and 72.8% in animals over 2 years of age.

The **occurrence of clinical lymphosarcoma** in countries where the infection occurs is about 1 per 1000 per annum and in infection-free countries, 1 per 50 000 per annum. All of these data are subject to serious error because of the selective nature of the surveys, and until much larger random surveys are conducted, it is not possible to give accurate figures. Even in countries or areas where the infection and the disease are common, there are many herds that remain uninfected. Dairy cattle are much more commonly infected than beef cattle, and have a much higher incidence of lymphosarcoma. In severely affected dairy herds, an annual mortality rate of 2% is unremarkable and it may be as high as 5%.

All breeds of cattle are susceptible to BLV infection. It occurs rarely in animals less than 2 years of age and increases in incidence with increasing age.[2] The prevalence of infection is higher in large herds than in smaller herds. The higher prevalence in dairy herds compared to beef herds is probably due to their closer confinement and the higher average age of the herds.

There are a number of forms taken by the disease:

- Enzootic bovine leukosis infection alone
- Enzootic bovine leukosis with persistent lymphocytosis
- Enzootic bovine leukosis with tumors – the common form in adults.

Methods of transmission

Direct contact

Horizontal transmission is the usual method by which the virus is spread under natural conditions. It appears that close physical contact and exchange of contaminated biological materials are required for transmission. The virus is present mostly in lymphocytes and can be found in the blood, milk and tumor masses. Most susceptible cattle become infected by exposure to infected lymphocytes, and not by cell-free virus.[2] Either 10 μL (45 240 lymphocytes) or 1 μL (4524 lymphocytes) of whole blood from a BLV-seropositive cow when injected into calves resulted in infection and seroconversion. It is likely that a threshold number of approximately 100 BLV-infected cells is required to establish infection in the recipient.[3] Therefore, any means by which BLV-infected lymphocytes can be transmitted from one cow to another is a potential means of transmission. Natural transmission occurs mostly in cattle more than 1.5 years of age, usually during the summer months between in-contact animals and possibly by insect or bat transmission of infected lymphocytes in whole blood. Some observations found an increased risk of infection in dairy cattle during the periparturient period; the crude odds ratio ranged from 4.7–6.0. This suggests that vaginal secretions, exudates and placentas from cows, as well as contaminated calving instruments may serve as sources of infected blood cells. The virus has been found in the nasal secretions of infected cattle for 2–4 years but there is no evidence that transmission to other animals occurred.

Semen, artificial insemination and embryo technology

Most workers have failed to find the virus in semen, and artificial insemination (AI) is not a method of spread, nor is embryo transplantation using zona pellucida intact embryos. Fertilized embryos from donors infected with BVL virus have been transferred without infection of the fetus. It is possible to produce transferable stage in vitro fertilized embryos which are free of in the integrated BLV provirus, from ooctyes which had been exposed to BLV

during maturation.[12] However, the virus has been found in semen collected by massage of the donor's urethra and accessory glands per rectum, a procedure which is associated with contamination of semen with blood.[2] While transmission by AI has not been demonstrated, it is possible that semen containing infected lymphocytes transmission could serve as a source of the virus. Thus bulls at AI centers will be required to be negative serologically to BVL virus. Properly collected semen from BLV seropositive bulls will not contribute to dissemination of viral infection.[13]

Transmission experiments suggest that the virus is not present in saliva but it does appear intermittently in urine.[2] It is present in nasal and tracheal washings but only in cells, not as a free virus.

Iatrogenic transmission

Transmission can occur via infected blood which contaminates surgical instruments, such as dehorning gouges, ear tattooing pliers and hypodermic needles used on infected and then susceptible animals without disinfection. Transmission can also occur during blood transfusions and vaccines containing blood such as those for babesiosis and anaplasmosis.[2] Amounts of blood as small as 0.1 μL are capable of transmitting the infection. Thus the infection can be transmitted via the tuberculin intradermal test. However, while some studies have found that use of common needles for blood sampling infected and non-infected cows at the same time poses a great risk of transmission of the virus to non-infected cows, other studies suggest that the quantities of infective blood passed during injection with common needles is too small to induce infection. The routine practice of brucellosis vaccination, ear-tagging and tattooing in dairy herds did not seem to be associated with the spread of the disease but infection could be reduced from 80% to 4% in heifers between the time of weaning to calving by altering dehorning methods. Transmission via infective milk is possible by the passage of infected lymphocytes through intestinal mucosal epithelium during the first few hours of life. However, infection via this route appears to occur very rarely, if at all, possibly because of the presence of maternal antibodies in the milk.

Rectal palpation

The virus can be transmitted by rectal inoculation of infected blood into cattle and sheep. Using blood-contaminated sleeves from palpating seropositive heifers to palpate seronegative cows resulted in transmission of infection as evidenced by antibody formation.[14] This poses the possibility that the virus can be transmitted by rectal examination of cattle, particularly in dairy herds, when a single rectal palpation sleeve is used repeatedly during reproductive tract examinations as part of a health management program when many animals are palpated. Field studies to examine whether using the same sleeve for more than one animal or an individual sleeve for each animal, indicate that rectal transmission is a potential route of spread of BLV, but that it is related to frequency of palpation and age of cattle. Controlled studies of rectal palpation of cows in a dairy herd over a period of 22 months, using a single sleeve per animal or not changing the sleeve between an infected animal and seronegative animals resulted in a 2.8-fold increase in the risk of BLV infection.[15] Thus rectal examination without a change of sleeve may be a risk factor in some herds.

Insects

Blood-sucking insects may be involved in transmission of the virus. Evidence implicating arthropod vectors in BLV transmission is indirect, involving experiments in which virus-carrying arthropods or parts of them were transferred to uninfected cattle. In several experiments, infected tabanids, other biting flies, and ticks were placed by hand on cattle and sheep. Minced mouthparts or hematophagus insects previously fed on BLV-infected cattle also were injected into hosts. In some countries there is empirical evidence that the incidence of seroconversion is higher after the tabanid fly season.[2] A space–time study found a significant positive geographical correlation between the rate of incidence of BLV infection and the density of the horsefly population. Seasonal variations in the incidence rates also occur; the highest rates are generally observed during summer, and the lowest during winter, spring and early summer. There is also a time link between the rate of seroconversion and the variations in activity of the horsefly population. Experimentally, the virus has been transmitted by horse flies, *Tabanus fuscicostatus*, from a seropositive cow to recipient calves and goats. Horse flies take relatively large blood meals, have a painful bite, and are often interrupted in feeding and must finish feeding on other animals. This behavior and the large number of flies, and the low volume of blood and small number of lymphocytes required to transmit BLV, make tabanid flies candidates for mechanical vectors of the virus. The stable fly, *Stomoxys calcitrans*, has an insufficient mouth part volume to carry enough blood lymphocytes to transmit the virus.

Congenital infection

Congenital infection occurs in 4–8% of calves born from BLV-seropositive cows in naturally infected herds. These probably occur as a result of transplacental exposure to the virus during gestation. Calves born from clinically healthy cows naturally infected with BLV are negative for BLV before receiving colostrum, and in utero transmission of BLV may occur but is infrequent.[16] Calves born from seropositive cows acquire colostral antibodies if they ingest colostrum and the antibody levels decline during the first 6–7 months of life. In one study the minimum and maximum duration of colostral antibodies were 14 and 147 d, respectively with a half-life of 36). The decay of colostral antibodies and the age at which a calf can be expected to become seronegative is a function of the quantity of BLV antibodies absorbed by the calf and the infection status of the calf.

Prevention of in utero transmission can be done using embryo transfer.

Interspecies transmission

Cattle are the only species infected naturally, although sheep and goats can be infected experimentally. The infection does not spread from cattle to commingled sheep, nor between experimentally infected and non-infected sheep. However, horizontal transmission of a naturally occurring lymphosarcoma in sheep is associated with an antigenically similar virus to the BVL virus. It is assumed that horizontal spread of the BVL virus from cattle to sheep will not occur. The experimental transfer of infection from cattle to sheep is effected so readily that it has become a preferred technique for testing for the presence of a virus.

Source of infection

In cattle, infection with the virus is permanent, spontaneous recovery has not been demonstrated and the virus is maintained in the cattle population. The virus is located in lymphocytes in a covert non-productive state, resulting in an inability of antibodies to arrest the infection, and multiplication of the virus is not necessary for survival or transmission. The virus is also capable of periodic antigenic change and circumventing control by immune mechanisms, thus the infected animal remains a source of infection for long periods, probably for life, regardless of the simultaneous presence of specific antibodies. This virus–host system is the same as that of other retroviruses, especially equine infectious anemia (EIA) and visna–maedi of sheep. In most circumstances, infection occurs when animals are in close physical contact and are more than 12 months old. Infection is established readily by SC and ID injection and by intratracheal infusion, but it does not occur after oral administration.[2]

Experimental transmission of the infection using tumor material, infected

blood or tissue culture virus can be achieved in cattle, sheep, goats and with some doubts to chimpanzees, but the tumors are produced only in the three ruminants. A sheep bioassay can be used to determine the presence of the virus in infected cattle.[17]

Risk factors

Animal risk factors

The prevalence of infection based on seroprevalence is positively associated with increasing age in both dairy and beef cattle.[2] The prevalence of infection in dairy cattle under 17–24 months of age is much lower than in adult cattle and increases sharply after 24 months of age when heifers join the milking herd and are in close contact with older cattle.[2] The rate of spread may also be associated with the prevalence of infection; in herds with a prevalence of 13–22% when first tested, the spread was slow; in a herd with a prevalence of 42%, the spread was much more rapid.

Genetic resistance and susceptibility. Infection with the BLV is not synonymous with clinical disease. Most animals which become infected do not develop neoplastic disease. Once infection has occurred, the subsequent development of only an antibody response, or antibody plus persistent lymphocytosis (PL) or antibody plus lymphosarcoma, with or without PL, is determined by the host's genetic makeup. Lymphosarcoma, the terminal stage of BLV infection involving the clonal transformation of infected B-cells, occurs in about 1% of BLV-infected cattle and is under genetic control of the host.[18]

A complex relationship exists among genetic merit, milk production, *BoLA* genotype, and susceptibility to PL. Cows with high genetic potentials for milk and fat yields are more susceptible to PL than cows with lower genetic potentials, but cows with PL do not produce yields of milk or fat according to their predicted genetic values. Early attempts to quantify the economic impact of subclinical infection emphasized differences in milk production between seropositive and seronegative cattle. However, seropositive cattle may be in different stages of the disease complex. Antibodies to BLV may be present in recently infected cows with no other abnormality, in cows over 3 years of age with PL, and in animals older than 6 years of age with tumors.[18] In addition, the genetic potential was not considered. It is now known that genetic merit is correlated with susceptibility to BLV infection and PL and thus inconsistent results are not surprising. When seropositive cows are divided into PL and non-PL categories and the genetic potential for various measures of milk production for each animal are taken into account, the results are much more clear.[18]

The phenotype frequencies of two *BoLA-A* alleles are associated with resistance and susceptibility to PL.[18] Genetic resistance to PL maps closely to the class II genes of the bovine major histocompatibility complex, *BoLA*). The frequency of the PL resistance-associated *BoLA-A14* allele in any age group was higher in BLV-infected non-PL cattle than in BLV-infected PL cattle in the same age group and increased from 30% in 3-year-old cows to 52% and 59% in 7- and 8-year-old cows which were retained in the herd. In contrast, the frequency of *BoLA-A14* in cows with PL decreased in frequency from 7% in 3- to 5-year-old cows to 0% in cows older than 6 years. The relationship between *BoLA-A* allele frequencies and BLV infection over time, and between BLV infection and milk yield, imply an association of *BoLA-A* alleles with the full expression of milk and fat production potentials under conditions where BLV infection is prevalent. This suggests that genetic resistance to PL is associated with longevity in the herd, where there is a high prevalence of BLV infection.

Susceptibility to other diseases. A highly significant correlation was shown between BLV infection and the persistence of *Trichophyton verrucosum* infection, which suggests that the immune system may be impaired in BLV-infected cows. Observations in Sweden indicate many significant associations between BLV infection status and measures of incidence, reproduction and production, but most were of low magnitude. The risk for other infectious diseases seemed to be greater among BLV-infected herds, while the risk for non-infectious diseases did not differ.

Immune mechanisms

Bovine leukemia virus is a type C retrovirus infecting B-cells and causing enzootic bovine leucosis.[19] The disease is divided into three stages: serologically positive, but negative for lymphocytosis; serologically positive and positive for persistent lymphocytosis; and leukemia. Both humoral and cell-mediated immunity are induced in natural BLV infection. The cytokine profiles change as the infection progresses and interleukin-2 contributes to the development of BLV-induced persistent lymphocytosis. Tumor necrosis factor (TNF-α) are involved in the control of B-cell death, the virus-induced B-cell proliferation and the leukemogenesis of B-1 cells.

Following infection, a persistent antibody response occurs primarily to the envelope glycoprotein gp51 and the major core protein p24 of the BLV virions. The time from infection to development of antibodies can be as long as 14 weeks. Experimental infection of calves with the virus results in seroconversion which can be demonstrated with the ELISA in 4–5 weeks after infection.[20] Acute lymphocytosis occurs at about the same time after infection.

Environmental and management risk factors

Lack of biosecurity

The introduction of infected animals into a herd has a significant positive effect on the subsequent prevalence of infection and clinical disease.[21] The appearance of new outbreaks of leukosis is almost always the consequence of the introduction of BLV-infected animals in farms or areas previously free of the infection. Some outbreaks have followed restocking after brucellosis eradication. Others have occurred following the enlargement of the size of a dairy herd by purchasing animals from a variety of sources. In dairy herds in the Canadian Maritimes, those herds which had routine vaccination practices for other infectious diseases, the seroprevalence for BLV was lower than in herds which did not.[22] The infection was introduced into an accredited BLV-free dairy herd following the introduction of 75 pregnant heifers 2.5 years before a clinical case of lymphosarcoma occurred in the herd and recognized at slaughter.[23] Some of the heifers orginated from a BLV-infected herd including the animal with lymphosarcoma.

Calf management

The level of calf management in dairy herds is also a major risk factor. Any environmental factor or management practice which allows newborn calves access to infective blood will increase the level of infection in the calves, including:

1. Prolonged close contact between the cow and calf immediately after parturition
2. Feeding of colostrum and milk from infected cows
3. Use of:
   - Gouge dehorners and ear-tagging equipment
   - Tattooing equipment
   - Instruments used for castration or the removal of supernumerary teats
   - Use of single needles for vaccination
   - Instruments for control of excessive fly population in calf barns.

Some observations have found positive associations between BLV status of dairy herds and weaning age, housing pre-weaned calves in hutches or separate calf housing, and contact between young-

stock and older animals during the winter housing period.[24] In Ontario, dairy herds with at least one seropositive cow were more likely to have calves raised in calf hutches in winter, more likely to have calved in separate pens in the winter, and less likely to have cows calved in separate pens during the summer.[25] However, the calves housed in hutches were not the same animals sampled for BLV and the results indicate only that those farms using this management procedure had a higher prevalence of BLV. BLV-seropositive cows had a slight, significant increase in calving interval compared to BLV-negative cows.

Pathogen risk factors

The BLV is an exogenous C-type retrovirus closely related to the human T-lymphocyte virus types I and II.[2] It is highly cell associated and persists in a subpopulation of peripheral B-lymphocytes which proliferate as a result of the infection. Free virus is rarely or never found in the blood of infected cattle, and therefore not highly contagious. Once an animal is infected, the infection persists for life in the chromosomes of the infected host. The virus can be experimentally transmitted to a variety of animal species such as sheep, goats, pigs, rabbits, rhesus monkeys, chimpanzees, and buffalo.

Economic importance

General comments

Enzootic bovine leukosis causes significant economic losses associated with the costs of control and eradication programs. In Europe, the losses have been significant to the extent that an eradication campaign supported by the European Community has been in place for many years. Denmark has had an established national program for the control of the disease since 1959[26] and because of its importance, Sweden introduced a control program in 1990 with the aim of complete eradication of BLV from the Swedish cattle population.[3]

The nature and extent of the economic losses associated with enzootic bovine leukosis (EBL) have been controversial because the evidence has been conflicting. The obvious economic losses include the culling of cattle with lymphosarcoma, shortening of lifespan and loss of production potential, and restrictions on export of cattle and semen to importing countries. In Canada, BLV-seropositive bulls are barred entry into artificial insemination units.

In a spreadsheet analysis of dairy herds in the Maritimes in Canada, total annual costs for an average, infected 50 cow herd were $806.00 for enzootic bovine leukosis, compared to $2472.00 for Johne's disease, $2412.00 for BVD, and $2304.00 for neosporosis.[27] The association between EBL infection and annual value of production on dairy herds in the United States, as part of the National Animal Health Monitoring System's 1996 dairy herd study, found that compared to herds with no test-positive cows, herds with test-positive cows produced 218 kg less milk per cow.[28] The average reduction in average value of production was $59.00 per cow relative to test-negative herds. Most of the economic loss was due to reduced milk production in test-positive herds.

The effects of subclinical BLV infection on milk production, reproductive performance, longevity and culling rate are variable. In some observations, a BLV-seropositive cow had a shorter lifespan than both its seronegative counterpart and the entire milk cow population. Among older dairy cows, BLV-seropositive cows were culled prematurely, compared with uninfected cows.[29] The culling rate was higher and milk production was lower in BLV-infected herds compared to BLV-free herds. The effect on reproduction was minor. In other observations, milk production, somatic cell count, age at disposal and culling were not influenced by seropositivity. A comparison of culling rates among dairy cows grouped on the basis of serologic status for BLV did not find any association between culling rate and serological status.[30]

Economic effects on milk production traits

When the effects of infection were examined according to genetic potential for milk and fat production in dairy cows, the results were surprising. The genetic potential for milk production was significantly greater in seropositive cows with PL and in seropositive hematologically normal cows than in seronegative herdmates. At the individual cow level, infected cows had greater milk production than uninfected cows based on seropositivity to BLV and 305-day mature equivalent fat-corrected milk production.[31] Among seropositive cows, those with PL were culled at a younger age and had reduced production in the last lactation relative to other groups. Cows with PL do not produce butterfat according to their potential.

Using data collected over a 6-year period, milk and fat yields in BLV-infected cows with PL declined significantly relative to their BLV-infected non-persistently-infected herdmates.[18] The estimated annual loss in milk yield is 366 kg for cows which had PL for 2 years, and 1204 kg for cows with PL for 3 years.[18] The economic losses to the dairy industry in the United States have been estimated on the basis of the total number of cows with PL, price of milk, average milk yield, net income per cow, and loss in milk yield in cows with PL. Assuming 70% of cows are infected and 20% of infected cows develop PL, it is estimated that economic loss is about 0.25% of the gross income of milk production[18] and the percent annual loss in net profit to the dairy industry due to PL is 3%.

The estimated costs of bovine leukemia infection, including costs of clinical disease and subclinical infection, in a dairy herd representative of the mid-Atlantic region in the US are $412.00 for a case of lymphosarcoma; for a herd with a 50% prevalence of infection, annual incidence of lymphosarcoma was 0.66.[32] The mean annual cost of subclinical infection at 50% prevalence of infection was $6406.00. Mean annual cost of a test-and-manage control program was $1765.00. The cost of clinical disease and subclinical infection varied substantially with the prevalence of infection, whereas the cost of control varied with herd size. A basic BLV control program is considered economical in herds in which the prevalence of infection is ≥12.5%.

Economic effects of clinical disease

On an industry basis, the economic losses from lymphosarcoma are not large because only 0.1–5% of seropositive cows and 10–50% of cows with persistent lymphocytosis develop lymphosarcoma. However, for individual farms, a high incidence of the disease can be a major cause of economic loss, particularly in high producing elite dairy herds where pedigreed livestock are sold. In these pedigreed herds, individual animals are kept to a much older age than in the average commercial herd and, because of the increased prevalence of lymphosarcoma in cows over 5 years of age, the death losses are likely to be very severe in exactly the group of cows which is critical to the success of herd. In addition, there is the severe downgrading effect on the salability of stock from a herd known to have a disease in which genetic susceptibility is an important causative factor.

Loss may also result from lymphosarcoma by way of reduced production during the developmental stages of the disease. The course of the disease is usually sufficiently brief to make this a relatively unimportant consideration. Similarly, the immunosuppressive effect of infection with the virus appears not to have influence on the prevalence of other diseases.

Trade restrictions

A major economic effect of the disease lies in import restrictions placed by some countries on infected cattle and on semen either from infected bulls or from non-infected bulls from a positive herd. It is the practice, particularly in countries that do not have the disease, to require proof

of freedom from infection with the virus from animals about to be imported into the country. This trend has been increased by the introduction of the infection into the United Kingdom in cattle imported from Canada. This is a matter of major importance when the cattle are purebred and are sold at high prices as breeding animals. Some countries are already demanding a negative blood test for all cattle and meat to be imported, and this could represent a loss of export markets for some countries.

Zoonotic implications

The possibility of transmission of the virus from cattle to humans is a real one; the virus is commonly present in the milk of infected cows and the disease has been transmitted to chimpanzees in this way. However, in spite of exhaustive, but certainly not complete, studies there is no evidence to support the notion that transmission occurs from cattle to humans.[2] A case–control study failed to show any relationships between human acute lymphoid leukemia and exposure to dairy cattle and drinking raw milk nor with residence in the general area where dairy cattle are raised.[2] The measurement of occurrence of disease in persons living on farms is the critical measurement because short-term pasteurization procedures destroy the infective agent in milk; farm dwellers who take their milk from the supply before the pasteurization points are thus exposed. All the evidence suggests that humans are at minimal risk of acquiring BVL infection and the diseases clinically associated with the virus.[2]

Using an immunoblot test, a serological survey of 257 humans in California found at least one antibody isotype reactive with BLV in 74% of the sera tested.[33] This does not necessarily mean that humans are actually infected with BLV. Only 9% of the subjects indicated any direct contact with cattle or their biological products. The antibodies could be a response to heat-denatured BLV antigens from consumed milk or meat.

Other species

Lymphosarcoma occurs sporadically in all species, but natural infection with the BVL virus has been demonstrated only in sheep and capybaras.

Although there is no evidence of a relationship between bovine viral leukosis and any disease of pigs, there is a record of enzootic leukosis in that species which is inherited.

PATHOGENESIS

Virus and lesion

The virus establishes a persistent infection in a subpopulation of B-lymphocytes by integrating proviral DNA into the host cellular DNA.

The four possible outcomes after exposure of cattle to BVL virus are outlined in Fig. 21.1, including:

1. Failure of the animal to become infected, probably because of genetic resistance
2. Establishment of a permanent infection and the development of detectable levels of antibodies. (These animals are latent carriers of infection)
3. Establishment of a permanent infection; the animal becomes seropositive and also develops a persistent lymphocytosis, a benign lymphoproliferative process. It is not a preclinical stage of lymphosarcoma
4. Infected, seropositive animals that may or may not have been through a stage of persistent lymphocytosis and which develop neoplastic malignant tumors – lymphosarcoma.

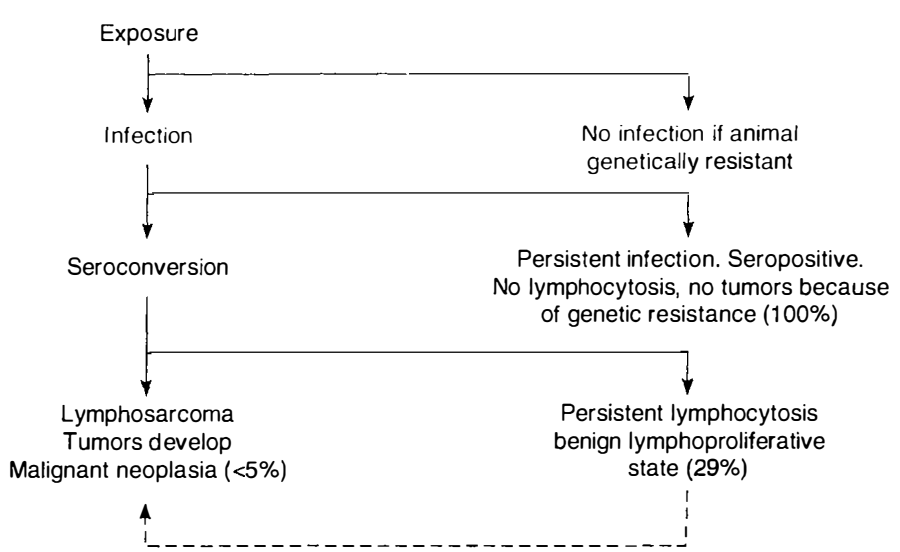

Fig. 21.1 Possible pathways after exposure to BVL virus (percentage figures indicate proportion of seroconverted animals that develop the particular form referred to[2]).

Whether or not the animal becomes infected or develops any of the other forms of the disease depends on the recipient's genetic constitution (see **Animal risk factors** above). The outcome may also be influenced by the animal's immune status and the size of the infective dose of virus. About 80% of animals with the adult form of the disease have a marked depression of IgM globulins. The immunological responsiveness of leukotic cattle to administered antigens is significantly depressed overall, especially to IgM, resulting from a deficiency in its production in the spleen and lymph nodes.

Lymphomatosis is a neoplasm of the lymphoreticular system. It is never benign and the lesions develop at varying rates in different animals so that the course may be quite short or protracted over several months.

The effects of BLV infection on milk production may not be related solely to overall animal health but may also be mediated directly at a cellular level.[34] An in vitro system revealed that the casein production and mRNA synthesis by mammary epithelial cells from a BLV-infected cow were reduced compared with control cell lines without BLV.

Lesions and clinical disease

In adult cattle, almost any organ may be the site of lesions, but the abomasum, heart, and visceral and peripheral lymph nodes are most commonly affected. In calves, the visceral lymph nodes and spleen and liver are the common sites. Depending on the organ which is most involved, several clinical syndromes occur. Involvement of the abomasal wall results in impaired digestion and persistent diarrhea. When the atrial wall is affected, congestive heart failure occurs. In nervous tissue, the primary lesion is in the roots of peripheral nerves and spreads along the nerve to involve meninges and cord. Involvement of the spinal meninges and nerves results in the gradual onset of posterior paralysis. The skin, reproductive tract, and periorbital tissues are commonly affected. In the cutaneous form, intradermal thickenings develop which persist but do not cause discontinuity of the epithelium. They are composed of aggregations of neoplastic lymphocytes. Invasion of periorbital tissues commonly results in exophthalmos. Esophageal obstruction may result from mediastinal lymph node involvement in calves.

The exact nature of the tumor is unclear. The tumors consist of aggregations of

neoplastic lymphocytes, but in many cases they may be more accurately described as reticulosarcoma. They are highly malignant and metastasize widely. The hemogram is variable and, although there may be an accompanying lymphocytosis, the presence of large numbers of immature lymphocytes in the blood smear is a more reliable indication of the presence of the disease. Some degree of anemia is common.

CLINICAL FINDINGS

Enzootic (adult) bovine viral leukosis (bovine lymphosarcoma)

This disease is characterized by the occurrence of multiple cases of adult multicentric lymphosarcoma, with tumors developing rapidly in many sites with an accompanying great variation in clinical signs and syndromes. An approximate indication of the frequency with which individual signs appear is set out in Fig. 21.2.[35]

The usual incubation period is 4–5 years with most occurring 4–5 years after the original case was introduced or a blood transfusion from an outside herd was given. This form is rarely seen in animals under 2 years of age and is most common in the 4–8 years age group. Persistent lymphocytosis without clinical signs occurs earlier but rarely before 2 years of age. Many cows remain in the preclinical stage for years, often for their complete productive lifetime without any apparent reduction in performance, but clinical disease appears in a proportion of these cows. The clinical signs and the duration of the illness vary with the number and importance of the sites involved and the speed with which the tumor masses grow.

In 5–10% of clinical cases the course is peracute and the affected animals often die suddenly or unexpectedly without any prior evidence of illness. Involvement of the adrenal glands, rupture of an abomasal ulcer or an affected spleen followed by acute internal hemorrhage are known causes. These animals are often in good bodily condition.

In most cases the course is subacute (up to 7 d) to chronic (several months) and initiated by an unexplainable loss of body condition and appetite, pallor and muscular weakness. The heart rate is not increased unless the myocardium is involved and the temperature is normal unless tumor growth is rapid and extensive, when it rises to 39.5–40°C (103–104°F). Although the following specific forms of the disease are described separately, in any one animal any combination of them may occur. In many cases, clinical illness sufficient to warrant the attention of the veterinarian is not observed until extensive involvement has occurred and the possibility of slaughter of the animal for beef purposes cannot be considered. On the other hand, many cases are examined at a time when diagnostic clinical signs are not yet evident. Once signs of clinical illness and tumor development are detectable the course is rapid and death occurs in 2–3 weeks.

Enlargement of the superficial lymph nodes

Enlargement of the superficial lymph nodes occurs in 75–90% of cases and is often an early clinical finding. This is usually accompanied by small (1 cm in diameter) SC lesions, often in the flanks and on the perineum. The skin lesions are probably enlarged hemolymph nodes and are of no diagnostic significance, often occurring in the absence of other signs of the disease. In many cases with advanced visceral involvement, peripheral lesions may be completely absent. Enlargement of visceral lymph nodes is common, but these are usually subclinical unless they compress other organs such as intestine or nerves. They may be palpable on rectal examination and special attention should be given to the deep inguinal and iliac nodes. In advanced cases, extensive spread to the peritoneum and pelvic viscera occurs and the tumor masses are easily palpable.

Although the enlargement of lymph nodes is often generalized, in many cows only a proportion of their nodes are involved. The enlargements may be confined to the pelvic nodes or to one or more SC nodes. Involvement of the nodes of the head is sometimes observed. The affected nodes are smooth and resilient and in dairy cows are easily seen and their presence may be marked by local edema. Occasionally, the entire body surface is covered with tumor masses 5–11 cm in diameter in the SC tissue.

Digestive tract lesions

Digestive tract lesions are common. Involvement of the abomasal wall results in a variable appetite, persistent diarrhea, not unlike that of Johne's disease and occasionally, melena due to bleeding of an abomasal ulcer. Tumors of the mediastinal nodes may cause chronic, moderate bloating.

Cardiac lesions

Lesions in the heart usually invade the right atrial wall primarily, causing right-side congestive heart failure. There is hydropericardium with muffling of the heart sounds, hydrothorax with resulting dyspnea, engorgement of the jugular veins and edema of the brisket and sometimes of the intermandibular space. The heart sounds are commonly muffled and other cardiac abnormalities may be obvious. Tachycardia due to insufficiency and arrhythmia due to heart block are common. A systolic murmur is also common along with an abnormal jugular pulse. The liver may be enlarged and palpable caudal to right costal arch, and passive congestion of the liver and visceral edema result in persistent diarrhea.

Nervous system involvement

Neural lymphomatosis is usually manifested by the gradual onset over several weeks of posterior paralysis. Knuckling of the fetlocks of the hind legs while walking is common and one leg may be more affected than the other. This is followed by difficulty in rising, and finally clinical recumbency and inability to stand. At this stage, sensation is retained, but movement

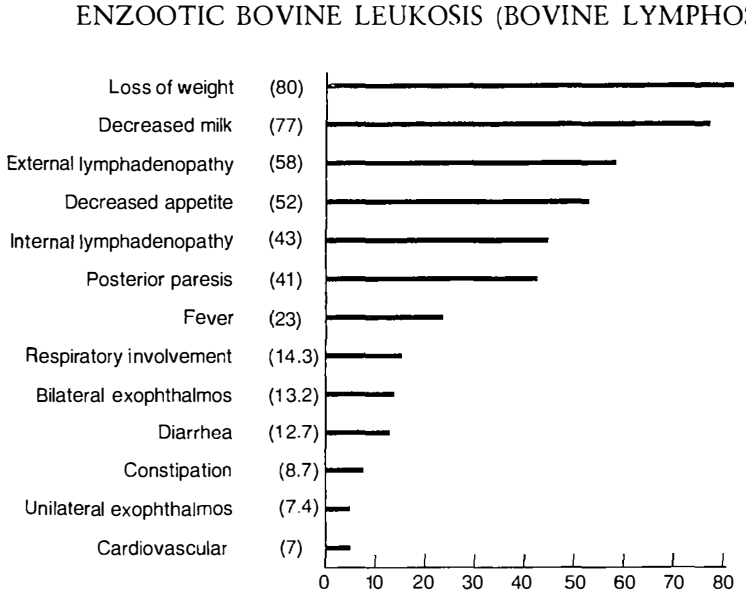

Fig. 21.2 Clinical diagnosis: frequency of predominant signs of bovine leukemia – 1100 field cases. (By courtesy of *Canadian Veterinary Journal*[34].)

is limited or absent. There may be a zone of hyperesthesia at the site of the lesion, which is usually at the last lumbar or first sacral vertebra. Appetite and other functions, apart from the effects of recumbency, are usually normal. Metastases in the cranial meninges produce signs of space-occupying lesions with localizing signs referable to the site of the lesion.

Less common lesions

These include enlargement of the retropharyngeal lymph nodes which may cause stertor and dyspnea. Sometimes clinically detectable lesions occur in the periorbital tissues, causing protrusion of the eyeball (exophthalmos), and in limb muscles, ureter and kidney,[36] and genitalia. Involvement of the uterus may be detectable as multiple nodular enlargement on rectal examination.[37] Severe bilateral exopthalmos may occur along with generalized lymphadenopathy.[38] Periureteral lesions may lead to hydronephrosis with diffuse enlargement of the kidneys while tumors in renal tissue cause nodular enlargements. In either case terminal uremia develops.

BLV particles have been detected by electron microscopy around lymphocytes in the mammary tissue of BLV antibody positive cows affected by subclinical mastitis.[39] Whether the virus is a causative agent or an immunosuppressent in bovine mastitis is unknown.

Sporadic bovine leukosis

The calf, thymic and cutaneous forms are designated sporadic bovine leukosis.

Juvenile or calf lymphosarcoma

This occurs in calves at 2 weeks to 6 months of age and is manifested by gradual loss of weight and the sudden enlargement of all lymph nodes, and depression and weakness. Fever, tachycardia and posterior paresis are less constant signs. Death occurs in 2–8 weeks after the onset of signs. Signs of pressure on internal organs, including bloat and congestive heart failure may occur. Diffuse infiltration of major nerves of a limb may also occur.[40] Unusually the disease may be fully developed in utero, so that the newborn calf is affected with tumors, or be delayed until 2 years of age. Lymphosarcoma of the pharyngeal region causing retropharyngeal swelling and dyspnea in a 7-month-old beef steer has been recorded.[41]

Bone and bone marrow necrosis associated with the calf form of sporadic bovine leukosis has been recorded in calves 3 weeks to 8 months of age. Clinical findings included unthriftiness and inactivity, posterior ataxia, superficial lymph node enlargement, lameness and respiratory distress. Involvement of the tibio-tarsal joint, ribs, and spinal canal may also occur resulting in ataxia and paresis.[42] Multiple bone infarcts and bone marrow necrosis were present at necropsy. Lymphosarcoma of the mandible of a 2-year-old heifer has also been recorded.

Thymic lymphosarcoma of young cattle

Infiltration of the thymus is a common finding in animals 1–2 years of age and is characterized by massive thymic enlargement and lesions in bone marrow and regional lymph nodes. Jugular vein engorgement and marked brisket edema extending to the submandibular region are common. Moderate bloat due to inability to eructate because of compression of the esophagus may occur.[25] The thymic mass is usually not palpable. This form is more common in beef than in dairy cattle. An atypical lymphosarcoma in a mature cow negative for BLV and similar to the thymic form has been reported.[43] Metastatic thymic lymphosarcoma in a calf has been recorded[36] including a case with metastases causing spinal cord compression. Cases of both the systemic and local forms of sporadic bovine leukosis have been described.[25] A large number of the thymic lymphosarcoma occurred in calves in five regions in France over a period of 5 months. Most of the calves had been sired by the same bull, which suggests that the disease had an inherited basis.

Cutaneous lymphoma

This is most common in cattle less than 3 years of age. It is rare and manifested by cutaneous plaques (1–30 cm diameter) appearing on the neck, back, croup and thighs. The plaques become covered with a thick, gray-white scab and the hair is shed; then the center becomes depressed and the nodule commences to shrink. The surface of some placques may become ulcerated and have a serosanguinous exudate. Some of the lesions have a cauliflower-like appearance, appear black, and are ulcerated and foul-smelling. After a period of weeks or months hair grows again and the nodules disappear as does the enlargement of the peripheral lymph nodes. Spontaneous regression of bovine cutaneous leukosis has been recorded. Relapse may occur in 1–2 years with reappearance of cutaneous lesions and signs of involvement of internal organs as in the enzootic form of the disease. In one series of 10 heifers, all animals had lymphadenopathy.[44] Some had leukoctyosis and some had lymphocytosis. The body condition may vary from normal to thin and underdeveloped. Some affected animals may have a fever.

Cutaneous T-cell lymphoma in two Friesian cows in the Azores has been reported.[4] The lesions consisted of raised pink plaques, with no pruritus or signs of associated pain, which were extensively distributed over both lateral and ventral body regions. Immunocytochemistry found the tumor cells positive for CD3, confirming the T-cell origin of the cells which involved both skin and regional lymph nodes.

Other species

Outbreaks of lymphosarcoma in sheep have been observed with clinical, epidemiological, hematological and necropsy findings similar to those of enzootic bovine leukosis. B-cell leukemia has been described in sheep.[45]

Infection of other species with BVL virus has not been demonstrated, but epidemic occurrences of lymphosarcoma have been observed in pigs, but only sporadic cases in horses.

In pigs, non-specific emaciation, limb weakness and anorexia are most commonly observed. Sporadic cases in this species are unlikely to be recorded, and although outbreaks have occurred, they and the enzootic form are not commonly encountered. In one herd with the enzootic disease all cases encountered were in pigs less than 6 months of age. There was stunting of growth, development of a pot belly, enlargement of peripheral lymph nodes, and a lymphocytosis, including the presence of immature cells.

In horses, the disease occurs most commonly in animals over 6 years of age. The common clinical manifestations are:

- Subcutaneous enlargements which may ulcerate
- Enlargement of internal and external lymph nodes
- Jugular vein engorgement
- Cardiac irregularity
- Exophthalmia
- Bilateral swelling of the eyelids
- Anasarca.

The course varies from acute to chronic, but most affected horses die within a month of first showing signs. Diffuse alimentary lymphoma of the small intestine in adult horses is characterized by:

- Malabsorption
- Hypoalbuminemia
- Increased gammaglobulin levels
- Anemia
- Chronic alimentary tract dysfunction but without diarrhea.

Malignant lymphoma with ulcerative pharyngitis in horses has been recorded.

CLINICAL PATHOLOGY

A definitive antemortem diagnosis depends on the clinicopathological examination of the animal. Several diagnostic techniques are available and it is important to make the appropriate selection for the particular

stage of the disease that is being considered, thus:

- Diagnosis of the viral infection is made by serological or virological techniques
- Persistent lymphocytosis is identified by hematology
- Neoplastic tumors are identified by histological examination of a biopsy specimen.

Because of the increasing economic impact of BLV infection in the cattle industry, the availability of a highly sensitive and specific assay for the identification of BLV-infected animals is of critical importance. Such an assay is needed for the selection of BLV-free cattle for commercial sale, prepurchase testing of breeding animals, and import or export testing, and for control and eradication programs. Ideally, the assay should be practical, inexpensive, and able to be adapted for large-scale use.

Diagnosis of the presence of infection with BVL virus

Serological tests

Virtually all cattle infected with BLV will continuously have antibodies against the major internal (p24) and envelope (gp51) virion proteins in their serum, and serological tests are commonly used for the diagnosis of BLV infection in cattle over 6 months of age.

Radioimmunoprecipitation assay (RIP). The RIP using gp51 or p24 as antigen, is a highly sensitive and specific method for serologic diagnosis of BLV infection.[46] The RIP assay has been used as the criterion-referenced standard to critically evaluate the performance of other diagnostic tests for BLV infection. Detailed comparisons of various BLV assays in a large number of cattle of various origins and ages found that the RIP assay is the most sensitive and specific test. However, its major disadvantage is that it requires a gamma counter and radioistopes, which are expensive.

AGID test. This is a good screening test to determine the presence of infection in an individual animal or herd.[2] The estimated specificity of 99.8% and the sensitivity of 98.5% indicate that the test is a reliable and accurate method to detect BLV infection. False-positive and false-negative results do occur and may be associated with some variability of the immune system or from human error. The AGID test is the official reference test of the Office International des Epizooties and the European Community and is the test recognized by most governments as the official test for purposes of testing imported animals. There is however, a lack of standardization between the BLV-AGID kits used in North America and Europe.[47]

Radioimmunoassay (RIA). This is suitable for individual cow testing because of its accuracy. There are several versions of this and the one using the virion gp antigen is preferred.[2] It is one of the most sensitive tests and is useful for the detection of BLV antibodies in cattle exposed no longer than 2 weeks, in milk samples, and in serum samples from periparturient dams.

Serum ELISA. In more recent years, ELISA-based testing has replaced the AGID in eradication programs in several countries. It is more sensitive than other serological tests and can be used on milk.[2] The superior sensitivity of the ELISA for pooled serum samples allows detection of antibodies in herds with a prevalence of less than 1%, whereas the AGID test detected only 50% of the herds detected by the ELISA.[2] Two commercially available ELISAs and the polymerase chain (PCR) were evaluated and compared with the AGID to detect antibodies to BLV or its nucleic acid.[5] The ELISA tests detected about 10% more reactors than the AGID and the elecrophoretic immunoblotting results. Some ELISA positive animals were not detected by the PCR.

Four commercially available BLV-ELISA kits from Europe or the United States were compared to the AGID test officially approved by the Canadian Food Inspection Agency. The ELISA tests were more sensitive than the AGID test kits and the gp51 BLV-ELISA is now recognized as an official test method for the serodiagnosis of bovine leukosis in Canada.[48]

A highly sensitive and specific blocking ELISA comparable to the radioimmunoprecipitation assay for the detection of BLV antibodies in serum and milk samples has been developed.[46]

The chronology of seroconversion is important in the serological diagnosis. Calves from infected dams have a 20% chance of being infected in utero and seropositive at birth. If they are serologically negative at birth they seroconvert at their first ingestion of colostrum from seropositive cows and this passively acquired immunity persists for 2–7 months. These calves, and calves from uninfected mothers become positive at varying ages depending on when they come into contact with infection, usually when they are placed into the infected adult herd. This can be as early as 9 months of age, but as a general rule positive reactions are uncommon in cattle which are less than 2 years of age. Seroconversion usually takes place 3–4 months after the negative animals are placed in the infective group, although the interval is longer in the winter than in the summer. Infected animals are seropositive and infected for long periods, usually for life.

Using the ELISA, experimental infection of calves at 3–4 months of age results in seroconversion to the virus at 4–5 weeks after infection.[20]

In a control and eradication program, early detection of infected calves is difficult because colostral antibodies to BLV cannot be differentiated from antibodies resulting from natural infection. By using measures of colostral antibody concentration, calves infected in utero could be identified by 80 d of age. Calves over 6–8 months of age with a positive immunodiffusion test will likely be infected permanently. Calves which have ingested colostrum from seropositive cows usually have maternal antibodies and polymerase chain reaction tests are necessary to detect the virus and distinguish between infected and virus-free calves.[49]

Milk ELISA. This is much more sensitive than the AGID and has been adopted for testing milk from individual cows and pooled milk samples.[46,50] A comparison of the ELISA and AGID tests for the detection of BLV antibodies in bovine serum and milk found a high level of agreement.[50] The bulk tank milk ELISA is useful for identification of herds which are negative for BLV infection.[51] The ELISA identified 80% of herds as positive for BLV and had an apparent sensitivity and specificity of 0.97 and 0.62, respectively.[51] But after accounting for the sensitivity and specificity of the AGID test in individual animals, the specificity of the ELISA test for milk was 0.44. With the moderately low specificity, herds identified as positive by the ELISA would require further testing at the individual or herd level to definitively establish their BLV status.

An indirect ELISA to detect antibodies to BLV in bulk-milk samples in Sweden is being used to assist in the eradication of infection from Swedish herds.[52] The antibody level in milk is lower than in serum but the sensitivity of the ELISA is as effective as for sera. Testing of bulk milk is a useful and practical method for large-scale epidemiological studies and initial eradication programs. Heifers, bulls, and dry cows are not included when bulk milk is tested and all animals over 1 year of age need to be sampled individually before a herd is declared free of the virus. The sensitivity and specificity of the milk ELISA is estimated to be adequate until the prevalence of BLV-infected individuals in the country is less than 1%.

Detection of virus

Polymerase chain reaction (PCR). The PCR is a sensitive and specific assay for direct diagnosis of BLV infection in peripheral blood lymphocytes.[53] The test

is useful for the early detection of BLV infection even before antibodies are present. It is more sensitive than the AGID test or the ELISA in detecting infected cattle where the prevalence of infection is less than 5%.[54] The test can identify proviral DNA of BLV in the lymphocytes of calves at birth which are born to infected cows.[55] All calves found to be infected at birth were born to BLV-positive cows with persistent lymphocytosis. At birth, the presence of a titer can be due to colostral antibodies or perinatal infection and the PCR test can differentiate uninfected newborn calves with colostral antibodies from BLV-infected calves and detect the presence of the virus in the presence of antibodies.[47] The PCR has a practical application in the identification of BLV-infected calves, regardless of colostral antibody, which allows immediate removal of the source from the herd. In a dairy herd with a high prevalence of BLV, a positive PCR assay result provided definitive evidence that a cow was infected with BLV.[56] However, sensitivity and specificity were 0.672 and 1.00, respectively. Predictive value of a positive test was 1.00, and predictive value of a negative test was 0.421. Thus PCR assay alone is unreliable for routine detection of BLV in herds with a high prevalence of BLV infection.

The PCR can also be used to ensure that cattle used in the production of a whole blood vaccine for tick-borne disease are free from BLV infection.[17] The sheep bioassay, currently in use, requires 4 months of serological testing to insure that donor animals are not infected. Replacement of the sheep bioassay with the PCR could result in considerable saving of time and effort. Use of the PCR requires stringent precautions to prevent false-positive results due to contamination of samples with PCR product.[17]

A nested PCR identified 98% of BLV seropositive cows from blood and 65% from milk, whereas real-time PCR detected 94% of BLV seropositive cows from blood and 59% from milk.[57] BLV was also detected in 10% of seronegative cows most likely because of early detection before seroconversion.

Differentiation between enzootic and sporadic bovine leukosis. The role of BLV in some cases of sporadic bovine lymphomas needs to be re-examined. The findings of persistently seronegative PCR-positive and seropositive PCR-negative cattle indicates that the BLV cannot be excluded as a causative agent in sporadic bovine leukosis. Enzootic bovine leukosis cannot be distinguished from sporadic bovine leukosis on histopathological examination. The ELISA is recommended as a method of choice to differentiate between EBL and sporadic bovine leukosis (SBL) because it is a rapid, reliable and sensitive test which is inexpensive and easy to perform. In cases where no blood or other fluids are obtained, the PCR test is the most useful method for the direct detection of BLV.

Diagnosis of persistent lymphocytosis (PL)

Approximately 30% of animals infected with the BLV develop PL, which is defined as an increase in the absolute lymphocyte count of three or more standard deviations above the normal mean as determined for that respective breed and age group of animals in leukosis-free herds. The PL is an increase in peripheral B-lymphocytes. It has been suggested that one additional criterion for PL should be that it persists for more than 3 months. When PL was first recognized in herds which experienced clinical lymphosarcoma, it was considered a subclinical expression of the tumor stage of the disease. It became an important diagnostic criterion in control and eradication programs until serological tests became available to more accurately identify infected animals. The majority of cells involved in PL are normal lymphocytes but atypical and abnormal forms have been described and are considered as indicative of preleukemic condition. The total count increases from a normal of 6000 to as high as 15 000/μL. The percentage of lymphocytes in the total white blood cell count increases from the normal of 50–65% is considered a positive result. The presence of 25% or more of the total lymphocyte count as atypical immature cells is also considered a significant aberration. The PL may subside in animals which subsequently develop lymphosarcoma.

The association between the strength of serologic recognition of BLV by the use of ELISA and lymphocyte count in bovine leukosis virus-infected cows has been examined.[52] The sample-to-positive ratio, which is the ratio between the test sample and a positive control sample, was compared among lymphocytotic and nonlymphocytotic cows. The sample-to-positive ratio and lymphocyte count were related but cows with high sample-to-positive ratio were not always lymphocytotic. Culling cows on the basis of sample-to-positive ratio will reduce culling of ELISA-positive cows, however, culling on the basis of lymphocyte count will eliminate a greater proportion of the reservoir of infection.

Diagnosis of lymphosarcoma

This can only be done by histopathological examination of a section of tumor material obtained by biopsy or necropsy. A needle aspirate of an enlarged peripheral lymph node may provide a rapid and inexpensive diagnosis. Enlarged lymph nodes or hemolymph nodes are the usual sources, but when the genital tract is involved an exploratory laparotomy is usually performed so that a sample can be obtained. The lymphocyte count may increase to 20 000–30 000 μL, and in some cases may reach values of 50 000–100 000 μL, and even 400 000–500 000 μL. Conversely, in some cases, the lymphocyte count decreases. Chromosomal changes may be detectable in cells from lymph nodes or in leukocytes from peripheral blood of affected animals. When there is myocardial involvement there may be obvious changes in the electrocardiogram but these are unlikely to be of value in differential diagnosis.

NECROPSY FINDINGS

In cattle, firm white tumor masses may be found in any organ although two rather different patterns of distribution are apparent. In newborn and young animals, the common sites are: kidneys, thymus, liver, spleen and peripheral and internal lymph nodes. This may or may not be a characteristic of the 'sporadic' form of the disease. In adults, the heart, abomasum and spinal cord are often involved. In the heart, the tumor masses invade particularly the right atrium, though they may occur generally throughout the myocardium and extend to the pericardium. The frequency of early changes in the subepicardial tissue of the right atrium suggests that this is an area from which tissues should be selected in latent or doubtful cases. The abomasal wall, when involved, shows a gross, uneven thickening with tumor material in the submucosa, particularly in the pyloric region. Similar lesions occur commonly in the intestinal wall. Deep ulcerations in the affected area are not uncommon. Involvement of the nervous system usually includes thickening of the peripheral nerves coming from the last lumbar or first sacral cord segment or more rarely in a cranial cervical site. This may be associated with one or more circumscribed thickenings in the spinal meninges. Affected lymph nodes may be enormously enlarged and be composed of both normal and neoplastic tissue. The latter is firmer and whiter than normal lymphoid tissue and often surrounds foci of bright yellow necrosis. Less common sites include the:

- Kidney
- Ureters (usually near the renal pelvis)
- Uterus (either as nodular masses or diffuse infiltration)
- Mediastinal, sternal, mesenteric and other internal lymph nodes
- Mandibular ramus.

When performing the necropsy, it is important to remember that lymphosarcoma can appear not only as discrete nodular masses but as a diffuse tissue infiltrate. The latter pattern results in an enlarged pale organ which is easily misinterpreted as a degenerative change rather than as a neoplastic process.

Histologically, the tumor masses are composed of densely packed, monomorphic lymphocytic cells. Attempts to better characterize the nature of these cell populations have been published.[58,59] The cleaved variant of the diffuse large cell type with a high mitotic index is characteristic of enzootic lymphoma and this high-grade type of B-cell tumor may be a consequence of the viral etiology of this form of the disease.[31] It is possible to confirm viral infection in some cases by a PCR test but such testing is rarely justified. Immunohistochemical staining of formalin-fixed, paraffin-embedded tissue sections of tumors can be used to confirm that neoplastic lymphocytes are of thymic origin when thoracic masses are examined.[60]

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed samples of gross lesions, plus enlarged lymph nodes, bone marrow, liver, spleen, thymus, right atrium, abomasum, uterus (LM, IHC)
- **Virology** – neoplastic tissue (PCR).

DIFFERENTIAL DIAGNOSIS

Because of the very wide range of clinical findings, a definitive diagnosis of BVL is often difficult. Enlargement of peripheral lymph nodes without fever or lymphangitis is unusual in other diseases, with the exception of tuberculosis, which can be differentiated by the tuberculin test. In the absence of these enlargements, the digestive form may easily be confused with Johne's disease. The cardiac form closely resembles traumatic pericarditis and endocarditis, but there is absence of fever and toxemia, and the characteristic neutrophilia of these two diseases is usually absent. Involvement of the spinal nerves of meninges may be confused with spinal cord abscess or with the dumb form of rabies. An examination of cerebrospinal fluid may be of value in determining the presence of an abscess and rabies has a much shorter course and other diagnostic signs. Multiple lymph node enlargements in the abdominal cavity, and nodular lesions in the uterine wall may be confused with fat necrosis, but the nature of the lesion can usually be determined by careful rectal palpation. Stertor caused by enlargement of the retropharyngeal lymph nodes is also commonly caused by tuberculosis and actinobacillosis.

Cases of atypical lymphosarcoma[43] and thymic lymphosarcoma[41] which are BLV-negative may resemble lymphosarcoma of enzootic bovine leucosis.[61]

Echocardiography is now being used to detect intracardiac masses which may be compatible with EBL.[62]

TREATMENT

There is no treatment.

CONTROL

The disease can be eradicated from a herd and even a country, or controlled at a low level. The **option chosen** depends initially on the **prevalence of infection in the herd**, the **value of the animals in the herd**, and whether a **governmental indemnity** offered for seropositive cows which are culled and sent to slaughter.

History of Compulsory Eradication Program in Denmark

Control and eradication programs have been in effect on a nationwide basis in several western European countries.[2] Denmark began an eradication program in 1959 based on the occurrence of clinical lymphosarcoma, and the identification of cattle with PL using the Bendixen hematological key for classifying cattle as **normal**, **suspect** or **lymphocytic**. Leukosis was declared a reportable disease, and all adult cattle from herds in which cases of leukosis originated were subjected to a hematological examination. Affected herds were quarantined, and indemnity was offered to induce owners to have their entire herd slaughtered. This herd-slaughter policy was continued until 1982. When the AGID test became available, the Bendixen key was discontinued and only the AGID test was used in the official program between 1979 and 1982. Routine testing was discontinued in 1982. Surveillance involved testing random sera collected from every sixth adult cow to be slaughtered. According to the official Danish control program, the incidence of tumors in adult cattle at the start of the eradication program was at least 10 times greater than 10 years later. The hematological test was less sensitive than subsequent serological tests but the specificity was fairly high and only a few herds were erroneously classified as leukosis herds.[61] When the serological tests were introduced, some herds which were classified as leukosis-free based on the hematological key, were found to be infected.

Voluntary eradication programs using the AGID test have been effective in other member countries of the European Community in the last two decades and have been successful in reducing the prevalence of infection and disease.[2] In the Federal Republic of Germany, eradication was achieved in 5 years. These programs have been successful in part because of the low prevalence of infection and the economic losses from culling seropositive cows has not been large.

In **Britain**, EBL is a reportable disease but is uncommon.[41] A national testing program was begun in 1992. All blood samples collected for routine periodic testing for brucellosis have also been tested for BLV and milk samples are collected every 3 months from dairy herds for BLV testing. The prevalence of infection has been low and the source of infection undetermined. Some of the animals had been imported from Canada but in other cases there was no association with importation.

Considering the animal-health aspects and possible consumer reactions against having a widespread retrovirus infection in food-producing animals, and the requirements for exporting cattle and semen, **Sweden** introduced a national program for the eradication of BLV in 1990.[52] An ELISA test was evaluated for detection of antibodies to BLV in individual and bulk milk and serum samples. It is proposed that eradication can be based on using the ELISA on milk samples in combination with other diagnostic tests and the prompt removal of infected animals.

In **Canada and the United States**, it is considered cost prohibitive to cull and slaughter all seropositive cattle because of the high prevalence of infection. Many seropositive cows are valuable pedigreed animals, and there are no indemnity programs available. Thus all control and eradication programs in these countries are herd based and strictly voluntary. Livestock producers are willing to adopt control programs because of the economic losses associated with export restrictions if their cattle are infected, and the losses due to the occasional clustering of cases of lymphosarcoma.

Enzootic bovine leukosis was eradicated from **Finland** in 1996.[63] The disease was first recognized in 1966 and it required 30 years using the key principle of test and slaughter policy to achieve eradication. The infection status was monitored at meat inspection, and hematologically between 1970 and 1977, serologically between 1978 and 1989. Annual surveys including all dairy herds and samples from beef animals were conducted in 1990–2001. Bulk tank samples represented the dairy herds in the surveys; beef animals were sampled individually at slaughter. The maximum positive herd-level percentage in the survey was 0.03%. The herd level prevalence of infection never exceeded 5%.

Eradication programs

Enzootic bovine leukosis can be eradicated only by:

- Test and slaughter of cattle infected with the virus. Programs based on the culling of seropositive cows are effective
- The maintenance of a closed herd which permits the entry of only those animals free of infection.

The efficiency of such a program depends on the accuracy of the test used to identify the infected animals, and the repetition of the test at an appropriate interval so that animals that were in the incubation stages of the disease at the time of the first test will have had time to seroconvert. The recommended procedure is:

1. Identify infected animals using the AGID test[2]
2. Cull and slaughter seropositive animals immediately
3. Retest the herd 30–60 d later
4. Use the PCR assay to test young calves and as a complementary test for clarifying doubtful test results in herds with a low prevalence of infection.[54]

Testing is repeated until the herd has a negative test. When the herd is negative, testing is repeated every 6 months and the herd declared free when there have been no positive reactors for 2 years. Future introductions into the herd are managed most safely by artificial insemination or fertilized ovum transfer, or importations of animals which have been tested and are seronegative on two tests carried out 30 and 60 days prior to arrival.

In herds where the prevalence is high, a two-herd scheme can be successful. Newborn calves are removed from seropositive cows immediately after birth, fed colostrum from seronegative cows and raised in isolation. All animals over 6 months of age are tested periodically and seropositive animals culled. The parent herd is eventually disposed of as negative replacement animals become available. Only those bulls which are seronegative may be used and they must be tested every 3 months.

Although eradication is biologically feasible, it is unlikely that area eradication programs will be implemented on an extensive scale because losses from the disease are not sufficiently high, and there is a high risk of insect vectors reintroducing it which poses a real threat to maintenance of a BVL-free herd. The cost-effectiveness of an eradication program on a national basis would be a major consideration. For an individual herd, it is feasible provided some steps were taken to increase genetic resistance of the residual stock and to reduce the chances of in-contact infection occurring.

Limitation of spread of infection

In herds with a high prevalence of infection, the test and slaughter method of eradication is not economically viable if the animals have a high economic value because of superior genetic potential. Control of infection in these herds is possible using embryo transfer from infected dams to negative recipients and isolation of newborn calves but these are not practical on a country-wide basis. An alternative method is segregation of BLV-infected and non-infected animals based on the AGID test. This is known as the test and segregation method, which is based on the evidence that the spread of infection between animals is relatively slow and that the virus is spread by movement of infected animals from one herd to another and within a herd. Following the initial testing of the herd, the herd is divided into two groups, BLV-positive and BLV-negative, and kept at least 200 m apart. A third separate location is used for quarantine of replacement animals. Replacement animals must be found negative in two consecutive AGID tests, the first within 30 d before purchase and the second after 60 d of isolation, prior to being moved into the negative group. The AGID tests are conducted every 3 months and the reactors removed to the positive group location until the remaining animals in the herd have attained BLV-negative status by the test. Thereafter, the tests are done every 6 months and continued until at least four consecutive negative tests are obtained for each herd. Variations of this method of test and segregation with subsequent removal of seropositive animals in the routine culling program have been successful. The colostrum and milk fed to calves in the BLV-negative group must be from seronegative cows or be pasteurized to inactivate the virus.

In Canada, cattle owners may enrol in the Canada Health Accredited Herd program to declare freedom from EBL. All reactors must be removed from the herd. If a large number of reactors are detected, two herds on two separate farms can be established: one herd comprised of the reactors and the other of cattle which are seronegative. Calves from the reactor herd can be added to the accredited herd in accordance with strict isolation and testing procedures. To qualify for accredited certification, a herd must have two consecutive negative herd tests, at least 4 and less than 12 months apart. The tests must include all cattle in the herd. The first annual renewal test must occur no more than 12 months following the second qualifying test for certification, and must include all cattle in the herd. Subsequent renewal tests must occur within the same 12-month interval. Only cattle 24 months of age and older must be tested but a herd inventory and audit must be performed on the whole herd. In herds with reactors, the two qualifying tests do not begin until at least 4 months after the removal of the last reactor uncovered during any test. Herd additions can be made during the qualifying test period or after certification has been achieved. Each animal must be accompanied by a health certificate and depending on the enzootic bovine leukosis status of the originating herd, certain testing and isolation procedures could apply. Owners wishing to have their animals attend exhibitions can do so providing they adhere to certain conditions. Properly processed semen and embryos can be introduced without restrictions. Owners are encouraged to follow preventive health management practices to augment the eradication of enzootic bovine leukosis from their herds. These include all areas where blood transfer could occur (needles, dehorning, castrating, extra teat removal, ear tagging, tattooing, hoof trimming, rectal palpations, drenching) and other procedures which transfer leukocytes, and routine insect control.

Prevention of infection in calves and young stock

Several management techniques can be used to prevent infection in calves from birth until they become herd replacements. The feeding of newborn calves with colostrum and milk from seronegative cows has been widely accepted as effective in preventing infection in calves. Postnatal infection in calves can also be minimized by feeding milk replacer, and/or whole milk from non-infected cows. The use of colostrum and milk from non-infected cows permits early serological detection of infected calves. However, feeding colostrum from seropositive cows to newborn calves can provide significant protection from infection during the first 3 months of life. Field studies indicate that colostrum-derived BLV antibodies may prevent as much as 50% of the infection during the first 3 months compared to calves which did not receive colostrum with BLV antibodies. Further reduction in the risk of infection via colostrum can be achieved by pasteurization of the colostrum – 63°C for 30 min.[64] The colostrum-derived BLV antibodies will however delay early detection of infection in calves. The replacement of whole milk feeding with high-quality milk replacer may also be considered.

Transmission to newborn calves can also be reduced by avoiding exposure to maternal blood at the time of parturition, housing calves in individual hutches with individual feeders and waterers, and management techniques to avoid iatrogenic transmission.[65] When handling a group of calves, the youngest ones should be handled first and the older and sick calves last. Equipment which could act as fomites in transferring blood should be disinfected with chlorhexidine when used between calves. These instruments include:

- Nose tongs
- Scissors
- Forceps
- Dehorning instruments
- Esophageal tubes
- Balling guns
- Tattoo equipment
- Ear taggers.

Dehorning calves using the electrocautery method before 2 months of age can reduce the prevalence of infection compared to gouge dehorning, which allows the transfer of infected blood between calves. Handling facilities which become contaminated with blood should be cleaned between calves. Fly control should be instituted as necessary. Single needles should be used for vaccination and calves should be tested serologically for BLV infection at about 6 months of age.

A marked reduction in the prevalence of infection within the heifer age groups of a dairy herd with a high prevalence can be achieved by:

1. Use of single needles and individual sleeves for rectal examination
2. Disinfection of tattoo equipment before use
3. Dehorning by use of electrocautery.

Biosecurity

Prevention of entry of infection into herd can be achieved by insuring that all imports into the herd have been tested at least 30 d prior to arrival and are seronegative. Control of insect vectors is highly desirable. Blood transfusions and vaccines containing blood, such as those used for babesiosis and anaplasmosis are particularly potent means of spreading the disease and donors must be carefully screened to insure that they are free of the disease. In the future the selection of cattle with inherent resistance to BLV may be a possibility. Embryo transfer from valuable pedigreed seropositive cows may aid in reducing prenatal infection. Insemination is not a method of transmission so that artificial breeding programs are not disrupted.

Vaccine

The possibility of a vaccine for BLV has been explored.[2] However, the prospects are not good thus far. A BLV vaccine would have to be non-infectious, non-oncogenic, and should not interfere with the serological tests commonly used to detect infection.

Bovine immunodeficiency-like virus

ETIOLOGY

Bovine immunodeficiency-like virus (BIV), also known as bovine lentivirus-1, is a lentivirus, within the larger family of Retroviridae. The virus shares structural and genomic similarities with other lentiviruses, such as equine infectious anemia virus, caprine arthritis-encephalitis virus, maedi-visna virus, feline, and the simian and human immunodeficiency viruses. The BIV was first described in cattle in the United States in 1972.[1] These viruses replicate primarily in the cells of the host's immune system following their insertion as provirus into the genome of these target cells, thus establishing a chronic, lifelong infection. The lentiviruses above are usually associated with specific diseases. However, a clear involvement of BIV in the development of a clinical syndrome is not well established.

EPIDEMIOLOGY

Prevalence of infection

Seroepidemiological evidence indicates that BIV infection has a worldwide distribution. Seropositive cattle have been identified in the United States, the Netherlands, New Zealand, Australia,[2] Bali,[3] Indonesia, Brazil,[4] and Canada with estimates ranging from 1–5%.[5,6] In Italy, the prevalence is 5.8% in dairy cattle and 2.5% in beef cattle.[7] In individual herds the prevalence of infection may be much higher. In the UK, the seroprevalence was found to be 5.9% in dairy cattle and 5.0% in beef cattle.[8] The dairy and beef herd prevalences were 60% and 59%, respectively. While the BIV infection in the UK is low, it is widespread. Recent studies, using DNA, derived from semen and buffy coat samples, analyzed by nested PCR, found no evidence of BIV infection in western Canadian cattle.[9]

A seroprevalence of greater than 50% was present in a dairy herd at a university in the southeastern United States, which is an area with a high prevalence of infection in the cattle population.[10] There is some evidence that in some cattle herds with a high incidence of unthrifty animals, the prevalence of seropositive animals may be as high as 95%.[11] The prevalence of BIV infection among dairy cattle in Ontario is low and may be associated with an economically important decrease in milk production.[6] Dual infection with BIV and BLV have been reported in Mississippi dairy cattle.[10]

The virus has been found in the seminal leukocytes of 82% of randomly selected semen samples from a bovine stud semen repository[12] suggesting the possibility that artificial insemination of dairy cows may have a major role in the transmission of the virus. The BIV may be involved in the pathogenesis of mastitis in cattle due to its immunosuppressive effects but no clear evidence is available.[13]

Retroviruses are heat labile and readily inactivated at 56°C, and pasteurization of milk for human consumption should provide an adequate safeguard. Feeding milk seeded with the virus and pasteurized before inoculation into calves is effective in inactivating the virus and preventing transmission.[14] There is no evidence that the virus is a potential human pathogen.

Methods of transmission

The virus is strongly cell-associated and may be transmitted in infected blood, colostrum, and milk that contains lymphoreticular cells.[15] There is some evidence of transplacental infection of the virus in cattle. In dairy cows naturally infected with BIV and seropositive at parturition, 40% gave birth to calves that were BIV seropositive before receiving colostrum;[16] seronegative cows do not. Calves born with anti- BIV-specific antibody do not demonstrate increased risk of clinical disease during the neonatal period but the calves born to dams which are seropositive at parturition appear to be at increased risk of occurrence of some clinical signs. The prevalence rate of infection among bulls housed in stud farms was 9.6% using serology, and 12.6% using PCR for the presence of BIV provirus in peripheral blood leukocytes.[17]

The BIV has no obvious morphological effects on the embryonic development of cattle and it is possible to obtain embryos at the transferable stage free of the virus from cows infected with the virus.[18] It is unlikely that BIV is associated with the zona pellucida-intact embryos derived by in vitro fertilization from oocysts obtained from infected animals or with oocysts fertilized with infected semen when embryos are washed as recommended by the International Embryo Transfer Society. Embryos from donors infected with the virus are not likely to transmit the virus to recipients and the resulting offspring.[19]

PATHOGENESIS

The pathogenetic mechanisms of BIV infection are unclear. Its pathogenicity is controversial. It is uncertain if the virus is a primary pathogen or a primary immunodeficiency virus which predisposes the animal to secondary infections.[15] Despite extensive experimental studies the pathogenic significance of the virus is uncertain.

Infection of cattle with BIV is associated with lymphoproliferation, lymphadenopathy, immunosuppression, neuropathy, and progressive emaciation.[15]

The virus was initially isolated from a cow with persistent lymphocytosis, lymphadenopathy, neuropathy and progressive emaciation. However, overt clinical disease in seropositive cattle is rare and experimentally induced infection in calves has resulted in only mild clinical consequences.[20]

Early studies of inoculation of calves with the virus resulted in lymphoproliferative disease and lymphocytosis and persistence of the virus.[1] Later studies have failed to reproduce significant clinical disease which may in part be due to the long incubation period.[11] It is also possible that the lentiviruses have variable virulence due to genetic variation producing viruses with both antigenic and biological heterogenicity in pathogenesis.[11] Experimental infection of an 11-month-old calf with the virus was followed by the development of a T-cell lymphosarcoma[21] and the bovine leukosis virus was not present.

The virus and its DNA have been detected in the blood and semen of experimentally infected bulls.[22] But the virus has not been detected in the semen, blood leukocytes, or semen leukocytes of samples supplied by artificial insemination centers.[23]

Retroviruses, including the lentiviruses, are characterized by the expression of the unique enzyme, reverse transcriptase, which facilitates the transcription of the RNA of an infectious virus to a complementary DNA copy. The viral DNA has the ability to become incorporated into the host's cell nucleus as a 'provirus'. Proviruses are non-infectious, can remain latent for many years and persist in the presence of antibody. Changing the virus from its latent form into an infectious RNA virus can occur and depends on activation of the latently infected cells. The stimuli for activation can include concurrent infection and stress, or both. While other lentiviruses such as equine infectious anemia virus can cause severe clinical disease, the cause and effect relationship between BIV infection in cattle and clinical disease has not yet been documented.

CLINICAL FINDINGS

Naturally occurring BIV infection in Holstein dairy cattle in Louisiana, US, have been described.[24] Progressive weight loss was common, and concurrent infections included metritis, subcutaneous abscesses, purulent arthritis, laminitis and infectious pododermatitis, fascioliasis, and mastitis. Reduced vitality, dullness and stupor were also common.

The course of the disease varied from 3 to 40 weeks.

CLINICAL PATHOLOGY

Detection of virus. A PCR test has been used to detect the BIV in the blood and milk of BIV-seropositive cows.[25] The virus can be detected in experimentally infected calves using PCR in peripheral blood mononuclear cells.[26]

Serological tests. Using the BIV ELISA, naturally occurring cases in dairy cattle are serologically positive.[24,27] An indirect immunofluorescent antibody test has been used to detect seroconversion in experimentally infected bulls by 17 days after infection.[22] The sensitivity and specificity of the indirect fluorescent-antibody assay (IFA) and the nested-set PCR have been compared using Bayesian techniques.[28] The PCR is the more sensitive assay.

NECROPSY FINDINGS

Moderate to marked enlargement of hemal lymph nodes have been described.[24] Lymphoid depletion is common and characterized by an absence of follicular development in nodes draining regions with secondary infections. Encephalitis characterized by meningeal, perivascular and parenchymal infiltration with lymphocytes, plasma cells and macrophages with perivascular edema has been observed.[27] Several secondary infections have been observed in cattle with BIV infection but the role of BIV as a prediposing pathogen is uncertain.

Viral diseases characterized by alimentary tract signs

FOOT-AND-MOUTH DISEASE (FMD, APHTHOUS FEVER)

Synopsis

Etiology Foot-and-mouth disease virus, an aphthovirus
Epidemiology Affects ruminants and pigs. Highly contagious, usually low mortality but great economic impact worldwide
Pathogenesis Inhalation/ingestion → oropharyngeal infection → viremia → epidermal cells → signs and lesions enhanced by mechanical trauma
Clinical signs Fever, profuse salivation, vesicles in mouth and feet, sudden death in young animals
Clinical pathology/diagnostic confirmation Virus isolation, serology and RT-PCR detection. Typing confirmed in a reference laboratory
Lesions Vesicular, erosive/ulcerative stomatitis and esophagitis, vesicular/ulcerative dermatitis (feet and teats) and in neonates, interstitial mononuclear and necrotic myocarditis
Differential diagnostic list
Vesicular stomatitis
Vesicular exanthema
Swine vesicular disease
Rinderpest
Bovine viral diarrhea
Treatment. None except symptomatically.
Control. Mass vaccination with killed vaccines in endemic areas, eradication by slaughter when feasible, and strict quarantine during outbreaks

ETIOLOGY

Foot-and-mouth disease is associated with an aphthovirus (family Picornaviridae) which occurs as seven major serotypes: A, O, C, Southern African Territories (SAT) 1, SAT 2, SAT 3 and Asia 1. However, there are a number of immunologically and serologically distinct subtypes with different degrees of virulence, especially within the A and O types. As there is no cross-immunity between serotypes, immunity to one type does not confer protection against the others. This presents difficulties to vaccination programs. Furthermore, there can be great changes in antigenicity between developing serotypes; virulence may also change dramatically. There are also biotypical strains which become adapted to particular animal species and then infect other species only with difficulty. There are strains that are much more virulent for pigs (so-called porcinophilic strains), some for buffalo, and some even for tropical breeds of cattle, which generally react only mildly to endemic strains. Newer techniques for identifying subtypes involve enzyme-linked immunosorbent assay (ELISA), reverse transcriptase-polymerase chain reaction (RT-PCR) and nucleotide sequence analysis.[1]

EPIDEMIOLOGY

Occurrence

FMD affects all cloven-footed animals and is endemic in Africa, Asia, South America and parts of Europe. The disease can occur in any country but Japan, New Zealand and Australia are disease free. A devastating epidemic occurred in Taipei, China in 1997 and over 4 million pigs died or were slaughtered within a few months.[2] The virus was believed to have been introduced from a neighboring country through the smuggling of animal products on fishing boats. Western Europe is essentially free of the disease but cattle imported from Eastern Europe gave rise to an epidemic in Italy during 1993. More recently, there was a massive outbreak in Britain in 2001 which spread to Ireland, France and The Netherlands before it was eventually contained. The outbreak was traced to illegal import to the UK of infected meat products. Spread within the country and to other countries was mostly through the movement of livestock not showing obvious clinical signs. As for North America, the last outbreak in the United States was in 1929, Canada in 1951–1952, and Mexico in 1946–1954. During the outbreaks, movement of cattle and cattle products between the United States and either Canada or Mexico was brought to a standstill. The importance of the Darien Gap in maintaining the disease-free status of North America is well known. This tract of impassable territory between Colombia and Panama prevents any chance of direct contact between cattle populations in North and South America.

Prevalence

There are no reliable figures for the prevalence of FMD in different countries. The disease generally occurs in the form of an outbreak that rapidly spreads from herd to herd before it is controlled. Of the seven standard types, O, A and C are prevalent in all continents where the disease occurs, SAT 1 is found in Africa and Asia, and SAT 2 and SAT 3 are limited to Africa, whereas Asia 1 occurs only in Asia. These limitations are due more to the pattern of the meat trade than to any inherent properties of the serotypes. Overall, outbreaks of types O and A occur more frequently than the others.

Morbidity and case–fatality rate

The morbidity rate in outbreaks of FMD in susceptible animals can rapidly approach 100% but some strains are limited in their infectivity to particular species. However, the case fatality is generally very low, about 2% in adults and 20% in young stock. Nonetheless, severe outbreaks of a more violent form sometimes occur as in the 1997 Taiwan outbreak in pigs where case fatality was 18% and reaching 100% in piglets,[2] or in calves of exotic dairy animals in Nigeria.[3] During outbreaks in non-endemic countries, most deaths are due to a slaughter policy that usually involves all susceptible animals and herds in contact with, or within a certain radius of, the infected herd.

Methods of transmission

FMD is transmitted by a variety of methods between herds, countries and continents but spread from one animal to another is by inhalation or by ingestion. In endemic areas, the most important method of spread is probably by direct contact between animals moving across state and national boundaries as trade or nomadic cattle. In non-endemic areas such as Europe, the first introduction to a new area is often via pigs which contract infection by ingestion of infected meat scraps. Spread from these pigs to cattle is via movement of people, abattoir waste or animals. Further spread between cattle is more likely to be by airborne means. The virus can persist in aerosol form for long periods in temperate or subtropical climates but not in hot and dry climates. The speed and direction of the wind are important factors in determining the rate of airborne spread. Humidity is also important but rain as such appears not to be. In the most favorable circumstances, it is now estimated that sufficient virus to initiate an infection can be windborne as far as 250 km (156 miles). There are peaks of spread at dawn and dusk. Animals in the United Kingdom are believed to be vulnerable to airborne transmission of the virus from the European mainland. It has been shown that pigs are the most potent excretors of airborne virus and cattle the most susceptible to airborne infections. During the 2001 outbreak in England,

there was no indication of airborne spread to the mainland, perhaps because ruminants rather than pigs were mostly affected.

In cattle, the first site of virus infection and subsequent rapid multiplication is the pharynx. Following a few days of viremia, the virus appears in milk and saliva for up to 24 h before vesicles appear in the mouth. All other excretions including urine, feces and semen may be similarly infective before the animal is clinically ill and for a short period after signs have disappeared. However, the period of maximum infectivity is when vesicles are discharging, since vesicular fluid contains the virus in maximum concentration. Although it is generally conceded that affected animals are seldom infective for more than 4 d after the rupture of vesicles, except insofar as the virus may persist on the skin or hair, some animals may remain as **carriers** and are now believed to be important in the epidemiology of the disease in the field.[4] In cattle, carriers may develop during convalescence from the natural disease, or more importantly in vaccinated animals which are exposed to infection. Up to 50% of cattle, sheep and goats may become carriers, but pigs do not.

The nasopharynx is the main site for persistence of the FMD virus and erratic low-level excretion may occur for up to 2 years. The virus may also persist in mammary tissue for 3–7 weeks. Wild fauna may serve as FMD reservoir and in southern, central and eastern Africa, the African buffalo (*Syncerus caffer*) is a significant reservoir. Humans are often a vehicle for transmission of the virus. It has been recovered from the nasal mucosa of persons working with infected cattle for up to 28 h after contact. Nose-blowing did not eliminate it nor did cotton face masks prevent infection. In a more recent study, the virus could not be detected in nasal secretions 12 h after contact, and contaminated personnel could not transmit the disease to susceptible pigs and sheep after they had showered and changed into clean outer wear.[5]

The disease is **spread from herd to herd** either directly by the movement of infected animals, or indirectly by the transportation of virus on inanimate objects, particularly uncooked and unprocessed meat products and other animal products, including milk. The pH and temperature of milk significantly affect survival, which may be as long as 18 h. Flash pasteurization procedures, as distinct from the holding method, do not inactivate the virus in milk – neither does evaporation to milk powder or processing into butter, cheese or casein products.

Introduction of FMD into a herd or country as a result of the use of infected cattle semen for artificial insemination is possible. The virus can also be detected in the semen of infected boars, but this has not been a means of transmitting it. Similarly, it is not transmitted through the transfer of embryos from viremic donor cows.[6]

Epidemics in free areas occur intermittently and from a number of sources. In England it was estimated that outbreaks arose in the following manner:

- Meat products used as pig food – 40%
- Completely obscure causes – 28%
- Transportation by birds – 16%
- Contact with meat and bones other than swill – 9%
- Unknown causes (probably swill) – 7%.

The greatest danger appears to be from uncooked meat scraps fed to pigs. A common pattern is the importation of the virus in sheep meat, from sheep which showed no illness, an initial infection in pigs, and then spread to cattle. However, more unusual methods of introduction must not be disregarded. With modern methods of transport, farm workers can carry the virus long distances in their clothing.

Risk factors

Host factors

The disease is most important in cattle and pigs but goats, sheep, buffaloes in India and llama in South America are also affected. Some strains of the virus are limited in their infectivity to particular species. Although cattle, sheep and goats can be carriers, they are not regular sources of infection, and early studies in Kenya showed that goats were infrequent carriers, and sheep not at all.[7] Immature animals and those in good condition are relatively more susceptible and hereditary differences in susceptibility have also been observed. Horses are not susceptible to the disease.

A variety of **wildlife species** such as the deer in England, the water buffalo (*Bubalus bubalis*) in Brazil and wild ungulates in Africa become infected periodically but are believed to play little or no role as reservoirs of infection for domestic animals. A notable exception is the **African buffalo** (**Syncerus caffer**), probably the natural host of the SAT types of the virus and the major source of infection for cattle in southern Africa.[8] The disease in buffalo populations is mild but the infection rate is often high and can be persistent. On the other hand, the domesticated **Asian buffalo** shows typical clinical disease and spread from buffalo to other species. Small rodents and hedgehogs in Europe and capybaras in South America may also act as reservoirs.

Environmental and pathogen factors

The virus is resistant to external influences including common disinfectants and the usual storage practices of the meat trade. It may persist for over 1 year in infected premises, for 10–12 weeks on clothing and feed, and up to a month on hair. It is particularly susceptible to changes in pH away from neutral. Sunlight destroys the virus quickly but it may persist on pasture for long periods at low temperatures. Boiling effectively destroys the virus if it is free of tissue but autoclaving under pressure is the safest procedure when heat disinfection is used. The virus can survive for more than 60 days in bull semen frozen to −79°C (−110°F). In general, the virus is relatively susceptible to heat and insensitive to cold. Most common disinfectants exert practically no effect, but sodium hydroxide or formalin (1–2%) or sodium carbonate (4%) will destroy the virus within a few minutes.

All uncooked meat tissues, including bone, are likely to remain infective for long periods, especially if quick-frozen, and to a lesser extent meat chilled or frozen by a slow process. The survival of the virus is closely associated with the pH of the medium. The development of acidity in rigor mortis inactivates the virus but quick freezing suspends acid formation and the virus is likely to survive. However, on thawing, the suspended acid formation recommences and the virus may be destroyed. Prolonged survival is more likely in viscera, bone marrow and in blood vessels and lymph nodes, where acid production is not so great. Meat pickled in brine, or salted by dry methods may also remain infective. For example, dry-cured Serrano and Iberian hams from experimentally infected pigs were shown to contain viable virus for up to 6 months.[9] Fomites, including bedding, mangers, clothing, motor tires, harness, feedstuffs and hides, may also remain a source of infection for long periods. There are claims that the virus can pass unchanged through the alimentary tracts of birds which may thus act as carriers and transport infection for long distances and over natural topographical barriers such as mountain ranges and sea.

Some outbreaks in Europe have been associated with vaccine virus either accidentally escaping from the laboratory or that was incompletely inactivated.[10]

Immune mechanism

In endemic areas, periodic outbreaks occur which sweep through the animal populations and then subside. A 6-year epidemic cycle has been demonstrated in India.[11] This is probably due to the disappearance of immunity which develops during an epidemic and the sudden flaring

up from small foci of infection when the population becomes susceptible again. Immunity after natural infection lasts for 1–4 years in cattle and for a shorter time in pigs. When outbreaks follow each other in quick succession, the presence of more than one strain of virus should be suspected. In countries where general vaccination is practiced every year, outbreaks are usually associated with different strains imported in carrier animals or infected meat.

Experimental reproduction

The clinical signs and lesions of FMD can be reproduced by rubbing virus-containing material on the oral mucosa of susceptible cattle or by intradermal inoculation into the dorsum of the tongue. The disease can easily spread from infected to susceptible animals housed in close proximity (cohabitation). With mice and guinea pigs, inoculation of footpads of hind feet is preferred (see Clinical pathology below).

Economic importance

With the possible exception of bovine spongiform encephalopathy (mad cow disease), FMD is the most feared animal disease in the developed world, even though the mortality rate is low. This is because it is the most contagious disease of livestock and has a great potential for causing severe economic loss in high producing animals. Losses occur in many ways although loss of production, the expense of eradication and the interference with movement of livestock and meat between countries are the most important economic effects. There are also significant losses in agriculture and tourism due to restriction on human movement. In Canada, it was estimated in the 1980s that if an outbreak were to occur in 10–15 farms and was eradicated in 6 months, it would still result in farm cash receipts declining by CAN$2 billion in 5 years.[12] The 2001 outbreak in the United Kingdom was eradicated within 7 months but resulted in the death of nearly 10 million livestock costing up to 8 billion pounds sterling (about US$12 billion).[13] However, in unimproved or low-grade *Bos indicus* cattle reared under extensive or nomadic system of management, or in pigs in some southeast Asian countries, FMD is often less severe and it impacts less on the subsistent producer. Nevertheless, because of its severity in exotic or improved breeds, and because of its impact in international trade, FMD control and eradication in such countries will still result in a strong benefit–cost ratio in places like Thailand.[14]

Zoonotic implications

Humans are believed to be slightly susceptible to infection with the virus and vesicles may develop in the mouth or hands. Very few cases have been reported even among people working with infected carcasses and laboratories. However, humans and particularly their clothing can be vehicles for transmission to animals.

Biosecurity concerns

Since FMD is highly contagious, there are biosecurity concerns regarding intentional or accidental introduction of the virus into nonendemic countries. Intentional introduction would be a form of agroterrorism and this would be devastating in any country that is FMD-free, since it would probably take some days before the disease would be recognized and much longer before it could be stamped out. Laboratories working with FMD virus or producing FMD vaccines and reagents must comply with OIE requirements for Containment Group 4 pathogens to ensure that there is no escape of the virus. There are also strict regulations for shipping diagnostic samples to national or international laboratories.

PATHOGENESIS

Virus particles first attach to mucosal epithelial cells, penetrate into the cytoplasm and replicate until the cells disintegrate. This releases more viral particles to infect other cells, including macrophages which drain into the efferent lymphatic system and then the blood. Irrespective of the portal of entry, once infection gains access to the bloodstream, the virus is widely disseminated to many epidermal sites, probably in macrophages, but gross lesions develop only in areas subjected to mechanical trauma or unusual physiological conditions[15] such as the epithelium of the mouth and feet, the dorsum of the snout of pigs and the teats. Characteristic lesions develop at these sites after an incubation period of 1–21 d (usually 3–8 d in most species). The initial phase of viremia is often unnoticed and it is only when localization in the mouth and on the feet occurs that the animal is found to be clinically abnormal.

The experimental disease in sheep is characterized by an incubation period of 4–9 d after contact or 1–3 d after virus inoculation. Thereafter, viremia occurs at 17–74 h and hyperthermia from the 17–96 h. Clinical signs are serous nasal discharge, salivation and buccal lesions in 75% and foot lesions in 25% of cases. At the end of viremia, the animal recovers but the virus may persist in the pharyngeal area of convalescent ruminants as previously discussed.

Bacterial complications generally aggravate the lesions, particularly those of the feet and the teats, leading to severe lameness and mastitis, respectively. In young animals, especially neonates, the virus frequently causes necrotizing myocarditis and this lesion may also be seen in adults infected with some strains of the virus, particularly type O.

CLINICAL FINDINGS

In typical field cases in cattle, there is an incubation period of 3–6 d, but it may vary between 1 and 7 d. The onset is heralded by a precipitate fall in milk yield and a high fever (40–41°C; 104–106°F), accompanied by severe dejection and anorexia, followed by the appearance of an acute painful stomatitis. At this stage, the temperature reaction is subsiding. There is abundant salivation, the saliva hanging in long, ropy strings, a characteristic smacking of the lips, and the animal chews carefully. Vesicles and bullae (1–2 cm in diameter) appear on the buccal mucosa, dental pad and tongue. These rupture within 24 h, leaving a raw painful surface which heals in about 1 week. The vesicles are thin walled they rupture easily and contain a thin, straw-colored fluid. Concurrently with oral lesions, vesicles appear on the feet, particularly in the clefts and on the coronet. Rupture of vesicles causes acute discomfort and the animal is grossly lame, often recumbent, with a marked, painful swelling of the coronet.

Secondary bacterial invasion of foot lesions may interfere with healing and lead to severe involvement of the deep structures of the foot. Vesicles may occur on the teats and when the teat orifice is involved, severe mastitis often follows. Pregnant animals may abort or have stillbirths. Very rapid loss of condition and fall in milk yield occur during the acute period and these signs are much more severe than would be anticipated from the extent of the lesions. Eating is resumed in 2–3 d as lesions heal but the period of convalescence may be as long as 6 months. Young animals are more susceptible and may suffer heavy mortality from myocardial damage, even when typical vesicular lesions are absent in mouth and feet.

In most outbreaks, the rate of spread is high and clinical signs are as described earlier but there is a great deal of variation in virulence and this may lead to difficulty in field diagnosis. For example, there is a malignant form of the disease in adults in which acute myocardial failure occurs. There is a typical course initially but a sudden relapse occurs on days 5–6 with dyspnea, a weak and irregular heart action, and death during convulsions. Occasional cases show localization in the alimentary tract with dysentery or diarrhea, indicating the presence of enteritis. Ascending posterior paralysis may also occur. On the other hand, there is a mild form which usually occurs when endemic strains infect only indigenous *Bos indicus* (Zebu)

cattle. This is the form most commonly seen in endemic countries in Africa, Asia and South America.

A sequel to FMD in cattle, due probably to endocrine damage, is a chronic syndrome of dyspnea, anemia, overgrowth of hair and lack of heat tolerance. Affected cattle are described colloquially as 'hairy panters'. Diabetes mellitus has also been observed as a sequel in cattle.

In sheep, goats and to a lesser extent, pigs, the disease is often mild and go unnoticed, and is important mainly because of the danger of transmission to cattle, but a devastating epidemic involving pigs only occurred in Taiwan in 1997.[2] Large vesicles and bullae occur in the snout and feet and these may rupture to expose large, raw surfaces. Adult sheep may develop a syndrome identical to that of cattle so that it becomes a crippling disease with occasional loss of hooves from bacterial complications. Goats are sometimes spared during an outbreak. The more common syndrome in these species is the appearance of a few, small lesions, but with more severe involvement of all four feet. As in cattle, young stock are more susceptible.

CLINICAL PATHOLOGY

Exhaustive laboratory studies are needed for diagnosis, determination of the type of the virus involved and to differentiate the disease from vesicular stomatitis, vesicular exanthema and swine vesicular disease. A handbook of the tests is available on line.[1] Fresh vesicular fluid and surrounding epithelial tissue should be collected in glycerol–saline for laboratory tests. This is the sample of choice. If the vesicles are already healing, blood should be collected, along with esophageal-pharyngeal (OP) fluid samples from ruminants or throat swabs from pigs. The OP samples should be collected from up to five animals with the use of a probang cup. The major methods for diagnosis are:

1. **Identification of the agent in tissue or fluid.**
   (a) *Virus isolation* by inoculation into cell cultures or unweaned mice. The FMD virus is cultivable on tissue culture and in hen eggs, and use is made of this in the preparation of live attenuated or inactivated vaccines. In diagnosis, neutralization of the virus by known antisera is highly efficient
   (b) Immunological methods:
   - *Enzyme-linked immunosorbent assay (ELISA)*: This is the preferred test. The indirect ELISA can detect the FMDV antigen in epithelial cells and in South America, this technique with polyvalent antisera against types O, A and C was more effective for the routine diagnosis of epithelial samples from field cases than was the same technique using monovalent antisera.[16] It can simultaneously test for SVD or VS
   - *Complement fixation test (CFT)*: Direct CFT on epithelial suspension is one of the fastest methods of making a positive diagnosis, within a few hours. But negative samples must be checked in tissue cultures because of the number of false-negatives which occur with the CFT, especially in poorly collected and packaged samples. Type-specific and strain-specific complement-fixing antisera can be prepared and this permits typing of strains in an outbreak. Diagnostic antisera can also be prepared for differentiation from vesicular stomatitis
   - *Nucleic acid recognition methods*: These include the reverse transcription polymerase chain reaction (RT-PCR) and the in situ hybridization (ISH). The RT-PCR amplifies fragments of FMD genome in samples and can be used for typing. It is more sensitive than ELISA. A portable real-time RT-PCR that can be performed within 2 h has been described.[17] The ISH detects FMD virus RNA in infected tissues including those obtained during necropsy

   (c) Virus morphology by electron microscopy.
2. **Serological tests for specific antibody response to FMD structural or nonstructural proteins:**
   - *Virus neutralization (VN)*, a prescribed test for international trade. It is serotype specific
   - *Solid-phase competitive enzyme-linked immunosorbent assay (ELISA)*, another prescribed test
   - *Liquid-phase blocking ELISA*
   - *Nonstructural protein (NSP) antibody tests* that enable detection of past or current infection, irrespective of vaccination status. They are more useful on a herd basis. The test

Table 21.3 Differentiation of acute vesicular disease

Adult chicken		+	+	–	–	

White skinned pigs fed on parsnips or celery and exposed to sunlight develop vesicles.

measures antibody to virus infection-associated antigen (VIAA) by agar gel immunodiffusion (AGIP), or better, antibody to NSPs produced by recombinant techniques.

3. **Experimental transmission.** The propagation of the virus in unweaned white mice can be used to detect the presence of virus in suspected material, the presence of antibodies in serum and for investigations into the transmission of immunity and the pathogenesis of the disease. In guinea pigs, intradermal injection of fresh vesicular fluid into the plantar pads causes vesicles to appear on the pads in 1–7 d and secondary vesicles in the mouth 1–2 d later. Large animal inoculation may be used for the differentiation of FMD, vesicular stomatitis and vesicular exanthema based on the different species' susceptibilities to the three viruses (Table 21.3) as well as to test the potency of vaccines. To avoid disseminating the virus, animal inoculation should be done only in specially equipped facilities.

NECROPSY FINDINGS

The lesions of FMD consist of vesicles and erosions in the mouth and on the feet and udder. The erosions often become ulcers especially if secondary bacterial infection has occurred. In some cases, vesicles may extend to the pharynx, esophagus, forestomachs, and intestines as well as trachea and bronchi. The teats and mammary gland are often swollen. In the malignant form and in neonatal animals, epicardial hemorrhages with or without pale areas are also present. Grossly, the ventricular walls appear streaked with patches of yellow tissue interspersed with apparently normal myocardium, giving the typical 'tiger heart' appearance. If the animal survives, there is replacement fibrosis and the heart is enlarged and flabby.

Histologically, vesicles start as foci of progressive swelling, necrosis and lysis of infected keratinocytes in the deeper layers of the epidermis and accumulation of fluid in the space. This is followed by necrosis of overlying keratinocytes and rupture of vesicles to form erosions that may extend deep into the dermis to form ulcers, especially on the feet. There is only mild leukocytic infiltration around the erosions and ulcers. Similar changes in mammary gland epithelium lead to acinar necrosis and mild interstitial cellular infiltration. Heart (and occasionally skeletal muscle) lesions in the malignant form are characterized by severe hyaline degeneration, necrosis and occasional calcification of myocardial fibers and marked interstitial infiltration by mononuclear cells. In addition, pancreatic islet and acinar degeneration has been reported in chronically infected cattle.

Tissues to be submitted for histopathology should include oral mucosa and skin containing vesicles or fresh erosions. The heart, mammary gland and pancreas should also be included. Viral antigen can be detected in tissues by immunohistochemistry. Since most animals infected with FMD will not die, and since it is important to make prompt diagnosis from clinical cases, histopathology of necropsy materials is often secondary.

DIFFERENTIAL DIAGNOSIS

The need to identify FMD is of paramount importance in all countries. It is of particular importance in those countries in which the disease is not endemic because of the need to introduce strict control measures quickly. The field veterinarian must be able to recognize suspicious cases, take appropriate samples and submit to a laboratory facility able to confirm the diagnosis promptly. Clinical signs in sheep and goats may be difficult to recognize. In countries where the disease is endemic, there are special difficulties in clinical recognition because of the frequent subdued severity of the oral and feet lesions even in cattle. Where the other vesicular diseases do not occur, suspicions will be readily aroused, but in North America, the presence of vesicular stomatitis and vesicular exanthema may result in misdiagnosis. Vesicular stomatitis in horses, cattle and swine, vesicular exanthema of swine and swine vesicular disease resemble FMD closely (Table 21.3). Three other vesiculoviruses – Piry, Chandipura and Isfahan – cross-react with vesicular stomatitis virus[18] but are much less virulent. The observations that white-skinned pigs fed parsnips or celery and exposed to sunlight will develop vesicles on the snout and feet,[19] and that cattle fed on grain treated with caustic soda can develop profuse salivation[20] are further confounding factors in the differentiation of the vesicular diseases.

Bluetongue of sheep may also present a problem in differentiation. Details of these are provided separately but a summary is given in Table 21.3. Rapid laboratory differentiation and diagnosis of these diseases may be achieved as described under Clinical Pathology (see above).

Bovine viral diarrhea/mucosal disease, rinderpest, malignant catarrhal fever and lumpy skin disease are easily differentiated by the lesions which develop in the mucosa and sometimes on the feet. The lesions are never vesicular, commencing as superficial erosions and proceeding to the development of ulcers. Pox infections of the mammary gland and foot rot in sheep should also be differentiated from FMD. Ingestion of any caustic material may cause oral vesiculation and salivation.

TREATMENT

Treatment with mild disinfectant and protective dressings to inflamed areas to prevent secondary infection is recommended in endemic countries where a slaughter policy is not in force. A good symptomatic response is reported to the administration of flunixin meglumine.[21]

CONTROL

Many factors govern the control procedure in a given area. The procedures commonly used are (a) control by eradication and (b) control by vaccination, or a combination of the two. In countries where the disease is endemic, or where there are wildlife reservoirs, eradication is seldom practicable. In areas with only occasional epidemics, slaughter of all infected and in-contact animals is usually carried out. It must be remembered that vaccination is costly and sometimes ineffective and that eradication would be the ideal objective in all countries. For countries in large continents, international cooperation is required for eradication. The European Union phased out mass vaccination in 1991 in order to increase its international competitiveness in trade in livestock and livestock products. Soon after, outbreaks of FMD in Italy were controlled by surveillance and slaughter of thousands of cattle, sheep/goats and pigs in all infected and contact herds.[22] A similar procedure was adopted in 2001 in England, Ireland and France and with some modification in The Netherlands, and the outbreaks were successfully controlled within months. Similar results were obtained in Taiwan in 1997.

As in the control of all epidemic infectious diseases, the problems posed for administrators are complex and continually changing. For example, the prospect of making a wrong decision about when to switch from an eradication-by-slaughter program to a containment-by-vaccination program, when an outbreak is raging and public sentiments are running high, is a daunting one. A wrong decision may cost a livestock industry many millions of dollars. To avoid making such errors, it is customary nowadays to develop a mathematical or computer model which simulates the progress of an outbreak in terms of numbers of animals infected, affected and dead, and how these numbers will change under pressure from control procedures, management practices and prevailing weather. An essential aspect of such an analysis is the economic effect of various control programs and their outcomes. The cost–benefit aspects of computer simulation models and the meteorological predictions of the likely spread of the disease are used to determine an appropriate strategy for control. Even

then, conclusions from such models may still be controversial as was the case in the 2001 outbreak in England.

Control by eradication

The success of an eradication program depends on the thoroughness with which it is applied. As soon as the diagnosis is established, all cloven-footed animals in the exposed groups should be immediately slaughtered and burned or buried on site. No reclamation of meat should be permitted and milk must be regarded as infected. Inert materials which may be contaminated must not leave infected premises without proper disinfection. This applies particularly to human clothing, motor vehicles and farm machinery. Bedding, feed, feeding utensils, animal products and other articles which cannot be adequately disinfected must be burned. Barns and small yards must be cleaned and disinfected with 1–2% sodium hydroxide or formalin or 4% sodium carbonate solution. Acids and alkalis are the best inactivators of the virus and their activity is greatly enhanced by the presence of a detergent. The effective pH at a disinfection surface may be grossly altered by the presence of organic matter and needs to be adequately maintained. When all possible sources of infection are destroyed, the farm should be left unstocked for 6 months and restocking permitted only when 'sentinel' test animals are introduced and remain uninfected. There are strict international requirements for demonstrating freedom from infection.

Recommendations for outdoor sites are difficult to make. Observations in Argentina suggest that contaminated pastures and unsheltered yards are clear of infection if left unstocked for 8–10 d. No animal movement can be permitted and human and motor traffic must be reduced to a minimum. Persons working on the farm should wear waterproof clothing which can be easily disinfected by spraying and subsequently removed as the person leaves the farm. Clothing not suitable for chemical disinfection must be boiled. Because of the rapidity with which the disease may spread, immediate quarantine must be imposed on all farms within a radius of 16–24 km (10–15 miles) of the outbreak.

Although the eradication method of control is favored when the incidence is low, it imposes severe losses on the animal industry in affected areas and is economically impracticable in many countries. However, it must be regarded as the final stage in any control program. The standard strategy is the containment of the disease by ringing the outbreak with a zone of vaccinated animals and setting about reducing the infection rate within the ringed area and eventually eradicating remaining hot-spots by slaughter. Containment of an outbreak is a difficult task with high rewards as shown by various cost–benefit analyses.

The controversy about whether to eradicate or vaccinate is ongoing. For example, the 1967–1968 epidemic in the United Kingdom involving the slaughter of nearly half a million animals at a cost of US$250 million was so damaging financially that it was arranged for vaccination to be available should there be a recurrence of such an epidemic. Nevertheless, the slaughter policy was still adopted in 2001 and a lot more animals killed. Part of the increased concern about a test-and-slaughter policy derives from:

- increasing size of herds
- risks involved if infection was introduced
- environmental concerns regarding carcass disposal if thousands or millions of animals are to be slaughtered within a short time. During the 1997 epidemic in Taiwan, it was reported that a disposal capacity of 200 000 pigs per day was reached despite ring vaccination. In England, disposal capacity was overwhelmed in 2001, even with military intervention, and carcasses were sometimes left for days before burial or burning.

Vaccination

Regular vaccination against FMD is a way of life for most of the world and vaccine production is a major industry. In the endemic countries, eradication does not seem possible within the foreseeable future and countries free of the disease may require regional vaccination during outbreaks. Consequently, it has been estimated that 1.5 billion monovalent doses of the FMD vaccine are administered annually, with South America alone accounting for some 1300 million doses.[23]

Killed trivalent (containing O, A, and C strains) vaccines are in general use, but because of the increasing occurrence of antigenically dissimilar substrains, the production of vaccines from locally isolated virus is becoming a more common practice. The virus is obtained from infected tongue tissue, a cell culture of bovine tongue epithelium or other cell culture. Baby hamster kidney (BHK) is a favored viral cultural medium and BHK vaccine is now in general use. Its principal virtue is its adaptability to deep suspension culture in contrast with its growth on monolayer culture, enabling large-scale production of virus to be carried out within practicable space limits. Inactivation of the virus to produce a killed vaccine used to be done with formalin but there are disadvantages with its use and more sophisticated agents, especially binary ethylene immine (BEI) are now used. Serviceable immunity after a single vaccination can be relied on for only 6–8 months. Vaccines produced from 'natural' virus give longer immunity than those produced from 'culture' virus. Vaccines produced in oil-adjuvant offer promise of providing longer immunity, and require only annual revaccination in adult cattle and biannual revaccination for young stock or every 4–6 months in pigs.

A general vaccination program for an area must be planned for that area. Thus in continental Europe, the program until 1991 included an annual vaccination of all adults with an additional campaign every 6 months to vaccinate calves as they reached about 4 months of age. In South America, the specific recommendations are that calves from unvaccinated dams should be vaccinated at 4 months and revaccinated at 8 months of age, but calves from vaccinated cows should be vaccinated twice, the first at 6 months and the second at 10 months of age.[24] The important considerations in calves are to avoid vaccination while the calf is still carrying maternal antibodies derived from colostrum and to avoid infection before they can develop active immunity. Calves as young as 1 week old respond as actively to vaccination as adult animals, provided they are free of maternally derived antibody. Immunity is present 7–20 d after vaccination, depending on the antigenicity of the vaccine. It is not usual to include sheep, goats, and pigs in a general vaccination program unless they are also affected during outbreaks. After the outbreak in Taiwan, it was recommended that piglets be vaccinated at 8–12 weeks followed by a boost 4 weeks later, and that sows be vaccinated 3–4 weeks before farrowing or every 4–6 months.[25]

Because of the short duration of the immunity produced by killed vaccines, attention has been focused on the production of an attenuated living-virus vaccine. The major difficulty encountered so far has been the narrow margin between loss of virulence and loss of immunogenicity. Attenuated vaccines have been produced by passage through white mice, embryonated hen eggs, rabbits and tissue culture. Their use has contributed to the eradication of the disease in cattle in South Africa and it has proved effective in Venezuela, where killed-virus vaccines failed to stem a major outbreak. Provided constant surveillance can be maintained over vaccinated animals, their value in such circumstances

cannot be denied. However, their early promise has not been fulfilled, and improved killed vaccines are most generally favored. In spite of the uncertain stability of the lapinized virus, control of the disease in Russia was reported after the use of a rabbit-passaged vaccine. In those countries where vaccination of very large numbers of animals is carried out annually, one of the emerging problems is the quality control of vaccines with respect to innocuity and to immunizing capacity or potency. The techniques to monitor these characteristics are available, but they do add to the costs of the vaccine, and if commercial competition is keen, this aspect of production may be spared. Some outbreaks have been linked to attenuated vaccines.

A great deal has been written about genetically engineered FMD vaccine produced by biotechnological manipulation and their distinct safety advantages over whole-virus vaccines. Initial reports of a polypeptide vaccine (protein VP1) in cattle are encouraging and the peptide can be chemically synthesized and incorporated into the core of hepatitis B virus to produce a vaccine.[26] However, much work still needs to be done and these newly developed vaccines cannot yet replace the classical inactivated vaccines.[27]

General vaccination as a means of control is recommended for countries where the disease is enzootic, or where the threat of introduction is very great, e.g. Israel. If an outbreak occurs, a booster vaccination with the relevant serotype will greatly increase the resistance of the population. However, the strategy of general vaccination has many difficulties. The following disadvantages are suggested:

1. To be effective, the program should consist of vaccination against a number of strains three times yearly. More frequent vaccination may be necessary in the face of outbreaks during optimum conditions for spread. Young animals with maternally derived antibodies do not respond to vaccination.
2. Vaccination of sheep and pigs is also used in control programs. In pigs a bi- or trivalent, inactivated, adjuvant vaccine gives strong immunity for 6 months and some resistance for 12 months. Severe local reactions (abscesses and granulomas) at vaccination sites can be reduced by the inclusion of an oil-adjuvant. However, vaccination of pregnant sows leads to a high rate of abortions and stillbirths. In sheep, monovalent or trivalent vaccines give immunity for 5–6 months but the sheep may act as inapparent carriers.
3. Inapparent infections may occur in animals whose susceptibility has been reduced by vaccination, permitting the existence of 'carrier' foci. It has become generally recognized that the number of carrier animals produced by vaccination is very much greater than was previously thought. Apart from the fact that these animals are a potent method of spreading the disease, they also provide an excellent medium for the mutation of existing virus strains, because the hosts are immune. The carrier state in vaccinated and unvaccinated cattle may persist for as long as 6 months and be capable of causing new outbreaks in all species. But the problem must be kept in perspective. The number of carriers produced in this way is directly related to the rate of occurrence of the disease in the population, and if this is kept to a minimum by an assiduous vaccination program and a strict limitation on the movement of infected animals into the population, the rate of occurrence of carriers can be very small. Nevertheless, in FMD-free countries, vaccinated animals are subsequently slaughtered to comply with OIE regulations so as to resume meat export as soon as possible.
4. Importation of vaccinated animals is often prohibited. An additional disadvantage is the production of sensitivity resulting in anaphylaxis in 0.005% of cattle vaccinated repeatedly, especially when the vaccines contain antibiotics or the vaccine contains foreign protein not associated with the antigen, or the virus has been killed with formalin which has also denatured the protein in the vaccine. Edema, urticaria, dermatitis, abortion and fatal anaphylaxis all occur. Cows in early and late pregnancy or otherwise stressed from other diseases, are most susceptible to adverse effects of vaccination.[28] Satisfactory purification and standardization of the vaccine can eliminate many of the problems because the hypersensitivity is to the culture medium, and to the agent used to kill the virus, rather than the virus itself.
5. Countries that vaccinate during an outbreak have to re-establish their FMD free status to the satisfaction of their trading partners. This is difficult because currently available vaccines stimulate production of antibodies indistinguishable from those following infection, and because vaccinated animals can be infected and become carriers. The detection of antibodies to nonstructural proteins is helpful in making the distinction at herd level and further research is ongoing to standardize the techniques.[29]

Alternatives to general vaccination are modified programs including 'ring' vaccination to contain outbreaks, 'frontier' vaccination to produce a buffer area between infected and free countries and vaccination of selected herds on a voluntary basis when an outbreak is threatened. Such emergency vaccinations can reduce the risk of spreading infection by reducing the rate of virus excretion. It is generally conceded that vaccination of an entire population may be necessary when eradication is incapable of preventing the spread of the disease. For this reason, many countries have strategic reserves of concentrated vaccines, but no such vaccine banks exist in Africa.

Prevention of entry of the disease into free areas is an ever-increasing problem because of modern developments in communications. The following prohibitions are necessary if the disease is to be excluded:

- There must be a complete embargo on the importation of animals and animal products from countries where FMD is endemic. The embargo should include hay, straw, and vegetables. Where the disease occurs only as occasional outbreaks, importation of animals can be permitted provided they are subjected to a satisfactory period of quarantine
- Particular attention should be given to preventing entry of uncooked meats from ships, airplanes and other forms of transport and in parcels originating in infected areas. In danger areas all swill fed to pigs must be cooked and all food waste satisfactorily disposed of
- Personal clothing and other effects of people arriving from infected areas should be suitably disinfected. Persons arriving from endemic countries or countries experiencing outbreaks should keep away from livestock for several days
- The risk of introducing the disease through importation of semen or fertilized ova is now thought to be minimal. The virus can survive in frozen bull semen and possibly in some fertilized ova, for example, zona pellucida-free bovine embryos but not in others, for example, zona pellucida-intact bovine embryos.[30] However, since even viremic animals do not transmit the disease through their embryos, bovine embryos with intact zona pellucida can be safely imported from enzootic areas regardless of the serological status of the donor.[6]

Consequently, if exotic or special animals have to be imported from enzootic countries, embryo transfer may be a means of controlling the transmission of FMD.[31] Even for Ilama embryos that lack a zona pellucida, the risk of FMD transmission was calculated to be close to zero if favorable epidemiological or ecological conditions exist in the region of origin of the embryos.[32]

SWINE VESICULAR DISEASE

Synopsis

Etiology Enterovirus of family *Picornaviridae*
Epidemiology Important because resembles foot-and-mouth disease. Occurs in Europe, Hong Kong, Japan, and Malta. Transmitted by direct contact, movement of pigs, feeding uncooked garbage containing pork products
Signs Fever, lameness, vesicles on coronary bands, recovery in 2–3 weeks
Clinical pathology Demonstrate antigen in tissues
Lesions Vesicles
Diagnostic confirmation Demonstrate virus in tissues
Differential diagnosis
- Foot rot of pigs
- Differentiate from other vesicular diseases by laboratory examination and virus identification

Treatment None needed
Control Control of garbage feeding, movement of infected pigs

The importance of this disease is that the clinical signs of this economically unimportant disease are indistinguishable from those of foot-and-mouth disease which is an economic disaster if it occurs in your country.

ETIOLOGY

The disease is associated with an enterovirus (family Picornaviridae) related to human coxsackie B5 virus, which may have arisen from a variant of this virus that has become adapted to swine. It was once regarded as porcine coxsackie virus.[1] Human isolates of coxsackie B5 virus do not cause disease in pigs although swine vesicular disease virus may infect humans and cause an influenza like condition. In animals, the disease is restricted to pigs, although experimental challenge of sheep has produced subclinical infection.

EPIDEMIOLOGY

Occurrence and prevalence of infection

The disease was first recognized as a limited outbreak in Italy in 1966 and was eradicated by slaughter. It then appeared in Hong Kong (1970), England (1972), many countries in Europe, including Poland, Austria, and France (1972–1974), Japan (1973), and Malta (1975). Eradication programs based on a slaughter policy were instituted and in most cases were effective. The disease occurred in 1992 and 1993 in several member states of the European Union, which had never before reported the disease or in which the disease had not occurred since the 1970s.[2] Italy had several outbreaks in 1996 and 1997. Serological surveys in 1993, using the virus neutralization (VN) test found no serological evidence of infection in the pigs in the United Kingdom, Denmark, Portugal and Greece.[2] Africa, America, and Australasia remain free from infection. There has been some variation in virulence[3,4] which is determined at two amino acids in the capsid[5] and there may be seven antigenic strains although there is no wide genetic variation. The epidemiological pattern of the disease in the various outbreaks is due presumably to different strains of the virus. The molecular evolution of the virus has been described.[6]

Methods of transmission

Infection generally occurs through minor abrasions on the feet but may occur through other routes. The incubation period is 2–14 days and the virus may be excreted prior to the onset of clinical signs. During and for a short period following the viremic phase, the virus is excreted in oral and nasal secretions. It is excreted in feces for periods up to 3 weeks, and vesicular fluid and shed vesicular epithelium are potent sources of infection. A chronic infection with shedding of virus for periods up to 3 months has been described.

Large amounts of virus are shed in the immediate vicinity of infected pigs. Transmission occurs by direct contact or contact with infected food or water or infected feces, and the disease spreads rapidly between pigs within the same group.[7] Airborne transmission of the virus is not a feature and the spread between groups of pigs is less rapid than that which occurs with FMD. The resistance of the virus and its persistence within the environment allows spread by mechanical methods such as trucks and contaminated boots. Areas which have housed infected pigs may remain infective for a considerable period of time. The potential for contaminated communal livestock trucks and markets to spread infection is considerable due to the occurrence of minor foot abrasions that occur during the movement of pigs. During the period 1972–1981 the major methods of spread were contaminated hauliers, movement of pigs, feeding contaminated waste, contact at markets, movement of equipment or personnel, local spread and recrudescence of previous infection. The biggest group was obscure in origin. In the UK the outbreaks were much fewer in the summer when it was supposed that not much pork was consumed and this resulted in much reduced pig movements.

The disease may be sufficiently mild to escape clinical detection. This plus the occurrence of subclinical infection and the reluctance of farmers to report suspicions of its occurrence facilitates spread by the

movement of infected pigs to other farms or through markets. Vertical transmission has not been demonstrated.

The disease may also be spread by the feeding of uncooked garbage but it is believed that more virus is needed to infect pigs via this route. Pigs killed during the incubation period of the disease or with subclinical infection possess a considerable amount of virus in body tissues. There is little reduction in infectivity with cold storage and the virus can persist in pork and pork products indefinitely. Recycling of the virus through garbage feeding with subsequent spread to other piggeries has been a major source of new outbreaks of swine vesicular disease in England. In addition, spread by direct movement of infected pigs to other piggeries or infection following movement through contaminated markets or livestock trucks accounts for the majority of outbreaks investigated.

Risk factors

Pathogen factors

There are minor antigenic differences and variation in virulence between some isolates of swine vesicular disease virus from different countries and two genetically and antigenically distinct variants exist in Europe.[8] Swine vesicular disease virus can be grown in tissue culture and has characteristics distinguishing it from the viruses associated with FMD, vesicular stomatitis and vesicular exanthema. The virus is extremely resistant to chemical and physical influences, which has made control of the disease very difficult. It is inactivated only at extremes of pH, (it can survive pH 2–12) and temperatures. It may remain infective in the environment and in manure for periods of at least 6 months. It is resistant to the action of many disinfectants and recommendations for disinfectants include 2% sodium hydroxide, 8% formaldehyde and 0.04% sodium hypochlorite if organic material is not present. It is easily transmitted in infected meat. The virus survives the processing of pork and pork products especially salami, except heating at greater than 68°C (154°F) and can persist in these products indefinitely (salami, 40 days).

Infected carcasses can be held in cold storage for months and then released at neutral pH and 40°C and the virus can still be found after 160 days. It is very stable and therefore difficult to decontaminate the environment, particularly where swine are housed on the soil. The virus can be found in earthworms from above the burial pits.

Economic importance

Although the economic effects of the primary disease are minor, the cost of the slaughter method for eradication is high. Although the morbidity rate with most strains is high, the disease generally runs its course in 2–3 weeks and produces a negligible mortality and only a minor setback to production. The major importance of the disease is its close clinical similarity to other vesicular diseases and the ban on export animals to other countries. The necessity for immediate differentiation of an outbreak from FMD and the problem of having such a similar clinical entity present in the pig population has made eradication of the disease desirable. In most countries this has proved extremely expensive.

PATHOGENESIS

The pathogenesis may be mediated by heparin sulfate which mediates virus attachment to the host cell.[9]

There is variation in the susceptibility of different sites of the body to invasion by swine vesicular disease virus and in natural outbreaks initial infection is most likely through damaged skin, particularly damaged feet. It has recently been suggested that 90% of the infection may be through the tonsil. A large amount of virus is in the tissues before the clinical signs develop. Once infection is established in a pig, virus excretion is so massive as to result in infection of others in the group through the tonsil and gastrointestinal tract as well as through skin abrasions. Massive amounts of the virus are excreted in the feces. Experimentally, the disease can be reproduced by IV, IM, SC and ID inoculation of virus. Virus spreads at the site of infection and enters the blood stream through the lymphatics. It is followed by viremia which may last 2–3 days. Recent research has suggested that the virus can persist for a longer length of time for up to 63 days but at 119 days post-infection the virus was again found in feces when two groups of pigs were mixed. This suggests that the virus and RNA can persist for a long time and possibly suggests a carrier state[10] but the same authors also suggest that persistent infection is rare.[11] Most virus is produced during the first week but lesions are infective for a long time. The virus has an especial affinity for epithelium of the coronary band, tongue, lip and snout and for myocardium. Lesions in the brain, especially the brainstem, are seen histologically but nervous signs are not a common clinical finding.

CLINICAL FINDINGS

The incubation period varies from 2–14 days. The disease is usually mild or even inapparent in its manifestation. It may be seen initially just as lame pigs. The morbidity rate varies from 25–65% and up to 100% of pigs within a pen may be affected. A transient fever (40–41°C; 104–105°F) and temporary mild inappetence may be seen. Lameness, arching of the back and other signs of foot discomfort are evident but are less severe than with FMD. Very occasionally they walk on the knees or scream. Both the incidence of lameness and of foot lesions are influenced by management and are less severe on bedding or with soft conditions underfoot. Characteristic vesicles occur at predilection sites frequently associated with trauma. They occur most commonly on the coronary band of the claws, especially at the heel, and of the supernumerary digits. They start as areas of blanching and swelling and progress in 1–2 days to thick-walled vesicles which rupture to give the appearance of an ulcer. Sometimes pigs may have a retracted recovery. In severely affected pigs, the lesions will encircle the coronary band and the horn may be shed as in FMD. Lesions also occur on the tongue, lips and snout and the skin of the legs and belly. They are much less frequent in these areas and frequently do not progress to typical vesicles. An examination of the feet of other apparently normal pigs within the group will often reveal the presence of minor lesions, and the extent of involvement of pigs within the group may be underestimated without careful examination. In some outbreaks, the incidence of clinical lesions has been minimal and even a single vesicle on the pig's foot should be treated as suspect. Some pigs show no clinical signs but develop significant titers of neutralizing antibody. The course of the disease within a group is generally 2–3 weeks, mortality is very uncommon and there is only a minor setback to production unless complete separation of the horny foot occurs. Nervous signs with ataxia, circling, head pressing and convulsions and paralysis have been observed rarely. Recovered pigs have immunity that protects against re-infection.

CLINICAL PATHOLOGY

Tests for the identification of swine vesicular disease include the demonstration of antigen in tissue and the detection of antibody. Vesicular epithelium provides the best material for direct antigen demonstration and it may be present even in the remnants of 10-day-old lesions. With fluorescent antibody or direct complement fixation, a result may be obtained within 8–12 h. The virus can also be grown on tissue culture and identified. Specific antibody is produced within 4–6 days and may be demonstrable before clinical disease is evident. Antibody may be detected by virus neutralization or the ELISA[12] for the diagnosis and surveillance of the disease.

Isotype-specific ELISAs were described.[13] The direct liquid phase blocking ELISA correlates well with the neutralization test which is used by the European Community authorities.[7] An RT-PCR has been developed[14] and PCR and PCR-ELISA have been described.[15–17] Monoclonal antibody trapping ELISA was used in Canada, Italy, and England to test results against other tests and it was found that virus neutralization should be used as a definitive test.[18]

NECROPSY FINDINGS

There are no gross or histological findings that differentiate swine vesicular disease from foot-and-mouth disease. Lesions in the skin consist of areas of coagulative necrosis with intraepithelial vesicle formation. Additional necrotic foci are present in the tonsils, renal pelvis, bladder, salivary glands, pancreas and myocardium. There is also non-purulent meningoencephalitis. Intranuclear inclusions are present in the ganglion amphicytes. An ELISA used on vesicular fluid or epithelium can give a result in 4–24 h. It grows well in culture in swine kidney cells and may show effects within 6 h. The intracerebral infection of mice causes paralysis and death.

DIFFERENTIAL DIAGNOSIS

The occurrence of vesicles differentiates this disease from other non-vesicular diseases of pigs. So-called footrot in pigs is associated with lesions on the sole and horn of the claw rather than the epithelial area of the coronary band. The differentiation of swine vesicular disease from other vesicular diseases relies on laboratory examination and virus identification as detailed above.

TREATMENT AND CONTROL

No treatment is described and none is warranted. In most countries where outbreaks have occurred, control has been attempted or achieved by slaughter eradication. Depopulation is followed by thorough cleansing and disinfection and limited repopulation effected after a period of 2–3 months. The disposal of infected carcasses can be important as the disposal site may remain infective.

The detection of infected herds can be a problem. The mild nature of the disease means that it can easily escape detection, especially in darkened pig houses or where conditions underfoot obscure observation of the feet. Mild infections may produce little clinical disease and any vesicular lesions should be treated with suspicion. The reluctance of some farmers to report suspicious lesions can also be important and it is essential to institute educational programs that emphasize the necessity for early detection and diagnosis of outbreaks. Serological surveys to identify present or past infections have proved of value in aiding detection of the disease. Serological single reactors cause a lot of trouble in trade.[19]

The three most important methods of spread are:

1. Feeding of garbage containing infected pig meat
2. Movement of pigs from infected farms either directly from farm to farm or indirectly through markets
3. Movement of pigs in contaminated transport vehicles.

Control of these methods of spread must include:

- Strict enforcement of garbage-cooking regulations
- Closing of markets, except perhaps for holding areas for pigs going directly to slaughter
- Strict control of movement and sale of pigs
- Adequate cleansing and sanitation of infected areas and transport vehicles.

Transmission through feeding of infected meat in garbage appears the most difficult to control and the latent period of this cycle means that outbreaks can recur at a time when eradication was thought to be complete. Disinfection of slurry is also difficult but can achieved by treatment with sodium hydroxide.[20]

In the United Kingdom, the most crucial item in its control was the introduction of a 21-day movement prevention after the initial movement. Sentinels put in after 8 weeks after the initial disinfection and are observed for about 3 weeks. If they are free after this time they are allowed to restock.

Vaccination has not been used for control in most countries however an inactivated vaccine is reported to provide significant protection in France.

VESICULAR STOMATITIS

Synopsis

Etiology Vesiculovirus in the family *Rhabdoviridae*
Epidemiology Disease of cattle and horses and occasionally pigs in the western hemisphere. Clustered outbreaks occur in summer and autumn. Vector, direct and mediate transmission
Clinical findings Vesicular lesions or healing ulcers on oral mucosa, teats and prepuce
Diagnostic confirmation Virus isolation or polymerase chain reaction, serology with rising titers
Treatment None specifically. Supportive
Control Notifiable disease. Quarantine and movement control

ETIOLOGY

The causative virus is a vesiculovirus (family Rhabdoviridae).[1] There are two antigenically distinct serotypes of the virus: vesicular stomatitis New Jersey (VS-NJ) and vesicular stomatitis Indiana (VS-IN). There are three subtypes of the vesicular stomatitis Indiana, Fort Lupton, Alagaos (Brazil) and Cocal (Trinidad). The **New Jersey serotype** is the most virulent and most common. The virus is much less resistant to environmental influences than the virus of FMD and it is more readily destroyed by boiling and use of disinfectants.

The disease is of major importance because it is indistinguishable from foot and mouth disease, and it can cause disease in humans.

EPIDEMIOLOGY

Occurrence

Geographic occurrence

The disease is limited to the **Western Hemisphere** and is **endemic** in Mexico and Panama and south to Venezuela and Peru, with periodic **incursions** into the United States, Brazil and Argentina to produce epizootic disease. It is also enzootic in Ossabaw Island, off the shore of Georgia in the United States.[2] The Island is the only recognized enzootic focus of vesicular stomatitis virus New Jersey (VSV-NJ). The VSV-NJ antibodies have been detected only from feral swine, cattle, horses and donkeys, deer, and

raccoons. However, despite high transmission rates, clinical disease is rarely detected.

The first major occurrence of the disease or 'sore tongue' in horses, cattle, and swine in the United States was in 1801.[1] The disease disabled 4000 horses needed to fight the Civil War in 1862. Major epidemics in US cattle and horses occurred in the Southwestern states from 1889 to 1995. A major outbreak occurred in military horses in the United States during the 1914–1918 war but in recent years, in addition to clinical disease in horses, it has come to assume greater importance in cattle and pig herds.

Vesicular stomatitis is the most important cause of vesicular disease in foot and mouth disease free countries in the Americas causing thousands of outbreaks annually from southern Mexico to northern South America.[3] Vesicular stomatitis is endemic from northern South America (Columbia, Venezuela, Ecuador, Peru) to southern Mexico, in which areas outbreaks occur annually. In endemic areas, outbreaks are seasonal, often associated with the transitions between rainy and dry seasons. The NJ serotype accounts for more than 80% of clinical cases and the IN-1 for the remaining. Sporadic cases of the disease occur in Brazil and Argentina where the viruses are related to VSV-IN and classified as VSV-IN2 and VSV-IN3.[4]

In the United States, there are two different patterns of occurrence; in the southern states (Georgia, Alabama, North Carolina, and South Carolina) a pattern of yearly occurrence of clinical cases in livestock occurred from the 1900s to the 1970s. Since then, viral activity in the region has been focal and limited to isolated wildlife populations. In contrast in the southwestern states (New Mexico, Arizona, Utah, and Colorado) outbreaks have occurred sporadically at approximately 10-year intervals, with last cycle of activity occurring from 1995 to 1998.

The disease occurs seasonally every year in the southwestern United States, southern Mexico, throughout Central America and in northern South America, and emerges from tropical areas to cause sporadic outbreaks in cooler climates during the summer months.[1]

In the **United States, outbreaks** occur periodically in the late summer and autumn; a major outbreak occurred in 14 western states in 1982–1983 and another in 1995 involving six states, with sporadic disease in intervening years. The outbreaks occur in the **western states**, start in the south and progress northerly, and **cluster** in areas of high livestock density in irrigated and green zone areas.[5]

In the 1997 outbreak the disease occurred in Arizona, Colorado, New Mexico, and Utah.[6] The epidemic curve suggested a propagating epidemic; the number of positive premises peaked during week 39 and then rapidly declined. As in previous outbreaks in the southwestern United States, there was a northerly progression of the disease over time. Nationwide, horses accounted for 88% of examinations done for the disease, and 97% of the premises on which species of infected animal were identified recorded horses positive. Cattle accounted for 10% of examinations carried out, and 3% positive premises on which species were identified had cattle positive.

Host occurrence

Cattle, horses, and donkeys are most susceptible but infection can also occur in pigs, camelids and humans and possibly sheep and goats. Outbreaks of the disease are **most common in horses and cattle** and to a lesser extent in pigs. Calves are much more resistant to infection than adult cattle. Many species of wildlife are seropositive.

Humans are susceptible – infection causes an influenza-like disease – and the development of high antibody titers in humans often accompanies outbreaks in cattle.

Serological surveys have found that in addition to domestic livestock, many species of wild animals such as bats, deer, monkeys, and humans living in endemic areas of Mexico, Central and South America are exposed to the infection and develop neutralizing antibodies. In the 1995 outbreak in the United States, the overall seroprevalence in livestock in Colorado was less than seroprevalence in epidemic areas, and seroprevalence rates in epidemic areas were greater for horses than cattle.[7] The seroprevalence results suggest that some animals had subclinical vesicular stomatitis infection during epidemics and that animals may be exposed to the virus between epidemics. Sentinel premises in Colorado visited quarterly during a 3-year period, when there was not clinical disease, found evidence of seroconversion to both serotypes of virus.[8]

The **morbidity rate** varies considerably; 5–10% is usual but in dairy herds it may be as high as 80%. There is usually no mortality in dairy herds but overall case–fatality rates ranging from 0–15% are recorded for beef herds. Morbidity in horse herds is high but there is no mortality. Outbreaks in an area are usually not extensive but the disease closely resembles FMD and has achieved considerable importance for this reason.

Source of infection

Sandflies and blackflies are capable of transovarial transmission and infection of susceptible hosts but the low frequency of transovarial transmission in these insects suggests that there are **other natural reservoirs** from which insect vectors obtain the virus. The VSV-NJ initially infects the gut of black flies in the natural situation but subsequent spread to the salivary gland may be blocked in older flies decreasing their ability to transmit the virus.[9]

Antibody to vesicular stomatitis virus has been demonstrated in a large number of **wildlife species** in Central America but their significance as wildlife reservoirs remains to be determined.[1,3] It is possible that outbreaks in the United States originated in Mexico and were transmitted via **windborne infection**. Feral pigs are believed to be the reservoir and amplifying host on Ossabaw Island.

The saliva and vesicular fluid from clinically affected animals are highly infective but infectivity diminishes rapidly and may be lost within 1 week after the vesicles rupture. However, **convalescent cattle** have been suspect as perpetuating disease and spreading it with movement to other herds. Vesicular stomatitis virus has been isolated from convalescent cattle 38 d after the disappearance of clinical signs and disease can recur in convalescent cattle. Viral RNA can be detected in the tongue and draining lymph nodes of cattle 5 months after experimental inoculation but there is no evidence for the long-term persistence of replication-competent virus in cattle.

Domestic animals appear to be dead-end hosts in which the virus does not persist and does not return to its natural cycle.[4]

Method of transmission

The reservoir host is unknown. However, biological transmission by blood-feeding insects, which have been demonstrated repeatedly to be abundant on case-positive premises indicates that the insect-vector hypothesis is plausible.[5] The virus can be biologically transmitted by black flies (*Simulium vittatum*) and mechanically by *Culicoides* spp. flies (*Musca domestica*, and *M. autumnalis*) and eye gnats (*Hippelates* spp.). Both genera of biting insects are common in the western United States and can inflict thousands of bites per hour on livestock.[10] Black flies are the likely vector over long distances. Biological transmission of the New Jersey virus by *Simulium vittatum* and *Simulium notatum* can occur.[11] Both wild and colonized black flies readily ingest the Indiana serotype and virus is present in a large percentage of susceptible black flies and it is likely that insects, including black flies, are responsible for transmitting the virus to livestock during epidemics. Experimentally, New Jersey

serotype infected black flies *Simulium vittatum* readily transmitted the virus to domestic swine.[12] Transmission was confirmed by seroconversion or by the presence of clinical vesicular stomatitis. As in other domestic animal species, where viremia has not been detected naturally or experimentally, viremia did not occur in the pigs infected by infected black flies.

In Ossabaw Island, transovarial transmission has been demonstrated in a phlebotamine sandfly (*Lutzomyia shannoni*), which may be a biological vector in that region from feral pigs acting as the amplifying host.[2] Other suspect vectors for vesicular stomatitis include *L. trapidoi* and mosquitoes.

Mediate or immediate contagion occurs by contact or ingestion of contaminated materials, especially in large intensive dairies where there is much communal use of water and feed troughs. It also occurs by the ingestion of contaminated pasture. In fed cattle the use of coarse roughage or hard pellets encourages the spread of the infection.

Spread within dairy herds also appears to be aided by milking procedures. The importation of embryos from infected areas is considered a minimal risk for introduction of infection.

Risk factors

Host factors

In Costa Rica, which is an endemic area for vesicular stomatitis in dairy cattle, parity (animals of parity 4 or 5 were 5.3 times more likely to exhibit clinical signs of vesicular stomatitis than animals of parity 3 or lower.[13] Animals of parity 6 and higher had an odds ratio of 4.6 times greater than animals of parity 3 and lower. Animals in premountain moist areas were 7.4 times more likely to exhibit clinical signs than those in lower rain forest. Factors associated with seropositivity at birth were farm and breed (Jersey calves had an odds ratio of 14.7 times greater than Holstein calves.

Environmental factors

There is a marked **seasonal incidence** of the disease, cases decreasing sharply with the onset of cold weather. The disease is enzootic in low-lying coastal countries with tropical climates, heavy rainfall and high insect populations. There is also a greater prevalence in geographically protected areas with heavy rainfall, such as valleys in the mountains and foothills. Areas of low incidence are protected by natural barriers to insect migration. These observations promote the importance of biting insects in the spread of the disease both locally and from infected to clean areas. In enzootic areas there is a much higher risk for dairies in forest land, the presence of sandflies, and a higher risk for clinical disease in older cows and cows in lactation.

The management factors affecting the risk for vesicular stomatitis in horses, cattle and sheep during the 1997 outbreak in Colorado, New Mexico, Utah, and Arizona, were examined.[10] Animals with access to a shelter or barn had a reduced risk of developing the disease with an odds ratio (OR) of 0.6. This was more pronounced for horses at an OR of 0.5. When horses had access to pasture, the risk of developing disease was increased with an OR of 2.01. On all premises, where owners reported insect populations were greater than normal, the OR was 2.5. Premises with animals housed <0.5 miles from running water were more than twice as likely to have clinical signs of vesicular stomatitis (OR 2.6). This suggests that rivers are a pathway or a risk factor for vesicular stomatitis which is consistent with outbreaks of the disease following major waterways northward during the summer.

Pathogen risk factors

The two major vesicular stomatitis serotypes are vesicular stomatitis virus-Indiana (VSV-IN) and vesicular stomatitis virus-New Jersey (VSV-NJ). The two serotypes are distinct viruses, with only 50% similarity in the glycoprotein gene sequence. VSV-NJ is more predominant than VSV-IN in North America. Phylogenetic analysis indicates that the 1995 VSV-NJ belongs to a lineage distinct from that of the 1982 to 1985 viruses which caused previous outbreaks in the western United States.[14] It is also distinct from strains of the virus from Central America and from the Georgian Hazelburst strain.

In the last 70 years, each sporadic outbreak in the southwestern US has been associated with viral lineages distant from those causing previous outbreaks in the US but closely related to viruses maintained in endemic areas in Mexico. This pattern of viral occurrence contrasts with that observed in endemic areas in Central and South America where viral genetic lineages are maintained in specific ecological areas over long periods of time. Thus the phylogenetic data and the geographical and temporal distribution of outbreaks indicate that vesicular stomatitis does not have a stable endemic cycle in the western United States.

Experimental reproduction

Livestock can be infected with vesicular stomatitis virus by injection or aerosol exposure but not by rubbing virus on intact skin. Intradermal injection causes obvious skin lesions at the inoculation site but intramuscular injection. Experimental inoculation with the virus kills neonatal mice and chick embryos, and most guinea pigs, hamsters, ferrets, and mice, and chicks.[1]

Experimentally, VS-NJ virus infected black flies when exposed to the abdomen or planum rostrale (snout) of young pigs results in lesions developing post-infection day 1.[12] The entire surface of the snout ventral to the nostrils becomes reddened and swollen, with pin point pale raised areas. This proceeds to vesiculation on day 2, and subsequent rupture, erosion, and crusting by day 3. Erosion persists for several days, and by day 7, the vesiculated area is almost healed. Secondary vesicles develop on the upper lips and the tip of the tongue by day 3. Virus can be recovered from tissues surrounding the snout lesions but cannot be isolated from whole blood or plasma.

Pigs can be experimentally infected with the 1995 equine isolate of VS-NJ (Colorado) and the 1997 equine isolate of vesicular stomatitis Indiana (New Mexico).[15]

Viremia has not been detected in any domestic animal species naturally or experimentally infected with the New Jersey serotype of the virus. Details of the Infection and pathogenesis of vesicular stomatitis virus at the cellular level are available.[1]

Economic importance

Most cases of vesicular stomatitis recover in a few days. The losses on large dairy farms due to disruption of continuity of milk supplies may cause severe financial loss.[1,3] There is also much inconvenience and temporary inability to feed.

There are also losses associated with quarantine such as loss of market opportunities and pasture damage from overgrazing of pastures used for quarantine. Other economic effects result from the cancellation of animal events such as fairs and the cost of loss of international markets.[1]

In the 1995 epidemic of VSV-NJ in the Western United States, the direct costs for increased labor and veterinary expenses incurred in caring for horses with the disease were estimated at $382.00 per case. In a dairy herd, losses were estimated at $787.00 per animal from increased culling, and in beef ranches the costs were $15 565.00 per ranch.[5] State regulations restricting the movement of animals within a zone of 10 miles around premises with confirmed cases for 30 days after the last lesion healed, and declaring a quarantine, all added to economic losses.

Vesicular stomatitis is classified by the Office Internationale des Epizooties as a List A disease, along with such economically important diseases as foot and mouth

disease and bovine spongiform encephalopathy. In the United States, all livestock with clinical signs of vesicular disease must be inspected by personnel from the USDA Animal Plant and Health and Inspection Service. Premises confirmed to have vesicular stomatitis positive animals remain quarantined until 30 days after all clinical signs of the disease have disappeared from livestock on the premises. Thus local and national activities involving horses and cattle may be disrupted, and international exports may be prohibited because of meat and livestock embargoes.

Zoonotic implications

Occasional human infections give the disease some public health significance, but the disease is mild, resembling influenza.[1]

PATHOGENESIS

Local infection of the mucous membrane of the mouth and the skin around the mouth and coronets is followed by the development of vesicles on the lips, muzzle, tongue, and also on the teats and interdigital clefts. The frequent **absence of classical vesicles** on the oral mucosa of affected animals in field outbreaks has led to careful examination of the pathogenesis of the mucosal lesions. Even in experimentally produced cases, only 30% of lesions develop as vesicles; the remainder dehydrate by seepage during development and terminate by eroding as a dry necrotic lesion.

Immune mechanisms

Following infection, serum neutralizing antibodies develop within a few days and may persist for 8 to 10 years.[3] Reinfection can occur in the presence of a high antibody titer. In cattle, horses, and swine, high titers of virus are found at the margins of lesions and in vesicular fluids for a short period after infection. However, viremia is undetectable and there is no known carrier state in cattle, horses, or swine.

CLINICAL FINDINGS

Cattle

In cattle after a short incubation period of 3–15 d, there is a sudden appearance of mild fever and the development of vesicles on the dorsum of the tongue, dental pad, lips and the buccal mucosa. The vesicles rupture quickly and the resultant irritation causes profuse, ropy salivation and anorexia. Confusion often arises in field outbreaks of the disease because of failure to find vesicles. In some outbreaks with thousands of cattle affected, vesicles have been almost completely absent. They are most likely to be found on the cheeks and tongue where soft tissues are abraded by the teeth. At other sites there is an erosive, necrotic lesion. In milking cows there is a marked decrease in milk yield. Lesions on the feet and udder occur only rarely except in milking cows where teat lesions may be extensive and lead to the development of mastitis. Recovery is rapid, affected animals are clinically normal in 3–10 d, and secondary complications are relatively rare.

Horses

In horses, the signs are broadly similar. There is fever, depression, inappetence, drooling of saliva and affected horses may rub their lips on troughs and jaw champ. Vesicles coalesce and rupture with detachment of the epithelium and the formation of shallow ulcers. The period of fever and vesicles is short lived. Not infrequently the lesions seen are limited to the dorsum of the tongue or the lips and are in the coalescing ulcer stage. Other less common sites include the udder of the mare and the prepuce of males. Lesions may occur at the coronary band and lead to lameness and deformity of the hoof wall.

Pigs

In pigs, vesicles develop on or behind the snout or on the feet and lameness is more frequent than in other animals.

CLINICAL PATHOLOGY

Inoculation of Vero cell cultures with epithelial cell material or vesicular fluid and subsequent staining with anti-vesicular stomatitis virus **fluorescent antibody** conjugate is commonly used for diagnosis. **Animal transmission** experiments as set out in Table 21.1 may be attempted using fluid or epithelium collected from unruptured vesicles. Typical vesicles develop after inoculation.

Serological tests include virus neutralization, complement fixation, and ELISA tests; the latter has advantages in speed and expense and has comparable sensitivity and specificity.[6] Titers, especially those to the serum neutralization test, can persist for years. In the 1997 outbreak in the United States, the definition of the index case was detection of clinical signs of vesicular stomatitis, accompanied by virus isolation or a fourfold increase in the titer (**complement fixation** test) or **serum neutralization** test in paired sera collected 7 days apart. A positive result for a **competitive ELISA** (**cELISA**), and clinical signs were also used for subsequent case definitions.[6]

NECROPSY FINDINGS

Necropsy examinations are not usually undertaken for diagnostic purposes but the pathology of the disease has been adequately described.

DIFFERENTIAL DIAGNOSIS

Because of its case-for-case similarity to FMD, prompt and accurate diagnosis of the disease is essential. In most countries the **disease is notifiable**.

All species
- FMD and other vesicular diseases.

Cattle
- Bovine virus diarrhea
- Bovine malignant catarrh
- Pseudocowpox.

Horses
- Blister beetle toxicosis
- Bullous phemigoid
- Phenylbutazone toxicity
- Grass seed awns.

TREATMENT

Treatment is seldom undertaken but non-steroidal anti-inflammatories may contribute to the comfort of the animal and the rapidity of recovery.

CONTROL

Hygienic and quarantine precautions to contain the infection within a herd are sufficient control and the disease usually dies out of its own accord. Animal movement off the farm should be prohibited until 30 d after all lesions have healed. There are usually restrictions of movement of animals from infected areas to different jurisdictional areas that are free of clinical disease and vesicular stomatitis is an Office of International Epizootics **List-A disease**.

Immunity after an attack appears to be of very short duration, probably not more than 6 months, but serological titers persist much longer. An **autogenous killed vaccine** was approved for use in dairy cattle in infected or at-risk areas during the 1995 outbreak in the United States but vaccine efficacy could not be determined.

A DNA vaccine expressing the glycoprotein gene from VS-NJ virus elicits neutralizing antibody titers in mice, cattle, and horses.[16] The level of protection of antibody required for protection is unknown.

A recombinant vesicular stomatitis (Indiana) virus expressing New Jersey and Indiana glycoproteins has been generated and examined as vaccine candidate. When inoculated into pigs it induced neutralizing antibodies and the pigs were protected against homologous high dose challenge.[17]

VESICULAR EXANTHEMA IN SWINE

Vesicular exanthema of swine is an acute, febrile, infectious disease of swine associated with a calici virus. At least 34 types of calicivirus have been recognized in the ocean[1] and new outbreaks continue to occur.[2] The relationship between these viruses and VES is a continual source of speculation.[3] The virus isolated in 2000 from sea lions was shown to be infectious for swine.[2] It is indistinguishable clinically from foot-and-mouth disease (FMD) in swine, vesicular stomatitis and swine vesicular disease. It has not been a problem for the pig industry for over 40 years.

ETIOLOGY

The causative virus is a calicivirus and 13 antigenic strains have been isolated with some variation in virulence between strains. Even in one herd the virus isolated may have been antigenically different from others. At least 17 antigenic types have been isolated since 1972. Only pigs are susceptible although experimental transmission to horses can be effected with some strains. All ages and breeds of pigs are susceptible to infection. The initial outbreak in pigs was traced to the feeding of meat from sea mammals.

EPIDEMIOLOGY

Occurrence

It was first diagnosed in Southern California in 1932. In 1952, it was diagnosed outside California and by 1953 had occurred in 42 states. However rigid control eradicated it by 1956 with particular importance being paid to garbage feeding control.

Except for isolated outbreaks in Hawaii and Iceland, the disease has occurred only in the United States. It is important because of its direct effect and because of its resemblance to FMD. Although vesicular exanthema is a mild disease with a low mortality rate (usually less than 5% although there may be many deaths in unweaned pigs) affected animals may suffer a severe loss of body weight and convalescence may require several weeks. Pregnant sows may abort and lactating sows may go dry with resultant heavy losses in baby pigs. The disease was eradicated from the United States in 1959, 27 years after its initial appearance.[4]

Methods of transmission

The sources of infection are infected live pigs and infective pork. Infected pigs excrete the virus in saliva and feces but not in the urine for 12 h before vesicles develop and for 1–5 d afterwards. Raw garbage containing infective pork scraps is the most common medium of spread from farm to farm. On infected premises the disease is spread by direct contact and, although the virus is resistant to environmental influences, spread by indirect means does not occur readily. Pigs frequently become infected, as evidenced by the development of immunity, without evidence of clinical disease. Ingestion of infected material is sufficient to produce infection.

The isolation from marine animals of an identical virus, which is capable of producing a disease identical to vesicular exanthema when inoculated into pigs, has led to the hypothesis that the primary reservoir for vesicular exanthema is in marine animals. Epizootics in pigs may have been initiated by the feeding of marine meat or garbage containing marine animal products.

Risk factors

Pathogen risk factors

The virus is resistant to environmental influences and persists in frozen and chilled meats. It is readily destroyed by several different commonly used disinfectants including sodium hypochlorite, sodium hydroxide and phenol. A good immunity develops after an attack and persists for about 20 months. There is no appreciable cross-immunity between the strains of the virus and a series of outbreaks, each associated with a different strain of the virus, may occur in the one herd of pigs.

A similar if not identical virus, San Miguel sea lion virus, has been isolated from sea lions and fur seals off the coast of California in the United States. It is physically, chemically and morphologically identical to the vesicular exanthema virus, although the same antigenic types have not been found. The virus produces an identical disease to vesicular exanthema when inoculated into pigs and appears to have a similar host range. The vesicular exanthema of swine virus is infective for the harp seal but the disease is inapparent and self-limiting. The intradermal inoculation of the vesicular exanthema of swine virus into otrarid (fur) seal pups will result in plaque-like lesions. Feeding swine the seal tissues from the inoculation experiments will result in seroconversion in swine which were fed tissues from seals infected with the vesicular exanthema of swine virus but not in those which were fed tissues from seals infected with the San Miguel sea lion virus. Antibody to this virus has also been detected in California gray whales and in feral swine inhabiting coastal areas.

PATHOGENESIS

As in other vesicular diseases there is a viremia, lasting for 72–84 h and commencing 48 h before vesication, with localization occurring in the buccal mucosa and the skin above the hooves. The intradermal inoculation of the vesicular exanthema of swine virus and the San Miguel sea lion virus into swine results in fluid-filled vesicles at the sites of inoculation in the snout, coronary band, and tongue. Lesions are usually limited to the non-haired portions of the integument and tongue. A mild viral encephalitis occurs in pigs inoculated with the swine virus and the sea lion virus can be recovered from the brain tissue of pigs infected with the virus.

CLINICAL FINDINGS

The incubation period varies with the virulence of the causative strain of virus but is usually 1–3 d. Morbidity is always high but mortality is low There is an initial high fever (40.5–41°C; 105–106°F) followed by the development of vesicles in the mouth, on the snout, on the teats and udder and on the coronary skin, the sole, the heel bulbs and between the claws, and accompanied by extreme lassitude and complete anorexia. The initial lesion is a blanched area which soon develops into a vesicle full of clear fluid. The vesicles rupture easily leaving raw, eroded areas. This usually occurs about 24–48 h after they appear and is accompanied by a rapid fall of temperature. Secondary crops of vesicles often follow and may cause local swelling of the face and tongue. Lesions on the feet may predominate in some outbreaks whereas in others they may be of little significance. The affected feet are very sensitive and there is severe lameness. Healing of the oral vesicles occurs rapidly although secondary bacterial infection often exacerbates the lesions on the feet. Recovery in uncomplicated cases is usually complete in 1–2 weeks. It may occasionally cause encephalitis, myocarditis, and diarrhea and failure to thrive. When sows become infected late in pregnancy, abortion frequently occurs and lactating sows may go dry.

CLINICAL PATHOLOGY
Fluid from the vesicles is used in transmission experiments and for tissue culture. Blood serum is used for the complement fixation, viral neutralization in cell culture and gel diffusion precipitin tests.

NECROPSY FINDINGS
Postmortem examinations are not of much value in the diagnosis of vesicular exanthema but the pathology of the disease has been defined. The lesions are limited to epithelial lesions where there are vesicles, necrosis, sloughing and rapid healing with mild scarring. Diagnosis involves virus isolation in cell culture, with electron microscopy as a possibility and various serologic tests including fluorescent antibody tests for the antigen. PCR tests have also been developed.

DIFFERENTIAL DIAGNOSIS
Because of its case-for-case similarity to FMD, prompt and accurate diagnosis of the disease is essential. In most countries the **disease is notifiable**.

All species
- FMD and other vesicular diseases.

Cattle
- Bovine virus diarrhea
- Bovine malignant catarrh
- Pseudocowpox.

Horses
- Blister beetle toxicosis
- Bullous phemigoid
- Phenylbutazone toxicity
- Grass seed awns.

TREATMENT
There is no effective treatment. The immunity is solid following infection but heterologous infection is possible.

CONTROL
Eradication of the disease should be attempted whenever practicable. In most instances it is essential to report to the regulatory authorities The first step is to quarantine infected premises and restrict movement of pigs in the area. Infected animals should be slaughtered but the carcasses may be salvaged for human consumption provided the meat undergoes special treatment to insure destruction of the virus. Normal freezing and chilling procedures are not sufficient to destroy it. All garbage fed to pigs must be boiled. Infected premises should be thoroughly cleaned and disinfected with a 2% sodium hydroxide solution before restocking. The implementation of these measures was eminently successful in eradicating the disease from the United States.

In view of the reservoir of virus in marine animals and apparent infection in feral swine in the coastal areas of California, it is possible that the disease could recur in domestic swine in the United States. Possible methods of reintroduction that need to be guarded against have been described.

Active immunization may be practicable if the disease reappears and other control measures fail. A formalin-killed virus preparation produces an immunity lasting for at least 6 months. Multivalent vaccines may be required if more than one strain of the virus is involved.

Recently the pathogenic class of VESV-like caliciviruses (genus vesivirus) endemic in certain ocean species and US livestock has possibly caused vesicular disease on the hands and feet of humans.[5]

RINDERPEST (CATTLE PLAGUE)

Synopsis

Etiology Rinderpest virus, a morbillivirus
Epidemiology Affects ruminants, rarely swine. Outbreaks in Asia, Middle East and tropical Africa, highly contagious and high mortality
Pathogenesis Inhaled/ingested virus → upper respiratory infection → viremia → target cells (lymphocytes and alimentary mucosa) → signs and lesions
Clinical signs High fever, oculonasal discharge, salivation, ulcerative stomatitis, diarrhea, dehydration and death
Clinical pathology Marked luekopenia
Diagnostic confirmation Virus isolation, serology and immunohistochemistry
Lesions Necrotic stomatitis and esophagitis, ulcerative and hemorrhagic enterocolitis, massive necrosis of lymphocytes in Peyer's patches, lymph nodes and spleen
Differential diagnosis list
- Bovine virus diarrhea
- Foot-and-mouth disease
- Malignant catarrhal fever
- Peste des petits ruminants.

Treatment None
Control Surveillance and annual vaccination with tissue culture vaccine in endemic areas, eradication by slaughter and rigid quarantine during outbreaks in non-endemic areas

ETIOLOGY
Rinderpest is associated with a morbillivirus (family Paramyxoviridae) and there are many strains with considerable variation in virulence between them but all are immunologically identical. Consequently, the immunity which develops after infection or vaccination with one strain protects against all other strains or isolates. Three genetically distinct lineages of the virus are now recognized, with lineages 1 and 2 being of African origin and lineage 3 of Asian origin,[1] but the differences between lineages are small and do not affect the immunity induced.[2] Rinderpest virus is quite fragile and is antigenically related to the other members of the morbillivirus group including the viruses causing peste des petits ruminants (PPR) in sheep and goats, canine distemper in dogs, measles in humans, phocine distemper in seals and hedgehog distemper.[2]

EPIDEMIOLOGY
Historically, rinderpest (cattle plague) was a most devastating disease spread from Asia to Europe, the Middle East and Africa, usually as a sequel to wars. The need to combat the disease was instrumental in the establishment of the first veterinary school in 1762 in Lyon, France. Its complete eradication is the goal of the Global Rinderpest Eradication Program (GREP) of the Food and Agriculture Organization and the geographic distribution of the disease has been shrinking steadily since the beginning of the 20th century. Rinderpest was eradicated from southern Africa, Europe and China by the middle of that century. In the 1960s, the disease was cleared from West Africa and most of East Africa, but there was a dangerous resurgence less than 10 years later and again in the 1990s.

Occurrence
Most countries today claim to be free of rinderpest. At the end of the last century, the disease was still endemic in parts of Asia and in a small area bordering on Kenya and Somalia. In the 1980s, outbreaks occurred over much of tropical Africa and Asia. The most recent outbreaks occurred in Kenya and Tanzania (1993–97, 2003) and in Pakistan (2000–2002). The disease has never appeared in North America but there have been single outbreaks which were quickly eradicated in Brazil and Australia. All ruminants and pigs are susceptible to infection with rinderpest virus. Natural infection occurs commonly only in domestic cattle, buffalo and yak but in some outbreaks, sheep and goats do become infected and show clinical signs. European pigs are susceptible to infection but only show a mild transient fever and do not spread the disease. Pigs indigenous to Thailand and Malaysia are highly susceptible and natural spread of the clinical disease can occur. Similarly, clinical disease is common in Asian sheep and goats and they contribute to the

persistence of the virus in the region. There is the belief that rinderpest became prevalent in small ruminants in Africa and Asia only after the introduction of goat-adapted rinderpest vaccine from which the virus of PPR probably mutated. One-humped camels become infected, but show no clinical signs.

Wildlife are often affected during outbreaks and the infection usually spreads to them from infected cattle. Nevertheless, it has been suggested that strains of the virus that are of low pathogenicity and low transmissibility could cycle in wildlife in the absence of disease in cattle. In the 1980–1983 outbreaks involving over 2 million cattle in Nigeria, free-living and captive wild animals also died but the disease did not occur in wildlife after it was eradicated from cattle.[3] Similarly, wildlife (especially buffalo and eland) did not appear to act as reservoirs but as fully susceptible hosts during the Kenyan epidemic of 1993–1997 involving the lineage 2 virus in national parks.[4] The wildlife most commonly affected are the buffalo, bushbuck, waterbuck and warthogs, all water and shade-loving. Others include the eland, giraffe, kudu, deer and wildebeest. An outbreak in the former Soviet Union involved yaks near the Mongolian border.[3]

Prevalence

In the absence of an outbreak, the prevalence of the disease in endemic countries is low. In India, it was less than 10 per 100 000 cattle before 1963, 5–7.5 per 100 000 in 1963–1974 and 2 per 100 000 in 1974–1988[5,6] as a result of great expansion of the numbers of vaccinated cattle. By mid-1990s, India was free of the disease. In general, recent vaccination campaigns in tropical Africa and Asia have greatly reduced the number of susceptible animals in the region, up to the point that one can say that the disease is currently under control worldwide.

Morbidity and case fatality

When epidemics occur in highly susceptible populations, the morbidity and case–fatality rates approximate 100% and 50% (25–90%) respectively,[7] and large numbers of in-contact animals may have to be destroyed. In endemic areas, most of the cattle population have some degree of immunity and case–fatality rates rarely exceed 30%. The African lineage 2 strain of the virus caused a high mortality in buffaloes but a milder form of the disease in transhumant cattle.[8]

Methods of transmission

Close contact between infected and non-infected animals is usually necessary for spread of the disease to occur because the virus does not survive for long outside the host. The virus is excreted by infected animals in urine, feces, nasal discharges, and perspiration. Transmission occurs through contaminated feed or by inhalation of aerosol. Survival of aerosolized virus depends particularly on humidity and it may last for more than 30 min at relatively low humidity. Ingestion of food contaminated by discharges of clinical cases, animals in the incubation stage, or animals with subclinical infections, may also be important modes of infection, especially in pigs. Aborted bovine fetuses may contain live virus.[9,10]

Insects, many of which have been shown to contain the virus, are unlikely to act as vectors. Other species, including European breeds of pigs in particular, and sheep, goats, camels and wild ruminants may serve as a source of the virus for cattle. Although there may be rare exceptions,[11] it is doubtful that recovered animals act as carriers for more than a few days. Because of the failure of the virus to persist outside the body, rinderpest can be controlled by interrupting its transmission.[12]

Risk factors

Host factors

Cattle and buffalo of all ages are susceptible to rinderpest, unless they have been vaccinated or have recovered from a previous infection or, in the case of calves, they have received colostral antibodies. European breeds of cattle are believed to be more susceptible than zebu cattle, but zebu cattle without antibodies from previous exposure or vaccination are fully susceptible. For example, the interruption of routine rinderpest vaccination in Central and West Africa in the 1970s was believed to be a major factor in the epidemics that ravaged zebu cattle populations in that region a few years later.[13] Rinderpest used to occur in explosive outbreaks when it was first introduced to a herd and it would spread easily to other in-contact herds. This was particularly common among nomadic herds that seasonally migrate over long distances in search of pasture and water. Any other legal or illegal movement of animals incubating the disease could be a mode of spread. Cattle raids and communal grazing can be risk factors. Other ruminants and pigs in contact with infected cattle or buffalo may develop the disease.

Environmental and pathogen factors

The virus is present in the blood, tissues, secretions and excretions of infected animals, reaching its peak of concentration at about the height of the temperature reaction and subsiding gradually to disappear about a week after the temperature returns to normal in those animals that recover. The risk of transmission is therefore greatest during the febrile stage. The virus does not persist outside the host for more than a few hours at normal temperatures. It is inactivated in cadavers within 24 h as a result of pH changes and putrefaction, and it is readily destroyed by heat, drying and most disinfectants. Even in untreated premises, it survives for only a few days. However, it is relatively resistant to cold and may survive for as long as 1 month in blood kept under refrigeration. The risk of transmission can therefore be greatly minimized by applying appropriate sanitary and other control measures.

Immune mechanism

Immunity after a natural infection or by vaccination is long and for all practical purposes, persists for life. The protection is associated with the induction of humoral antibodies, first IgM and later, IgG and IgA, which are detectable by enzyme immunoassay.[14] The disease is also associated with immunosuppression because the virus causes extensive necrosis of lymphocytes throughout the body. Older live vaccines can also cause immunosuppression. However, the newer tissue culture vaccine does not and can be simultaneously administered with other vaccines, for example, FMD and contagious bovine pleuropneumonia vaccines, without any diminished responses to any of the immunogens used.

Experimental reproduction

Rinderpest can be experimentally reproduced by bringing susceptible animals in close contact with an infected one or by directly inoculating with blood or tissues from an infected animal or tissue culture. Rabbits can be artificially infected and this was made use of in the production of a lapinized virus vaccine.

Economic importance

Rinderpest has been one of the major diseases of cattle that occur in the form of epidemics. It is a List A diseases by OIE classification. Under extensive systems of management as practised in many African and Asian countries, the disease easily spreads across national boundaries and can involve most of the national herds of cattle and buffalo. Losses can be colossal and are due to deaths, loss of productivity and cost of effective prevention and control. During the outbreaks that occurred in Africa in the 1980s, millions of cattle were affected in the central and western regions. Reports from Nigeria indicated a death toll of 0.4 million infected cattle in 1983 and that the toll was higher in poorer countries that could not procure adequate doses of the vaccine. Fortunately, the situation has improved considerably due to the vaccination and surveillance

programs of the Global Rinderpest Eradication Program (GREP) and the Pan African Rinderpest Campaign (PARC).

Zoonotic implications

The virus of rinderpest is not pathogenic to humans.

Biosecurity concerns

Although rinderpest is not highly contagious, the mortality rate can be so high that care should be taken in handling diagnostic specimens to avoid accidental spread. Under intensive system of management, any accidental infection can be easily curtailed and eradicated.

PATHOGENESIS

The virus is inhaled in infected droplets; it penetrates through the epithelium of the upper respiratory track and multiplies in tonsils and regional lymph nodes. From these sites, the virus enters the blood in mononuclear cells and is disseminated throughout the body, intimately associated with leukocytes and only a small proportion free in plasma. The virus has a high degree of affinity for lymphoid tissues and alimentary mucosa and replicates in monocytes, lymphocytes and epithelial cells.[11,15] There is a striking destruction of lymphocytes in tissues resulting in marked leukopenia. Lymphocytes are destroyed by apoptosis as well as necrosis. The focal, necrotic stomatitis and enteritis which are characteristic of the disease are the direct result of viral infection and replication in epithelial cells in the alimentary tract. However, because the virus induces a strong antibody response shortly after infection, there is a rapid decline and elimination of virus from the body as clinical signs and lesions become manifest. Death is usually from severe dehydration, but in less acute cases, death may be from activated latent parasitic or bacterial infections which are exacerbated because the animal is immunosuppressed as a result of the destruction of lymphoid organs by the virus.

CLINICAL FINDINGS

The following descriptions present the principal clinical signs of classical rinderpest but it must be remembered that an almost unlimited series of variations in syndromes may be encountered depending on the virulence of the strain of virus, the susceptibility of the host, and the presence or absence of concurrent diseases. Most outbreaks reported recently have been usually mild in cattle. In general, clinical signs may be **peracute, acute, subacute** or **inapparent** (in species other than cattle and buffalo).

The **peracute form** is not common except after experimental administration of the virus. It is characterized by high fever, congested mucous membranes, respiratory distress and death 1–3 d later.

Acute cases may be seen in naive cattle in areas or countries that were previously free of the disease. An incubation period of 6–9 d is usual. The first stage of the disease is several days of high fever (40.5–41.5°C; 105–107°F), without mucosal lesions (phase of prodromal fever). Anorexia, a fall in milk yield, lacrimation and a harsh, staring coat accompany the fever and this corresponds to the period of peak virus production in tissues. This is followed by the mucosal phase characterized by inflammation of buccal, nasal and conjunctival mucosae and, in some cases, hyperemia of vaginal mucosa and swelling of vulva. The lacrimation becomes more profuse and then purulent and is accompanied by blepharospasm. Bubbly salivation of clear blood-stained saliva is followed by purulent saliva and halitosis. A serous nasal discharge similarly becomes purulent. Discrete, grayish, raised necrotic lesions (1–5 mm in diameter) develop, appearing first on the inside of the lower lip and adjacent gum, on the cheek mucosa at the commissures, and on the lower surface of the tongue. Later they become general in the mouth, including the dorsum of the tongue, and may become so extensive that they coalesce. Similar lesions are common on nasal, vulval and vaginal mucosae. The necrotic material sloughs, leaving raw, red areas with sharp edges and these may coalesce to form shallow ulcers. Vesicles are not present.

Severe diarrhea, and sometimes dysentery with tenesmus, appear as lesions develop in abomasum and intestines. Skin lesions affecting the perineum, scrotum, flanks, inner aspects of thighs and the neck are less common. The skin becomes moist and reddened and later covered with scabs.

After a period of illness lasting from 3–5 d, there is a sudden fall in temperature, accompanied by exacerbation of the mucosal lesions. Other signs include dyspnea, cough, diarrhea, severe dehydration and sometimes abdominal pain. Prostration and a further fall in body temperature to subnormal levels occur on days 6–12, after which death usually occurs within 24 h. A few animals may survive and go into a convalescent phase during which the mucosal lesions heal rapidly, the diarrhea eventually stops and recovery of body condition takes several weeks. Pregnant cattle may abort at this stage, discharging infective virus in the fetus and vaginal secretions for up to 24 h.[10]

In enzootic areas, both a **subacute form** and a **skin form** occur with lower morbidity and mortality. In the subacute form, the temperature reaction is mild and the accompanying anorexia and malaise are not marked. The inflammation of the mucosae is catarrhal only and there is no dysentery. In the skin form, the systemic reaction is absent and small pustules develop on the neck, over the withers, inside the thighs and on the scrotum. Most affected animals recover and convalescence is short. However, because of the severe lymphocytolysis, latent pathogens, particularly *Anaplasma marginale*, are often activated and the resulting disease may overshadow the primary rinderpest.

Signs and lesions similar to those which occur in cattle develop in **sheep** and **goats** and in **Asian pigs**. The disease in European pigs is clinically **inapparent** and wild ungulates exhibit a wide range of clinical signs, from severe to mild. Keratoconjunctivitis has been described in buffaloes and kudus affected with lineage 2 virus.[4]

CLINICAL PATHOLOGY AND LABORATORY DIAGNOSIS

A marked leucopenia occurs at the height of the infection and after vaccination in cattle and in experimentally infected sheep and pigs. The total count usually falls to below 4000 μL and is due to a precipitous drop in lymphocytes. With diarrhea, animals also become severely dehydrated. Later, they may show neutrophilia.

Various methods for diagnosing rinderpest have been described and basically involve identification of the agent and serological tests.[1] A rapid chromatographic strip test (Penside test) that can detect rinderpest antigen in lachrymal fluid[16] is a useful tool for field personnel. In areas where there had been recent outbreaks, a presumptive diagnosis also can be made on the basis of the history, clinical signs and postmortem findings. Since the prevalence of the disease is decreasing, it is recommended that for each outbreak, the virus should be isolated, its lineage identified and its virulence in cattle assessed.[1] Antibody detection in paired serum samples is not recommended during an outbreak because of the length of time required to confirm a diagnosis but it is used for disease surveillance and vaccine evaluation. For antigen detection and virus isolation, the key to diagnostic success is the collection of suitable samples at the optimum time (3–5 d after fever commences) from many animals rather than many samples from one sick or dead animal. The proportion of positive reactors falls sharply after diarrhea commences and in moribund or dead animals.

A technique suitable for laboratory and field use is the agar gel diffusion (AGID) technique in which needle biopsy samples

of lymph node are used as antigen. Other satisfactory methods of detecting rinderpest antigen in feces, buccal scrapings, and ocular and nasal discharges in the early stages of the disease are the complement fixation, counterimmunoelectrophoresis (CIEP),[17] immunofluorescence, immunohistology and passive hemagglutination tests. The virus can be detected immunohistochemically in the tonsil despite marked autolytic changes.[18] Using specific cDNA probes, isolates of rinderpest and PPR viruses can now be differentiated[19] and a test employing the polymerase chain reaction has been developed that can detect viral RNA in tissues otherwise unsuitable for standard techniques.

The isolation of the virus in tissue culture and its identification is best done with washed leukocytes harvested from blood buffy coat or from fresh lymph node. Rapid virus isolation is possible using continuous growing lines of bovine T-lymphocytes.[9]

For antibody detection, a CFT is of limited value on a herd basis. Antibodies in serum reach peak levels about 14 d after the development of clinical disease. In animals which have recovered for longer periods, the antibody level may be so low that the test is unsatisfactory. For this reason, the serum neutralization test is used more widely, even though it is time consuming and involves the use of tissue culture facilities. Neutralizing antibodies remain detectable for years and they correlate very closely with clinical and virological immunity. This test is at present the most suitable assay for surveillance for virus circulating in the field and for monitoring the efficiency of a recent vaccination campaign. Other available serological tests include those based on the detection of fluorescent antibody and immunoperoxidase,[11] an ELISA which is accurate and easy to perform[20] and can differentiate between rinderpest and PPR,[21] and a rapid dot-enzyme immunoassay test suitable for field use.[22]

Confirmation by the experimental transmission of the disease is expensive and dangerous unless isolation facilities with maximum security are available. The recipient group should include one or more animals known to be immune to rinderpest. The intravenous inoculation of 5 mL of blood from an affected animal at the height of the disease into susceptible cattle is followed by the development of signs in 3–10 d. Sheep as recipient animals may only show mild febrile reaction and mucosal erosions.

NECROPSY FINDINGS

The important necropsy findings are in the alimentary and upper respiratory tracts and in the external genitalia in females. The carcass is dehydrated, emaciated and soiled with fetid feces. Small, discrete, necrotic areas develop on the oral mucosa and separation of the necrotic material leaves sharply walled, deep erosions with a red floor which may coalesce to form large erosions or ulcers. These lesions extend to the pharynx, upper esophagus and abomasum, particularly the pyloric region. The forestomachs are spared and lesions are mild in the small intestine except at the Peyer's patches which are swollen, hemorrhagic and necrotic. Severe changes occur in the mucosa and lymphoid nodules in the large intestine, particularly at the cecocolic junction. Zones of hemorrhage and erythema running transversely across the colonic mucosa produce a characteristic striped appearance, the so-called 'zebra stripes'. The nasal turbinates and septa are coated with a tenacious mucopurulent exudate beneath which is an eroded and ulcerated surface. Lesions may extend to the upper trachea but not beyond and the lungs are usually not affected. Congestion, swelling and erosion of the vulval and vaginal mucosae may occur.

Histologically, the mucosal changes are characterized by necrosis of stratified squamous epithelium of the upper alimentary tract and necrosis of crypts in the intestine, with resulting erosions and superficial ulcers. Inflammatory cells are minimal but multinucleated syncytia are characteristic. Intranuclear and intracytoplasmic viral inclusion bodies may be present, especially in the tonsils. Lymph nodes and spleen may appear normal grossly but microscopically, they show characteristic massive necrosis of lymphocytes.

Materials sent for laboratory examination should include fixed sections of lymph node, tonsil and alimentary tract lesions, as well as fresh spleen, blood and alimentary tract for antigen detection or virus isolation.

DIFFERENTIAL DIAGNOSIS

Rinderpest should be suspected when a number of cattle or buffalo are affected by a febrile, fatal, highly infectious disease with characteristic signs. FMD and hemorrhagic septicemia are other diseases which occur in epidemics but are sufficiently dissimilar to present no difficulty in differentiation. Malignant catarrhal fever (MCF) and bovine virus diarrhea/mucosal disease (BVD/MD) present the major difficulty in diagnosis. MCF rarely affects many animals in one herd and is characterized by specific eye lesions and nervous signs. BVD/MD occurs either in explosive outbreaks like rinderpest but the mortality rate is low, or it occurs sporadically, but is uniformly fatal. The postmortem lesions of rinderpest and BVD/MD are virtually identical. Jembrana disease in Indonesia is another highly fatal disease of cattle and buffalo but anemia will be a feature and the microscopic lesions are different from those of rinderpest. Infectious bovine rhinotracheitis may produce similar mucosal lesions. In sheep and goats, PPR presents the greatest problem in differentiation but pneumonia is usually a feature of PPR but not rinderpest. If only sheep and goats are affected in an outbreak, it is most likely PPR. Other diseases to be considered are bluetongue, sheep, and goatpox and Nairobi sheep disease.

TREATMENT

Treatment is ineffective and should not be undertaken because of the danger of disseminating the disease. Vaccines are of no value in treating already infected animals or those infected up to 48 hours after vaccination.

CONTROL

Rinderpest is a simple disease and outbreaks can be effectively controlled by **slaughter and rigid quarantine measures**. In endemic areas, control used to be by **annual vaccination and surveillance**. Preparation of the vaccines is simplified by the common antigenicity of all known strains of the rinderpest virus, thus a vaccine prepared from one strain will protect against all other strains. Rinderpest vaccine protects goats against infection with the virus of PPR, probably for life despite antigenic differences between the two viruses. Although rinderpest virus has no serological similarity to BVD virus, immunity to the latter is believed to provide some protection against infection with the former.

The introduction of rinderpest to a previously uninfected country is most likely to occur through importation of infected animals, particularly to zoological gardens, but the possibility does exist that carcass meat infected with the virus could be a portal of entry. Uncooked, infected garbage has been shown to be capable of infecting pigs which subsequently spread the infection to other pigs and to cattle. Prevention of the introduction of ruminants and pigs from known infected areas is routinely practiced in countries which do not have the disease. Countries with land borders to enzootic areas can usually be adequately protected by satisfactory quarantine at the border and the erection of immune barrier zones.

When epidemic occurs in normally free areas, it is necessary to prevent movement of both living animals and fresh animal products. All susceptible animals in infected and in-contact groups must be slaughtered and disposed of on the respective farms. All ruminants and pigs

must be considered susceptible and special attention should be given to native fauna. Infected premises should be cleaned and disinfected. Solutions of caustic soda and lysol are ideal and the premises can be restocked after 1 week. When outbreaks are threatened or when an outbreak is extensive and likely to get out of control, all ruminants and pigs in the danger area should be vaccinated with an attenuated virus vaccine.

In endemic areas, control depends upon the use of an efficient vaccination procedure and disease surveillance at national, regional or continental level as is being done under the auspices of GREP. For example, African countries successfully initiated the Joint Project 15 in 1962–1976 followed later with a Pan-African Rinderpest Campaign (PARC) to rid the whole continent of the disease. The initial step was to vaccinate all animals in each national herd annually until the immune status exceeded 90%. Thereafter, calves were vaccinated annually and revaccinated the following year until there were no more outbreaks for at least 5 years. Currently, there is periodic surveillance to monitor the immune status of each national herd and to deal quickly with any new outbreaks by control of animal movement and ring vaccination of all surrounding herds. Suitable legal and administrative powers are necessary for the proper use of control by vaccination. The ideal vaccine is one which can be produced with varying degrees of attenuation suitable for safe and effective vaccination of cattle with different levels of susceptibility. It should also be highly thermostable, inexpensive and easy to administer under current systems of animal husbandry in Africa and Asia.

The second most important problem associated with rinderpest vaccination is the activation of existing latent infections in vaccinated animals. In general, the problem is greater after the use of less attenuated vaccines. Although protozoal infections present the greatest risk, bacterial and viral diseases may also be activated.[23] Vaccination of cattle with ears heavily infested with the tick *Rhipicephalus appendiculatus* should be avoided.

Calves present a special problem. If they receive no antibodies in the colostrum, they can be successfully vaccinated at 1 d of age, but if they are from immune cows the vaccination will be ineffective if carried out while they still have high levels of maternally derived antibodies. Colostrum-fed calves from immune cows are believed to be passively immune for periods of 4–8 months, the duration depending upon the immune status of the dam. A recent study recommended vaccinating calves after 3–3.5 months of age when maternal possibility that vaccinated animals can be infected and become active carriers of the virus is unresolved, but this is unlikely to occur with tissue culture vaccines. With the older vaccines, vaccinated calves or calves with colostral antibody were susceptible to experimental intranasal infection with the rinderpest virus, which was subsequently excreted to susceptible in-contact animals.[25]

In areas where PPR is endemic, antibodies to PPR in cattle, sheep and goats could prevent an immune response to rinderpest vaccine. Since PPR antibodies are both cross-neutralizing and cross-protective against rinderpest virus, further vaccination in the presence of these antibodies would be wasteful.[26]

A dual vaccine against rinderpest and contagious bovine pleuropneumonia has been in use in Africa but its efficiency against contagious bovine pleuropneumonia (CBPP) is less than maximal and it is not generally recommended.[27]

The principal vaccine used to control rinderpest throughout the world is the tissue culture rinderpest vaccine (TCRV) produced in calf kidney cells[14,28] for cattle. Before its development, attenuated vaccines were prepared by passage of the virus in goats, rabbits and chicken eggs to produce caprinized, laprinized and avianized vaccines, respectively. TCRV is easy and cheap to produce and can be freeze dried or lyophilized[29] and therefore has a long shelf-life before it is reconstituted. Furthermore, it is capable of varying degrees of attenuation and is thus safer in all situations. Finally, it produces a life-long immunity and does not spread from vaccinated to in-contact cattle. Its main drawback is that after reconstitution, the vaccine must be used within a few hours unless refrigerated. The establishment of cold chains in the tropics thus adds to the cost of the vaccination program. Another drawback is the difficulty in distinguishing between antibodies due to infection and those due to vaccination since both lead to life-long immunity. Cultures should also be free of infection with BVD virus.[23] The use of Vero cell line obviates this risk and a lyophilized vaccine that can be kept without refrigeration at high ambient temperatures for up to 2 months has been developed from this cell line.[9] TCRV used for cattle is suitable for use in buffaloes and also in sheep and goats which can also be protected against rinderpest by vaccination with attenuated PPR virus.[30]

The measles vaccine protects calves against rinderpest at an age when ordinary rinderpest vaccines are ineffective due to interference from colostral antibody. It is also an efficient vaccine for use in adult cattle.[31] Recombinant vaccines against rinderpest are being developed [illegible] the duration of immunity conferred. A highly attenuated vaccinia virus double recombinant that expressed both the F and H genes of rinderpest virus was found to protect cattle against experimental rinderpest and did not cause pox lesions.[32] The vaccine is heat-stable and calves can be vaccinated at any age, even in the presence of colostral antibodies.[33] A variant of this vaccine which expressed only the H protein protected experimental cattle for up to 3 years.[34] Cattle can also be protected against rinderpest and lumpy skin disease (LSD) with a recombinant capripoxvirus vaccine expressing the fusion gene of rinderpest virus.[35] In another study, two of four vaccinated animals were solidly protected from virulent rinderpest challenge after 2 years, and all four from challenge with virulent LSD virus.[35] The recombinant vaccine showed no loss of potency when stored lyophilized at 4°C for up to 1 year. Nevertheless, there is still the need to improve the cold chain for many veterinary products and samples in parts of Africa and Asia.

PESTE DES PETITS RUMINANTS (PPR, GOAT PLAGUE OR KATA)

Synopsis

Etiology Peste des petits ruminants virus, a morbillivirus
Epidemiology Contagious disease of goats and sheep; endemic in west and central Africa, outbreaks in northeastern Africa, Middle East and Asia, high mortality in goats
Pathogenesis Inhaled/ingested virus → upper respiratory infection → viremia → target cells (lymphocytes, alimentary and respiratory mucosae) → signs and lesions
Signs Fever, oculonasal purulent discharge, necrotic stomatitis, diarrhea and respiratory distress
Clinical pathology Marked leukopenia
Diagnostic confirmation Virus neutralization test and immunohistochemistry
Differential diagnosis list
- Rinderpest
- Contagious ecthyma
- Bacterial pneumonias
- Coccidiosis

Treatment Hyperimmune serum and symptomatic treatment for valuable animals
Control Segregation of new stock, vaccination with tissue culture or other vaccines

ETIOLOGY

Peste des petits ruminants (PPR) is associated with PPRV, a morbillivirus (family Paramyxoviridae) closely related to the rinderpest virus as well as the viruses of canine distemper in dogs, phocine distemper in seals, and measles in humans.[1] Four lineages of PPRV have been identified; lineage 1 and 2 viruses in west Africa, lineage 3 in east Africa, Arabia and southern India, and lineage 4 in the Middle East and Asia subcontinent, reaching east as far as Nepal and Bangladesh.[2] The African and Asian lineages (strains) of the virus have some biochemical and genetic differences, implying that both strains may have evolved separately.[3] All four lineages have been shown to be genetically distinct from the rinderpest virus, thereby raising some doubt to the notion that PPRV might have evolved in the first half of the 20th century from goat-adapted rinderpest vaccines.

EPIDEMIOLOGY

Occurrence

The disease occurs mostly in goats and sheep. Outbreaks were first described in West Africa in 1942 and the disease is now endemic in the region. In addition, outbreaks have been reported from much of sub-Saharan Africa north of the equator. Since the 1990s, outbreaks have been reported from the Arabian Peninsula as far north as Turkey and extending through Pakistan and India to Nepal and Bangladesh. It is possible that some of the earlier reports of rinderpest in sheep and goats in Asia might have been PPR outbreaks since the two diseases in these species are not easily distinguishable on clinical examination only. Cattle and pigs develop serum-neutralizing antibodies but no disease following experimental infection. Natural disease may occur in the wild sheep, gazelle and the deer but there are no known reservoirs in domestic animals and wildlife. Based on clinical signs and detection of antibodies, PPR and rinderpest viruses were suspected to be involved in a highly contagious disease of Ethiopian camels in 1995,[4] but the role of the two viruses in camels requires further studies. PPR is not transmissible to humans.

Outbreaks invariably occur when new stock is introduced into a farm. In West Africa, this usually takes place when Sahelian goats and sheep believed to have high innate resistance to the virus are moved southwards and commingle with the dwarf breeds in the humid and subhumid tropics. Such mingling occurs during seasonal migrations and religious festivals. Market goats do harbor and can transmit the virus. The first outbreaks in Saudi Arabia were associated with the importation of sheep from Africa or the return of unsold lambs from livestock markets.

Morbidity and case–fatality rate

Infection rates in enzootic areas are generally high (above 50%) and can be up to 90% of the flock during outbreaks. The percentage of sheep and goats with antibodies rises with age. The disease, however, is more severe in goats than in sheep and is rapidly fatal in young animals. Case–fatality rates are also much higher in goats (55–85%) than in sheep (less than 10%). Goats have also been more severely affected in the more recent outbreaks involving the virus of Asian lineage.[5]

There is no significant seasonal variation in the prevalence of the disease but since maternal antibodies are lost at about 4 months of age, the number of susceptible animals is likely to increase 3–4 months after peak kidding and lambing seasons.

Methods of transmission

As in rinderpest, close contact with an infected animal or contaminated fomites is required for the disease to spread. Large amounts of the virus are present in all body excretions and secretions, especially in diarrheic feces. Infection is mainly by inhalation but could also occur through the conjunctiva and oral mucosa.

Risk factors and immune mechanisms

Kids over 4 months and under 1 year of age are most susceptible to the disease. Sahelian breeds of sheep and goats are believed to be more resistant than the dwarf breeds in the humid and sub-humid zones of West Africa. In a particular flock, the risk of an outbreak is greatly increased when a new stock is introduced or when animals are returned unsold from livestock markets. Recovered animals have lifetime immunity.

Experimental reproduction

The disease can be experimentally transmitted through close contact with an infected animal or through inoculation of infected tissues or blood.

Economic importance

PPR is regarded as the most important disease of goats and sheep in West Africa and possibly in all countries where the disease occurs. In many of those countries, these animals are a major source of animal protein.

Zoonotic implication

The virus of PPR does not affect humans.

Biosecurity concerns

Like rinderpest, PPR requires close contact with an infected animal for transmission to occur. Nevertheless, since live goats and sheep are traded and may be carried over long distances, the disease can be easily introduced to a new herd or even a new country unknowingly from animals incubating PPR or showing only mild lesions.

PATHOGENESIS

PPR virus penetrates the retropharyngeal mucosa, sets up a viremia and specifically damages the alimentary, respiratory and lymphoid systems. Infected cells undergo necrosis, and in the respiratory system, also proliferation. Death may occur from severe diarrhea and dehydration, before respiratory lesions become severe, or is hastened by concurrent diseases such as

pneumonic pasteurellosis, coccidiosis or coliform enteritis. Lymphoid necrosis is not as marked as in rinderpest and the possibility of immunosuppression has not been investigated. Most sheep and some adult goats recover.

CLINICAL FINDINGS

The disease can be acute or subacute. The acute form is seen mainly in goats and is similar to rinderpest in cattle except that severe respiratory distress is a common feature of PPR. Signs generally appear 3–6 d after being in contact with an infected animal. A high fever (above 40°C) is accompanied by dullness, sneezing and serous discharge from the eyes and nostrils. A day or two later, discrete necrotic lesions develop in the mouth and extend over the entire oral mucosa, forming diphtheric plaques. There is profound halitosis and the animal is unable to eat because of a sore mouth and swollen lips. Nasal and ocular discharges become mucopurulent and the exudate dries up, matting the eyelids and partially occluding the external nares. Diarrhea develops 3–4 d after the onset of fever. It is profuse and feces may be mucoid and blood tinged. Dyspnea and coughing occur later and the respiratory signs are aggravated when there is secondary bacterial pneumonia. Erosions have been described in the vulva and prepuce. Abortions have been reported during outbreaks in India.[5] Death usually occurs within 1 week of the onset of illness.

Subacute forms are more common in sheep but they also occur in goats. The signs and lesions are less marked and a few animals may die within 2 weeks, but most recover. Contagious ecthyma (orf) may complicate the labial lesions or develop in surviving animals.

CLINICAL PATHOLOGY

A leukopenia occurs but is not as marked as in rinderpest. As diarrhea develops, there is a progressive hemoconcentration and low serum sodium and potassium.[6]

Diagnostic techniques used in the past were virus neutralization test (VNT), agar gel immunodiffusion (AGID), complement fixation, counter immunoelectrophoresis (CIEP), virus isolation in cell cultures, and animal inoculation. Some are still used on a herd basis and VNT is the prescribed test for international trade.[7] More recently, competitive or blocking enzyme-linked immunosorbent assays (c-ELISAs) have been developed based on monoclonal antibodies specific for the nucleocapsid (N) or hemagglutinin (H) proteins of PPR and rinderpest viruses, and which enable differential diagnosis of the two viruses.[6] The efficacy of c-ELISA compares very well with virus neutralization test for detection and titration of antibodies to PPRV in goats and sheep.[8] Viral antigen can also be detected in buffy coat, body secretions, feces, lymph node and tonsils by immunohistochemical[9–11] and dot-ELISA[12] methods as well as by AGID and CIEP. Furthermore, the reverse transcription-polymerase chain reaction (RT-PCR) has been reported to be more rapid and far more sensitive than conventional titration technique on Vero cells.[13] Unlike rinderpest, PPR viral antigen is still high in tissues of animals dying from the disease.

NECROPSY FINDINGS

The carcass is severely dehydrated, the hindquarters are soiled with fluid feces, and crusts of exudate are present around eyes, nose and lips. Discrete or extensive areas of erosion, necrosis, and ulceration are present in the oral mucosa, pharynx, and upper esophagus and may extend to the abomasum and distal small intestine. Hemorrhagic ulceration is marked in the ileocecal region, colon and rectum where they produce typical 'zebra stripes'. Regional lymph nodes are enlarged and wet and the spleen may be enlarged. Severe lesions are often present throughout the respiratory tract. A mucopurulent exudate extends from the nasal opening to the larynx whereas the trachea and bronchi may be hyperemic and contain froth due to pulmonary congestion and edema. An interstitial pneumonia is usually present.[9,10] Grossly, the pneumonia is diffuse or more commonly, antero-ventral or apical. With bacterial complications, there will be purulent or fibrinous bronchopneumonia and pleuritis.

Microscopic lesions in the alimentary tract are similar to those in rinderpest but are often more severe. In the early stages, syncytial cells are present in the oral mucosa and intracytoplasmic eosinophilic inclusion bodies in intestinal crypt epithelium. The respiratory tract shows proliferative rhinotracheitis, bronchitis, bronchiolitis, proliferation of type II pneumocytes, and formation of huge syncytial giant cells. Intracytoplasmic and intranuclear inclusion bodies are common in these cells. In a recent immunohistochemical study of natural PPR pneumonias in goats, viral antigens were found most frequently in the cytoplasm and rarely in the nucleus of lower respiratory epithelial cells, type 11 pneumocytes, syncytial cells and alveolar macrophages.[14] Lymphoid organs are depleted of lymphocytes but not usually as marked as in rinderpest.

For diagnostic purpose, specimens should be collected from several live animals and should include swabs of conjunctival, nasal and buccal mucosae, as well as whole blood in anticoagulant for virus isolation and other tests. At necropsy, the following specimens should be collected for virology and histopathology:

- Lungs
- Small and large intestines
- Oral mucosa
- Tonsil
- Mesenteric lymph nodes.

DIFFERENTIAL DIAGNOSIS

Other diseases that cause diarrhea or pneumonia in sheep and goats may pose a diagnostic challenge but a history of recent introduction of new stock and the clinical and postmortem findings of stomatitis, enteritis and syncytial giant cell pneumonia are typical for PPR. Laboratory tests are required to rule out rinderpest. Other diseases to be considered are:

- Heartwater
- Pneumonic pasteurellosis
- Contagious caprine pleuropneumonia in goats
- Contagious bovine pleuropneumonias
- Helminthosis
- Coccidiosis
- Contagious ecthyma
- Possibly Nairobi sheep disease.

TREATMENT

Valuable sick animals in the early stages of the disease should be isolated and given hyperimmune serum, which may be obtained from cattle hyperimmunized against rinderpest. Supportive treatment includes fluid therapy for dehydration and antibiotics to prevent secondary bacterial infections. Lesions around the eyes, nostrils and mouth should be cleaned, and good nursing provided.

CONTROL

The disease can be prevented by not introducing new stock from unknown sources, especially animals bought at livestock markets. In addition, animals returned unsold from markets should be segregated unless the entire herd or flock has been vaccinated. The tissue culture rinderpest vaccine is effective but its use in enzootic areas is not as organized as it is for rinderpest. Kids and lambs should be vaccinated at 3–4 months of age by which time maternal antibodies would have waned. Newly developed recombinant vaccinia[15] or capripox[16] viruses expressing the fusion (F) and hemagglutinin (H) protein genes of the rinderpest virus are also effective against PPR. More recently, a homologous PPRV tissue culture vaccine was produced by serial passages in Vero cells. This vaccine is now widely used in the control of PPR.[17] The homologous vaccine has the advantage that it avoids confusion with rinderpest vaccine when serological surveys are performed.[7]

JEMBRANA DISEASE

Jembrana disease is the name of a highly fatal, infectious, disease that occurs in Bali cattle (*Bos javanicus*) and buffaloes (*Bubalus bubalis*) on the island of Bali in Indonesia. The disease is endemic in areas of Indonesia, but the severe disease of the initial outbreak has modified with time.

ETIOLOGY

The disease is caused by a lentivirus, genetically related but distinct from bovine immunodeficiency virus.[1] Both viruses are present in Bali cattle but the bovine immunodeficiency virus has been identified in cattle on islands where Jembrana disease has not occurred.[2] Jembrana disease virus has not been propagated in vitro and there is difficulty in differentiating infection with the two viruses by serological methods.[3,4]

EPIDEMIOLOGY

Occurrence

The disease originally occurred in Jembrana district on the Island of Bali, Indonesia in 1964 and rapidly spread to the rest of the island resulting in the deaths of approximately 17% of Bali cattle.[5] Since 1964 the disease has been endemic on Bali island but with lower morbidity and mortality rates. It has subsequently spread to the Indoensian islands of Sumatra, Java and Kalimantan, producing initial epidemic diease with high mortality followed by endemic disease with lower morbidity and mortality.[5]

Transmission

Transmission probably occurs by direct contact with infective secretions in the acute phase of the disease and by mechanical transmission by hematophagous insects or mechanically by needles during mass vaccination of animals for the control of diseases, such as hemorrhagic septicemia.[6]

Experimental reproduction

The disease can be experimentally transmitted by IV or intraperitoneal inoculation of blood or spleen into *B. javanicus*. The virus is present in high titer in the blood during the febrile phase and in the saliva and milk.[6,7] In *B. javanicus* an incubation period of 4–12 days is followed by fever lasting from 5 to 12 days and clinical signs typical of the enzootic form of the disease. Persistent infection occurs for periods of at least 2 years following recovery.

Experimental challenge of *B. indicus*, *B. taurus* and crossbred (*B. javanicus* and *B. indicus*) cattle results in only a transient febrile response, mild clinical disease and a viremia that persist for 3 months, although antibody persists for at least 4 years following infection.[8] Infection, as determined by antibody response, but not clinical disease can be transmitted experimentally to pigs, sheep, goats and buffaloes.[5]

PATHOGENESIS

Jembrana disease is not typical of other lentivirus infections, which are characterized by chronic progressive disease with long incubation periods. There is a high viremia during the febrile stage. Initial virus proliferaton in the spleen is followed by widespread dissemination during a second proliferative phase and infection in lymph nodes, lungs, bone marrow, liver and kidney. The specific cell types infected by Jembrana virus have not yet been identified but appear to be of lymphocyte origin or of the monocyte/macrophage lineage.[9]

CLINICAL FINDINGS

Natural clinical disease is reported only in *B. javanicus*, other cattle types and buffalo are subclinically infected in natural outbreaks. Clinical signs include fever (40–42°C; 104–107°F), which lasts up to 12 days, anorexia, generalized lymphadenopathy, nasal discharge, increased salivation and anemia. In severely affected cattle there is diarrhea followed by dysentery. Mucosal erosions can occur but are rare. Hemorrhages are present in the vagina, mouth and occasionally the anterior chamber of the eye in the severe disease.

Where the disease is enzootic and less severe in presentation clinical signs include inappetence, fever, lethargy, reluctance to move, enlargement of the superficial lymph nodes, mild erisons of the oral mucosa and diarrhea.

CLINICAL PATHOLOGY

During the febrile period there is a moderate normocytic normochromic anemia and a leukopenia with lymphopenia, eosinopenia and thrombocytopenia.[7] Bone marrow shows no changes historically. Elevated blood urea concentrations and diminished total plasma protein are seen in *B. javanicus* but not *B. taurus*.[6] An ELISA test and an agar gel immunodiffusion test can be used for serological surveys. Both are specific but the ELISA test has greater sensitivity but limited sensitivity.[4,10]

NECROPSY FINDINGS

Necropsy lesions in *B. javanicus* include generalized lymphadenopathy, with enlargements up to 20-fold, and generalized hemorrhages. The spleen is enlarged to three to four times its normal size. Histologically, there its vasculitis and perivasculitis and follicular atrophy in the spleen and lymph nodes, and parafollicular proliferation of mononuclear cells in intestinal lymphoid tissue.[5,9]

TREATMENT AND CONTROL

Treatment is supportive. There is currently no specific control. Vaccination has been attempted using virus-containing plasma and spleen tissue from acutely affected cattle with the virus inactivated with triton X-100 and the vaccine adjuvanted with either mineral oil or Freund's incomplete adjuvant.[11] Protection is only partial and not of real value in control.

NAIROBI SHEEP DISEASE

This is a tick-transmitted disease of small ruminants, particularly sheep, associated with the Nairobi sheep disease virus (NSDV), a bunyavirus (genus *Nairovirus*)

and characterized by fever, hemorrhagic gastroenteritis, abortion and high mortality.[1,2] It is endemic in East and Central Africa (Kenya, Uganda, Tanzania, Ruanda, Somalia, and Ethiopia) and antibodies to the virus and other bunyaviruses have been detected in southern and northeastern Africa and Sri Lanka.[3,4] Genetic and serologic data have shown that the Ganjam virus in Indian goats is an Asian variant of NSDV.[5] Other antigenically related viruses are the Crimean-Congo hemorrhagic fever virus in humans and the Dugbe fever virus in west African cattle. NSD virus does not affect cattle but can cause a mild febrile disease in humans, hence a zoonosis. The most common vector is the brown ear tick *Rhipicephalus appendiculatus*, but other species may be involved, as well as the bont tick, *Amblyomma variegatum*. Transmission by *R. appendicaltus* is both trans-stadial and trans-ovarial. Animals in endemic areas are usually immune and the virus can persist in ticks for long periods, more than two years in unfed adults.

Clinical disease occurs when susceptible animals are moved into endemic areas (e.g. for marketing purposes) or when there is a breakdown in tick control measures. Outbreaks occur outside endemic areas when there has been unusual increase in tick population brought about by excessive or prolonged rains. There are differences in susceptibility among different breeds of sheep and goats, and unlike in most other diseases, some indigenous breeds are more susceptible than exotic breeds. A sudden onset of fever is followed by anorexia, nasal discharge, dyspnea and a severe diarrhea, sometimes with dysentery, abortion and death in 3–9 d. The case–mortality rate is 30–90% but is lower in goats. The necropsy picture is typical of a hemorrhagic diathesis and consists of hemorrhages on serous surfaces of visceral organs and on mucosal surfaces, particularly the abomasum, colon and female genital tract. Lymph nodes are enlarged. Later, a hemorrhagic gastroenteritis becomes more obvious and there may be zebra striping of the colon and rectum.[1] The uterus and fetal skin are hemorrhagic. Ticks are likely to be found in the body, especially in the ears and head. Common histopathologic lesions outside the gastrointestinal tract include myocardial degeneration, nephritis and necrosis of the gall bladder.[1]

Differential diagnoses include peste des petits ruminants (PPR), rinderpest, Rift Valley fever, heartwater, parasitic gastroenteritis and salmonellosis, all to be confirmed by laboratory tests. Specimens for laboratory diagnosis should include uncoagulated blood, mesenteric lymph node and spleen collected safely to avoid aerosol infections. The virus is first isolated in tissue culture or in infant mice, and the disease can be reproduced in susceptible sheep. The recommended serological test is the indirect fluorescent antibody test, but others are the complement fixation test (CFT) and the indirect hemagglutination test.[1] For viral identification, the recommended tests are immunofluorescence, agar gel immunodiffusion, CFT and ELISA. Apparently, there are no reports of involving the use of reverse transcription-polymerase chain reaction (RT-PCR) test in small ruminants but the test was found to be less sensitive in ticks.[6] There is no treatment for NSD but the disease can be controlled by vaccination and vector control. Animals to be moved to endemic areas should receive a killed tissue culture vaccine or an attenuated live virus vaccine.

MALIGNANT CATARRHAL FEVER (BOVINE MALIGNANT CATARRH, MALIGNANT HEAD CATARRH)

Synopsis

Etiology Alcelaphine herpesvirus-1, the wildebeest-associated malignant catarrhal fever (MCF) virus: Ovine herpesvirus-2, the sheep-associated MCF virus
Epidemiology Highly fatal disease of cattle and farmed deer and occasionally pigs. Disease associated with contact with sheep, often lambing ewes, and in Africa also with wildebeest calves. Disease may occur sporadically or in outbreaks
Clinical findings Erosive stomatitis and gastroenteritis, erosions in the upper respiratory tract, keratoconjunctivitis, encephalitis, cutaneous exanthema and lymph node enlargement. The head and eye form is most common and there is a distinctive lesion in the cornea
Clinical pathology Competitive inhibition enzyme-linked immunosorbent assay (ELISA) for serology. Polymerase chain reaction (PCR) detection of viral DNA
Necropsy findings Erosions in gastrointestinal tract and lymphadenopathy. Necrotizing vasculitis
Diagnostic confirmation. Detection of viral DNA by PCR.
Treatment Supportive
Control Avoid cattle contact with sheep and wildebeest

ETIOLOGY

Malignant catarrhal fever (MCF) is really two diseases, clinically and pathologically indistinguishable, but associated with two different infectious agents with different ecologies:

- Alcelaphine herpesvirus-1 (AHV-1) in the genus *Rhadinovirus* of the subfamily Gammaherpesvirinae. This is the wildebeest-associated MCF virus, transmitted to cattle from blue wildebeest (*Connochaetes taurinus*)
- A virus designated ovine herpesvirus-2 (OvHV-2) also a *Rhadinovirus* of the subfamily Gammaherpesvirinae. This is the sheep-associated MCF virus transmitted to cattle from sheep.

Neither agent appears to transmit from cattle to cattle and neither of the viruses cause any disease in their principal host, the wildebeest and the sheep. AHV-1 can be grown in eggs and tissue culture but OvHV-2 has never been propagated in vitro. The molecular genomic structure of these viruses is described.[1] A gammaherpesvirus closely related to OvHV-2 has been isolated from goats[2] and called caprine herpesvirus-2 (CpHV-2) and another, also closely related, has been isolated from deer[3] and called deer herpesvirus (DVH). The pathogenicity of these newly recognized viruses is not known.

EPIDEMIOLOGY

Occurrence and prevalence

Alcelaphine MCF

Wildebeest-associated MCF occurs in most African countries in cattle which commingle with clinically normal wildebeest and hartebeest. It is epizootic and seasonal. It can also occur in zoological gardens in other countries.

Sheep associated MCF

Sheep-associated MCF occurs worldwide. Cases mostly occur when cattle have had contact with lambing ewes and usually start 1–2 months later.[4–6] Goats can also act as a source of OvHV-2 infection for cattle.[7] Cases without apparent or recent exposure to sheep do occur but are uncommon.

The morbidity rate varies. Usually the disease is sporadic and presents as a single or small number of cases over a short period but on occasion up to 50% of a herd may be affected in rare but devastating outbreaks which may be short-lived or last for several months.[8,9] The disease with both agents is **almost invariably fatal**.

Besides cattle, MCF is also an important disease of farmed deer. It is an occasional disease of pigs and is recorded in pigs that had contact with sheep on a farm and in a petting zoo.[10,11]

Methods of transmission

Alcelaphine MCF

Infection with AHV-1 in wildebeest occurs in the perinatal period by horizontal and occasional intrauterine transmission, and infected young wildebeest up to the age of about 4 months have viremia and shed virus in ocular and nasal secretions. The disease is transmitted from wildebeest to cattle by contact or over short distances, probably by inhalation of aerosol or ingestion of pasture contaminated by virus excreted by young wildebeest in nasal and ocular discharges. In contrast, infected cattle do not excrete virus in nasal or ocular secretions.[12] The disease can transmit between wildebeest and cattle over a distance of at least 100 m and it is suggested that cattle need to be kept at least 1 km from wildebeest to avoid disease.[13]

In Kenya the peak incidence of alcelaphine MCF occurs when 3- to 4-month-old wildebeest are in maximum numbers.[14] In South Africa the peak incidence is at a time when young wildebeest are 8–10 months old and not infectious, requiring that there be another, high volume, source of the infection.[15] The proportion of sheep in a wildebeest area which are serologically positive and presumably infected with the wildebeest-associated virus is very high.[16]

Sheep associated MCF

Virtually all domestic sheep raised under natural flock conditions are infected with OvHV-2. **High rates of seropositivity** have been found in domestic sheep and goats over 1 year of age in several surveys.[5,17–19] In a study of 14 species of North American wildlife, a high rate of seropositivity was also found in muskox (*Ovibos moschatus*) and bighorn sheep (*Ovis canadensis*), suggesting that they might be sources of infection. There were low seropositivity rates in clinically susceptible species such as deer and bison.[17]

In contrast to AHV-1 infection in wildebeest, the transmission of OvHV-2 between sheep appears minimal in the perinatal period. There is no evidence for transplacental infection and although antigen, detected by PCR, is present in colostrum and milk from infected ewes, the majority of lambs are not infected until after 2–3 months of age.[19,20] The rate of infection in lambs and the age at infection is not influenced by passively acquired maternal immunity and appears to be dose dependant.[21,22] Infected sheep excrete OvHV-2 in nasal secretions but very high levels of excretion occur between 6 and 9 months of age, suggesting the 6 to 9-month period as the time when most virus is shed into the environment. Viral antigen has been detected in the ejaculate of rams[23] but there is little epidemiological evidence for significant venereal transmission.

The means by which OvHV-2 spreads but is presumably by inhalation or ingestion. The common epidemiological association of diseased cattle having had contact with lambing ewes suggests that perinatal lambs play a role in transmission similar to that played by wildebeest calves, however the age at infection of lambs and the excretion patterns of virus do not fit this assumption. Shedding from ewes does not increase in the lambing period.[21]

Contact with ewes is not a prerequisite, one outbreak having occurred when cattle commingled with rams.[24] Infection can also occur when sheep and cattle are housed in the same building but with no common contact through feeding or watering points.

Occasional cases occur in cattle that have had no apparent contact with sheep and the persistence of the infection in a particular feedlot, or on a particular farm, from year to year when no contact with sheep exists, is unexplained. Persistence of the virus on inanimate fomites has been suggested but the virus is a most fragile one and this seems unlikely. The observation that some recovered cattle show a **persistent viremia** for many months suggests that carrier cattle may be the source of these carryover infections.[12,25,26] In addition, the virus, detected by PCR, has been demonstrated in cattle and farmed deer with no evidence of MCF disease.[27] It is possible that stress could activate a latent infection in animals with no sheep contact.

Experimental reproduction

Sheep-associated MCF virus does not replicate in tissue culture. It has a close association with lymphoblastoid cells, particularly large granular lymphocytes, which can be grown in tissue culture, and induce MCF when injected. MCF can also be transmitted to cattle by transfusion of large volumes of blood if given within 24 h of collection. Wildebeest-associated MCF virus, can be readily transmitted by several routes. It has been adapted to grow on egg yolk-sac and tissue culture, and transmission to rabbits to yolk-sac to cattle has been achieved.

Environment risk factors

The disease shows the greatest incidence in late winter, spring and summer months. There have been suggestions that copper deficiency or exposure to bracken fern might be environmental stressors that predispose the expression of the disease in cattle.[8,28]

Animal risk factors

Clinical disease had been described in over 30 species of ruminants.[29] In Africa assorted **wild ruminants** contract the disease and suffer a severe illness and a high mortality rate. Similar species in zoos are also commonly affected, e.g. Père Greater kudu (*Strepsiceros kudu*).

Amongst **domestic animals**, all ages, races and breeds of cattle are equally susceptible but banteng (*Banteng sondaicus*), buffalo (*Bubalus bubalis*), bison (*Bison bison*) and deer are more susceptible and suffer a more severe form of the disease than do commercial cattle. Disease is recorded in captive deer or farmed deer including sika deer (*Cervus nippon*), roe deer (*Capreolus capreolus*), white-tailed deer (*Odocoileus virginianus*), rusa deer (*C. timorensis*), and red deer (*C. elaphus*).[30,31]

MCF is considered one of the most important diseases of **farmed deer**. The clinical signs and necropsy findings closely resemble those of MCF in cattle but the morbidity and mortality can be disastrously high, resulting in heavy losses for the deer farmer.

Economic importance

Losses due to the disease can be catastrophic on rare individual farms. For the most part it is a nuisance because of its resemblance to rinderpest and mucosal disease.

PATHOGENESIS

MCF is a fatal, multisystemic disease characterized by lymphoid proliferation and infiltration, and widespread **vascular** epithelial and mesothelial lesions, which are morphologically associated with lymphoid cells. $CD8^+$ T-lymphocytes are the predominant cells associated with the vascular lesions. Involvement of the vascular adventitia[32] accounts for the development of gross lesions, including the epithelial erosions and keratoconjunctivitis. The lymph node enlargement is due to atypical proliferation of sinusoidal cells and the cerebromeningeal changes, usually referred to as encephalitis, are in fact a form of vasculitis. There is commonly a synovitis, especially involving tibiotarsal joints and this also is associated with a lymphoid vasculitis. It is believed that the pathogenesis of this disease is the result of direct virus–cell interactions or perhaps immune-mediated responses directed against infected cells.[33]

CLINICAL FINDINGS

The **incubation period** in natural infection varies from 3–8 weeks, and after artificial infection averages 22 d (14–37 d). MCF is described as occurring in a number of forms:

1. Peracute
2. Alimentary tract form
3. Common 'head and eye' form
4. Mild form, but these are all gradations, cases being classified on the predominant clinical signs. In serial transmissions with one strain of the virus all of these forms may be produced. The most common manifestation is the head and eye

Head and eye form

There is a sudden onset of the following symptoms:

- Extreme dejection
- Anorexia
- Agalactia
- High fever (41–41.5°C; 106–107°F)
- Rapid pulse rate (100–120/bpm)
- Profuse mucopurulent nasal discharge
- Severe dyspnea with stertor due to obstruction of the nasal cavities with exudate
- Ocular discharge with variable degrees of edema of the eyelids
- Blepharospasm
- Congestion of scleral vessels.

Superficial necrosis is evident in the anterior nasal mucosa and on the buccal mucosa. This begins as a diffuse reddening of the mucosa, and is a consistent finding about day 19 or 20 after infection. Discrete local **areas of necrosis** appear on the hard palate, gums and gingivae. The mouth is painful at this time and the animal moves its jaws carefully, painfully and with a smacking sound. The mucosa as a whole is fragile and splits easily. The mouth and tongue are slippery and the mouth is hard to open. The erosive mucosal lesions may be localized or diffuse. They may occur on the:

- Hard palate
- Dorsum of the tongue
- Gums below the incisors
- Commissures of the mouth
- Inside the lips.

The cheek papillae inside the mouth are hemorrhagic, especially at the tips which are later eroded. At this stage there is excessive salivation with saliva, which is ropy and bubbly, hanging from the lips. The skin of the muzzle is extensively involved, commencing with discrete patches of necrosis at the nostrils which soon coalesce causing the entire muzzle to be covered by tenacious scabs. Similar lesions may occur at the skin–horn junction of the feet, especially at the back of the pastern. The skin of the teats, vulva and scrotum in acute cases may slough off entirely upon touch or become covered with dry, tenacious scabs.

Nervous signs, particularly weakness in one leg, incoordination, a demented appearance and muscle tremor may develop very early, and nystagmus, head-pushing, paralysis and convulsions may occur in the final stages. Trismus has been described, but it is probably due to pain in the mouth rather than a neuromuscular spasm.

In natural cases the superficial lymph nodes are often visibly and usually palpably enlarged. **Lymphadenopathy** is also one of the earliest, most consistent, and persistent signs of the experimental disease. The consistency of the feces varies dysentery. In some cases there is gross hematuria with the red coloration most marked at the end of urination.

Opacity of the cornea is always present to some degree, commencing as a narrow, gray ring at the corneoscleral junction and spreading centripetally with conjunctival and episcleral hyperemia. Hypopyon is observed in some cases. In cases of longer duration, **skin changes**, including local papule formation with clumping of the hair into tufts over the loins and withers, may occur. In addition, eczematous weeping may result in crust formation, particularly on the perineum, around the prepuce, in the axillae and inside the thighs. Infection of the cranial sinuses may occur with pain on percussion over the area. The horns and rarely the hooves may be shed. Persistence of the fever is a characteristic of MCF, even cases that persist for several weeks with a fluctuating temperature, usually exceeding 39.5°C (103°F).

During some outbreaks an occasional animal makes an apparent recovery but usually dies 7–10 d later of acute encephalitis. In the more typical cases the illness lasts for 3–7 days and rarely up to 14 d.

Peracute and alimentary tract forms

In the peracute form the disease runs a short course of 1–3 d and characteristic signs and lesions of the 'head and eye' form do not appear. There is usually a high fever, dyspnea and an acute gastroenteritis. The alimentary tract form resembles the 'head and eye' form, except that there is marked diarrhea and only minor eye changes consisting of conjunctivitis rather than ophthalmia. This form of the disease has been encountered in outbreak form in cattle in large dairy herds in drylots, with only indirect contact with sheep, and in cattle to which transmission was attempted and farmed deer. A feature of this form of the disease is reported to be a brief period of slight illness followed by the final fulminating disease which is common in deer.

Mild form

The mild form occurs most commonly in experimental animals but is observed in natural outbreaks. There is a transient fever and mild erosions appear on the oral and nasal mucosae. Mild disease may be followed by complete recovery, recovery with recrudescence or chronic MCF. A distinctive clinical feature in chronic MCF is persistent bilateral ocular leukomata.[26]

Pigs

The disease in pigs is similar to the head and eye form in cattle and manifests with fever and tremor, ataxia, hyperesthesia and convulsions and death.[10,11]

CLINICAL PATHOLOGY

A leukopenia, commencing at first illness and progressing to a level of 3000–6000/μL observation. The leukopenia recorded was due mainly to an agranulocytosis. In our experience a moderate leukocytosis is more common.

Virus isolation is not practical with either virus because of the instability of cell-associated AHV-1 and the fact that OHV-2 does not replicate in cell culture. **Transmission** can be used for diagnosis using whole blood, nasal swabs or washings and preferably lymph node collected by biopsy, with histological lesions in the recipient rabbits or calves as the criterion. **Detection of viral nucleic acid** by PCR has largely replaced transmission experiments.

There are a number of **serological tests** that can be used but they have limited value for diagnosis of clinical cases because only a small percentage of animals seroconvert and do so late in the course of the disease. The antibody titer is low and there is cross reaction with other herpes viruses. A **competitive-inhibition ELISA** using a monoclonal antibody to a broadly conserved epitope of the MCF virus can be used for detection of antibody[34] and has largely replaced other serological tests. It is of particular value for epidemiological studies. The development of antibody following infection is delayed in a significant proportion of young animals and serology is unreliable for determining infection status until after one year of age.

Uninfected lambs or kids under 4 months of age may test positive due to the presence of maternal antibody.

Detection of viral nucleic acid by PCR techniques is the current accepted diagnostic technique.[5,27,35–37] The buffy coat is probe-positive 2 d after experimental infection with alcelaphine herpesvirus-1.[37] Virus can be present in cattle without clinical MCF and if these have a disease that is not MCF, but test probe positive, a **false diagnosis** is possible.[37]

NECROPSY FINDINGS

Lesions in the mouth, nasal cavities and pharynx vary from minor degrees of hemorrhage and erythema, through extensive, severe inflammation to discrete ulcers. These lesions may be shallow and almost imperceptible or deeper and covered by cheesy diphtheritic deposits. **Erosion** of the tips of the cheek papillae, especially at the commissures, is common. Longitudinal, shallow erosions are present in the esophagus. The mucosa of the forestomachs may exhibit erythema, or sparse hemorrhages or erosions. Similar but more extensive lesions occur in the abomasum. Catarrhal enteritis of moderate degree and swelling and ulceration of the Peyer's patches are constant. The feces may be loose and blood stained.

Similar lesions to those in the mouth

and sometimes in the bronchi but the lungs are not usually involved except for occasional emphysema or secondary pneumonia. The liver is swollen and severe hemorrhage may be visible in the urinary bladder. All lymph nodes are swollen, edematous and often hemorrhagic. The gross ocular lesions are as described clinically. Petechial hemorrhages and congestion may be visible in brain and meninges.

Histologically, MCF is characterized by perivascular, mononuclear cell cuffing in most organs and by degeneration and erosion of affected epithelium. The pathognomonic lesion is a **necrotizing vasculitis** which features infiltration of the tunica media and adventitia by lymphoblast-like cells and macrophages. Acidophilic, intracytoplasmic inclusion bodies in neurons have been described[7] but their identity as viral inclusions has not been established. Large numbers of inclusion bodies have been observed in the tissue of artificially infected rabbits. The histologic features of the panophthalmitis have been described.[38]

Cattle with chronic MCF have chronic bilateral central stromal keratitis with or without corneal pigmentation. An **obliterative arteriopathy** is characteristic and this vascular lesion is present in all major organs.[26] Results of a competitive inhibition ELISA serologic test suggesting a role for the virus in the development of obliterative arterial lesions in cattle[5] have been supported by in-situ PCR and immunohistochemical studies of the disease in bison[33] which demonstrated OHV-2 within the infiltrating lymphocytes. These lymphoblast-like cells were also shown to be CD8 (+) T-cells.

A PCR technique or immunohistochemical stains can be used to confirm the presence of viral antigen in whole blood or in tissues harvested at necropsy.[35,39] When transmitted to rabbits, both the wildebeest- and sheep-associated viruses elicit a rapidly fatal lymphoproliferative disorder. The newer molecular biology-based techniques have made this bioassay method obsolete.

Samples for confirmation of diagnosis

Histology – fixed brain, lymph node, alimentary tract mucosa including pharynx, esophagus, rumen and Peyer's patch, liver, adrenal gland, kidney, urinary bladder, salivary gland (IHC, LM); Bouin's-fixed eye (LM)

Virology – lymph node, spleen, lung (PCR).

DIFFERENTIAL DIAGNOSIS

- Mucosal disease
- Infectious bovine rhinotracheitis
- Sporadic bovine encephalomyelitis
- Rinderpest
- Jembrana disease.

TREATMENT

Treatment of affected animals is unlikely to influence the course of the disease. Non-steroidal anti-inflammatories may ease the discomfort.

CONTROL

Isolation of affected cattle is usually recommended but its value is questioned because of the slow rate of spread and the uncertainty regarding the mode of transmission. Because of the field observation that sheep are important in the spread of the disease, **separation** of cattle and sheep herds is recommended. The introduction of sheep from areas where the disease has occurred to farms with cattle should be avoided. A program to produce sheep free of OVHV-2 infection by separation and isolation of lambs before they become infected is recommended for sheep used in petting zoos.[40]

Attempts to immunize cattle with live or inactivated culture vaccines with Freund's incomplete adjuvant do not provide protection against experimental challenge or natural challenge by exposure to wildebeest herds. High and persistent levels of virus-neutralizing antibody are demonstrable following vaccination but humoral mechanisms are probably not important in determining resistance to infection with the virulent virus. An inactivated wildebeest-associated MCF virus vaccine has provided protection against challenge with virulent viruses.

BOVINE VIRUS DIARRHEA, MUCOSAL DISEASE. BOVINE PESTIVIRUS DISEASE COMPLEX

Synopsis

Etiology Bovine virus diarrhea virus. Type 1 and type 2 genotypes and subtypes. Noncytopathic and cytopathic biotypes. Antigenic diversity and cross-reactivity among strains of virus

Epidemiology Occurs worldwide and major economic importance. Prevalence of infection high in cattle population. Persistently-infected (PI) calves are major source of virus. Young and unvaccinated cattle in herd most susceptible

Pathogenesis Virus causes subacute infections, peracute infections and thrombocytopenia and hemorrhagic syndrome, immunosuppression, fetal infections which persist in the fetus until and after birth in persistently-infected cattle which are also immunotolerant and may develop mucosal disease

Signs Inapparent subclinical bovine virus diarrhea acute mucosal disease, in persistently infected cattle 6–24 months of age with fever, diarrhea, oral erosions and high case–fatality rate, peracute bovine virus diarrhea in cattle of all ages including adults with severe diarrhea, fever, agalactia and rapid death in few days, thrombocytopenia and hemorrhagic disease in veal calves; reproductive failure (decreased conception rate, abortion, stillbirth, weak neonates, congenital defects)

Clinical pathology Leukopenia in acute mucosal disease. Virus isolation from persistently infected animals and from cattle with acute viremia, serology for serum neutralizing antibodies

Lesions Erosive stomatitis and gastroenteritis, depletion of Peyer's patches. Widespread hemorrhages in peracute form. Abortions. Congenital defects of calves (cerebellar hypoplasia, ocular defects)

Diagnostic confirmation Virus isolation from blood and tissues. Antigen detection (antigen capture ELISAs and immunohistochemical tests). Polymerase chain reaction amplification of RNA. Viral neutralization serum antibody and ELISA tests

Differential diagnosis list Diseases with oral erosions and diarrhea (rinderpest, bovine malignant catarrh). Diseases with oral lesions and no diarrhea (foot-and-mouth disease, vesicular stomatitis, bluetongue, bovine papular stomatitis, necrotic stomatitis), disease with diarrhea and no oral lesions (salmonellosis, winter dysentery, Johne's disease, copper deficiency, ostertagiasis, coccidiosis, arsenic poisoning, carbohydrate engorgement)
Treatment None
Control Detection and elimination of PI animals from the herd. Prevention of introduction of infection into herd. Vaccination of breeding females to prevent fetal infection. Eradication by detection and elimination of persistently-infected animals, no vaccination and strict biosecurity measures to prevent introduction of PI animals into the herd

ETIOLOGY

The bovine virus diarrhea virus (BVDV) is one of **three pestiviruses:**

1. Bovine virus diarrhea virus (also known as mucosal disease virus or bovine pestivirus),
2. Border disease virus of sheep
3. Hog cholera virus (also called European or classical swine fever virus).

The viruses are classified in the virus family Flaviviridae and are members of the genus *Pestivirus*.[1] Cross-infection between species can be achieved experimentally and has been demonstrated in field infections.[1] The molecular biology of the BVDV has been reviewed.[2]

Pestiviruses are nonsegmented, single, sense stranded (positive polarity (+)) RNA viruses. The genomic structure has been described.[1] Phenotypic diversity, such as antigenic variation, infectivity and replication rates, which can affect viral virulence, can be attributed to genomic reassortments, mutations or recombinations.[1]

Among the ruminant pestiviruses, particularly BVDV, there are two biotypes designated as **non-cytopathic** (**NCP**) and **cytopathic** (**CP**) depending on their effect on tissue culture cells. The non-cytopathic type is the most common and most important. Only the non-cytopathic type crosses the placenta, invades the fetus and establishes persistent infection in the fetus, which is crucial for spread of the virus. It is the cause of a wide range of congenital, enteric and reproductive diseases. In contrast, the cytopathic biotype of the virus is usually associated with only mucosal disease in animals already persistently infected with the non-cytopathic biotype. Both biotypes can be isolated from animals dying of mucosal disease and there is evidence that the cytopathic biotype evolves by mutation from the non-cytopathic biotype within PI animals. There is considerable antigenic diversity and antigenic cross-reactivity among isolates of BVDV which has implications for diagnostic testing and for control by vaccination.[2] Antigenic and genetic differences have divided the BVDV into type I and type II genotypes. Each genotype has been subdivided into subgenotypes. BVDV-1 isolates are grouped by phylogenetic analysis into at least 11 genetic groups.[3]

Two subgenotypes of BVDV-1 are designated 1a and 1b. BVDV 1a strains are considered to be American in origin, whereas BVDV 1b is considered to have originated in Europe. However, genetic typing of bovine pestiviruses from both Northern Ireland and the Republic of Ireland were found to be BVDV 1a.[4] Most strains in England and Wales are BVDV 1b. It is suggested that the widespread importation of Holstein cattle from North America may have contributed to the predominance of BVDV 1a in the British Isles. Import restrictions which limited importation of livestock from continental Europe may explain the prevention of introduction of BVDV 1b strains to Great Britain and Ireland which will change with increased levels of animal movement following the introduction of the Single European Market.

Genomic recombination can occur in noncytopathic viruses from either genotype giving resulting in cytopathic viruses.[5] Only noncytopathic BVDVs cause severe acute bovine virus diarrhea. Genetic drift results in genotype; genomic recombination is associated with changes in phenotype (biotype). Variation in genotype is more significant to detection and control than variation in biotype.[5]

BVDV-2 genotypes are antigenically distinct and some isolates cause severe disease outbreaks.[6] Not all BVDV-2 isolates cause clinically severe disease; avirulent strains do exist. Virulent BVDV-2 strains inoculated into calves produce disease characterized by fever, diarrhea, leucopenia, lymphopenia, neutropenia, thrombocytopenia, and death. Infection with avirulent BVDV-2 strains causes leucopenia and low-grade fever.[6]

EPIDEMIOLOGY

Occurrence

Diseases associated with the BVDV have been recorded in most countries where cattle are raised and in some countries may be the single most important virus infection of cattle. The prevalence of infection is high but the incidence of clinical mucosal disease is low.

The BVDV causes several different diseases including:

- Benign bovine virus diarrhea, which is usually subclinical
- Fatal mucosal disease which occurs in persistently viremic animals and those specifically immunotolerant as a result of an infection acquired in early fetal life
- Peracute, highly fatal diarrhea
- Thrombocytopenia and hemorrhagic disease
- Reproductive failure
- Congenital abnormalities in calves as a result of fetal infection in mid-gestation.

The virus may also be immunosuppressive.

Mucosal disease was first recognized in 1946 and for the next 35 years it was assumed that the disease was the result of an infection prior to the onset of illness. It is now clear mucosal disease occurs only in PI animals as a result of a congenital infection with a non-cytopathic strain of the virus acquired in early fetal life. These animals remain specifically immunotolerant to the homologous strain of the BVDV throughout postnatal life, and fatal mucosal disease is precipitated by a superinfection with a cytopathic strain of the virus occurring usually at 6–24 months of age or older.

In the late 1980s and early 1990s, a peracute form of the enteric form of the disease and thrombocytopenia in young and adult immunocompetent animals infected with highly virulent strains of the virus were recognized. **This was the first indication that mucosal disease could occur in immunocompetent animals as a result of postnatal infection.**

Prevalence of infection

Of cattle over 1 year of age, 60–80% have serum neutralizing antibodies to the virus.[7] Vaccination programs and the existence of persistently viremic animals which excrete the virus are responsible for the serologically positive animals in a herd.[7] In a survey of 256 beef breeding herds in the United States, over 90% of herds and more than 68% of cattle have been exposed to the BVDV either through vaccination or natural exposure.[8] Based on serum neutralization assays of type 1 and type 2 BVDV in a diagnostic laboratory in the Upper Midwest United States over a 7-year period there has been a progressive increase in the number of cases with high SN titers.[9] The increase is due in part to more extensive use of vaccination but probably also related to a rise in field infections. However, the lack of standardization of the serum neutralization testing between laboratories may affect the interpretation of such surveys.

Young cattle which are persistently infected with a non-cytopathic strain of the virus are the major source of infection in a herd. Conversely, the absence of PI animals in a herd could result in a

serologically negative herd. Seroepidemiological surveys of feedlot cattle also reveal that animals seroconvert to the BVDV during the first several weeks following the arrival in the feedlot due to presence of PI animals.

The mean prevalence of PI animals in herds is about 1–2%. A survey of all cattle in 19 Danish dairy herds with unknown status of BVDV infection revealed that 1.4% of the animals were PI. The prevalence of seropositive animals in herds with one or more PI animals was 87%; in herds without PI animals the prevalence was 43%. The prevalence is also much higher in animals under 1 year of age compared to the older animals in the herd. The theoretical risk of fetal infections occurring during the first 3 months of pregnancy was estimated to be 3.3%.[10] The age distribution of PI animals may be clustered into two separate groups based on the introduction of infected animals followed by the birth of infected animals.[10] In 66 selected herds in the United States, the mean frequency of persistent infection was 1.9% from six herds and nil from 60 herds.[11] However, in two of the six herds the prevalence of PI animals was 27% and 18%, and in one herd all PI animals died of mucosal disease within 5 months of the initial sampling.[11] Of randomly selected beef herds in the United States, about 3% had calves with persistent BVDV infection, and 19% of herds suspected by the herd veterinarian to be a BVDV infected herd had calves with persistent infection.[12] Most persistently infected calves survived to weaning and could provide a constant source of virus throughout the breeding season and early gestation.

Serological surveys in Norway revealed a prevalence rate of 18.5% in cattle, 4.5% in sheep and 2.2% in pigs.[11] In all three species, the prevalence rate varied considerably according to herd and geographical location.

The prevalence of PI cattle may vary between countries due to vaccination practices, the population densities of cattle and housing compared to pastured animals, the selling of male calves after birth, and housing young animals on different premises.[11]

The prevalence of BVDV infection in a population of feedlot calves in western Canada was 27% according to the ELISA test and it varied from 0–63%; according to the virus neutralization test the seroconversion risk was 40% and it varied from 0–100%.[13] In the same survey, the prevalence of PI calves was <0.1%, which is unusually low suggesting that few PI calves were purchased. The prevalence of acute viremia in the calves treated in the feedlot hospital was low at 4%, thus the prevalence of persistent infection was low but serological tests suggested a high risk of seroconversion to BVDV.

The prevalence of PI calves born in a beef herd in 1 year ranged from 9.1–12.7%.[14] When isolation of the calves on a commercial feedlot to mimic normal management conditions in western Canada, was compared to BVDV-negative herdmates, persistently infected calves were 'poor doers' and had poor survivability to 1 year of age.

A high rate of BVDV infections in replacement dairy heifers between weaning and 9 months of age has been observed.[15] The risk of BVDV infection increased with age from 150 to 260 days of age and coincided with removal from the relative isolation in hutches, diminished expected protection from colostral antibodies, and increased exposure to a large number of cattle, some of which possibly shed the virus.

Congenital infection (not persistent infection) with the BVDV in apparently healthy dairy calves, at a rate of about 10% has been reported.[16] Calves with congenital infection had a 2-fold higher risk of a severe illness, compared to calves without congenital infection.

Over a 20-year period in the northwestern United States from 1980 to 2000, there was a shift in disease profiles associated with the BVDV infection and in the age of animal at onset of disease.[17] In 1980, data indicated a low fetal infection rate (<5%), followed by steady increases of clinical cases and peaking at 6 months of age (30%). By 2000, the shift of BVDV cases was noticeable and indicated a biphasic occurrence of disease. The first phase was fetal infections, which increased to >25%, followed by a second phase at 6 months(>35%). The changing patterns may have been due to increased susceptibility of pregnant cattle to BVDV infection and the emergence of type 2 BVDV. The second phase at 6 months of age may be associated with increased susceptibility following decline of passive immunity. Over a 2-year period (1998–2000) type 2 BVDV isolates were most common and associated with abortion-open cows. BVDV type 1a was associated least with early infection (<100 days gestation) and most with late infections (>100 days); BVDV 1b was intermediate, followed by BVDV type 2 which was associated more with early infection (45%) and less with late infections (55%) when compared with BVDV 1a and BVDV 1b.

Other ruminant species. Pestiviruses also infect a wide range of other domestic animals, **captive and free-living ruminants**.[18] There is serological evidence of BVDV infection in exotic ruminants, but outbreaks of disease are recorded only occasionally and usually as single fatal cases. The clinical and pathological findings in some animals are similar to those of mucosal disease in cattle. Serological surveys indicate that many species of free-living ruminants in North America, Europe and Africa have varying prevalence rates. BVD antibody has been found in some free-living red deer in various districts in Denmark probably as a result of infection from cattle[19] The virus has been isolated from a free-ranging mule deer in Wyoming and 60% of mule deer in the same area had antibody to type 1a BVDV suggesting the virus circulates in the mule deer population.[20] Experimental infection of New World Camelids, llamas, results in no clinical signs, fetal infection or persistent infection of crias.[21]

Pestiviruses have also been associated with outbreaks of disease among captive ruminants in zoological collections.[18]

Serological surveys of some populations of sheep and goats revealed that 11% of sheep and 16% of goats were seropositive.[18] A pestivirus which cross-reacts with the BVDV causes border disease in lambs following in utero infection of pregnant ewes.[18] Sheep can be infected naturally and transmission of the virus from cattle to sheep has been demonstrated. In Sweden, cattle infected with the BVDV are considered responsible for the majority of pestivirus infections in Swedish sheep.[22] Experimental pestivirus infections in pregnant goats causes reproductive failure, abortions, stillbirths, and persistent infection in newborn kids with a disease similar to border disease in lambs.[18] Experimental infection of newborn kids may result in minor lesions of the central nervous system but no clinical evidence of disease.[18]

Experimental ruminant pestivirus infection in pigs causes reproductive disease and growth retardation in piglets.[18] Some strains of the BVDV inoculated into pigs cause false-positive reactions to tests for swine fever antibodies and may protect against subsequent challenge with swine fever virus.[18] The importance of these and other species as a source of infection for cattle is unknown.

Morbidity and case–fatality rates

Mucosal disease in PI immunotolerant seronegative animals occurs in all classes of cattle mostly between 6 and 24 months of age, rarely in calves as young as 4 months of age, or cattle older than 2 years of age. The incidence of mucosal disease in a herd is usually less than 5% of the animals up to 2 years of age. Occasionally, epidemics have been observed in which up to 25% or more of the animals of the most commonly affected age group will develop mucosal disease.

Outbreaks of the recently recognized **peracute BVD** occurs in **immunocompetent non-PI animals** are characterized by a high case rate among all clinically affected animals. Morbidity rates may reach 40% and population mortality rates 20%. Herd outbreaks of acute disease associated with BVDV in veal calves caused population mortality rates ranging between herds from 10–25%.[7]

Methods of transmission

The major source of infection is the PI viremic animal. The virus can be isolated from nasal discharge, saliva, semen, feces, urine, tears and milk, each of which would allow wide dissemination of the virus.

Direct contact

The virus is transmitted by direct contact between animals, and by transplacental transmission to the fetus. Discharges from the reproductive tract of an infected cow, either PI or systemically immune, including aborted fetuses, can be potent sources of the virus. Nose-to-nose contact is an effective method of transmitting the virus from PI to susceptible animals.[11,23] Thus PI animals may introduce the infection into a herd, or when infected animals are mixed with susceptible animals at the time of breeding or under conditions requiring emergency movement because of drought, flood or fire. The accidental mixing of a PI bull with susceptible breeding females during the breeding season in a beef herd may result in a major herd outbreak of mucosal disease. A pestivirus has been transmitted by contact from a PI bullock to pregnant sheep, resulting in the birth of PI lambs, one of which was able to transmit the virus by contact to pregnant cattle.[24] Two of these animals gave birth to PI calves, one of which transmitted the virus again by contact with pregnant sheep, leading to another generation of PI lambs.

Transmission of the virus between healthy immunocompetent animals is probably insignificant because they produce antibodies and eliminate the virus. However, the spread of transmission from transiently viremic cattle to seronegative animals in a dairy herd was slow, requiring about 30 months to spread to about 83% of the susceptible group. Primary infected animals are not effective transmitters of the virus.[23] Animals with primary infection even when co-infected with the bovine coronavirus do not transmit the virus to susceptible animals in close contact.[25] Susceptible animals introduced into a herd, typically heifers, become infected by contact with persistently viremic animals and major economic losses can occur if they are at a vulnerable stage of pregnancy. The introduction of an unknown persistently infected cow or heifer into a susceptible herd can also cause major economic losses.[11]

The fetus can be infected by transplacental transmission of the virus from the infected dam, whether the dam is transiently or persistently infected.[11] Fetal infection has been produced by inoculation of non-immune pregnant dams.[7] Epidemics of abortion and congenital defects of calves have occurred when transplacental virus infection of the fetuses of cows in the first trimester, in previously virus-free herds, has followed the introduction of BVDV-infected animals.[7]

PI females can remain clinically normal for several years, during which time they may breed successfully and their progeny may also be apparently normal but are invariably also PI. In this way a maternal viremic family can be established which can persist for several generations and provides one of the major mechanisms for maintenance of the virus as endemic in the herd.[7]

PI bulls may also introduce the virus into artificial breeding units. A PI bull can shed the virus in his semen for a long period,[26] and if introduced into a susceptible herd could have immediate undesirable effects on reproductive performance. However, PI bulls may have acceptable semen quality and fertility.[26] Previously unexposed heifers have been shown not to conceive to service by a PI bull until they have seroconverted. The virus may be transmitted in cattle by artificial insemination with semen from a PI bull.[26] The use of semen from a transiently infected bull has the potential to introduce pestivirus infection into a group or herd of susceptible animals but the conception rates are usually within normal ranges.[26] However, once the infection is established in such a herd there is the potential for its amplification through a secondary cycle of transmission from heifers which were infected from the semen. The virus can persist in the semen of acutely infected bulls for several months after experimental exposure of immunocompetent, seronegative postpubertal animals.[27] There is also a record of a post-pubertal bull in an artificial insemination unit which was shedding the virus in semen over a period of 11 months while not demonstrating any evidence of viremia but with a high level of serum antibodies.[28] The virus could not be isolated from numerous blood samples and somatic organ tissues but at necropsy the virus was sequestered in the testes. It hypothesized that infection occurred shortly before the blood-testes barrier became fully functional thus allowing the virus to enter the seminiferous tubules but excluding the ensuing high levels of antibody from the site.

Indirect contact

Airborne transmission. Indirect airborne transmission of the virus can occur in calves housed near a PI calf for one week at distances of 1.5 and 10 m – without having direct contact with a PI calf.[23] Infection can also occur in calves housed in a pen directly after removal of a PI calf, but without the pen being cleaned and disinfected.

Flies. The virus has been experimentally transmitted by allowing blood feeding flies to feed on a PI animal followed by feeding on BVDV-free seronegative recipients. The virus was isolated from some of the flies, and from the recipient animals which also seroconverted.[11]

Fomites. The BVDV has been transmitted from a PI animal to susceptible heifers which were examined per rectum using the same glove.[29] Reusing a hypodermic needle on susceptible animals 3 min after the needle had been used on a PI animal or reusing a nose tong within 3 min after it had been used on a PI animal could also transmit the infection. The virus can be spread by hypodermic needles used on vaccine bottles contaminated by the nasal discharge of PI calves.[23]

Risk factors

Animal risk factors

In general, young cattle are most susceptible to BVDV infection but adult cattle may develop severe disease if infected with the highly virulent genotypes of the virus. **Persistent infection can be established only** in approximately the first half of fetal life. Compared to many other pathogens, fetal survival following early intrauterine infection with non-cytopathic BVDV is common and can be as high as 70%. Unvaccinated animals, improperly vaccinated animals, or animals whose immune status has waned are most susceptible to infection and the potential for clinical disease. Vaccinated animals may be susceptible if field isolates of the virus are distinct from those used in the vaccine. PI animals are susceptible to the development of mucosal disease following superinfection with the cytopathic virus. They are also susceptible to other infectious diseases such as pneumonia.

Immune mechanisms

The literature on the immune response to the BVDV has been reviewed.[30] The interaction of the virus with both innate and adaptive immunity has been made much clearer.

Transient immunosuppression occurs in acutely infected animals. The virus infects cells pivotal in control of the innate and acquired immune response. The effects on the innate immune system have been examined in granulocytes, monocytes,

and natural killer cells. The virus infects cells of the innate immune system affecting the function of neutrophils, monocytes, macrophages, and dendritic cells. Neutrophils are impaired in microbicidal, chemotactic, and antibody-dependent cell-mediated cytotoxicity.

In vitro or in vivo infection with BVDV, either cytopathic or noncytopathic biotype, depresses various aspects of macrophage function which can adversely affect normal defense mechanisms of the lung which can facilitate bacterial colonization.[30] The effect of the different biotypes of the virus on interferon activity are variable.

In the acquired or adaptive immune response, BVDV infections have their major effect on thymic and follicular T-lymphocytes.[30] The effect on the number of circulating T-lymphocytes is strain dependent and varies from a mild to severe lymphopenia with highly virulent strains. The virus also affects T-helper lymphocyte and cytotoxic T-lymphocyte responses. BVDV infections have their major effect on follicular B-lymphocytes. The effect on the number of circulating B-lymphocytes varies but depletion of B-cells occurs in the lymphoid follicles of the lymph nodes with highly virulent NCP BVDV and in Peyer's patches with both mucosal disease and highly virulent BVDV infections.

The BVDV humoral antigens have been examined.[30] There are four major structural antigenic polypeptides. Glycoprotein E2 is the major glycoprotein and antigenic target for antibodies. E2 is highly antigenic and elicits the production of neutralizing antibodies in the host after infection or vaccination with live or killed vaccines. The ability of BVDV antibodies to protect against BVDV infection and the development of long-term virus infection is dependent on the virus strain and the level and isotype of antibodies produced. BVDV antibodies are indicators of the presence of a particular immune response rather than an indicator of a protective immune response. High levels of neutralizing antibodies prevent disease following homologous challenge. However, animals with neutralizing antibodies may develop viremia. Shedding of the virus in nasal secretions may occur in the presence of serum neutralizing antibodies.

In vitro cross protection studies with serum from cattle vaccinated with either modified live virus or inactivated vaccine demonstrated wide crossneutralization against 12 to 22 different BVDV strains but not field studies do not show this extensive crossneutralization.

The immune response in the calf is influenced by two factors: the development of active immunity and the decay of maternal or passive immunity. Young calves at 10 to 14 days of age seronegative to BVDV can develop a protective immune response following vaccination with MLV vaccine.[31,32] However, the presence of maternal antibody in calves interfered with the immune response and the animals were not protected from a challenge 4.5 months later. A predictive study estimated that calves must be 142 days of age to become seronegative for BVDV type 1 antibodies and 114 days for type2 antibodies.[33]

The immunology of BVDV persistence has been examined and reviewed.[30] The interaction of NCP BVDV in pregnant animals demonstrated that heifers carrying PI calves develop BVDV antibody titers 5 to 10 times higher than heifers carrying non-PI calves. The inability of NCP BVDV to induce IFN-alpha in the fetus is one of the major immune evasion mechanisms that allows BVDV to establish persistence. The major mechanism for persistence is tolerance of the $CD4^+$ cells. The specificity is very high, as PI animals can respond to homologous virus changes as small as a single amino acid. This explains why some PI animals can develop an antibody response to the homologous virus from the multiple BVDV quasispecies that will arise as the PI animals mature. Experimental infection of PI animals with antigenically related CP BVDV resulted in 50% developing mucosal disease. Those which did not develop mucosal disease had higher levels of circulating gamma-delta T-cells before the challenge with CP BVDV. Vaccination of BVDV type 1 b tolerant PI animals with vaccines containing either CP BVDV type 1 a or a NCP type 1 b and also *Mannheimia haemolytica* resulted in an BVDV antibody response only in those animals receiving vaccines containing the heterologous type 1a. All of the PI animals had lower *M. haemolytica* antibody response.

Following natural infection of seronegative immunocompetent cattle with most of the strains of BVDV which do not cause severe disease, there is a transient viremia; serum neutralizing antibodies develop within 2–3 weeks, peak at 8–10 weeks, and remain detectable for many months. The humoral immune response after natural BVDV infection in cattle is considered to be lifelong, and includes antibodies to a range of virus-encoded proteins, including the immunodominant surface glycoprotein gp53 and the highly immunogenic, non-structural, catalytic serine protease NS2-3.[34] Vaccination of naïve cattle with inactivated BVDV vaccines, results in virus neutralization peak titers at about 5 weeks after the second vaccination with a return to seronegativity within 12 weeks of vaccination.[35] This pattern of response is typical of inactivated vaccines. Experimentally and naturally infected animals may have moderate to high levels of serum neutralizing antibodies to the virus for three years after being infected.[34] The ability to cross the placenta of susceptible pregnant animals and cause a variety of fetal infections is the most important evidence of the success of the BVDV in the evasion of the host immune system.[30]

The high percentage of animals which are seropositive in the cattle population or in herds which have experienced the disease is due to the presence of PI animals in the herd. Vaccination of immunocompetent cattle with the live virus vaccines induces a broad spectrum and durable immunity. It is generally accepted that cattle respond to natural infections or vaccination with modified live-virus vaccines with a long-lasting immunity, and it is likely that the immune response includes cell-mediated immunity. Immunization with an inactivated virus vaccine may result in an only very short-lived immunity with a narrow antigenic spectrum. Existence of neutralizing antibodies is generally considered to be the most significant predictor of an effective immune response.[36] The presence of neutralizing antibodies in breeding females will protect the fetus against BVDV infection during pregnancy. Passively acquired antibodies, usually IgG, protect against nasopharyngeal shedding of the virus, and reduce viremia in challenge-inoculated calves. There is considerable antigenic variation among strains of the virus but there is also considerable cross-protection against heterotypic strains of the virus. Recent outbreaks of severe disease due to type II BVDV infections occurred primarily in herds which were not properly vaccinated. Current vaccines derived from type I strains appear to protect against infections with type II strains.[36]

Colostral antibody in calves lasts until 4–6 months depending on the initial level achieved after the ingestion of colostrums.[37] The half-life of the antibody is 21 d in normal calves but in persistently-infected calves titers decline more rapidly and by 4–8 weeks no antibodies may be detectable.

The predicted ages of dairy calves when colostrum-derived BVDV antibodies would no longer provide protection against disease or interfere with vaccination has examined.[33] About 50% of calves become seronegative for BVDV type 2 by 114 days of age. Rate of antibody decay was significantly associated with antibody titer at 1 to 3 days of age and with whether calves were congenitally infected with the virus. Three-month old calves were

predicted to have a mean BVDV type-1 antibody titer of 1:32 and mean BVDV type-2 antibody titer of 1:16. These data can be used to estimate the age by which a group of calves would be expected to lose passive protection.

Passively acquired antibodies can prevent clinical disease in experimentally inoculated calves at 2 to 5 weeks of age and protection continues to exist after the decay of passive antibodies which implies the existence of additional immune mechanisms other than serum antibodies.[38]

PI calves are infected during early fetal life and are born seronegative and immunotolerant to the specific strain of virus in their tissues. Most PI calves remain seronegative to specific virus but will respond immunologically to other pathogens.

The immunosuppressive effects of the BVDV are discussed later under that heading.

Environmental and management risk factors

The major management risk factors are the introduction of PI animals into a susceptible herd and the failure of a vaccination program or an inadequate vaccination program. In the recent outbreaks of severe disease in cattle herds in Ontario and Quebec, failure to vaccinate or failure to use the vaccine properly was a common historical finding.[39]

Pathogen risk factors

The bovine pestivirus is one of the most widespread and important virus infections in cattle throughout the world. While only one serotype of BVDV is recognized, isolates of these viruses vary genomically, antigenically and biotypically. These pathogen characteristics are important in the pathogenesis of the various diseases associated with the virus, the immune response of animals to different isolates of the virus, and the laboratory diagnosis.

Antigenic diversity. Positive-strand RNA viruses, like BVDV, are subject to genomic modifications that involve point mutations or recombination of RNA and thus are highly mutable.[40] The genetic diversity among isolates of the virus is characteristic of RNA viruses which exist in nature as quasispecies (a swarm of viral mutants). The high frequency of mutation, propensity for recombination, and selective pressure from immune responses stimulated by natural infection or vaccination has led to the creation of a large assortment of genetic and antigenic variants of the virus. The consequences of diversity include diversity of clinical disease, diagnostic difficulties, and vaccination failures.[2,40]

Several isolates have been identified that are antigenically related, but there may be antigenic variants that are immunologically distinct. In addition to antigenic diversity among strains, there are major molecular differences between the same strains. Differences in neutralizing antibody titers against specific isolates of BVDV are detectable in polyclonal serum from convalescent cattle. Monoclonal antibodies that have neutralizing activity differentiate BVD viruses into several groups. The antigenic variability of this virus may also explain the wide range of lesions and disease complexes which have been observed. Outbreaks of disease associated with the virus in commercial beef herds in Argentina were characterized by different clinical manifestations such as mucosal disease, enteritis and generalized dermatitis each caused by different genotypes of the virus.[41] This requires further virology and molecular studies which are necessary to improve diagnostic methods and formulate effective vaccines. The practical consequences of antigenic diversity are that neither natural infection nor vaccination can provide complete protection against most of the naturally occurring strains. There is also considerable cross-reactivity between isolates of the virus, which explains why properly vaccinated animals have considerable immunity.

Phylogenetic analysis of the viruses from persistently infected cattle on a number of farms in Sweden found a strict herd-specific clustering of the virus.[42]

Genotypes. The BVDV can be segregated into two subgroups termed BVDV I and BVDV II.[1,2] Type 2 isolates are those commonly used in vaccine production, diagnostic tests and research. Type II isolates are predominantly from fetal bovine sera, persistently infected calves born to dams vaccinated against BVDV, and cattle which have died from an acute form of BVDV termed 'hemorrhagic disease'. The epidemic of BVDV-associated disease in cattle in Quebec in 1993, associated with morbidity rates of up to 80% in some herds, and mortality rates up to 30%, was associated with isolates belonging to type 2.[43] Experimentally, type 2 BVDV induces the highest degree of viremia and more pronounced lesions and more extensive distribution of viral antigen compared to Type 1 BVDV which induced the lowest.[44,45]

Non-cytopathic and cytopathic BVD virus biotypes. Bovine viral diarrhea viruses exist as non-cytopathic or cytopathic biotypes.[1,2] Non-cytopathic biotypes produce little if any visible cytopathic change in cell cultures, and infected cells generally appear normal. Cytopathic biotypes, in contrast, cause cellular vacuolation and cell death. The biotypes are classified by their ability or lack of ability to cause overt cytopathic change in cell cultures without reference to their ability to cause disease in the animal. The two biotypes of BVDV are not distinguishable serologically. However, at the molecular level, cytopathic viruses produce one additional protein known as p80. There is strong evidence that cytopathic viruses are derived from non-cytopathic viruses by mutation. In most cases RNA recombination is responsible for the generation of the cytopathic viruses.[39] A second method is based on the introduction of a set of point mutations within the NS2 gene. The non-cytopathic virus is thus the natural 'wild-type' virus.

The BVDV is maintained in the environment by PI animals which were infected by non-cytopathic virus in utero from 42–125 d of gestation, when their immune system does not recognize the persisting virus as foreign and the animal is said to be immunotolerant. In general, PI animals lack neutralizing and non-neutralizing antibodies to the BVDV. The immune tolerance is highly specific, as these animals can mount an immune response to superinfections from antigenically dissimilar BVDV. PI animals with BVDV antibodies, other than calves with passively acquired colostral antibody, probably acquire them because they have encountered a BVDV, via natural exposure or vaccination that is dissimilar antigenically. There is no evidence that cytopathic viruses can produce persistent infections.

The non-cytopathic BVDV, the NADL-A strain, infects the bovine fetus following oronasal exposure of the pregnant dam, whereas the closely related cytopathic NADL-A are incapable of fetal infection.[46] The inability of the CP BVDV to establish fetal infections following oronasal exposure explains the preponderance of NCP BVDV in the cattle population. The extraordinary ability of the NCP BVDV to establish fetal infections leading to the birth of PI calves provides a robust viral reservoir. Shedding and horizontal transmission maintains a high degree of viral infections in cattle herds.

In some PI animals, viral antigen may be widespread in many tissues, including the cerebellum and other parts of the brain, spleen, kidney, lungs and parts of the intestine. Yet, the PI calf is often born normal and vigorous, and reaches adulthood due to the non-pathogenicity of the virus. But the virus continues to replicate lifelong in the tissues of these animals and virus is shed continually into the environment.

Mucosal disease is the result of PI animals being superinfected with a cytopathic virus that is antigenically similar to the persisting non-cytopathic virus and both types are isolated from cattle with mucosal disease. Because of the antigenic similarity of the viruses, it is thought that the immune system of the PI animal does

not recognize the cytopathic virus as foreign and thus fails to protect the animal from severe disease. The uncontrolled infection with cytopathic virus causes the severe lesions in mucosal disease.

Until recently, it was thought that postnatal infections of non-pregnant cattle with BVDV were benign, and only sometimes produced clinical disease. Following infection of immunocompetent animals, there was viremia, mild fever and diarrhea and recovery. The animals seroconverted, which accounted for the high percentage of normal animals in the cattle population which were serologically positive. In the late 1980s and early 1990s in the northeastern United States, Ontario, and Quebec, virulent BVD non-cytopathic viruses emerged which caused severe acute disease in both calves and adult cattle.[43] The majority of viral isolates were non-cytopathic and were typed as BVDV 2.[43] Thrombocytopenia and hemorrhagic disease associated with non-cytopathic BVDV has been recognized in adult dairy cattle and weaned beef calves. The disease occurred in veal calves in the same geographical area. In addition, highly virulent BVDV are causing severe diarrhea and death in adult cattle with clinical findings and lesions similar to those of acute mucosal disease. There are now reports of severe illness resembling acute mucosal disease in adult cattle in Britain, attributed to infections with non-cytopathic BVDV. Type 2 viruses have been isolated in British cattle.[47] Only non-cytopathic BVDV have been isolated from these animals. All of the available evidence suggests that these animals are immunocompetent and not persistently infected but they may be non-immune because of lack of vaccination or acquired antibody. Type 2 BVDV has been isolated in Slovakia which means that this genotype is now in central Europe.[48] Experimentally, differences in virulence between two non-cytopathic bovine viral diarrhea viruses in calves have been described. Type 2 BVDV strains have been isolated in Brazil affecting young cattle with severe gastrointestinal and respiratory disease.[49]

Antigenic similarity between the biotypes is a consistent finding in animals dying from fatal mucosal disease, which suggests that cytopathic strains may arise by mutation from non-cytopathic strains. The literature on the molecular biology of the virus has been reviewed.[6] Analysis of viral proteins with monoclonal antibodies has yielded detailed information about the antigenic composition of both structural and non-structural proteins.

Economic importance

In Canada, the BVDV disease complex is considered as one of four infectious diseases known as production limiting diseases in dairy herds.[50] The other three are Johne's disease, enzootic bovine leukosis, and neosporosis. These diseases are present on many Canadian dairy farms and have significant economic loss due to disease and lowered productivity. The direct production losses (milk loss, premature voluntary culling and reduced slaughter value, mortality loss, and abortion and reproductive loss) and treatment costs (veterinary services, medication cost, an extra farm labor cost) due to four infectious diseases in the Maritime provinces of Canada were determined.[51] Total annual costs for an average, infected, 50 cow herd in 1997 were: Johne's disease $2472; BVDV $2421; neosporosis $2304; enzootic bovine leukosis $806. The largest effect on costs was due to milk yield effects.

Calculation of the losses associated with BVD outbreaks in dairy herds vary widely.[52] In most cases the estimated losses only include those due to abortion and dead animals whereas indirect effects such as increasing the risk to other diseases are not included and therefore are considered as conservative estimates. The economic losses associated with outbreaks of the various forms BVDV infection in herds vary from a few thousand up to $100 000.[52] Most estimations of losses at the national level range from $10 and 40 million per million calvings. National eradication schemes as done in Scandinavian countries has been cost-effective.[52]

The economic losses associated with the introduction of the BVDV into a susceptible herd of pregnant cattle are due to abortion, congenital defects, stillbirths, increased neonatal mortality, increased occurrence of other infectious diseases, prenatal and postnatal growth retardation, suboptimal reproductive performance due to infertility, deaths from mucosal disease, and the early disposal of PI animals. Large losses due to fetal infection occur during the first 2–3 years following introduction of infection to a susceptible herd.[10] The economic losses are high when epidemics of fatal mucosal disease occur. While the incidence of mucosal disease is usually below 5%, it can be as high as 22%, which is costly because of veterinary visits, the submission of animals to the diagnostic laboratory, the death of animals, and the anxiety the epidemic creates in the mind of the producer who wonders if the entire herd will become affected.

Economic losses due to BVDV infection vary depending on the immune status of the population and the pathogenicity of the infecting virus strains. Introduction of the infection into a totally susceptible population invariably causes extensive losses until a state of equilibrium is reached. Infection with highly virulent strains cause severe clinical disease and death.

The magnitude of the losses in an infected herd may be expected to fluctuate. They may be relatively large with the occurrence of disease on an epidemic scale after initial horizontal transmission to non-immune pregnant cows, but considerably lower when endemic infection is maintained in the herd through the presence of viremic families. However, a further phase of high losses may occur should management allow heifers to reach breeding age without being exposed to infection or vaccinated. A linear programming model to estimate the economic impact of bovine viral diarrhea at the whole-farm level has been described.[53]

Using the output from an epidemiological model of an outbreak of BVD in a Scottish beef suckler herd, the estimated losses associated with an outbreak of BVD were 59 Euros mean loss per cow per annum without taking into account any financial premiums associated with disease-free status of the herd.[54] Two highly significant areas of loss often ignored in the field are immunosuppression and reproductive failure.[54]

PATHOGENESIS

The pathogenesis depends on multiple interactive factors. Host factors which influence the clinical outcome of BVDV infection include:

- Whether the host is immunocompetent or immunotolerant to the virus
- Age of the animal
- Transplacental infection and gestational age of the fetus
- Induction of immune tolerance in the fetus and the emergence of fetal immune competence at about 180 d of gestation
- Immune status (passively derived or actively derived from previous infection or vaccination)
- Presence of stressors. Genetic diversity among isolates may account for differences in the clinical response to infection. Differences in virulence between non-cytopathic isolates and between genotypes have been described.[7] Apart from those infected with the virus in utero, most cattle are immunocompetent to the virus and will successfully control a natural infection, develop antibodies and eliminate the virus so that latency and shedding does not occur.

The consequences of infection with the BVDV are divided into the following

different categories based on the status of the animal. **There is a spectrum of clinical responses based on the host factors and the virulence of the isolates involved.**

Immunocompetent non-pregnant cattle

Subclinical BVDV

This is a subacute infection in seronegative, immunocompetent cattle usually after colostral immunity has waned and it occurs in both sexes and any class of cattle. It is usually a clinically unrecognizable infection with the development of serum-neutralizing (SN) antibodies and elimination of the virus from normal immunocompetent animals. This accounts for the high percentage of normal animals that are serologically positive to the virus. A mild transient clinical disease characterized by inappetence for a few days, depression, fever, mild diarrhea, transient leukopenia and recovery in a few days may occasionally occur.

In some cases, outbreaks of diarrhea occur in animals ranging from 6 months to 1 year of age, characterized by high morbidity and low or no mortality. The most likely source of infection is PI animals in the herd.

Peracute bovine virus diarrhea

A severe and highly fatal form of bovine virus diarrhea associated with noncytopathic Type II isolates of the BVD virus is recognized.[43] Outbreaks were most common in dairy herds with inadequate vaccination programs and which recently introduced animals into the herd.

Thromboctyopenia and hemorrhagic syndrome

Thrombocytopenia and the hemorrhagic syndrome occurs in adult cattle and veal calves affected with the peracute form of BVDV infection.[55] Platelet counts are reduced to below 25 000/μL, and clinically are bloody diarrhea, petechial and ecchymotic hemorrhages of the sclera of the eyes, epistaxis and abnormal bleeding from injection sites. Hyphema may also occur. Thrombocytopenia due to destruction of platelets has been reproduced experimentally in young calves by inoculation of the BVDV. type 2 BVDV isolates are most commonly associated with the hemorrhagic syndrome. Experimentally, altered platelet function occurs in calves with type 2 BVDV isolates but not with type 1 BVDV strains.[56] In calves experimentally infected with ncp type 2 BVDV isolates of different virulence induced clinical signs and cytopenia which appeared to be proportional to infection severity.[57] The important virulence characteristics are duration of neutropenia, severity of thrombocytopenia, delayed increase in proliferating myeloid cells, and the presence of virus in bone marrow percursor cells. Infection of bone marrow megakaryocytes myeloid cells may also be involved. The North American hypervirulent type 2 BVDV induces severe thrombocytopenia, profuse diarrhea and pneumonia in all experimentally infected calves, while none of the European strains tested, all belonging to genotype 1, induced significant pathological signs even though isolated from cases of hemorrhagic syndrome.[57] It is suggested that induction of sporadic hemorrhagic syndrome by BVDV type 1 requires the presence of other cofactors.

Osteopetrosis, anemia, thrombocytopenia and bone marrow necrosis can occur in beef calves naturally infected with type 2 strains of the virus. Experimental infection of calves with the non-cytopathic virus causes thrombocytopenia whereas cytopathic virus did not.

Diarrhea of neonatal calves

The role of the virus causing diarrhea in calves under a few weeks of age is uncertain. Naturally occurring cases of acute neonatal diarrhea due to infection with the virus in immunocompetent calves under 6 weeks of age have been reported only rarely. Calves born with PI status may be unthrifty and be affected with chronic diarrhea and pneumonia as young calves. However, if the virus causes diarrhea in calves the pathogenesis is not clear. Calves born from cows free of the infection are not likely to be exposed to the infection. Immunocompetent dams provide colostral immunity to their calves, which should protect them against viremia due to BVDV for 6 months or longer.[59] Fatal enteritis has been reproduced experimentally by infecting colostrum-fed and colostrum-deprived neonatal calves with the virus.[7] In older colostrum-fed calves, experimental infection resulted in mild disease with rapid recovery. Experimentally, calves from 7–50 d of age with colostral virus neutralizing (VN) antibody titers below 256 or lower, developed a fever and systemic spread of the virus when challenged with the virus.[59] Calves with titers lower than 16 developed severe clinical disease characterized by fever, leukopenia, thrombocytopenia and diarrhea. The severity and duration of clinical signs decreased as titers of passively acquired viral neutralizing antibody increased. Another requirement for effective protection, is that the colostral antibody must be specific for the virulent virus. Experimentally, the intranasal inoculation of healthy BVDV-free calves 6 months of age with either the non-cytopathic or cytopathic BVDV results in a mild form of entercolitis, and mild follicular lymphocytic depletion.

Meningoencephalitis

A type 2 BVDV strain has been isolated from the brain tissue of 15-month-old heifer with neurological clinical findings and pathologic evidence of multifocal meningoencephalitis.[60] This suggests a neurovirulent strain of the virus.

Immunosuppression

There is evidence that postnatal BVDV infections of cattle can cause immunosuppression and enhance the development of other infectious diseases.[36] However, the evidence is controversial and must take into account the immune mechanisms of PI animals compared to animals with primary infections. There is circumstantial evidence that BVDV infections may be a major factor in multiple etiological diseases such as pneumonia and enteritis. Cytopathogenic isolates from genetic cluster 1 d of BVDV type 1 experimentally induced a primary respiratory disease in previously seronegative and immunocompetent calves.[61] All infected calves seroconverted and contact calves also developed a respiratory infection following exposure to infected calves.

The lesions of BVDV in cattle suggest immunosuppression because of lymphoid depletion and neutropenia.[36] Similarly, some of the modified live-BVDV vaccines are considered immunosuppressive in calves or may potentiate intercurrent infections.

In vitro evidence of immunosuppression. This indicates that the virus interferes with lymphocyte and macrophage function. BVDV infection of peripheral monocytes in vitro causes a significant decrease in their random locomotion and chemotactic response to a lymphokine. These abnormalities could impair the ability of the host to localize monocytes and macrophages in the vicinity of other infections. Neutrophils from BVDV-infected cattle may have their bactericidal, fungicidal and virucidal mechanisms impaired, which could increase susceptibility of BVDV-infected cattle to secondary infections. Alveolar macrophage function is reduced in calves experimentally infected by the respiratory route with a cytopathic biotype of the virus and with the other immunosuppressive attributes of the virus, could favor a predisposing role for the virus in the pathogenesis of respiratory disease in calves.[22]

Experimentally, the virus can:

- Alter neutrophil function[36]
- Impair immunoglobulin secretion by peripheral lymphocytes
- Allow the infectious bovine rhinotracheitis (IBR) virus to be more widely distributed in various tissues and infect tissue culture cells

- Cause the release of substances which can suppress the proliferative response of bovine mononuclear cells to blastogenic substances.

Impairment of neutrophil function in cattle persistently infected with the BVDV differs from impairment of neutrophil function in healthy cattle mounting an immune response to the infection.[36]

In vivo evidence of immunosuppression. Primary postnatal infections cause a transient reduction in the absolute number of T- and B-lymphocytes and in the percentage of T-lymphocytes. The evidence incriminating the virus as a predisposing pathogen in naturally occurring cases of bovine respiratory disease is largely circumstantial. The presence of the virus in the respiratory tract tissues of cattle affected with pneumonia is difficult to interpret. Several different viruses have been incriminated in the cause of acute bovine respiratory disease but experimental evidence to support their involvement has centered on the IBR and PI-3 viruses.

In outbreaks of respiratory disease in calves and adult cattle associated with multiple viral infections, the BVDV is often the most frequent viral agent. This could indicate that the virus is an important contributory pathogen in respiratory disease of cattle.

Experimentally the BVDV can facilitate the colonization of *P. haemolytica* in the lungs, resulting in severe pulmonary lesions.[36] Severe fibrinopurulent bronchopneumonia and pleuritis involving 40–75% of lung volume developed in calves experimentally inoculated sequentially with the BVDV and *P. haemolytica*. However, in some experiments the BVDV has no effect. BVDV may be present with other pathogens, such as those viruses or *Pasteurella* sp. and this may indicate that synergism occurs. However, it is also possible that the virus may be coincidentally present in some animals and have no adverse effect. It has been argued that there is no substantive evidence to implicate the BVDV, as it occurs in the benign form of the disease, in the pathogenesis of naturally occurring acute undifferentiated respiratory disease of cattle. Field observations suggest that following the introduction of BVDV infection into a susceptible herd, there may be an increased incidence of viral and bacterial pneumonia in the calves, which may continue for up to 2 years.

BVDV types 1 and 2, along with the PI-3 virus, and the BRSV, have been isolated from lung tissue in recently weaned beef calves with acute respiratory disease soon after arrival in the feedlot.[62] The BVDV1b was the predominant subtype identified in recently weaned beef calves affected with pneumonia due to *Mannheimia haemolytica* and *Pasteurella multocida*.[63]

Bovine viral diarrhea virus in the feedlot

There is epidemiological evidence that the BVDV may be one of the most economically important infectious pathogens of feedlot cattle.[64] The Academy of Veterinary Consultants has proposed that the beef and dairy cattle industries adopt measures to control and target eventual eradication of BVDV from North America.[65] The immunosuppressive potential of the virus or its synergistic effects with other pathogens are considered to be associated with bovine respiratory disease in feedlot cattle. Individual, unknown persistently infected animals which are purchased and introduced into the feedlot, serve as reservoirs of the virus for naïve cattle which are subsequently co-mingled in the feedlot. BVDV has been incriminated in bovine respiratory disease in feedlot cattle from which pathogens such *Mannheimia haemolytica, Mycoplasma bovis, Histophilus somni, infectious bovine rhinotracheitis virus*, have been isolated from lung lesions.[64] Chronic, antibiotic-resistant pneumonia, often with concurrent polyarthritis, occurs in feedlot cattle in western Canada. The prevalence of *M. bovis* and the BVDV in the tissues of affected animals suggests there may be synergism between the BVDV and *M. bovis*.[66]

There is considerable seroepidemiological evidence that the BVDV titers of feedlot cattle on arrival are associated with subsequent respiratory disease. Cattle arriving with a titer were at decreased risk of respiratory disease; those cattle which seroconverted after arrival were associated with increased risk of disease. Seroepidemiological studies of undifferentiated fever in recently weaned beef calves arriving in the feedlot indicates that animals arriving with a higher BVDV antibody titer were associated with a decreased risk of undifferentiated fever compared to those with lower levels on arrival.[67] Persistently-infected calves introduced into the feedlot usually are unthrifty at the time of weaning, and most will die during the feeding period.[10] Cross-sectional and cohort studies a large number of cattle arriving in a feedlot determined the prevalence and effect of PI animals on subsequent disease. The prevalence of PI cattle on arrival was 0.3%, 2.6% in chronically ill feedlot cattle, and 2.5% in dead cattle.[68] The risk of initial treatment for respiratory disease was 43% greater in cattle exposed to a PI animal compared with those not exposed to a PI animals. Overall, 15.9% of initial respiratory tract disease events were attributable to exposure to a PI animal.[68]

Primary BVDV infections occur in feedlot cattle which are not persistently-infected and may be the inapparent or subclinical form or the peracute form of the disease. The thrombocytopenic form of BVDV infection has also been described in feedlot cattle.[64]

Ovarian dysfunction

Ovarian dynamics may be changed in cattle infected with BVDV.[26] Ova exposed to the virus in vitro can have virus particles attached to the zona pellucida but the intact zona pellucida protects the developing embryonic cells from infection. However, following removal of the zona pellucida, cytopathic BVDV may have detrimental effects on survivability of blastocyts. Bovine follicular cells and oocytes are permissive to BVDV at all stages of follicular development[69] and there may be a transient fall in estradiol secretion following acute infection; both may reduce fertility. Infection during the critical period of growth of preovulatory follicles causes varying degrees of necrosis of the granulosa cells which can result in a spectrum of ovarian dysfunction including retarded follicular growth, delayed ovulation and anovulation.[70] Return to ovarian function following BVDV infection may take several months in some cases.

Immunocompetent pregnant cattle and fetal infections

The BVDV can cause significant early reproductive loss in non-immune pregnant cattle including fertilization failure, embryonic mortality and abortion.[71] In addition, infection of the fetus between 42 and 125 d of gestation may result in persistently-infected fetuses which are carried to term and the calf may be born alive and thrive normally or be unthrifty.

The experimental and clinical observations of the effects of the virus on early parts of the reproductive cycle are conflicting. The virus can be transmitted by natural service or artificial insemination with the possibility of fertilization failure or early embryonic mortality, which in turn, leads to repeat breeding. The principal determinant of the outcome of in utero infection in cattle is the age of the conceptus and fetus when infection occurs. The BVDV can cause reproductive failure in susceptible cattle during the following stages of the reproductive cycle:

1. **Infection prior to insemination.** Exposure of cattle to the virus during the estrus cycle prior to insemination can result in a decrease in conception rate due to failure of ovulation or delayed ovulation. BVDV has been associated with ovaritis in infertile heifers.[26] PI cows may have morphologic changes in their ovaries,

suggesting a reduction in normal ovarian activities. It is not known if similar findings occur in cows acutely infected with the virus.

2. **Insemination of cattle with semen containing bovine pestivirus.** The insemination of seronegative and virus-free heifers with BVDV-contaminated semen can result in poor conception rates initially, followed by normal conception following seroconversion to the virus, and the birth of normal calves with no evidence of infection with the virus.[26] Experimentally, the intrauterine infusion of the virus into cattle at the time of insemination has prevented conception and has been attributed to prevention of fertilization or simply recognized as an empty uterus at 5 weeks after breeding. It seems that intrauterine infection at the time of breeding may have some effects on the very early stages of reproduction, in addition to those that could be attributed to infection by other contact routes. Infection of susceptible cows either 9 d before or soon after insemination can result in a marked reduction in conception rates and significant embryo–fetal loss.[26]

The BVDV can be present in the semen of bulls either due to a persistent infection or an acute postnatal transient infection of the bull. The semen of an immunotolerant PI bull may be normal and the pregnancy rates of heifers bred by him may be normal thus the spermatozoa from an infected bull do not necessarily carry the virus. In other situations the quality of the semen of PI bulls may be abnormal. Acute infection of immunocompetent BVDV seronegative bulls with the virus can result in transient shedding of the virus in semen and to a marked deterioration of semen quality.[26] The amount of virus in the semen of acutely infected bulls is much less than that found in the semen of PI bulls. Experimental acute infection of bulls with the BVDV can result in shedding of the virus in raw, unprocessed, and diluted and extended semen during and after the end of the period of viremia.[26] The most productive sites of virus replication are in the seminal vehicles and prostate gland.[26]

The economic losses can be considerable if the virus is introduced into herds undertaking an embryo transfer and artificial insemination program.[26] Infection may occur following the use of infected semen for artificial insemination or through the use of infected bovine serum as a transport medium or diluent for embryo transfer.

3. **Infection during embryonic period: 0–45 d gestation.** Natural BVDV infection of seronegative heifers 4 days after insemination results in viremia between 8 and 17 d and a decrease in conception rate and pregnancy rate compared to uninfected heifers.[26] Infected heifers which fail to conceive return to estrus approximately 20 d later. Experimentally there is no indication of impairment of in vitro development of bovine embryos when they are exposed to the BVDV.[72] The zona pellucida appears to prevent the virus from gaining access to the embryonic cells.[73]

Fetal infections

4. **Infection during late embryonic–early fetal period: 45–125 d gestation.** Following the infection of a non-immune pregnant animal the virus is capable of crossing the placental barrier and invading the fetus. In experimental infection of pregnant heifers with a noncytopathic strain of the virus at 85 days of gestation, fetal infection can occur 14 days post-infection without preceding or simultaneous high concentration of the virus in uterus or placenta.[74] This supports the proposition that the passage of virus can occur via the vasculature and not via local cell-to-cell spread and that fetal infection can occur in the absence of significant levels of virus in the placenta.

Fetal infection can result in a wide spectrum of abnormalities from death of the fetus to congenital defects, to a persistent infection of the fetus until term and birth of a calf with lifelong infection without clinical signs. The results are mainly dependent on the stage of fetal development at which infection takes place. In general, the risk for the fetus is highest during early pregnancy. Infection of the fetus from 50–100 d of gestation may result in fetal death and expulsion of the fetus **(abortion)** from days to several months after fetal infection, or **mummification**. However, fetal survival following infection is common and can be as high as 70%.

Persistent viremia and mucosal disease. One of the most important effects of BVDV infections of the fetus is the development of PI animals. Following infection of the fetus with a non-cytopathic isolate of the virus from about 45–125 d of gestation, it will not develop serum virus-neutralizing antibodies and may be carried normally to term and be born with a persistent infection.[75] Mucosal disease occurs in a proportion of these, and only in these, PI animals. From birth to the time of clinical disease, which usually occurs between 6 and 24 months of age, and rarely up to 3 years of age, these animals are persistently viremic and specifically immunotolerant to the homologous strain of the persisting virus.[76] They may appear clinically normal or unthrifty and small for their age. Occasionally, PI cattle may survive and remain healthy for up to 5 years during which time they shed the virus in their mucous secretions and may be seropositive to a range of BVDV strains, including their own persisting strain. Calves with either transient or persistent infections with BVDV have lower than normal serum concentrations of thyroid hormones which may be associated with the retarded growth.[77] The heart girth of PI calves is smaller than controls. PI animals are infected only with the non-cytopathic biotype of the virus and they excrete large quantities of the virus into the environment and serve as the major source of the non-cytopathic virus in a herd.

During the postnatal period, superinfection with a cytopathic isolate of the virus may precipitate fatal clinical mucosal disease in these animals. PI calves have been reproduced experimentally by the inoculation of fetuses with a non-cytopathic isolate of the BVDV from 42–125 d of gestation. Fatal mucosal disease has been reproduced by the inoculation of persistently viremic specifically immunotolerant calves with a **homologous cytopathic isolate of the virus**. It is suggested that the cytopathic virus has a qualitative preference for intestinal lymphoid tissue in older postnatal calves, which may not be sufficiently developed for the cytopathic virus to establish a persistent viremia in the young fetus. Following the experimental production of mucosal disease, the cytopathic biotype of the virus can be found in lesions of the lymphoid tissue of the small and large intestines, in Peyer's patches, in intramural ganglia and in duodenal glands. Severe tissue damage is also related to the presence of the cytopathic virus. Both biotypes of the virus are present in animals which develop fatal mucosal disease.

It is now likely that mutation of the non-cytopathic virus to the cytopathic virus occurs within the animal rather than the introduction of a cytopathic virus from an infected animal introduced into the herd.[75] The non-cytopathic biotype could mutate to a cytopathic biotype by taking up cellular sequences during a recombination event. Once a homologous cytopathic virus has arisen, it can quickly spread to other PI animals within the same group and this may explain the rapid development of an outbreak of fatal mucosal disease. Recombination between a non-cytopathic BVDV-1 virus and a cytopathic BVDV-1 vaccine virus causing mucosal disease 3 months after vaccination has been described but is probably rare [78]

Typical mucosal disease occurs within 2–3 weeks following development of the antigenically homologous cytopathic virus in the PI animal. The affected cattle do not respond serologically to the homologous cytopathic virus. Superinfection with an antigenically heterologous cytopathic virus does not result in typical, but rather atypical, mucosal disease several months later, or not at all, and infected animal respond serologically to the heterologous cytopathic virus.[75]

The pathogenesis of the lesions of mucosal disease remains obscure.[75] The viral antigen can be detected in many tissues including:

- Lymph nodes
- Peyer's patches
- Ileum and lymphoid tissue in the proximal colon
- Palatine tonsils
- Spleen
- Bronchiolar epithelial cells
- Crypts of the intestinal mucosa
- Salivary glands
- Tongue
- Esophagus
- Skin.

The pathological changes which characterize the disease involve the integument and the epithelia of the respiratory and alimentary tracts as well as lymphoid tissues.

The basic lesion is a small vesicle ulcer which affects only epithelial cells. The erosions occur throughout the:

- Oral cavity
- Esophagus
- Forestomachs
- Abomasum
- Small intestine
- Cecum
- Colon.

Vascular injury leading to vasculitis is a characteristic feature of the disease due to the pestiviruses, which may explain the type and distribution of the lesions which occur in fatal mucosal disease. The vascular injury may be initiated by degenerative changes of the endothelial cells; this may lead to formation of a thrombus, which can detach and circulate as emboli, and resulting in generalized vasculitis.

Death from acute mucosal disease usually occurs within 2 weeks of the onset of clinical signs and both cytopathic and non-cytopathic isolates of the virus can be recovered from the tissues of affected cattle.[75]

Animals that are immunotolerant to the BVDV are immunocompetent to other antigens.[79] They develop neutralizing serotiters to the IBR and PI-3 viruses and agglutinating titers to *P. haemolytica*.[36] They will also produce VN antibody titers, following the administration of commercial live-BVDV vaccine, against the vaccine virus as well as other laboratory strains. Furthermore, in spite of this antibody formation, the original virus will persist.

Spontaneous insulin-dependent diabetes mellitus associated with persistent BVDV infection in young cattle has been described.[80,81] Lesions were present in the pancreatic islet cells.

5. **Infection during fetal period: 125–175 d gestation. Congenital defects.** Transplacental infection of the fetus approximately between 125–175 d of gestation can result in numerous congenital defects. This period of development corresponds to the final stages of organogenesis of the nervous system and the development of the fetal immune system, which can result in the generation of an inflammatory response to the virus.

   Cerebellar hypoplasia occurs and ocular abnormalities consist of retinal atrophy, optic neuritis, cataract, and microphthalmia with retinal dysplasia.[26] Calves with cerebellar hypoplasia are unable to stand and walk normally immediately after birth. Defects of the eyes result in varying degrees of blindness; the cataracts are obvious when they occur. Calves may be smaller than normal and have a curly hair coat.[26]

   Congenital morphological defects follow infections which occur somewhat later in gestation than do infections resulting in persistent viremia, and may be due in part to the emerging immunological capability. The presence of either persistent infection or antibody is variable.

6. **Infection during fetal period between 180 d gestation and term.** Infection of the fetus with the BVDV after approximately 150 d gestation results in a fully competent immune response and elimination of the virus. At birth, the fetus has antibody to the virus but is virus free. The effects of late-gestation infections are not well documented but abortions, stillbirths, and weak calves are reported.

Border disease

Border disease of sheep is associated with an in utero infection with a related pestivirus which cross-reacts with the BVDV.[18] Ewes are clinically normal, but affected newborn lambs have a hairy fleece, clonic rhythmic tremors and are unthrifty. Hypomyelination and abnormal cells occur in the central nervous system. The hairy birthcoats have been attributed to hypertrophy of primary follicles and medullation of wool fibers. Surviving lambs are also PI with the virus. The virus can be isolated in cell culture and detected by immunofluorescent staining of the peripheral leukocytes, cellular debris in urine and cerebrospinal fluid of lambs up to 1 year of age. Affected lambs, like calves, have no detectable serum-neutralizing antibody. Adult sheep, after recovery from infection by the virus, have no detectable virus in the leukocytes and have serum neutralizing antibodies. Pestivirus of sheep and cattle will readily infect the alternative species, both naturally and experimentally, but the role that such cross-reaction plays in causing the respective diseases has not been determined. More details are available under border disease.

Sheep are an excellent animal model for studying the pathogenesis of congenital BVDV-2 infection. Experimental infection of pregnant ewes with a Brazilian non-cytopathic BVDV-2 isolate results in many features of BVDV-1 infection of pregnant sheep and cattle.[82] Transplacental transmission of the virus to the fetuses is very efficient and results in fetal and perinatal deaths and the production of persistently-infected viremic lambs. The bovine pestivirus can spread to the ovine fetus within 4 days following intranasal inoculation of ewes in early pregnancy in the absence of maternal immunity.[83] An enteric disease characterized by diarrhea and unthriftiness in 6- to 12-month-old lambs, and death in 3 to 14 days was similar to mucosal disease in cattle.[84] At necropsy, the changes

resembled mucosal disease in cattle and the Border disease virus was isolated.

CLINICAL FINDINGS

Inapparent or subclinical infection (bovine virus diarrhea)

The most frequent form of BVDV infection in cattle is non-clinical or a mild disease of high morbidity and low case fatality characterized by a mild fever, leukopenia, inappetence and mild diarrhea followed by rapid recovery in a few days and the production of virus-neutralizing antibodies. This form occurs in immunocompetent seronegative cattle which are infected in postnatal life, accounting for the high proportion of adult animals which possess SN antibodies.[7] The literature commonly refers to this subclinical infection as bovine virus diarrhea. A similar infection, with no long-term consequences other than the development of antibody, can occur in fetuses over about 150–180 d gestation.

Acute mucosal disease

The acute mucosal form of the disease is characterized by the sudden onset of clinical disease in animals from 6–24 months of age which were infected during early fetal life. The morbidity is low and the case–fatality rate is high (over 90%). Within herds, 5–25% of animals in this age group may develop the disease over a period of several days or sporadic cases may occur over several weeks or months. Morbidity rates of 44% and case–fatality rates of 100% have been reported in isolated herds. Well-nourished, thrifty and previously clinically normal animals can be affected. In severe outbreaks, deaths from mucosal disease may account for only a proportion of the actual number of PI animals in the herd; some of the PI animals may have been culled, died for other reasons or were slaughtered. Following outbreaks of mucosal disease in a herd, there may be a rapid decline in the number of PI animals born in the subsequent few years because of spread of the infection and development of acquired immunity in the breeding females.

Affected animals are depressed, anorexic and drool saliva, wetting hair around the mouth. Fever 40–41°C (104–105°F), tachycardia and polypnea are common. Ruminal contractions are usually absent and a profuse and watery diarrhea occurs 2–4 d after the onset of clinical illness. The feces are foul smelling and may contain mucus and variable quantities of blood. Occasionally, small tags of fibrinous intestinal casts are present. Straining at defecation is common and the perineum is usually stained and smeared with feces.

Lesions of the oral cavity mucosa consist of discrete, shallow erosions which become confluent, resulting in large areas of necrotic epithelium becoming separated from the mucosa. These erosions occur:

- Inside the lips
- On the gums and dental pad
- On the posterior part of the hard palate
- At the commissures of the mouth
- On the tongue.

The entire oral cavity may have a 'cooked' appearance with the grayish colored necrotic epithelium covering the deep-pink, raw base. Similar lesions occur on the muzzle and may become confluent and covered with scabs and debris. Although the oral lesions are significant in the identification of the disease, they may be absent or difficult to see in up to 20% of the affected animals. Esophagoscopy has been used for visualization of the typical erosions of the mucosa of the esophagus.[85]

There is usually a mucopurulent nasal discharge associated with some minor erosions on the external nares and similar lesions in the pharynx. Lacrimation and corneal edema are sometimes observed. Lameness occurs in some animals and appears to be due to laminitis, coronitis and erosive lesions of the skin of the interdigital cleft, which commonly affect all four feet.

Dehydration and weakness are progressive and death occurs 5–7 d after the onset of signs. In peracute cases, which die within a few days after the onset of illness, the diarrhea may not be evident even though the intestines are distended with fluid. Presumably, there is paralytic ileus and the intestinal fluid is not moved down the intestinal tract.

Chronic mucosal disease

Some acute cases of mucosal disease do not die within the expected time of several days and become chronically ill. There may be intermittent bouts of:

- Diarrhea
- Inappetence
- Progressive emaciation
- Rough dry hair coat
- Chronic bloat
- Hoof deformities
- Chronic erosions in the oral cavity and on the skin.

Shallow erosive lesions covered with scabs can be found on the perineum, around the scrotum, preputial orifice and vulva, between the legs and at the skin–horn junction around the dew claws, in the interdigital cleft and at the heels, and there may be extensive scurfiness of the skin. The failure of these skin lesions to heal is an important clinical finding suggesting chronic mucosal disease. Chronic cases will sometimes survive for up to 18 months during which time they are unthrifty and ultimately die from chronic inanition.

The chronic clinical form of the disease described above must be distinguished from the unthrifty persistently viremic animal described next.

Unthrifty PI calves

Calves which are born PI may be smaller in body size than their contemporaries and may fail to grow normally. A curly haired coat is characteristic of some PI calves.[13,14] They may survive and appear unthrifty for several months or more until they develop fatal mucosal disease or some other infectious disease such as pneumonia. While these calves are stunted and unthrifty in appearance they do not have detectable clinical evidence of mucosal disease and they are seronegative to the BVDV. The birth of a high percentage of PI calves may result in a high incidence of fatal respiratory disease when the calves are 7–9 months of age.

Peracute bovine virus diarrhea

This is a severe form of the enteric form of the disease; it is often highly fatal, occurs in immunocompetent seronegative cattle in postnatal life and is associated with highly virulent isolates of the Type II virus.[21,39] Dairy herds, beef breeding herds and beef feedlots have been affected in the outbreaks recorded in Ontario,[43] Quebec and Pennsylvania (in the United States), and in the United Kingdom in the early 1990s. Inadequate biosecurity of animals imported into the herd, and the failure to vaccinate for BVDV or an inadequate BVDV vaccination program were common risk factors in affected herds. In affected herds, all ages of cattle are affected including calves, yearlings and adults. Mortality was highest in the young-age groups.

The most common complaint given by the owners was the presence of respiratory disease in affected animals. The outbreaks were slowly progressive and lasted for several weeks. Severe depression, respiratory distress, anorexia, profuse watery diarrhea, dysentery, conjunctivitis, fever up to 42.0°C, and agalactia in adult lactating dairy cows were common. Oral erosions were inconsistent. Abortion, usually in late gestation, was a common but inconsistent occurrence. Morbidity rates may be up to 40% and crude mortality rates may reach 25%. Many animals may die within a few days after the onset of clinical signs, and persistently infected calves were commonly born several months following the outbreaks.

Thrombocytopenia and hemorrhagic disease

Thrombocytopenia and hemorrhagic disease have been associated with BVDV

infection but whether or not the affected animals were previously PI is uncertain; only non-cytopathic BVDVs have been isolated.[55,58] Bloody diarrhea, petechial and ecchymotic hemorrhages of the visible mucosae, hyphema, epistaxis and prolonged bleeding from injection sites or insect bites have been observed. Cattle have platelet counts of less than 25 000/fl and clinically there is bloody diarrhea. Fever, diarrhea, rumen stasis and dehydration are also common. The case–fatality rate is approximately 25%; survivors can recover and thrive normally or remain unthrifty. A similar syndrome of thrombocytopenia has been described in weaned beef calves but the virus could not be isolated from affected calves.[64]

Reproductive failure and neonatal disease

The introduction of BVDV infection into groups of susceptible breeding females around the time of insemination and during the embryonic early- to mid-fetal period can result in **conception failure, increased embryonic mortality, fetal mummification, abortion, premature births, stillbirths, congenital defects, the birth of stunted weak calves, and the birth of PI calves which subsequently may develop mucosal disease**.[26] Following introduction of infection into a beef herd, losses may be insidious and characterized by reduced pregnancy rates, abortions, excessive postnatal calf losses and the premature culling of young cows because of their failure to wean a well-grown calf.[86] These losses including those due to mucosal disease in PI animals may continue for 2–4 years.[10] In dairy herds in Norway, time to first calving was increased by 14 to 16 days in the second year after seroconversion, with the effect restricted to young stock.[55] Studies in dairy herds in Switzerland indicate that infection with the virus during the first 45 days of gestation did not influence the rate of return to estrus.[87] By contrast, there was an increase in the abortion rate in mid-term gestation (days 46 to 210) while no such effect occurred in animals which seroconverted later stages of gestation. At least 7% of fetal deaths were attributable to infection with the virus.

A large scale assessment of the effect associated with BVDV infection on fertility of dairy cows in 6149 herds in France, found that the virus was associated with an increase in the risk of embryonic death and fetal death.[88]

Under field conditions, the effect of subclinical BVDV infection on subsequent dairy heifer fertility may be due to a complex interrelationship among multiple BVDV infections dependent on the type of and timing of infection relative to reproductive performance. A high BVDV type 2 antibody titer (1:4096) in dairy heifers at 10 months of age was associated with 32 more days to conceive, compared with a low titer (1:128).[89] Conversely, infection with BVDV by 5 to 6 months of age and a high BVDV type 2 titers one month before conception or breeding was associated with improved fertility. Heifers with evidence of congenital BVDV infection had lower fertility than non-infected heifers (15–42 days longer time-to-first AI), which depended on BVDV type 2 titers at 10 months of age.[89]

In beef herds, although abortions due to BVDV may occur at any time during gestation, typically several cows in a herd abort during a short period of time before the start of the calving season. At the beginning of the calving season, premature births and stillbirths occur. Some calves are born alive, take a few breaths and die. Weak calves are generally born during the first 2–4 weeks of the calving season. Affected calves are weak and flaccid at birth, and may appear small or normal. Death usually occurs within several hours despite intensive care and the feeding of colostrum. The prevalence of fetal infection with BVDV can be as high as 21%.[90] In a study of health and performance in 213 dairy herds in Sweden, the risks for clinical mastitis, retained placenta, and estrus-stimulating treatments were higher and the calving intervals were longer in those herds with an increasing or maintained high prevalence of BVDV antibody-positive cows.[91] A persistent BVDV infection in a dairy herd severely affects reproductive performance of heifers and cows at risk and can have an adverse effect on calf health over a period of time. In multiparous cows giving birth to PI calves there may be increased gestation lengths and retained placentas.

Congenital defects in calves

A number of congenital defects in calves are present[26] including: micro-encephalopathy, hydrocephalus, hydranencephaly, porencephaly, cerebellar hypoplasia, and hypomyelination. Cerebellar hypoplasia was the first recognized teratogenic effects of the virus and has been well documented. At birth, affected calves exhibit varying degrees of severity of ataxia, wide-based stance, stumbling gait, and falling backwards when attempting to walk. Mildly affected calves may survive if hand-fed and managed carefully but severely affected cases usually die or are euthanized. Other congenital defects include cataracts, microphthalmia, optic neuritis, retinal degeneration, thymic hypoplasia, hypotrichosis and alopecia, curly hair coat, hyena disease, deranged osteogenesis, mandibular brachygnathism, and growth retardation.

CLINICAL PATHOLOGY

The clinical diagnosis of mucosal disease is usually made on the basis of the presence of characteristic clinical and pathological findings. A severe leukopenia is characteristic of acute mucosal disease. The decrease is commonly to below 50% of normal and total leukocyte counts of 1000–3000/μL are common and may persist for weeks.

The laboratory diagnosis of BVDV infections relies on the isolation or detection of the virus or components and/or the demonstration of a serological response to the virus. The literature on the laboratory diagnosis of bovine virus infections has been reviewed.[92]

The type of samples to be submitted depends on the clinical and herd history, whether acute or persistent infections are suspected, and the vaccination history is needed to interpret serology.

Virus isolation

Despite recent advances in BVDV diagnostic science, culture and identification of the BVDV from clinical specimens remains the 'gold standard' diagnostic technique.[92] Strains of virus can be characterized in vitro as cytopathic or non-cytopathic biotypes. Cytopathic strains cause characteristic in vitro cell changes that are evident in inoculated cell cultures within 48 h. Most BVDV isolates obtained from field cases are non-cytopathic in cell culture. The isolated virus is recognized by identifying viral antigen in positive cell cultures by immunofluorescence or immunoenzyme staining. Virus isolation can be attempted by inoculation of nasopharyngeal and ocular swabs, semen, intestinal tissues, spleen, or most other tissues, or the buffy coat or serum of blood to cell cultures. In the live animal, the best sample for BVDV isolation is whole blood from which blood (buffy coat) cells are extracted and used as inoculum. Both cytopathic and non-cytopathic viruses have been isolated from the spleen or blood of individual cattle with mucosal disease. Whole blood or serum from PI animals is used for the isolation of the virus. The virus can be isolated successfully from blood which has been stored at room temperatures for up to 5 d before being processed.

For handling of large numbers of samples such as in a whole herd screening for PI animals, a microtiter virus isolation method, the immunoperoxidase monolayer assay (IPMA), using serum as the diagnostic specimen is widely used. The assay requires approximately 5–7 working days which allows for two passages to be completed. The main limitation of IPMA in PI

testing is its nonapplicability on sera from animals under 3 months of age in which maternal antibodies can interfere with growth of the virus in cell cultures. Some adult PI cattle have been IPMA negative on serum but virus can still be isolated from the buffy coat cells.[93] However, the prevalence of such animals is extremely low, and IIPMA is widely accepted as a reliable test for detecting PI cattle of 3 months or older.

The **indirect immunoperoxidase staining technique** is recommended for certification of BVDV-free bovine semen for artificial insemination units when the immunofluorescent test is not available.

Antigen detection

Immunohistochemistry. The BVDV antigen can be identified rapidly in tissue samples using immunohistochemical methods such as immunofluorescence or immunoenzyme staining in sections of frozen tissue.[92,94,95] A monoclonal antibody 15C5, which reacts with the E0 protein, has been shown to react broadly with most strains of BVDV and can be used to detect BVDV antigen in formalin-fixed, paraffin-embedded tissues. This has broad diagnostic and research applications. Using these methods, the identification of BVDV antigen in fixed tissues can be used as positive laboratory confirmation of BVDV infection without positive virus isolation and is useful when investigating disease syndromes such as enteric disease, respiratory tract disease and reproductive tract disease.

Skin biopsy. Immunohistochemical (IHC) staining for BVDV in formalin-fixed, paraffin embedded skin biopsies is an effective method for the diagnosis of persistently-infected cattle.[95] The technique is easy, accurate, and a less expensive antemortem diagnostic test for the detection of PI animals compared to virus isolation. It is suitable for herd screening because samples can be taken from cattle of any age, sample collection is simple, the samples are stable for transport and handling, and the test is both sensitive and specific for BVDV PI cattle. Positive IHC staining is most pronounced in the keratinocytes and in the hair follicle epithelium, hair matrix cells of the hair bulb, and the dermal papilla. IHC on skin samples is an effective method for screening neonatal calves for persistent infection.[97] Skin samples from cattle with acute BVDV infection or transient infection may stain positive with IHC but the distribution of staining is confined to the epidermal keratinocytes and follicular ostia, in contrast to PI animals with antigen-positive staining cells in all layers of the epidermis. Uncertain cases should be retested a few weeks after the first test.

A **monoclonal antigen-capture ELISA test** is capable of rapidly and accurately detecting pestivirus-specific antigens in peripheral blood leukocytes, blood clots, and tissue samples of PI cattle.[12,92,94] It has demonstrated good agreement with conventional virus isolation procedures and is suitable for routine diagnostic and certification testing. Monoclonal antibody techniques have also been used to detect the virus antigen in the central nervous system of PI cattle. Four commercially available ELISAs for the detection of BVDV antigen in the blood of PI cattle have been compared and are highly sensitive and specific and considered valuable in eradication programs when monitoring large numbers of animals.[98]

Herd Chek BVDV Antigen Serum Test Kit (IDEXX). This is an enzyme immunoassay for the detection of BVDV antigen in serum, plasma and whole blood. It is based on the detection of the E^{ms} (gp44-48) glycoprotein of the BVD virus. The E^{ms} protein is known to be secreted in serum, plasma or whole blood samples, which can be tested without laborious sample presentation. It has the following attributes: detects types 1 and 2 isolates; designed for identification of PI animals; can be used on serum, plasma or blood; no sample preparation; rapid testing method-quick (<2 hours) and overnight protocols; ready-to-use reagents; same substrate, wash and stop solution as other IDEXX BVDV family assays; compatible with xChek software.

Polymerase chain reaction (PCR) amplification

PCR amplification of an RNA genome involves the binding of specific DNA oligonucleotides to cDNA target sequences, resulting in amplification of size-specific DNA fragments that are detectable by gel elecrophoresis.

The PCR test is able to detect small amounts of viral nucleic-acid from samples of blood and tissues including preserved material.[92,94] Factors such as cost, technical expertise, equipment and automation, and RNA extraction methods are considerations in comparing with the standard methods of virus isolation. The PCR is 10–50 times more sensitive than the dot blot hybridization technique.

The reverse transcriptase-polymerase chain reaction (RT-PCR) amplification has gained widespread use as a routine diagnostic method for BVDV.[99] The high analytical sensitivity of the RT-PCR allows for pooling of specimens to reduce unit cost test. Pooling is especially applicable for persistent infection testing whereby a single positive specimen can still be detected in a pool of several dozen samples.

The RT-PCR test has been used to detect the presence of the BVDV in somatic cells from bulk milk samples.[100] Compared to existing methods, RT-PCR test showed 100% specificity and sensitivity in detecting PI lactating cattle in milking herds.

The reverse transcriptase-nested polymerase chain reaction (RT-nPCR) assay is a rapid and sensitive method to detect BVDV in extended semen samples.[101] While the prevalence of persistent testicular infection with the BVDV is very low, use of the rapid, sensitive RT-nPCR assay on extended semen samples can be used to ensure that the virus is not transmitted in cryopreserved semen.

Serology

Serological techniques are used to detect and measure antibodies. The **serum neutralization (SN) test** has been the standard test to determine the occurrence of a rising BVDV titer between acute and convalescent sera. The test carried out in microtiter plates, takes 3–5 d to complete and is relatively simple to interpret. A cytopathic virus is used in order to easily detect the neutralization of the virus. Because of the antigenic differences that exist within the BVD viruses, the reported antibody titer for a specific serum sample may vary greatly between laboratories depending on the strain of virus used in the test.

Following acute infection, serum antibody is first detectable at 2–3 weeks and peak antibody levels occur 8–10 weeks later. Following successful vaccination, SN titers will be high for many months.

PI animals are seronegative, except if they have colostral antibody for the first several weeks after birth. Antibodies are usually not detectable in the sera of most cattle with mucosal disease. The specific immune tolerance of the persisting virus is also not broken by the cytopathic virus if it is antigenically similar or identical to the persisting virus and results in fatal mucosal disease. PI cattle exposed to other isolates of cytopathic viruses that do not immediately induce mucosal disease may produce highly specific serum-neutralizing antibodies.[75]

Precolostral serum from calves infected in utero as immunocompetent fetuses may have virus-specific neutralizing antibodies and their demonstration is meaningful for the diagnosis of past infection. A short 3-day incubation serum neutralization test is now available which is an improvement over the 5-day test.

Antibody ELISA

ELISAs are available to measure serum antibodies to BVDV and are a rapid and economical alternative to the serum neutralization test. However, because of laboratory requirements for extensive

purification of antigen for the BVDV ELISA, it has not gained wide acceptance, even though ELISA titers correlate well with SN titers. The Cedist blocking ELISA for BVDV antibodies is a simple, rapid and reliable test for the detection of specific antibodies in serum, plasma, or bulk tank milk.[102] Test results correlate well with virus neutralization test results and may be useful for large-scale screening and eradication programs.

Using a blocking ELISA test, the level of antibodies in bulk milk is a valuable aid to indicate the infectious status of a dairy herd and for identifying herds suspected of harboring an active infection.[103] A herd with two consecutive bulk milk results four months apart of 60% (percentage inhibition) is more likely to have a very high percentage of infection. Testing of bulk tank milk for antibody using the ELISA can be used to determine the prevalence of dairy herds with antibodies, the relationships between the ELISA values in bulk milk and the location, milk yields and somatic cell counts of the herds, the annual incidence risk of new infections, and combined with the RT-PCR to detect viral RNA, to obtain an estimate of the herd prevalence of lactating persistently-infected animals.[104]

Use of laboratory tests in the herd

Because of the complex nature of BVDV infections, it is often difficult to obtain a definitive etiological diagnosis. The type of samples to be submitted to the laboratory and the interpretation of the results depends on clinical and herd history, and the vaccination status of the herd. The testing strategies to be used will depend on the specific disease history of the herd, the age of animals to be tested, the cost of the test, the needs of the owner of the herd, and the reasons for doing the testing.[92]

Acute infections

The diagnosis of acute infections must be done as early as 3 d after infection to 8–10 d after infection. A whole-blood sample is the best sample for virus isolation to identify acutely infected animals. In herd outbreaks, blood samples from normal animals should also be submitted. For serology, paired acute and convalescent samples collected 30 d apart are required to identify a four-fold increase in serum antibody titers. In abortions, the dam may have already seroconverted before the abortion and there may be no seroconversion between acute and convalescent sera. However, some aborted fetuses may be serologically positive, which confirms intrauterine infection in the later part of fetal life. If the dam is negative, BVDV can be ruled out as a cause of abortion. Calves born with congenital defects may have antibody but blood samples must be taken before the ingestion of colostrum.

Persistently infected animals

Persistently infected animals in a herd can be identified using any or a combination of the following testing procedures:

1. Collect whole blood from all animals in the herd including calves. An RT-PCR can be done on every sample which is very expensive but highly sensitive.[93] The test can be done pools of whole blood. The number of samples in the pool is a function of the sensitivity of the test a particular laboratory.
2. Collect serum on all animals over 3 months of age. Test younger calves as they age or use an alternative test. With serum testing colostral antibodies may interfere with the test or eliminating detectable virus from the fluid fraction of blood for some variable period of time. Virus in mononuclear cells is unaffected by colostral antibodies. Tests that can be done on serum include the microplate virus isolation, antigen-capture ELISA, or RT-PCR.
3. Collect skin biopsies (ear notches) from all animals in the herd including calves. The tests of choice are the IHC on formalin-fixed tissues or antigen-capture ELISA using fresh samples. Use of fresh tissue samples eliminates the need for formalin.
4. For dairy herds, collect composite milk samples from lactating cows and screen remainder of herd using procedure 1 or 3 above. Somatic cells from the milk are screened for the virus by RT-PCR or virus isolation.
5. Test calves as they are born with 1 or 3. If the producer has accurate calving records, the determination that the calf is not PI automatically defines the status of the dam as not being PI. Using this protocol, ongoing surveillance is maintained with a single test defining the status of two animals. For dairy herds, bull calves must be tested as well as the heifer calves to achieve a complete herd screening program.

Before the development of the PCR test, identification of PI animals depended on virus isolation from sequential samples collected 30 d apart. By testing 30 d apart, it is also possible to test for a four-fold increase in antibody titer should the first virus isolation be the result of an acute infection. In most cases, serum is adequate for virus isolation. In young calves under 3 months of age, colostral antibody may decrease the level of free virus in the serum and may result in a false-negative test. For this reason, the use of whole blood which allows isolation of the virus from the buffy coat is recommended in calves under 3 months of age.

Most PI animals are seronegative after the colostral immunity has waned, but they may develop SN antibodies to heterologous strains of the virus.

Prenatal diagnosis of persistent infection

Pregnant dams with PI fetuses (PI carriers) have exceptionally high antibody titers.[105,106] Testing pregnant dams can be used to identify and exclude PI carriers from livestock markets without completely blocking the trade with pregnant seropositive cattle. Testing is most reliable when done in late pregnancy (not before the 7th month of gestation). In dams carrying PI fetuses, the immune response was markedly higher (13 811 ± 1273 U ELISA) than those in dams carrying uninfected fetuses (2542 ± 588 U ELISA).[106]

The BVDV has also been detected in amniotic and/or allantoic fluid from both cattle and sheep with infected fetuses.[107] A blind puncture technique for collection of fetal fluid in late pregnancy is used to collect fetal fluid. The site of collection is over the right ventral abdominal wall approximately 10 cm cranial of the udder and 10 cm medial of the flank. A nested PCR test is used to amplify the viral RNA.

Herd screening

When a diagnosis of BVDV infection has been made in a herd, for example in the case of mucosal disease in a yearling, then further investigation for the detection of infected animals at the herd level is indicated. The most common strategy for herd screening is to submit serum samples from all animals over 3 months of age and whole blood samples from calves under 3 months of age. All animals in the herd should be tested. The samples may be tested for SN antibodies and/or the presence of the virus. Virus isolation using the microtiter immunoperoxidase test is the most common method used for large numbers of samples. Calves born for the next 9 months should also be tested to detect any additional PI animals that are born which may have been infected in utero at the time of the herd infection. The goal is to insure that no additional PI animals appear and that the maternal–fetal transmission cycle is broken. In herds in which cases of mucosal disease have been recognized, most of the normal animals will have high levels of SN titers.

During the 9–12 month period of testing, management strategies should ensure that all young stock and breeding females are not in contact with infected animals. However, in some countries where vaccines are unavailable, breeding females are placed in direct contact with persistently-infected animals prior to the

breeding season as a method of natural vaccination.

The serologic evaluation of unvaccinated heifers 6 to 12 months of age is an accurate method for identifying herds containing PI animals.[108] Both type 1 and type 2 BVDV antibody titers should be determined to prevent misclassification. The sensitivity and specificity of serologic evaluation of five heifers for identifying these herds were 66 and 100%, respectively, in herds which contained PI cattle. Pooled-sample testing using PCR/probe testing, can be used as a herd screening test for detection of BVDV persistently infected cattle.[109] However, random serologic testing of a small sample size of beef calves or cows did not satisfactorily predict the presence of a PI in a extensively managed beef cow-calf herd.[110] Whole-herd screening by use of one of the methods for detecting virus or viral antigens such as IHC of skin (ear notch) specimens is required for detection and elimination of animals persistently infected with BVDV in a herd.[110]

NECROPSY FINDINGS

Acute mucosal disease

The gross abnormalities are usually confined to the alimentary tract.[111] Characteristic shallow erosions with very little inflammation around them and with a raw, red base are present on the muzzle, in the mouth, and to a lesser extent in the pharynx, larynx and posterior nares. In the esophagus these erosions are linear in shape and lie in the direction of the folds of the esophageal mucosa. Erosive lesions may be present in the forestomachs, but are usually confined to the pillars of the rumen and the leaves of the omasum. Histologically, the lesions of the squamous mucosa of the alimentary tract begin with necrosis of individual cells and groups of cells. These foci enlarge and result in areas of necrosis with little or no inflammation of the lamina propria. If the necrotic foci are abraded, erosions and ulcers develop. In the abomasum, there is often a marked erythema of the mucosa accompanied by multiple submucosal hemorrhages and gross edema of the wall. Erosions and ulcers are common on the sides of the rugae of the abomasum and may be punctuate or more than 1 cm in diameter. The lesions have raised margins with a distinct pale halo. Histologically, there is epithelial necrosis of the deep parts of the glandular epithelium.

The mucosa of the small intestine often appears normal except for patchy or diffuse congestion and edema in some cases. In cases with a short clinical course it is common to find coagulated blood and fibrin overlying and outlining the mucosal aspect of Peyer's patches, which are also eroded. This is a very distinctive lesion which is paralleled only by rinderpest and sometimes bovine malignant catarrh. Severely affected Peyer's patches may be obvious through the serosa as red-black oval areas up to 10–12 cm long on the antimesenteric border of the intestine. In the large intestine the mucosa may be congested, often in a 'tiger stripe' pattern following colonic folds. The characteristic microscopic lesion in the intestinal mucosa is destruction of the epithelial lining of the crypts of Lieberkuhn. In Peyer's patches, there is lysis of the follicular lymphoid tissue, collapse of the lamina propria and often consequent downgrowth of cryptal epithelium. A less frequently noted microscopic finding is a vasculitis with fibrinoid necrosis of the media; this change may also be observed in a variety of other organs.

Non-alimentary tract lesions which may be seen on occasion include ulceration of the muzzle, interdigitial skin and conjunctival membranes. Growth arrest lines in the long bones may be seen and secondary bacterial bronchopneumonia can also occur.[14]

Peracute BVD

The lesions of this form of the infection are similar to acute mucosal disease and it is *usually not possible to differentiate between the two forms based on gross and histopathological findings.* There may be an absence of gross enteric lesions, especially in animals which die within 24 h after the onset of clinical signs and in calves less than 6 months of age.[6] In these peracute cases, pneumonia may be the most obvious lesion. Cases in which there is widespread hemorrhage attributable to **thrombocytopenia** may also be a form of peracute infection. Experimental infections with non-cytopathic type 2 strains have resulted in viral infection and necrosis of marrow precursor cells, especially megakaryocytes, as well as peripheral thrombocytopenia and leucopenia.[57]

Chronic mucosal disease

The necrotic epithelium may not be eroded by alimentary movements but instead remain in situ as slightly elevated, yellow, friable plaques, especially on the tongue and in the rumen. Subacute cases with a very prolonged course may show very few gross lesions in the mouth, some in the esophagus and no lesions in the stomachs and intestines. Peyer's patches may be difficult to locate in these animals and when examined histologically the lymphoid follicles are hypocellular.

In naturally occurring mucosal disease, non-cytopathic and cytopathic viruses can be found in the spleen, intestines and esophagus. Viral antigens are also detectable in mucosal cells of the nares, rumen, abomasum, gallbladder and salivary glands.[33] In PI animals, viral antigen can be found in myenteric ganglion cells, cells within crypts, mononuclear cells of gut-associated lymphoid tissue, and mononuclear cells of mesenteric lymph nodes. Viral antigen can also be found in adrenocortical cells, cerebral neurons, endocrine cells of the pituitary gland, thyroid follicles, and pancreatic islets.

The virus can be demonstrated in sections from formalin-fixed, paraffin-embedded tissue using various immunohistochemical techniques, including a method utilizing a monoclonal antibody[96] and the detection of viral antigen in formalin-fixed sections of skin collected at post mortem remains strongly indicative persistent infection. Such IHC techniques have also enabled the demonstration of viral antigen in association with specific lesions, such as within the Purkinje fibers and conduction system of the myocardium of a 4-month-old calf,[112] pancreatic islet cells of diabetic cattle[81] and various cells of the central nervous system in a heifer with meningoencephalitis.[60] This virus is also recognized as a cause of myocarditis[113] which may include a mild lymphoplasmacytic myocardial arteritis with or without fibrinoid necrosis. It must be remembered that the demonstration of BVDV antigen, or the isolation of the virus from necropsy material, does not mean that the animal suffered from mucosal disease or the peracute form of infection unless supportive lesions are observed. The virus is often found in animals dying as a consequence of other disease processes, such as pneumonia.[66,114] Confirmation of the presence of the virus is nevertheless significant. In terms of the individual animal, the virus may have caused a degree of immunosuppression. For the herd, the presence of circulating virus has important implications for the animals of breeding age.

Abortion

The pathological criteria for the diagnosis of BVDV as a cause of abortion have not been established.[85] Finding antibody in a fetus, as in an unsuckled neonate, indicates that intrauterine infection has occurred but its diagnostic significance in regard to the abortion is not clear. The recovery of virus from the fetus, or demonstration of viral antigen within fetal tissues is only suggestive of a diagnosis of pestiviral abortion. Recognized BVDV-associated congenital defects in calves, including cerebellar hypoplasia, cataracts, retinal degeneration and dysplasia, hypoplasia and neuritis of the optic nerves, and musculoskeletal deformities[52] are clear-cut indicators of compromised

fetal health. However, microscopic lesions associated with BVD abortion have been described in fetal eyelid, lung and myocardium yet at the present time their diagnostic value is still controversial.[87] Growth arrest lines are sometimes noted in the long bones of aborted fetuses infected with the BVDV and in utero the infection may also produce **osteopetrosis**. Osteopetrotic lesions, as well as anemia, thrombocytopenia and marrow necrosis have been described in 2-month-old beef calves infected with a non-cytopathic strain of BVDV.[115] Infection of megakaryocytes with non-cytopathic strains of BVDV has been confirmed experimentally.[116] Immunohistochemical analysis of cryostat sections of brain, skin, thyroid gland, abomasum and placenta is a rapid, sensitive method for detecting pestiviruses in bovine and ovine fetuses.[117] However, in most bovine fetuses, immunohistochemical testing of formalin-fixed, paraffin-embedded tissues is recommended, as the detection of BVDV antigen in formalin-fixed fetal tissues appears to be superior to traditional virus isolation techniques and fluorescent antibody techniques.[107]

Samples for confirmation of diagnosis

Histology – formalin-fixed oral/esophageal lesions, thymus, Peyer's patches, colon, abomasum, rumen, mesenteric lymph node, heart, ear. *Abortions* – eyelid, lung, thymus, spleen, intestine, liver, kidney, heart, brain, eye (LM, IHC)

Virology – thymus, thyroid, Peyer's patch, spleen, lung, mesenteric lymph node (ISO, FAT, PCR).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of diseases associated with BVDV infection must be considered according to the many different subclinical and clinical forms of the disease affecting many body systems. Each manifestation of clinical disease must be differentiated clinically and pathologically from similar diseases. The distinguishing features of each manifestation and the diseases they resemble are summarized here.

Mucosal disease. The differentiation of the diseases causing erosive lesions of the oral cavity mucosa can be perplexing both clinically and at necropsy. The similarity between them is the more important because rinderpest and foot-and-mouth disease are major plague diseases. The situation is so dangerous that if there is any doubt as to the identity of the disease under examination, samples should be submitted for laboratory examination.

There are many diseases of the alimentary tract of cattle which can be grouped according to the **presence or absence of oral lesions with or without diarrhea.** These have been summarized in Table 21.4. An erosive stomatitis and gastroenteritis are characteristic of **rinderpest, bovine virus diarrhea** and **bovine malignant catarrh.** The stomatitis and hyperemia are remarkably severe in bovine malignant catarrh along with a corneoscleral opacity, lymph node enlargement, hematuria and terminal encephalitis. **Rinderpest** is characterized by a high morbidity and mortality and knowledge of the disease in the area.

The **vesicular diseases**, foot and mouth disease and vesicular stomatitis, are characterized by the presence of vesicles on the tongue and buccal mucosa, teats and coronets and should be distinguishable from erosions.

Diseases causing diarrhea with no oral lesions include **winter dysentery, salmonellosis, Johne's disease, molybdenum poisoning (conditioned copper deficiency), parasitism (ostertagiasis), and arsenic poisoning.**

A definitive diagnosis depends on isolation of BVDV from the buffy coat or serum of blood and other tissues. Calves with congenital defects can be provisionally identified as bovine virus diarrhea by detection of specific antibodies in calves which have not sucked; this is not an easy specimen to obtain in beef cattle running at pasture.

Although bovine virus diarrhea is not a disease of the respiratory tract it is not uncommon for respiratory signs to be evident and confusion in diagnosis between it and infectious bovine rhinotracheitis (IBR), and even pneumonic pasteurellosis, does arise. It is necessary to depend on a careful clinical examination of oral and nasal mucosae to ensure that there are no mucosal lesions. It is also necessary to include bovine virus diarrhea in the list of diagnostic possibilities when considering the causes of abortion and stillbirth in cattle. Immunoglobulin determinations in aborted fetuses may be of diagnostic value.

The definitive diagnosis of **chronic mucosal disease** presents problems because often the affected animal has no specific neutralizing antibody because of immunosuppression or the inability to secrete antibody. A presumptive diagnosis can be made on the basis of the clinical characteristics of the acute disease, the absence of other lesions to account for the chronic form of the disease and the presence of pancytopenia. Virus isolation must be attempted along with detailed pathological examination.

- **Inapparent subclinical BVDV infection.** Common diseases include acute undifferentiated fever, acute undifferentiated bovine respiratory disease
- **Peracute bovine virus diarrhea.** Malignant catarrhal fever. Acute salmonellosis
- **Respiratory disease.** All common causes of bovine respiratory disease. See Table 18.5
- **Thrombocytopenia and hemorrhagic disease.** Malignant catarrhal fever. Moldy sweet clover poisoning
- **Unthrifty persistently infected calves.** General malnutrition. Copper deficiency. Chronic pneumonia
- **Reproductive failure.** Common causes of reproductive failure in dairy and beef cattle herds characterized by anestrus, failure to breed, unsatisfactory semen, failure of fertilization, embryonic mortality, fetal resorption, fetal mummification, abortion, stillbirth, and perinatal mortality
- **Neonatal calf diarrhea.** All common causes of acute undifferentiated diarrhea of calves under 30 days of age.
- **Congenital defects of calves.** All inherited defects of the nervous system of calves manifested clinically at birth, and diseases of uncertain etiology characterized by nervous system involvement

TREATMENT

There is no specific treatment for any of the diseases associated with the BVDV.

The prognosis for severe cases of mucosal disease with profuse watery diarrhea and marked oral lesions is unfavorable and slaughter for salvage or euthanasia should be considered. Animals with chronic BVD should be culled and destroyed.

CONTROL AND PREVENTION

The continued presence of the BVDV in the bovine population is not due to the lack of quality diagnostic tests. BVDV continues to cause significant economic losses because of failures in implementing a sound immunization program, failures in establishing herd-monitoring programs, and failures in developing effective biosecurity and biocontainment programs.

The ultimate goal of BVDV prevention and control measures is to eliminate the potential for the birth of calves persistently infected with the virus.[118] 'Persistence is the key'.

A combination of biosecurity, vaccination, and biocontainment strategies are necessary to control and prevent BVDV infection and its consequences in a herd and country.[119–121]

Biosecurity is the action taken to prevent the introduction of a disease agent into a herd or region. The goal of a BVDV biosecurity program is to prevent the introduction of the virus into the cattle herd and preventing transmission of the virus to susceptible animals. Biocontainment includes the strategies to control an already existing disease in a herd or region. The goal of biocontainment is to minimize the occurrence or severity of disease associated with BVDV infection, or to completely eliminate the virus from the herd. Biocontainment includes actions to increase host immunity, remove PI cattle from the herd, and prevent effective contact between BVDV-infected and BVDV-susceptible animals.

Table 21.4 Differential diagnosis of diseases of cattle in which there are either oral lesions or diarrhea alone or together in the same animal

Etiology	Epidemiology	Clinical findings	Clinical pathology and pathology	Response to treatment
Diseases with oral lesions and diarrhea *N.B.*: Rinderpest, mucosal disease and bovine malignant catarrh closely resemble each other clinically. The erosive stomatitis and gastroenteritis are common to all three and in outbreaks of mucosal disease or bovine malignant catarrh it may be impossible to distinguish either disease from rinderpest on clinical grounds. This necessitates notification of regulatory authorities and confirmation of the diagnosis by transmission tests or suitable laboratory tests.				
Rinderpest	Occurs most commonly in rinderpest areas, young and mature cattle, outbreaks common, rapid spread, up to 90% of susceptible cattle affected and mortality may reach 90%. Subacute and chronic forms occur in relatively resistant populations	Severe erosive stomatitis, bloodstained saliva, blepharospasm, high fever, severe diarrhea and dysentery, many cattle affected and many die	Marked leukopenia, lymphopenia, karyorrhexis (submit lymph nodes)	Nil
Bovine virus diarrhea (BVD) mucosal disease	Young cattle (8 months to 2 years) which have been persistently infected since fetal life. Low incidence (5%) of acute clinical disease but high case mortality. Sporadic cases of chronic form. Acute clinical disease rare in over 2 years of age	*Acute*: Diffuse erosive stomatitis, moderate fever for few days, profuse diarrhea and severe dehydration, skin lesions of coronets and interdigital clefts common, die in 7–10 days. *Chronic*: Inappetence, progressive loss of weight, scant soft feces, normal temperature, small rumen, intermittent bloat, chronic skin lesions which do not heal (especially interdigital space)	Leukopenia, neutropenia and lymphopenia. Seronegative. Blood for virus isolation to identify persistently infected animals. Nasal and fecal swabs. Erosions throughout gastro-intestinal tract	Almost all die
Peracute bovine virus diarrhea.	Affects young and adult immunocompetent cattle not vaccinated Type II BVDV. Morbidity up to 30%; case fatality rate up to 40%	Sudden onset of anorexia, respiratory distress, fever, anorexia, agalactia, diarrhea, dysentery, death in few days	Blood for virus isolation. Acute and convalescent sera. Lesions similar to mucosal disease	No treatment. High case fatality rate
Bovine malignant catarrh	Usually sporadic in animals. Affects mature and young animals. In North America outbreaks occur commonly after contact with sheep. In Africa outbreaks after contact with wildebeest. Varying forms:peracute, alimentary tract, head and eye, and mild	Severe diffuse intensely hyperemic, erosive stomatitis; persistent high fever, severe conjunctivitis, corneoscleral opacity, hematuria, enlarged lymph nodes, prominent skin lesions, horn coverings shed, terminal encephalitis, diarrhea and dysentery. Peracute die in 3 days, acute in 7–10 days and chronic form may live few weeks	Leukopenia and neutropenia early. Leukocytosis later. Transmission tests. Vasculitis	Nil
Alimentary tract form of infectious bovine rhinotracheitis	Outbreaks in newborn calves (25–50% morbidity). Recent herd introduction of carrier. Case mortality high (90–100%)	Small pin-point gray pustules on soft palate, rhinotracheitis, conjunctivitis, persistent mild fever, usually die from secondary tracheitis and pneumonia	Virus isolation from feces and nasal swabs. Lesions in turbinates, rumen and abomasum	Unlikely to respond
Diseases with oral lesions and no diarrhea				
Foot-and-mouth disease	High morbidity (100%), low mortality. Spreads quickly. Occurs in enzootic areas	High fever, severe dejection, painful stomatitis, ropey saliva, large vesicles in mouth, vesicles on teats and coronets, recovery in 3–5 days, deaths in myocardial form	Animal transmission tests. Serology rapid and accurate	No specific treatment
Vesicular stomatitis	In certain geographical areas, variable morbidity and mortality, insect-borne	Mild fever, anorexia, vesicles in oral cavity, less commonly on teats and feet. Recover in few days	Animal transmission tests. Serology rapid and accurate	Usually not indicated
Bluetongue	Clinical disease not common in cattle, insect vector, seasonal	Fever, stiffness, laminitis, coronitis, erosive lesions in oral cavity, edema of lips, drool saliva, nasal and ocular discharge, most cattle recover	Animal transmission tests. Serology rapid and accurate	No specific treatment
Bovine papular stomatitis	Worldwide, common in young cattle (2 weeks to 2 years), morbidity may reach 100%, nil mortality, may occur coincidentally with ostertagiasis	Round, dark red, raised papules on muzzle, in oral cavity. Heal in 4–7 days but remnants of lesion persist for several weeks. No significant effect on animal. In same age group as, and often associated with, severe ostertagiasis	Clinical diagnosis obvious	Spontaneous recovery

Table 21.4 (*Cont'd*) Differential diagnosis of diseases of cattle in which there are either oral lesions or diarrhea alone or together in the same animal

Etiology	Epidemiology	Clinical findings	Clinical pathology and pathology	Response to treatment
Necrotic stomatitis	Young calves. In dirty conditions or on dry rough pasture	Painful stomatitis with large deep necrotic foul-smelling ulcers on tongue, cheek and pharyngeal mucosa	Clinical diagnosis. Necrotic esophagitis	Respond in few days to parenteral antimicrobials
Diseases with diarrhea and no oral lesions (does not include diarrhea of calves)				
Salmonellosis	All ages. Outbreaks occur, case mortality may be high. Stress-induced. Contaminated feed supplies. Veal calves. Auction mart problem	*Acute*: High fever, diarrhea, dysentery, feces foul-smelling, fibrinous cast, abdominal pain, die in 24 to 48 hours. *Subacute* and *chronic*: diarrhea occurs too	Leukopenia, neutropenia. Fecal culture. Fibrinohemorrhagic enteritis	Favorable response to antimicrobials in early stage. Later many cases die or become chronically ill
Winter dysentery	Housed dairy cattle, winter, explosive outbreak, 100% morbidity, no mortality	*Acute* profuse watery diarrhea and dysentery, mild fever, inappetence and drop in milk yield for 24 hours, recover spontaneously Nil	Nil.	Recovery is spontaneous
Johne's disease	Single animal, 2 years and older, low morbidity, long course of several months. Chronic granulomatous-like enteritis	Chronic diarrhea, feces homogeneous, progressive loss of weight, normal temperature, appetite usually normal, hydration almost normal	Serological tests and culture feces	No response to treatment
Secondary copper deficiency (molybdenosis).	Enzootic to farm/area. Young cattle particularly. Marginally copper-deficient areas, especially spring	Chronic diarrhea without smell, mucus or blood. Black coats are gray-flecked; red coats are rusty yellow. Very thin	Plasma copper below 0.5 μg/mL, liver copper below 20 mg/kg DM	Excellent response in body weight and resolution of diarrhea to copper, by injection, drench, pasture dressing
Ostertagiasis.	Mostly young cattle 6 months to 2 years, can be adults. Many in group affected	Persistent diarrhea, without smell, mucus or blood. Decreased appetite, bottle jaw, very thin	May be heavy egg count, not if larvae inhibited but plasma pepsinogen level greater than 5000	Several treatments with fenbendazole. Good results. But lesion may be irreversible
Coccidiosis	Young cattle, when overcrowded, fed on ground, gather at water source	Subacute dysentery, mild fever, 2–3 days, appetite and hydration remain normal. About 20% develop 'nervous signs' and die	Feces for oocysts. Hemorrhagic cecitis and colitis	Self-limiting disease. Amprolium and sulfonamides
Arsenic poisoning	Access to arsenic	Sudden and rapid death. Acute abdominal pain, bellowing, regurgitation, diarrhea, muscular tremors, convulsions, die 4–8 hours after onset of signs	Feces and tissues and feed supplies or analysis. Edema of abomasum. Unfavorable response	Difficult to treat
Carbohydrate engorgement	One to several animals. History of access to grain	Anorexia, depression, ataxia, recumbency, dehydration, profuse, foul-smelling diarrhea, grain-kernels in feces, rumen static with fluid-splashing sounds, no rumen protozoal activity	Rumen pH below 5, lactic acidosis, hemoconcentration	Respond favorably if ruminal and systemic acidosis; may need rumen lavage or rumenotomy
Renal amyloidosis	Single animal, mature cow	Profuse chronic diarrhea, anasarca, inappetence, decreased milk production, enlarged kidney	Proteinuria, hypoalbuminemia, grossly enlarged kidneys	Nil
Ragwort (*Senecio jacobea*) poisoning	Group problem. Access to ragwort on pasture or ensiled as feed	Dull, depressed, dark diarrheic feces, severe straining and prolapse of rectum, staggering and ataxia, head pressing	Liver enzymes	
Squamous cell carcinoma of upper alimentary tract	Scotland and northeast England. Adult beef cows grazing marginal land infested with bracken, *Pteridium aquilinum*	Weight loss, diarrhea, bloat, feces are fibrous and watery	Tumors in oropharynx, esophagus, and rumen	

The most important subpopulation to protect from exposure it pregnant cattle, especially those in early gestation. The herd must be protected from direct exposure to cattle from other herds that may be BVDV transiently infected or persistently infected. Examples of these exposures include fenceline contact, movement to and from fairs and exhibitions, and new herd additions. Quarantine of new additions for 2 to 3 weeks after arrival prevents exposure of the native herd to unknown infected animals. Each addition must be tested for BVDV PI while in quarantine or before arrival so that these primary reservoirs of virus can be removed before they are commingled with the native herd. New additions that arrive pregnant

should not calve in the presence of pregnant cattle from the native herd. The calves born to pregnant new additions must be isolated from the native herd until their BVDV status can be determined.

Beef feedlots and heifer rearing operations present a special biosecurity challenge because the opportunity to introduce BVDV PI animals into these systems is increased by the frequent introduction of cattle usually co-mingled from multiple sources. The introduction of PI cattle may affect the health and performance of penmates and dairy and beef heifers exposed to BVDV during gestation at a heifer development facility may later give birth to PI calves in destination herds. BVDV exposure could be minimized in these facilities by testing all new arrivals and removing PI cattle during a quarantine period of 2 to 3 weeks and before entering into the primary facilities.

Elimination of BVDV PI cattle early in the production system, such as at the cow-calf herd level, benefit the cattle industry at subsequent points, such as at the feedlot and heifer development enterprises. Ideally, procurement of animals from biosecure herds and animals previously tested negative for BVDV PI would eliminate the risk for virus exposure from PI animals in these types of operations[65,122] (Figs 21.3–21.5).

In response to significant biologic and economic loss due to the bovine virus diarrhea complex, the Academy of Veterinary Consultants drafted and approved a position statement in 2001, The position states: *'The beef and dairy industries suffer loss due to effects of the bovine viral diarrhea virus infection. The highly mutable nature of the BVDV and the emergence of highly virulent strains of the BVDV contribute to limited success of present control programs. Also, persistently infected cattle are the primary source of infection and effective testing procedures are available to identify those infected carriers.[65] Therefore, it is the resolve of the Academy of Veterinary Consultants that the beef and dairy industries adopt measures to control and target eventual eradication of BVDV from North America.'* The 'BVD Decision/Management Guidelines for Beef Cattle Veterinarians' are available[65] and were adopted July 2003.

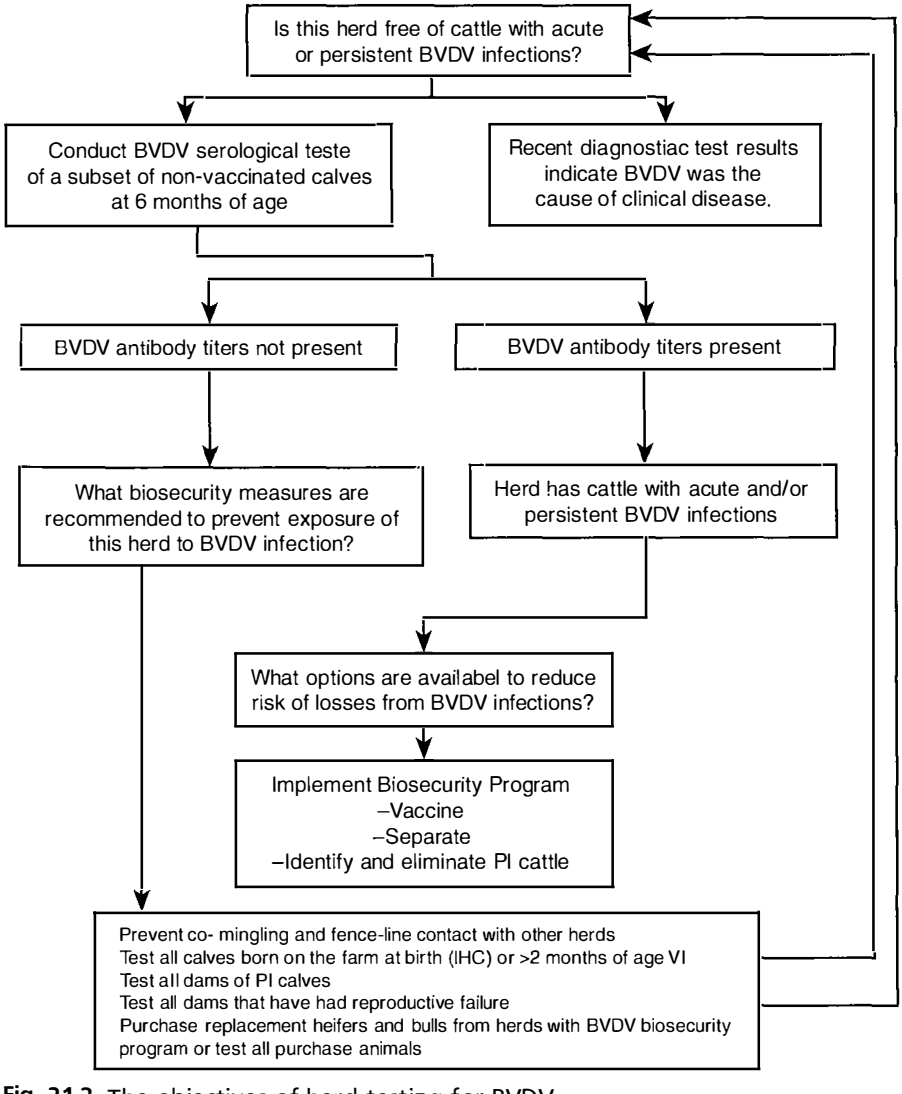

Fig. 21.3 The objectives of herd testing for BVDV.

The successful control and prevention of the bovine virus diarrhea–mucosal disease complex depends on:

- Identification and elimination of PI animals from the herd
- Prevention of introduction of infection into the herd (biosecurity)
- Immunization programs and biocontainment
- Eradication of the virus from herds.

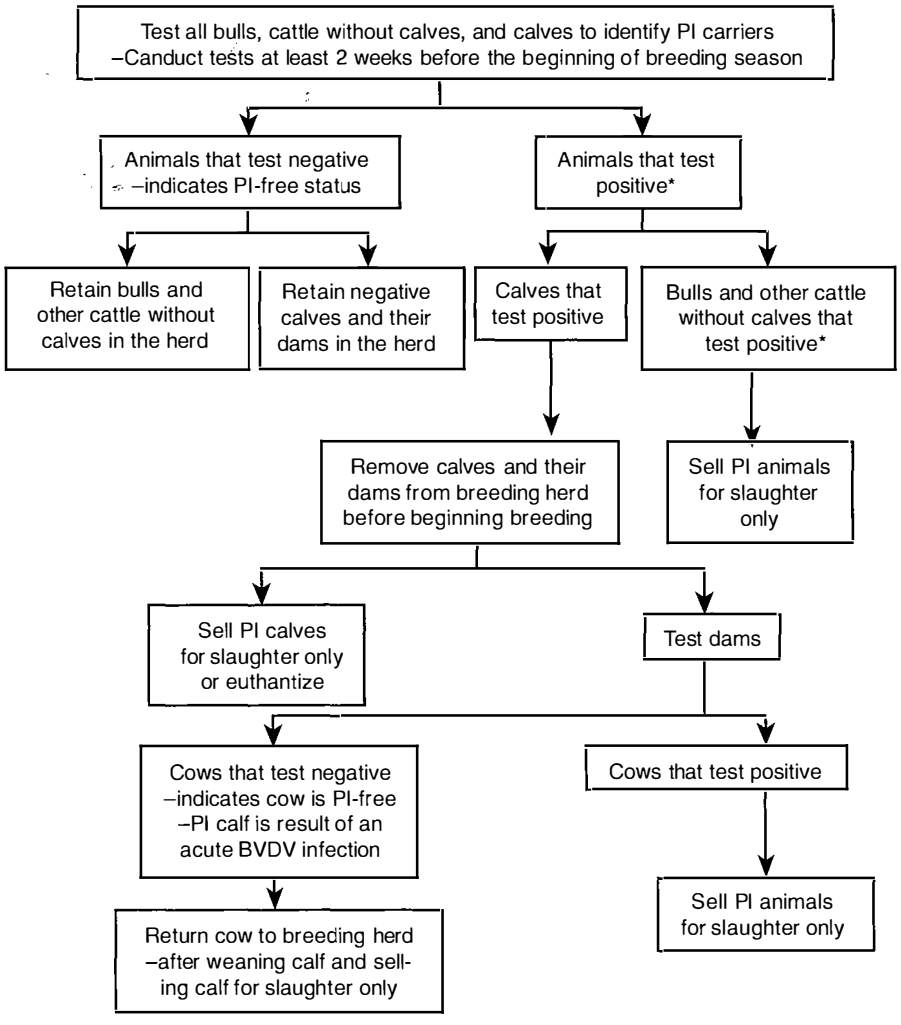
Identification and elimination of PI animals from the herd

Identification and elimination of PI cattle is an essential component of a control program in an infected herd.[119] Elimination of such animals, also known as **'clearance of infection'** will result in the improved health of the herd. The testing procedures to detect PI animals are described under **Clinical pathology.**

In beef herds, to prevent contact with pregnant cows, PI animals should be identified and removed prior to the start of the breeding season. All calves, all replacement heifers, all bulls, and all non-pregnant dams without calves must be tested for PI status. Any female pregnant at the time the herd is tested should be isolated from the breeding herd and kept isolated until her calf is tested and found to be negative. In most whole herd testing situations, IHC testing of skin samples is the test of choice because it can be accurately performed on animals of any age, and a single sample is all that is usually required.

Herd monitoring for PI animals can be done with pooled whole blood or serum samples for PCR testing. By pooling samples, the expense of screening herds with a low prevalence of PI animals is minimized. The PCR test is ideal for pooled sample testing for PI animals because it is sensitive enough to detect minute amounts of virus. A single PI animal can be detected in pools of 200 to 250 negative samples. If the initial pool is PCR-positive, it must be split and retested to differentiate viremic and non-viremic animals. Once the viremic animals are identified, they must be classified as transiently infected or PI with either a subsequent PCR, virus isolation, or IMPA test in three weeks, or using the IHC testing of a skin sample.[122] Using a two-test strategy to screen feeder calves with a PCR assay of pooled samples and the second of immunohistochemical testing only of those animals represented in pooled samples with positive assay, will reduce the cost of screening incoming feedlot cattle, compared with immunohistochemical testing of all animals.[123]

Following the successful detection and removal of PI animals, **'self-clearance'** or elimination of all evidence of the infection from the herd will occur. Transient infections which occur in non-pregnant animals



* After 30 days, retest animals that test positive to confirm PI status.
Animals that test negative in second test indicates that they were transiently infected when tested initially, and are therefore, non-PI

Fig. 21.4 Flow chart for testing a beef herd pre-breeding to detect and eliminate BVDV carrier cattle.

are inefficient in transmitting the virus. The main route of transmission within a herd is from PI animals to susceptible animals. The virus is commonly maintained in a herd when seronegative animals in early pregnancy are exposed to PI animals. Self-clearance is also more likely in small herds compared to large herds which commonly have rearing conditions which increase the risk of exposure of PI animals to susceptible seronegative animals in early pregnancy.

Prevention of introduction of infection into herd (biosecurity)

After identification and elimination of the PI animals, the new virus-free status of the herd should be maintained by a program of testing of all introduced animals for freedom from infection. In many cases introductions can be guaranteed, as far as is reasonably possible, to be free of infection by selecting animals which have convincing titers of serum antibody or are negative and are derived from a totally negative herd or stable subherd. According to the period over which the herd of origin has been established and has been free from introductions, its free status may be established by testing an adequate sample of animals. In other cases, antibody-negative introductions should be examined for virus or held for a period of on-property quarantine in close contact with a few serologically negative test animals which are subsequently examined for antibody.

Significant reproductive wastage due to BVDV infection can be prevented by the testing of introductions to the herd or management of the herd to maximize immunity prior to breeding. Cattle producers purchasing pregnant heifers to expand their herds must be aware of the possibility their fetuses may already be PI. At that stage there is no simple test which will identify those heifers which are pregnant with a PI fetus. Calves from these purchased heifers of unknown vaccination history should be considered infected until proven otherwise.

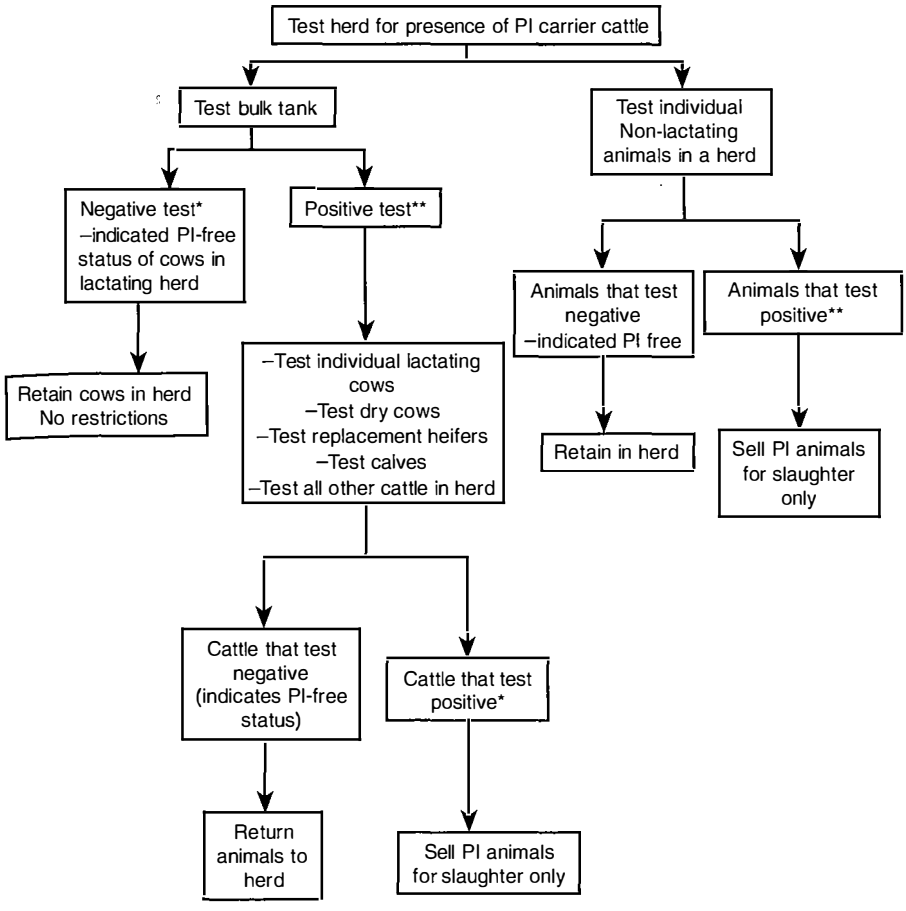
Artificial insemination units are now adopting comprehensive testing programs to identify PI bulls and immunocompetent bulls with the transient acute BVDV infection. PI bulls are detected by virus isolation from blood and not by serological testing. The semen of PI bulls will usually contain the virus but the quality of the semen will not necessarily be abnormal. This emphasizes the need for virological surveillance of breeding herds, and artificial insemination and embryo transfer centers. It is also important to prevent contamination by this virus of the fluids used for recovery, in vitro manipulation and transfer of bovine embryos.

Immunization programs and biocontainment

Infectious disease models demonstrate that after BVDV is eliminated, the cattle become increasingly susceptible to new infections and the possibility increases of an outbreak with severe clinical signs following a new BVDV exposure. Thus, in the absence of strict biosecurity, recurring patterns of reinfection with severe clinical signs are expected every few years following actions which eliminate the virus. In North America and other regions where BVDV is endemic and reexposure is likely, it remains prudent to continue vaccination after eliminating the virus from the herd.[119] Considering the high prevalence of BVDV infection that causes high economic losses, vaccination of cattle herds is certainly indicated, provided efficacious and safe vaccines are available. The literature on vaccination of cattle against bovine virus diarrhea[124] and the evolution of the BVDV vaccines have been reviewed.[120]

To be effective, vaccination against BVDV infection should protect against viremia, block infection of target cells of the reproductive and lymphatic systems to avoid occurrence of fetal infection and immunosuppression, respectively.[120] Antibodies present in the systemic circulation effectively neutralized viral infectivity, promote clearance of the virus, and prevent seeding of target organs such as the fetus. The goal of immunization is to stimulate both the B and T-cell arms of the immune systems. The B-cell arm of the immune response has the major responsibility for inactivating free virus. This is achieved primarily by immunoglobulin, which neutralizes the BVDV infectivity and secondarily aggregates BVDV and enhances clearance. Cell-mediated immunity, particularly $CD4^+$ cells, which is type-2 like is important for the resolution of acute infection with noncytopathic BVDV.

An important strategy for successful control is vaccination of the breeding female at least several weeks before



*A bulk milk sample may yield false positive results if; 10 to shedding in milk, 2) shedding virus in milk below detectabel levels, 3) viral RNA destroyed in milk, or 4) there are PCR inhibitors present.
** After 30 days, retest animals that test positive to confirm PI status. Animals that test negative in second test indicates that they were transiently infected when tested initially, and are therefore, non-PI.

Fig. 21.5 Flow chart for testing a dairy herd to detect and eliminate BVDV PI carrier cattle.

breeding.[119] **The vaccination program must be vigilant**. Experimental exposure of pubertal heifers to the virus 6 weeks before breeding stimulates the production of SN antibodies which protects against transplacental infection of the fetuses when the pregnant dams are challenged with homologous virus at 100 d of gestation. A high incidence of fetal death and intrauterine growth retardation occurs in the non-immune dams which are challenged with the virus. Thus the presence of maternal immunity protects the fetus from infection. These observations provide justification for the use of BVDV vaccines in females before breeding in an attempt to stimulate maternal immunity to provide protection for the fetus. However, immunization in terms of protecting the fetus may not be effective against strains which are different from that contained in the vaccine and the ultimate precaution is to prevent cows or heifers from making new contacts shortly before or during the first half of pregnancy. It should also be emphasized that control of the infection, and of mucosal disease, depends entirely on control among the breeding stock. Infection among non-breeders is of no long-term consequence, except insofar as they may be a source of infection to breeders and compromise the continuing freedom from infection of that group.

The emphasis must be on the vaccination of immunocompetent animals which do not have persistent viral infection. This should provide at least partial, if not complete, protection against fetal infection, abortion, stillbirth, intrauterine growth retardation, congenital defects and persistent viral infection of the newborn calf. The aim of a vaccination program is therefore to ensure that all breeding females have antibodies to the virus before they become pregnant. It is important to emphasize that vaccination should be done at least 3 weeks before breeding so that the breeding females become seropositive to the virus before conception. This is necessary regardless of the type of vaccine used. The suppliers of inactivated virus vaccines commonly promote their vaccines on the basis that they can be given safely to pregnant cows. While it is true that the inactivated virus vaccines are not fetopathogenic, only successful vaccination before conception will protect the fetus from natural infection for the entire gestational period.

BVDV vaccines

Both **modified live-virus** (**MLV**) and **inactivated-virus** vaccines are available. Currently there are many BVDV vaccines which are federally licensed in North America alone and all meet or exceed requirements for purity, potency and safety. These requirements ensure that vaccines elicit an immune response, are free from extraneous agents and do not induce disease.

The important variables to consider when selecting a vaccine for use in different production systems include: immune response; cross reactivity; fetal protection; duration of immunity; immunosuppression; reversion to virulence; effect of maternal antibody on immune responses, and purity.

The MLV vaccines usually contain a single strain of attenuated cytopathic BVDV. The strains most commonly are BVDV–NADL, BVDV–Singer and BVDV–C24C. Several inactivated vaccines contain both cytopathic and non-cytopathic strains of the virus.

MLV–BVDV vaccines

MLV–BVDV vaccines are attenuated so that replication of the virus is restricted, reducing both viral virulence and shedding of the vaccine virus by the vaccinate.[120] The **advantages** of MLV-BVDV vaccines are numerous and significant. Because antigen is amplified by replication in the animal, only small numbers of viral particles are necessary and thus the vaccines are inexpensive and only a single vaccination is necessary for adequate immunization. Within 3 weeks after vaccination, antibody is detectable which will neutralize an antigenically wide range of BVDV strains. It is suggested that the duration of antibody following vaccination is similar to that following natural infection which persists for more than 1 year and for several years in most cattle. However, in some cattle, detectable levels of neutralizing antibody which are distinct from the vaccine virus wane within 2 years. Immunization of calves with MLV vaccine is not inhibited by colostral antibody at titers up to 1:32. Assuming both a half-life of 21 d for colostral antibody and an initial viral neutralizing titer of 1:2000 after ingestion of colostrum, immunization should be successful in most calves that are 4–6 months of age. Revaccination before the first breeding is recommended.

The **disadvantages** of MLV vaccines include failure of immunization if the vaccine is not stored or handled properly. MLV

vaccines may cause disease if the vaccine virus regains virulence. Adventitious agents may also be present, which are capable of causing disease but these are rare. Outbreaks of mucosal disease sometimes occurred about 10–14 d following vaccination. The possible causes postulated for these so-called **vaccination breaks** included the following:

1. The vaccine virus may not have been sufficiently attenuated and actually caused the disease.
2. Calves may have been incubating the disease when vaccinated.
3. Some calves were immunologically tolerant because of infection during fetal life, allowing the vaccine virus to cause the disease. These vaccination breaks gave modified live vaccines a poor reputation and as a result they have not been used on a regular basis. Also, veterinarians began to make regular reports that the vaccine was ineffective against mucosal disease, but the reasons were unknown.
4. MLV vaccines are also potentially fetopathogenic and should not be used in pregnant cows. The possible effects of such vaccination are variable and dependent on the stage of gestation when the vaccination occurs. The vaccination of pregnant cattle, without detectable neutralizing antibodies to the virus, between 51 and 190 d of gestation with a commercial modified BVDV live vaccine can result in transplacental transmission of the vaccine virus and is not recommended. Abortions, congenital abnormalities of the nervous and musculoskeletal systems, perinatal deaths, growth retardation, persistent viral infection and the late onset of mucosal disease are all possible outcomes of vaccinating pregnant cattle with a MLV before 120 d of gestation. Between 120 and 190 d of gestation, the fetus can be expected to become immunocompetent and produce serum-neutralizing antibodies which can be detected in the precolostral serum of the calf at birth. The vaccination of pregnant cattle without neutralizing antibodies to the virus between 190 and 265 d of gestation will also result in transplacental transmission of the virus and the presence of neutralizing antibodies in the precolostral serum of calves at birth. Calves derived from dams vaccinated between 90 and 118 d of gestation may exhibit ataxia, torticollis, opisthotonos and/or growth retardation.

A **temperature-sensitive BVDV vaccine** will cause seroconversion, produces no clinical signs of disease or leukopenia and, when used experimentally in pregnant cows, does not result in fetal infection as evidenced by lack of virus isolation and absence of precolostral antibodies in the calves which are born healthy.

Immunosuppression and genetic recombination are other potential risks associated with MLV vaccines. Vaccine strains retain some immunosuppressive properties which may predispose animals to the development of other infectious diseases.

Inactivated BVDV vaccines

The disadvantages of the MLV vaccines stimulated the development of inactivated-virus vaccines.

The **advantages** of inactivated BVDV vaccines include:

- Lack of infectivity
- Unlikely presence of adventitious agents
- Absence of postvaccinal disease
- Safe use in pregnant animals.

The **disadvantages** of inactivated BVDV vaccines include:

- High cost of the vaccine
- Need for two vaccinations to achieve primary vaccination.

Adverse reactions at the site of vaccination may occur and are associated with the adjuvant in the vaccine. Maternal antibody may interfere with inactivated vaccines and calves may need to be revaccinated periodically from 6 months of age to just before breeding.

Combination vaccines

BVDV vaccines are often incorporated in multivalent vaccines to prevent respiratory diseases of cattle. These vaccines include combinations of the live and inactivated antigens of bovine herpes virus-1, parainfluenza-3 virus, bovine respiratory disease virus, and *Mannheimia haemolytica*, and *Histophilus somni* for administration all at the same vaccination time.

Immune response to BVDV vaccines

Efficacy of BVDV vaccines

It is not possible, on the basis of scientific information available, to recommend the use of one form of the vaccine over another. The lack of comparative efficacy data on different vaccines makes it difficult for veterinarians to recommend which vaccines to use. Ideally, the selection of vaccines should be based on efficacy data from controlled field trials. To be effective, vaccination against BVDV infection should protect against viremia to prevent dissemination of virus throughout the host following infection, to block infection of target cells of the reproductive and lymphatic systems to avoid fetal infection, and to prevent immunosuppression.

Fetal protection. The efficacy of BVDV vaccines for the prevention of fetal infection has been uncertain. Most BVDV vaccines have not been tested for efficacy against protection of infection of the fetus. The criteria used for the evaluation of BVDV vaccines have been assessment of the magnitude of the serological response, safety and purity following vaccination of young calves 4–6 months of age. There are a limited number of studies available which have critically evaluated the efficacy of BVDV vaccines to protect the fetus.

A single dose of a modified live NADL-derived BVDV type 1 vaccine will confer protection to dams and their fetuses against challenge exposure to heterologous BVDV type 1 virus.[124] A single dose of a modified live type 1 isolate of BVDV vaccine protects young calves vaccinated at 10–14 d of age and experimentally challenged intranasally 21 d later with a virulent type 2 isolate of BVDV.[31]

An inactivated vaccine has been evaluated to protect the fetus against experimental challenge.[126] Heifers were vaccinated two or three times before breeding and challenged when between 25 and 80 d of pregnancy. There was no evidence of a viremia in the vaccinated heifers after challenge, or of infection of the fetuses. The challenge strain of the virus was fetopathogenic in control unvaccinated animals. The inactivated vaccine also protected calves against experimental respiratory challenge with the same live strain of the virus as evaluated by an absence of nasal shedding, viremia and leukopenia in vaccinated calves.[127] Because of the high costs of evaluating BVDV vaccines for the protection of the bovine fetus, sheep can be used in initial BVDV vaccination-challenge experiments to evaluate vaccine efficacy, to determine optimal composition of the vaccine, protective dose, method of immunization and duration of protection.[128] A EU licensed inactivated BVDV vaccine provided fetal protection when heifers vaccinated 6 months previously were challenged at about 87 days of gestation by close contact with three persistently infected carrier heifers.[129] However, in another study heifers vaccinated with two inactivated vaccines were challenged at 82 days of gestation with three different Dutch field strains and all calves born from unvaccinated control animals were persistently infected. Calves born from dams vaccinated with two different inactivated BVDV vaccines were persistently infected in 78% and 60%, respectively.[130]

Vaccination of heifers with a non-cytopathic type 1 MLV BVDV vaccine prior to breeding protected fetuses from infection with a heterologous type 1 BVDV

challenge at 55 to 100 days of gestation.[131] A MLV vaccine containing types 1 and 2 BVDV provided fetal protection in 91% of heifers challenged with type 1 virus and 100% heifers challenged with type 2 virus at 60 to 90 days of gestation.[132] A commercial MLV combination vaccine containing type 1 and type 2 BVDV given prebreeding protected 100% of fetuses against type 1 BVDV infection and 95% of fetuses against type 2 BVDV infection.[133] In summary, there is considerable fetal protection provided by vaccines administered prior to breeding but the protection is not 100%.

Postnatal protection. Postnatal protection is necessary to provide immunity against the forms of BVDV infection which occur after birth including subclinical infection, acute infections, peracute bovine virus diarrhea, and immunosuppression associated with respiratory disease and other infections predisposed by the BVDV.

The pathogenesis of mucosal disease in PI animals explains why vaccination of calves at about 6 months of age may not provide protection in all cases. If mucosal disease is a late sequel to fetal infection, then some calves will be PI, specifically immunotolerant, and may eventually develop mucosal disease whether they respond to the vaccine virus or not. Thus they could become infected with clinical disease regardless of vaccination. Also, new cases of mucosal disease may occur in 5–10% of calves within a few weeks following vaccination with a live-virus vaccine. It has been postulated that this is likely to be due to the vaccine virus fulfilling the role of a superinfecting virus to precipitate clinical disease. However, it is a relatively infrequent occurrence and it did not occur on one occasion when known persistently viremic cattle were experimentally vaccinated with a cytopathic live-virus vaccine. Clinical disease was subsequently induced following experimental inoculation of persistently infected animals with a different cytopathic strain.

Cross-reactivity of vaccines

While there is considerable antigenic similarity between the biotypes of the virus and among isolates of either biotype, there is also antigenic diversity among the isolates and neutralizing antibodies induced by vaccination might not react with certain isolates of the virus. There are significant antigenic differences between certain strains of the virus. Vaccination of yearling cattle with either of two commercially available monovalent modified live BVD vaccines stimulated the production of SN antibodies to each of 10 cytopathic and 10 non-cytopathic isolates of the virus by one or more of the animals by 14 d after vaccination. No animal produced detectable SN antibodies to all 20 viruses.

The use of three different inactivated vaccines in cows stimulated the production of SN antibodies in all animals to each of 10 non-cytopathic and 10 cytopathic isolates of the virus when measured 14 d after the second vaccination. The reciprocals of SN antibody titers varied from 4–256, thus both the attenuated and inactivated vaccines induced antibodies to a broad range of BVD viruses.

The administration of a single dose of a MLV-BVDV vaccine to seronegative cattle, 3–8 years of age, induced an antibody response detectable for 18 months and the antibodies were able to cross-neutralize 12 antigenically diverse stains of the virus.[134] A commercial vaccines containing two inactivated strains of Type 1 BVDV, an inactivated strain of bovine herpesvirus-1, and modified-live strains of bovine respiratory syncytial virus and parainfluenza-3 virus provided virus neutralizing antibodies against 22 BVDV isolates in vaccinated calves.[135]

The sera from a beef herd of 5725 cows which had been vaccinated annually for 7 years with an inactivated vaccine was tested for SN antibodies against several isolates of cytopathic and non-cytopathic viruses.[136] Approximately 96% of the cattle did not have detectable antibody titers to the virus used in the vaccine but did have titers to other isolates of the virus. Non-cytopathic virus was isolated from three of 448 samples of sera which had titers of 64 or less against a particular isolate of the virus. The failure to detect antibody titers against certain isolates of the virus may have been due to antigenic diversity and natural decay of antibodies. Other possibilities include the use of excessive concentrations of virus in the neutralization test, and the failure of the inactivated vaccine to induce antibodies.

Cross protection of genotypes. The cross-protective efficacy of BVDV vaccines according to genotypes has been examined with contradictory results. In some cases, prior exposure of cattle to type 1 virus (as either a MLV or inactivated vaccine) does not always provide protection against infection with type 2 virus.[124] A type 1 vaccine provided protection against type 2 challenge.[137] A single vaccination with a type 1 strain was efficacious against a type 2 strain challenge for at least 231 days. Following challenge, most vaccinates were free of febrile response and leukopenia; in contrast challenge virus was isolated from all control calves. A commercial inactivated type 1 BVDV vaccine provided significant but not complete clinical and virological protection against challenge a heterologous type 2 strain of BVDV.[138] A single dose of MLV type 1 vaccine given at 10 to 14 days of age can protect susceptible calves from virulent type 2 BVDV for at least 4 months but high concentrations of BVDV-specific maternally derived antibodies can block the induction of the response.[32] Properly used vaccines containing type 1 virus may reduce the incidence and severity of disease associated with type 2 virus. The recent occurrence of type 2 virus in North America and the UK warrants a review of current laboratory testing to ensure adequate procedures are in place to detect type 2 virus, or antibody to it.[47]

Commercially available vaccines

Most of the commercially available vaccines for the BVDV are combined with other antigens such as the IBR, PI-3 and BRS viruses. In one study, the serological responses of beef calves 6–8 months of age were compared following vaccination with eight commercial vaccines containing IBR, PI-3, BRSV, and BVDV.[139] In general, the serological responses to the viruses varied among different commercial vaccines, between and within MLV and killed-virus vaccines, and routes of administration. All vaccinated calves developed higher antibody titers to the antigens than unvaccinated controls. The serological responses to the BVDV were low; only 20% of the calves had a four-fold seroconversion to the virus after two vaccinations. There are wide variations in onset of antibody responses and duration dependent on vaccine type and virus involved.[140] The possibility that multiple antigen vaccines may not contain sufficient antigenic mass of individual antigens to stimulate an adequate level of each specific antibody has not been explored.

Field observations indicate that vaccine potency may vary considerably. Some lots of vaccines have failed to induce seroconversion in calves following carefully controlled vaccination. Unpublished observations by some clinicians found a wide variation in the amount of virus present in vaccines, and manufacturing processes may vary considerably resulting in destruction of live virus. Thus part of the vaccination program may necessarily include evaluation of the vaccine by SN testing before and after vaccination, and submitting a sample of the vaccine to a laboratory for PCR testing or viral isolation.

The use of a multivalent MLV vaccine containing bovine herpes virus-1, BVDV1 and BVDV2 in beef calves in close contact with pregnant control cows did not result in any shedding of the viruses over a period of 103 days following vaccination.[141]

Strategies for BVDV vaccination programs

The strategies for effective vaccination against BVDV infections are: prevention of fetal infection, and control and prevention of postnatal infections.

Prevention of fetal infection in dairy and beef herds. With the present state of knowledge, a rational vaccination program to prevent fetal infection, for both beef-breeding herds and dairy herds, consists of vaccinating all calves at 4–6 months of age with an MLV vaccine. **The emphasis must be on immunization of the heifers before breeding so that the virus does not reach the fetus before 120 d of gestation.** All heifer replacements and cows are vaccinated 3–6 weeks before breeding with an MLV vaccine. Such vaccination of immunocompetent animals should result in a lifetime of protective immunity. However, to insure a level of herd immunity, all breeding females are revaccinated annually 3–6 weeks before breeding. All bulls are revaccinated annually.

Colostral immunity is present for up to 6 months of age in calves born from immune cows. Calves with even higher titers of colostral BVDV antibody may have an active response to vaccination but it is questionable whether this is of any useful purpose. If vaccination of the dam before conception is the vital part of the program, the vaccination of calves born from immune cows may be unnecessary until they approach breeding age.

Postnatal BVDV infections. There is currently no information available on the efficacy of the available BVDV vaccines for the control of the acute and peracute forms of the disease, including the hemorrhagic form, which have been recognized in the early 1990s and described earlier. A rational vaccination program for the control of the new BVDV infections occurring in immunocompetent animals would be similar to the earlier mentioned program in dairy and beef breeding herds. However, to date there is insufficient information based on clinical field trials or experimental challenge to make recommendations. However, in herds experiencing outbreaks of bovine virus diarrhea infection due to the highly virulent strains of the virus, it would seem rational to vaccinate all animals in the herd with the precaution that pregnant animals will have to be vaccinated with the inactivated virus vaccine.

Vaccination schedules

Strategic vaccination schedules for the various situations should emphasize induction of maximal protective responses to correspond with the stage of the production cycle when the risk and consequences of BVDV infections are greatest. This means into well-timed administration of vaccines prebreeding and preweaning to protect against reproductive losses and respiratory tract disease, respectively.[120] Recommendations for vaccination schedules for beef and dairy cattle herds are outlined here.

Beef cow–calf herd

All beef heifer replacements should be vaccinated with a MLV BVDV vaccine at least three weeks before breeding. Cows should be vaccinated annually, at least three before breeding.

Beef calves should be vaccinated at least three weeks before weaning in order to have maximum protection during subsequent periods of high risk at and after weaning.

Beef feedlot

There is no indication for vaccination of feedlot cattle for mucosal disease in PI animals. In a population of feedlot cattle originating from several sources, the PI animals will likely develop mucosal disease regardless of any BVDV vaccination. However, if there is a risk of the postnatal forms of BVDV such as the peracute BVD associated with the highly virulent strains of BVDV, the thrombocytopenia, and the immunosuppressive effects of benign BVDV infection, feedlot cattle should be vaccinated on arrival with a MLV vaccine. A review of bovine respiratory disease vaccine efficacy concluded that there were no reliable reports of field trials evaluating the clinical effects of BVDV vaccines in North American feedlot cattle.[64]

The use of multivalent MLV viral vaccines containing IBR, PI-3, BVDV, and BRSV have been evaluated in fall-placed, auction market derived, feedlot calves in western Canada.[142] Those cattle receiving the multivalent vaccine had significantly lower treatment rates than those in the univalent vaccine group. Cattle receiving the multivalent vaccine had higher carcass weights, weight gain, and average daily gain throughout the feeding period. There was a net economic advantage when the multivalent vaccine was used compared to a univalent IBR vaccine. However, it is not possible to determine which of the viral antigens of the vaccine were responsible for the advantage.

Dairy herd

Dairy heifer calves should be vaccinated at about 4 months of age, and with a booster at 5 to 6 months of age. MLV BVDV vaccines containing both type 1 and type 2 genotypes should be used.

Heifer replacements are vaccinated with a MLV BVDV vaccine about 45 days before being bred for the first time. This will boost serum neutralizing titers as much as possible to prevent fetal infection in the first 140 days of gestation. Dairy bulls are vaccinated at 8 to 12 months of age.

In situations where pneumonia in calves is associated with the BVDV, it is recommended that calves be vaccinated with an inactivated vaccine containing types 1a and 1b and type 2. Vaccination of dairy calves with a killed BVDV type 1 vaccine at 15 days of age, and MLV BVDV type 1 vaccine at 40 to 45 days of age provided an estimated overall protective effect of 48% against type 1 through 4 to 9 months of age.[143] However, the type 1 vaccine did not affect transmission of type 2 virus.

Recently calved cows are vaccinated with MLV BVDV vaccine at about 30 days before breeding. This will ensure high SN titers to prevent fetal infection, reduce transmission of homologous viruses to older fetuses thus preventing some congenital infections, abortions, and stillbirths; and to stimulate high colostral antibody titers so that calves receive a large mass of BVDV antibody.

Inactivated BVDV vaccines can be used in pregnant cows when BVDV abortions are occurring in the herd. Two vaccinations, 2 to 3 weeks apart beginning at the time of pregnancy diagnosis or one month before the estimated time of abortion. Vaccines containing both type 1 and type 2 genotype are recommended. Inactivated vaccines have also been used at drying off and 3 to 4 weeks later to enhance colostral antibody titers. The strains of the virus used in inactivated vaccines tend to be different than those used in MLV vaccines, so using inactivated products and alternating manufacturers may provide greater cross protection and cross-react with as many field strains as possible.

Booster vaccination of dairy cows 35 days after calving with a MLV BVDV vaccine greatly increased the antibody response compared with saline controls and cows vaccinated with inactivated vaccines containing BVDV, IBR, BRSV, and PI-3 viral antigens.[144]

Vaccination of pregnant cows and heifers with a multivalent vaccine containing MLV BHV-1, BVDV, PI-3, and BRSV during all three trimesters of pregnancy is safe provided the animals have been previously vaccinated prior to breeding with the same MLV components.[145]

Veal calves should be vaccinated after arrival with a MLV vaccine containing types 1 and 2 genotypes.

Current vaccination practices

Surveys of livestock producers indicate that about 40% of dairy producers in the United States do not vaccinate dairy heifers against BVDV, and the proportion of improperly vaccinated herds is unknown. In the 1993 outbreaks of peracute/acute forms of BVD in the United States and Canada, initial field reports indicated that affected herds had not been vaccinated or had been vaccinated improperly. When the inactivated vaccine was used, cattle had not been given the second dose of vaccine 2–4 weeks after the primary vaccination as recommended by the manufacturers.

Surveys in Pennsylvania indicate that many producers did not vaccinate all susceptible groups of cattle in the herd.[146] Many producers did not administer the secondary vaccination of the inactivated vaccine. While 82% of dairy producers indicated they routinely vaccinated their herds, only 27% of the herds were found to be adequately vaccinated. A survey of vaccination practices in Saskatchewan dairy herds indicated that only 34% of dairy herds were vaccinated against BVDV.[147] In addition, only 25% of producers who vaccinate follow the label directions for administering inactivated virus vaccines, and more specifically, the requirement to give two doses at the recommended interval. The three most common practices were annual vaccination (50%), vaccination prior to breeding (19.5%) and biannual vaccination (7.3%).

Producers may not vaccinate for a number of reasons:

1. They may not believe in the efficacy and cost-effectiveness of the vaccine
2. They may forget to vaccinate on a regular basis
3. They may have vaccinated only part of the herd when they thought the entire herd was vaccinated.

As dairy herds increase in size by importing animals from dispersed herds, the owners may not consider the necessity to vaccinate and significant numbers of animals in the herd are susceptible. Inadequate vaccination practices can be minimized by the veterinarian who can play an important role in clearly outlining in written form the vaccination program for individual herds. **Constant surveillance of the health management strategies are necessary. Good and reliable records which keep track of vaccinations, when they were given, which animals were vaccinated, and which vaccines were used, are vital.** Veterinarians must work with their clients to develop a specific vaccination and biosecurity protocol for each herd. The specific details of the vaccination program must be very clear (preferably in written form) including:

Which vaccines are to be used
How they should be used
Needles and syringes to be used
Dose of the vaccine
Route of administration
Which groups of animals should be vaccinated
Often booster doses are required.

Vaccine failures may occur because of improper use and storage of the vaccine. Syringes must be not washed with water or solutions containing chemicals or ingredients which will readily kill any live virus in the vaccine.

Veterinarians providing a health management service should also follow up their recommendations to insure client compliance. Veterinarians can also assist producers in developing methods to handle livestock and purchased replacements by designing protocols for importing animals into the herd.

Immunization without vaccines

In Australia, where no BVDV vaccine is available, controlled exposure of nonpregnant heifers to a PI carrier animal for 12 d on pasture resulted in seroconversion by about 20 d.[148] The subcutaneous, intranasal, or conjunctival inoculation of blood from PI animals into yearling heifers also resulted in seroconversion. Neither inoculation nor contact infection produced any clinical illness. The highest dilutions of serum at which seroconversion occurred were conjunctival undiluted; intranasal 101 and subcutaneous 105. With the subcutaneous route all heifers seroconverted at 103.

Eradication of BVDV infection without vaccination

The bovine virus diarrhea disease complex has been known since the late 1940s and early 1950s. Since about 1985, veterinarians have attempted to control the disease by culling PI animals, vaccination and certain levels of biosecurity. The diverse and vague clinical signs of the infection have made diagnosis difficult, costly and often elusive and frustrating. Several diagnostic tests have been developed to aid in diagnosis of BVDV infections, and most importantly for the detection of PI animals. Many vaccines have been developed since about 1960 which have reduced losses but not adequately enough because none of the vaccines will provide complete protection given the antigenic diversity of BVDV isolates. Anything less then absolute fetal protection by vaccines will still allow some PI animals to be present in the herd. Because of these difficulties and the high economic losses associated with BVDV, total eradication of the virus from herds of cattle and from countries has now become a reality.

A control and eradication program against BVDV without vaccination has been initiated in the Scandinavian countries with very promising results.[49] The literature on eradication of BVDV from cattle herds and countries has been reviewed.[121,149,150] The basic strategy, achievements, and status of 'test and cull' control programs implemented in Scandinavian countries and some other European countries are summarized here.

Concepts which are considered universal for developing control and eradication programs for BVDV include: (i) a herd is not infected until one or more persistent infections have been established; (ii) the high incidence of self-clearance will reduce the prevalence of BVDV infections in cattle populations even without active disease clearance, provided virus is not re-introduced; and (iii) BVDV cannot persist within a herd when contacts between PI animals and susceptible animals in early pregnancy do not occur.[149] Thus, the **'test and cull'** strategy is the major principle for effective eradication.

Before considering an eradication program in a region or country, an overall assessment of the economic importance of the BVDV disease complex should be estimated. Cost is an important factor in determining whether any measures against the infection should be initiated. Ideally, the overall cost of organized an eradication program should be administered by dairy and beef cattle associations, and animal health organizations. Diagnostic laboratories must be able to assist with the planning of sampling and providing information on the epidemiology of the infection to cattle producers in general, ensuring that known risk factors are identified and minimized.

Success of any eradication program is dependent on: making farmers aware of the improvements in animal health which can be gained from disease clearance as well as losses anticipated if disease occurs; making them realize that they themselves are responsible for the herd's biosecurity; and, providing them with the information to do so.

The components of an organized eradication program based on test and cull include several factors including the following:[121]

Population dynamics. In the region of concern, basic cattle population data such as average size of herd, production type (dairy, beef or others) and population density. Basic knowledge of the dynamics of the cattle industry such as movement patterns, restocking of breeding herds, vaccination programs, livestock markets, community pastures, and cattle exhibitions and sales

Prevalence monitoring. A comprehensive knowledge of the prevalence of infection is necessary to identify herds with an ongoing infection with BVDV as well as those susceptible to infection

Diagnostic tests. Reliable diagnostic tests for test and cull programs are necessary. The tests must be as sensitive and specific as possible, and they must be easy to use, reproducible, suitable for large-scale testing, and of reasonable cost

- **Education.** All those involved in the actual program must be fully informed with the latest information about the various aspects of the BVDV disease complex, including how the virus is transmitted, diagnostic testing and interpretation of results, and the strategies to be used
- **Biosecurity.** Biosecurity measures to prevent introduction of infection into virus free herds must be given high priority. This includes consideration of the possibilities of direct and indirect contact with infectious animals outside of the herd, and ensuring that all replacement animals imported into herd cleared of BVDV are kept in quarantine facilities until they (and their fetuses) are verified free of the virus. If different herds share common pastures, rules should be set out to ensure only BVDV free animals are allowed onto the pastures. Other means of reinfection are by biologic products, including semen, embryos, colostrum, vaccines, and other veterinary drugs, which should be verified free from BVDV before being used
- **Logistics.** The overall plans for sampling and testing should be outlined by an advisory body with access to all available data on epidemiology and laboratory capacity. On a regional basis, organization of testing, actions after initial screening of herds, as well as follow-up testing could be organized advantageously by a district veterinary officer or someone with similar experience in surveillance for notifiable animal diseases
- **Animal identification.** Individual animal identification with easily read ear tags or electronic identification is a strict requirement
- **Legislation.** Organized efforts to control BVD on a national level, requires legislation or some means of regulating free movement of potentially viremic animals. Initially, this may become a requirement of herd managers who have successfully cleared their animals of BVDV or livestock trade or breeding companies who want to promote a specific health status of their animals. At later stages, test certificates documenting freedom from BVDV issued by district veterinary officers engaged in organization of BVD control activities may evolve as mandatory documentation to allow access to livestock auctions, exhibitions, or communal grazing land.

Scandinavian countries

The Scandinavian countries, and some other regions in Europe, have successfully achieved control of BVDV without the use of vaccines, and are aiming towards complete eradication. The seroprevalences of BVDV in the cattle populations of these countries ranged from very high to low. In the early 1990s, the herd-level seroprevalence of BVDV in Denmark was 100%, 40% in Denmark, 25–40% in Norway, and 1% in Finland. No vaccines against BVDV have been licensed or used in the Scandinavian countries and thus the seroprevalence was due to natural infection.

The basic elements of the control programs in all Scandinavian countries are similar. Three different activity levels can be distinguished. The first level included screening of all cattle herds with the principal aim to identify BVDV-free herds and maintain them free. Bulk milk samples collected for milk quality monitoring or sera from a limited number of animals representing all epidemiologic groups of the herd are tested for antibodies to BVDV. Next they are scored to indicate freedom from BVDV or a more or less likely ongoing infection with BVDV. This population-wide screening is repeated annually to monitor the spread of BVDV or the effect of the control program. The second level of activity aims to identify herds with an active infection among those positive for BVDV, for example, those with one or more PI animals. By limiting the number of herds which require a full herd screening, efforts can be focused where needed and the overall cost minimized. The aim of the third level activity is to identify all PI individuals in herds with active infection. This involves an initial sampling of all cattle on the farm, plus a follow-up phase to test calves born to BVDV antibody positive dams which were pregnant during or shortly after the initial testing. After the herd clearing is completed, surveillance at level 2 serves to verify success and eventually to certify that cleared herds are free from BVDV, despite still strongly positive by level 1 antibody surveillance results.

Swedish program. Sweden launched its eradication program in 1993 as a voluntary scheme operated by farmers' organizations with advisory input from veterinary virologists in diagnostic laboratories and animal health authorities. Upon joining the scheme, herd owners agreed to comply with a set of rules restricting free movement of animals of unknown BVDV status, including specific hygienic measures designed to minimize the risk of virus spread. The farmers subscribing to scheme benefited by regular screening to determine BVDV status and by further guidelines on how to identify PI animals from BVDV-positive herds. When cleared of BVDV, herds were also certified as BVDV free and thus allowed farmers to engage in livestock trade with other affiliated herds. Except for some grants from the Board of Agriculture to assist with testing in high prevalence areas, the farmers covered the expenses of the control program. The program was designed for both dairy and beef herds. In dairy cattle herds, prevalence surveillance could easily be done using antibody testing of bulk milk samples. In beef cattle herds, the 'spot test' strategy was used with either pooled milk from primiparous cows or sera from young animals, using the same antibody ELISA as used for bulk milk. For virus detection, a cell culture-based microplate immunoperoxidase assay was used. By 2002, 99% of the beef herds were affiliated and the percentages of certified BVD-free dairy and beef herds had increased to 93 and 88%, respectively. To address the problem of nonsubscribing herds which acted as potential sources of reinfection, the Board of Agriculture declared in 2002, that subscription to the control program was mandatory for all cattle holdings. In 1998, it was predicted that Sweden would become free of BVDV in 2002 if the rate herd clearing continued as planned. Based on the currently available figures, it might be reasonable to assume that national BVDV free status can be achieved in 2004.

Norwegian program. Norway launched a nation wide control program in 1992 with the long term aim of eradication. Most cattle were dairy production herds. Soon after the program was begun, BVD was designated a notifiable disease by the Animal Health Authority. This included legislative power to impose movement restrictions on cattle from infected herds to limit further spread of BVD as much as possible. The diagnostic activities included annual bulk milk antibody testing of dairy herds and spot test serology of beef herds with both sample categories analyzed by ELISA. Herds with high bulk milk antibody levels were selected for further testing of milk from primiparous cows or sera from young animals. Herds with antibody positive second-level samples were considered infected, and movement restrictions were imposed. Samples negative for or with low levels of antibodies to BVDV were tested for BVDV antigen by ELISA. Calves born to antibody-positive dams in recently cleared were not sampled for antigen testing until they reached 3 months of age to avoid analytic interference of maternal antibodies.

The cost of surveillance testing at levels 1 and 2 was covered by the control

scheme, whereas the cost of sampling and testing to clear individual herds for BVDV was paid for by the farmers. Remarkable progress was made and eradication is expected in 2004.

Danish program. In Denmark, the high prevalence of infection, the animal density and the structure and management of cattle herds required a specific approach but using the same principles outlined above. A nation-wide control program was begun in 1994. Participation initially was voluntary but since 1996, legislation was introduced to prohibiting transportation of viremic animals. By early 1999, 9% of the dairy and 5% of the beef herds were still registered with PI status. These were attributed to reinfection of previously cleared herds, in part due to non-compliance with biosecurity recommendations on how to avoid infection. There was no legislative requirement of for owners of herds with PI status to get them cleared.

Finnish program. In Finland, the herd seroprevalence of BVDV infection has always been much lower at about 1%. In 1999, a voluntary control and eradication program was begun. Bulk milk samples from dairy cattle herds were tested by ELISA, and sera from beef cows tested by microneutralization. Between 1994 and 1997, the prevalence of BVD positive herds declined from 1% to 0.4% of dairy herds, and from 30% to 3.2% in beef herds. The prevalence continued to drop but remained at a low level analogous to the tailing pattern also seen in antibody prevalence in Scandinavian countries. The program was not mandatory and some farmers did not join.

United Kingdom. In 1999, in the UK, the cattle industry established Cattle Health Certification Standards (Checs) as a non-trading organization to promote and regulate voluntary schemes for the control of BVDV and other pathogens. The basis is the identification and removal of PI animals from herds, combined with changes in husbandry procedures to prevent infection from being reintroduced. There are three programs, allowing the farmer to work with the veterinarian to formulate a BVDV health strategy to meet the particular needs of that farm. The Accreditation Program demonstrates the herd is free from BVDV, to maintain freedom from the virus, and to allow the sale of animals as accredited free of the virus. In the screening and eradication program the objective is to implement a control program to reduce the detrimental effects on the herd productivity associated with the BVDV and to allow sale of animals of known status. The program applies where there is already evidence of recent BVDV infection in the herd or where positive results have been found in the course of an accreditation program. In the Vaccination Monitored Free Program the objective is to control BVDV infection through vaccination of the breeding herd and, by regular monitoring of young animals, to demonstrate that the control is effective and exposure of young animals to the virus has not occurred. The goal is to allow the sale of animals that are accredited as being from a vaccinated herd and monitored free of active BVDV infection. This program is considered appropriate for commercial herds selling animals for finishing. The status of these herds is lower than that of BVDV Accredited Herds.

Shetland Islands. A scheme to control and eradicate BVDV was initiated in 1994 in the Shetland Islands.[151] Over a three-period every bovine animal on the islands was blood-sampled and laboratory tested using Mab-based ELISAs for BVD virus antibody and antigen detection for evidence of disease. Virus positive cattle were culled from infected herds and compensation was paid as part of the control program. The pilot scheme indicated that it is possible to control and eradicate BVDV in herds in a defined geographical area. If pregnant replacement breeding stock are purchased and imported into a herd, even if they may be antibody positive and virus negative, they may be carriers of persistently-infected fetuses, and their calves when born must be tested before colostrum ingestion for persistent infection and culled if positive.

Continental Europe. No countrywide BVDV control schemes involving entire cattle populations have been launched on the European mainland. There is some interest in control of the disease complex using the test and cull procedures in individual herds, in groups of herds supervised by animal health organizations, or even regions within certain countries. Programs have been developed in Lower Saxony in Germany[152] and in Austria.[153]

In Austria, cattle herds are identified as infected or not by using herd-level antibody tests on bulk milk or on groups of young animals. PI animals are detected and eliminated to prevent spread of infection between animals which are commonly grazed on communal pastures.[152] A modified commercially available antigen-capture ELISA, and a RT-PCR tests were used and both were confirmed as 100% when compared to the Ag-ELISA kit (Herd Chek, IDEXX).

In Lower Saxony, because of the high seroprevalence of infection due to vaccination, control and eradication will involve a combination of identification of PI animals, systematic vaccination programs, biosecurity measures to prevent the introduction of infection into BVDV free herds, followed by eventual cessation of the use of vaccines.

North America. In response to significant biologic and economic loss due to the bovine virus diarrhea complex, the Academy of Veterinary Consultants drafted and approved a position statement in 2001, The position states: *'The beef and dairy industries suffer loss due to effects of the bovine viral diarrhea virus infection. The highly mutable nature of the BVDV and the emergence of highly virulent strains of the BVDV contribute to limited success of present control programs. Also, persistently infected cattle are the primary source of infection and effective testing procedures are available to identify those infected carriers.*[65] *Therefore, it is the resolve of the Academy of Veterinary Consultants that the beef and dairy industries adopt measures to control and target eventual eradication of BVDV from North America.'* The 'BVD Decision/Management Guidelines for Beef Cattle Veterinarians' are available[65] and were adopted July 2003.

There are no plans to eradicate BVDV from North America as is being done in the Nordic Countries. However, it is very realistic and possible that the virus could be eradicated on a herd by herd basis using detection and elimination of PI animals, the judicious use of effective vaccines, regular diagnostic testing for PI animals, and implementation of biosecurity measures to ensure that re-infection of the herd of does not occur.

BOVINE PAPULAR STOMATITIS

Bovine papular stomatitis (BPS) is a mild viral disease of young cattle characterized clinically by papules on the muzzle, inside the nostrils and in the oral cavity. It is important because of the confusion it creates in the differential diagnosis of erosive and vesicular viral diseases of the alimentary tract of cattle. The disease has a worldwide distribution.[1] It is of minor importance, although it may cause mild illness and serve as a portal of entry for secondary bacterial infection.

Papular stomatitis has occurred in Finnish reindeer for many years.[2] Sequence analysis of the viral DNA isolated from an outbreak of disease in reindeer indicates that the virus is most closely related to *Pseudocowpox virus*.

The parapoxviruses (PPV) are members of a genus in the family *poxviridae* which currently includes four species: the prototype parapoxvirus ovis or Orf virus (**ORFV**), parapoxvirus bovis 1 (bovine papular stomatitis (**BPSV**), and parapoxvirus bovis 2 (milker's nodule or pseudocowpox (**PCPV**).[3] A new fourth PPV species affects red deer in New Zealand (**PVNZ**).[3] The literature on the molecular characterization of the parapoxviruses has been reviewed.[3] The genomes of the orf virus and bovine papular stomatitis virus have been sequenced and the genomic differences are consistent with their classification as two PPV species.[1]

Both the bovine papular stomatitis virus and the orf virus have been found circulating in wild ruminants and PPV isolates from wild ruminants have been experimentally transmitted to sheep, goats, and cattle.[1] Both the BPS and orf viruses have caused infections in sheep, cattle and Japanese serows (goat antelope).[4] A North American strain of orf virus isolated from a goat caused an epidemic of atypical, multifocal, persistent, severe, proliferative dermatitis in young goats.[5]

The bovine papular stomatitis virus can cause occupational infections in humans with lesions characterized by large, painful nodules on the hands and, less frequently, the face.[1]

The disease occurs in young animals from 2 weeks up to 2 years of age and in a group the morbidity often approximates to 100%. There may be transient anorexia, weight loss, ptyalism, and a slight fever (39.5°C; 103°F) but in most instances the disease goes unnoticed unless a careful examination of the mouth is made. Lesions are confined to the muzzle, just inside the nostrils and on the buccal mucosa. Occasional cases occur in which the only lesions are in the esophageal mucosa.[1] They commence as small (0.5–1 cm) papules which become dark red in color, develop a roughening of the surface and expand peripherally so that the lesions are always round or nearly so. Confluence of several lesions may cause the development of a large irregularly shaped area. As the lesion expands the periphery becomes reddened and the center depressed, gray-brown in color and rough on the surface, and eventually covered with necrotic tissue or on external lesions by a scab. Those lesions on the muzzle may be difficult to see if the area is pigmented. In the mouth the lesions occur on all mucosal surfaces except the dorsum of the tongue, and are most common inside the lips and in close proximity to the teeth. Individual lesions heal quickly, sometimes in as short a time as 4–7 d, but evidence of healed lesions in the form of circular areas of dark pink mucosa usually surrounded by a slightly paler raised zone, may persist for weeks. In the one animal there may be successive crops of lesions so that they can be found continuously or intermittently over a period of months. It is suggested that no immunity occurs and the virus may only cause lesions when intercurrent disease causes lowering of the animal's resistance.

The disease in reindeer associated with a virus closely related to the pseudocowpox virus is characterized clinically by erosions, papules, pustules and ulcers in the oral cavity.[2] Outbreaks have occurred in Finland, particularly during the winter, and case fatality rate can be up to 25%.

Histological examination reveals a characteristic ballooning degeneration and the presence of cytoplasmic inclusions in affected cells. The infection can be transmitted by the inoculation of scrapings from lesions into the oral mucosa of susceptible calves and by submucosal inoculation of undiluted tissue culture virus. Diagnosis of the presence of the virus can be made by electron microscopy of the saliva. It can also be grown in cell culture and a virus neutralization test is available for positive identification. Indirect immunofluorescence can be used on cattle sera to distinguish antigenic differences between bovine papular stomatitis, milker's nodules and contagious ecthyma.

A polymerase chain reaction (PCR) method has been developed for the specific detection of parapoxvirus infections in both domestic and wild animals.[6] The PCR specific primers specific to each virus have not yet been designed.

The disease, known as 'rat-tail syndrome' in young cattle in feedlots, is probably a manifestation of sarcocytosis. However, there is also a high prevalence of bovine papular stomatitis lesions and virus in these cattle and it is possible that it may contribute to the development of the disease. A concurrent infection of bovine papular stomatitis and bovine virus diarrhea has been described in a calf.

TRANSMISSIBLE GASTROENTERITIS IN PIGS

Synopsis

Etiology Transmissible gastroenteritis virus, member of the family Coronaviridae
Epidemiology Highly contagious disease of newborn piglets but may affect pigs of all ages in susceptible herd. High morbidity and high case-fatality rate in piglets under 10 d of age. Large economic losses. Epidemics of disease occur in susceptible herd. Transmission by oral and aerosol routes. Recrudescence of infection and endemic disease commonly follows epidemics. Infection of pregnant sows results in protection of piglets by secretory IgA in milk. Porcine respiratory coronavirus mutant of transmissible gastroenteritis (TGE) virus has reduced incidence of TGE
Signs *Epidemic disease*: Acute diarrhea, vomiting, dehydration and death in piglets under 10 d of age. Less severe diarrhea in older pigs of all ages
Endemic disease: diarrhea in young pigs 6 d of age and older, including weaned pigs.
Clinical pathology Detection of virus in tissues. Serology
Lesions Fluid-filled intestines. Villous atrophy
Diagnostic confirmation Detection of virus in mucosal scrapings of intestine
Differential diagnosis list
- Enteric colibacillosis
- Coccidiosis
- *Clostridium perfringens* type C
- Rotavirus enteritis
- Porcine epidemic diarrhea
- Vomiting and wasting disease
- Diarrhea of adult sows, gilts and boars

Treatment Supportive therapy. Fluids and electrolytes. No specific treatment
Control Isolation of sows due to farrow. Planned exposure to virus. Biosecurity and acquisition of virus-free replacement stock. All-in all-out management system. Vaccines

ETIOLOGY

The disease is associated with the transmissible gastroenteritis (TGE) virus, a member of the Coronaviridae family[1] belonging to

the Order Nidoviridales. The nucleotide sequences from 20 TGE virus isolates obtained from eight countries between 1946 and 1996 have been compared.[2] The virion is enveloped, large-single stranded RNA genome with positive polarity. There are three major structural polypeptides-200 Kda spike protein (S protein), 30 Kda membrane protein (M) and a minor 10 Kda protein (E).[3] These are produced by ORFs 2, 5 and 6. The function of ORF products from 3a and 3b are not known but they have been postulated as an important determinant for virulence.[4]

EPIDEMIOLOGY

Occurrence and prevalence of infection

The disease occurs in pig-producing areas of North America, Europe and many parts of Asia, principally in the northern hemisphere. During the past three decades, TGE has changed from a sporadic disease as it historically occurred in the mid-western United States to an endemic disease in most countries of the northern hemisphere. In densely swine-populated areas such as the midwestern United States, the disease is one of the major causes of morbidity and mortality in young pigs.[5] The disease has not been diagnosed in Australia and New Zealand.[6] In 1990, the prevalence of infection in the United Kingdom was low, at 0.6% of sows sampled as being seropositive compared to 3% in 1984.[2] No major epidemics have occurred since 1981. In 1984, a seroconversion to the TGE virus occurred in a closed herd in the absence of any clinical disease. The TGE virus was not isolated and it is possible the seroconversion was due to emergence of the porcine respiratory coronavirus (PRCV) throughout Europe and the United Kingdom beginning in 1986.[2] The PRCV is a deletion mutant of the TGE virus and its high rate of prevalence has markedly reduced the number of TGE outbreaks in European swine herds. The TGE virus probably coexists in these herds together with the PRCV. In 1999, a single case was diagnosed in East Yorkshire as a one-off.[7] Other isolated outbreaks in herds which were seropositive for PRCV were also reported.[8] An outbreak of TGE occurred in the UK in 1996 in which the virus was a variant with an intact spike gene but with a large deletion in the ORF3a which may not be necessary for enteric virulence.[9]

The **prevalence of infection** of the TGE virus based on serological surveys of swine herds varies with the size of the herd, the distance between herds and the purchase of breeding stock from non-specific pathogen-free herds.[10] Depending on the geographical location, up to 50% of herds may be seronegative, and in 45% of herds the prevalence of infection in sows will vary from 10–80%.[10] In the United States in 1990, a national survey of swine herds found that 36% of herds were positive for the TGE virus and 24% of the producers' herds were vaccinated for the virus.[11] By 1997, up to 100% of survey herds and 91% of the sera were positive for both the TGE virus and the PRCV, which indicates a marked increase probably due to subclinical infections.

The disease is highly contagious and affects piglets primarily under 10 days to 2 weeks of age. Pigs over 5 weeks of age often have milder clinical signs. **Epidemic TGE** occurs when the virus is first introduced into a susceptible herd and is usually of short duration and no longer clinically evident after herd immunity develops. Epidemics of the disease occur most commonly during the winter months. **Endemic TGE** occurs when the virus persists in a partially immune herd into which susceptible swine are introduced or if the epidemic form is not well managed. Endemic TGE is a common sequel to a primary epidemic in herds of more than 300 sows in which diarrhea occurs in piglets from 6 days of age to about 2 to 3 weeks after weaning.[11] Recurrence of clinical TGE often occurs in endemically infected herds about 9 months after the first outbreak as the piglets of susceptible sows are exposed to the virus. Recurrence has been associated with:

- Breeding herd sizes of over 100 sows
- Presence of finishing pigs in large herds
- Introduction of purchased gilts.

Morbidity and case fatality

Typically, an epidemic in a herd is explosive and dramatic. There is rapid spread and high morbidity of pigs of all ages within 2–3 days but major clinical disease is restricted to pigs prior to weaning and to lactating sows. Case–fatality rates may approach 100% in pigs under 10–14 days of age but are much lower with increasing age, and mortality is low in postweaned and adult pigs. The epidemic commonly terminates in 3–5 weeks with the loss of young susceptible pigs and the development of herd immunity and, generally, the disease does not recur again for a 3–6-year period.

Risk factors

Animal risk factors

Level of herd immunity. Epidemics of clinical disease occur following the introduction of the virus into a **susceptible herd with no previous exposure** to the virus. All age groups will become infected and most pigs will be affected clinically to variable degrees. Nursing piglets under 2–3 weeks of age are most susceptible to clinical disease and experience the highest case–fatality rate. Clinical disease disappears when the herd becomes immune. Endemic TGE develops when the virus and clinical disease persists within partially immune herds, caused by continual or periodic introduction of susceptible pigs. In endemic situations, diarrhea is generally observed in pigs from the age of about 6 days until about 14 days after weaning. Overall pig mortality is lower and generally occurs in recrudescent episodes. After weaning, piglets no longer have the protection provided by TGE-specific secretory IgA antibody in milk and are susceptible to infection and clinical disease if the infection rate in the weanlings is high. Thus weanling pigs serve as a major reservoir of infection.

Sow parity may be a risk factor. Parity-1 sows with no previous exposure to the virus may be a risk factor on some farms.[10] On other farms, parity-3 sows were at increased risk for unknown reasons. A single boar may be a high-risk animal on some farms.

Herd size. There is a higher likelihood that sows will be seropositive if the herd size exceeds 500 sows and if more than 25 replacement breeding animals are purchased from non-specific pathogen-free herds.[10] A mathematical model of detection and dynamics of disease in Australia indicates that the disease is likely to establish in breeding and finishing swine herds of average size.[6] The threshold number of susceptible pigs for establishment of the infection is 90–160. Swine herds most at risk are those with[1] large numbers of susceptible pigs,[5] continuous breeding of susceptible pigs,[6] high numbers of purchased pigs, and[2] close contact between feral pigs and susceptible domestic pigs.[6] The risk is highest in herds which do not make a rapid diagnosis when there is little or no veterinary involvement in health and disease management. In small farms (containing 15 to 40 sows) outbreaks of TGF are characterized by rapid spread of infection to most animals of all ages but a duration of only 3–5 weeks.[12]

Environmental and management risk factors

Climatic factors appear to be important in the occurrence and establishment of the disease. Climate does not yet have significance in the tropics or southern hemisphere and there is evidence that its spread is limited in hot climates. In areas where the disease is endemic, it has a distinct seasonal occurrence with the majority of outbreaks occurring from midwinter to spring, and cyclic occurrence is recorded.[13]

Virus is labile above 21°C and is very sensitive to sunlight. It is also killed by most disinfectants. The disease tends to occur in area outbreaks in which herds in close proximity are affected within several weeks. Within swine barns, the location of the farrowing crates may be a risk factor if the cold air inlets are directly above the crates.

The use of a continuous flow system of production in a herd is a major risk factor. The constant overlap of farrowing sows in farrowing rooms, overlap of weaned pigs in nursery rooms, and a continuous flow of finishing pigs without adequate cleaning and disinfection between each group of pigs are major risk factors, and perpetuate persistent infection and the endemic form of the disease. An all-in all-out system for each group of pigs reduces the risk of infection between pigs.

Lack of adequate biosecurity is a major management risk factor. Infection can be introduced into herds by the importation of infected breeding stock, contaminated trucks and other vehicles, or on workers' clothing and boots.

Pathogen risk factors

The virus does not persist in infected premises for more than a few weeks and is readily destroyed by standard solutions of phenol and formalin, by boiling and by drying but not by freezing. The virus is photosensitive, which may account for the more frequent occurrence of the disease during the winter and spring months. The virus survives freezing, and infected pork scraps or offal may provide a source of infection either directly through feeding of uncooked garbage or possibly indirectly via dogs. Purposeful infection by the feeding of frozen infected piglet intestine to sows to induce immunity may also be a significant source of continued infection of a herd or area.

The genome and the genetic basis for the pathogenesis of the virus have been described.[5] Antigenic differences between TGE viruses have been examined and the nucleotide sequences of isolates from various countries have been compared.[14]

The TGE virus is not antigenically related to the two other porcine coronaviruses, hemagglutinating encephalomyelitis virus and porcine epidemic diarrhea virus but it is related to PRCV.

Porcine respiratory coronaviruses (PRCV)

The PRCV is a deletion mutant of the TGE virus with altered tissue tropism to the respiratory tract, first recognized in Belgium in 1984. It has a partially deleted receptor binding protein. The virus closely resembles the TGE virus antigenically and pigs infected with the PRCV develop a serological response which cannot be distinguished by virus-neutralization tests from the response of pigs infected with the TGE virus.[2] In other words it provides cross protection.[15] Despite the antigenic relation of PRCV and the TGE virus, they can be differentiated with monoclonal antibodies.[16] All PRCV strains have around 600–700 nt deletions within the amino-terminal S gene resulting in the loss of hemagglutination activity[17] and two antigenic sites.[18] European PRCVs have an identical deletion of 672 nt at the same position, whereas US strains have 621–681 nt deletion located at different positions which suggests that they arose separately. Natural infection of the sow with the PRCV induces natural antibodies which neutralize classic enteric transmissible gastroenteritis. The virus has spread throughout Europe [19] and has been identified in the United States[20] and Canada.[16] Spread of the virus has been explained in part by airborne transmission and infection shows a seasonal pattern, affecting farms during winter and spring. Seroprevalence studies in Belgium indicate that 95% of sows are PRCV positive.[21] The infection is widespread in swine herds in Spain [22]. The risk factors associated with seropositivity in Danish swine herds include: (a) increasing herd size; (b) certain geographical locations; (c) presence of a slurry system with slatted floors; and (d) purchase of pigs.[19] The serological status of neighboring herds was also risk related and the closeness of a seropositive herd was associated with an increased risk of a herd becoming serologically positive.

The PRCV replicates in the respiratory tract of pigs but to a very limited extent in the intestines. Its pathogenicity is controversial. Some studies indicate that the virus causes only subclinical respiratory infections while others have linked the virus with field outbreaks of respiratory disease. Experimentally, inoculation of the virus intratracheally into 8-week-old piglets results in clinical respiratory disease and bronchointerstitial pneumonia, and the virus can be recovered from the respiratory tract.[23] Some isolates of the virus produce interstitial pneumonia in neonatal piglets with no recognizable clinical respiratory disease.[24]

Methods of transmission

The exact mode of transmission of the TGE virus is uncertain. Virus shedding in the feces of infected pigs usually ends at or within a few weeks of recovery, although recovered pigs may harbor the virus in pulmonary or intestinal tissue for periods of more than 100 days. The shedding period is supposed to be 14 days. After weaning, the pig is no longer protected by specific secretory IgA antibody of the sow's milk and is highly susceptible to infection if the rate of infection is high in the weanling population. The weanling pig is a major reservoir of infection for continuous infection in the herd. Feeder pigs with no clinical signs can be an important reservoir of the virus. The virus has also been isolated from pharyngeal swabs taken from farm-raised sows sent to slaughter.

Epidemics commonly follow the introduction of pigs into a herd and the carrier pig is a major source of infection. Frequently the disease first appears in older pigs in the herd and then subsequently spreads to newborn pigs and sows in the farrowing area. **Spread is much more rapid in a continuous-flow system of production compared to an all-in all-out system, whereby groups of pigs of the same age or production stage are handled as groups and their housing facilities are cleaned and disinfected before and after being occupied.** Visitors, their boots, transport vehicles, equipment, and starlings have also been incriminated in the transfer of infection to new locations. Starlings may act as vectors to spread to adjacent farms. The virus can also multiply in house flies (*Musca domestica* Linneaus) and they may be a vector. Feral pigs are not a significant reservoir for the TGE virus in the southern United States, but are capable of becoming infected and developing virus-neutralizing antibodies against the virus.[25] Subpopulations of infected pigs may exist within the herd and although shedding is normally for 14 days it is possible for animals to be infected for 100 days.

Once infection has gained access to a herd, transmission occurs by both oral and respiratory routes. The speed of spread without direct contact indicates that the virus can be spread by aerosol. Respiratory transmission appears significant in adults and replication in the respiratory tract is followed by excretion in nasal secretions and milk within 1 day of infection, and also in feces. Excretion in milk results in rapid transmission to suckling piglets which in turn may excrete large quantities of the virus within 2 days of infection.

Immune mechanisms

Immunity to clinical disease in newborn piglets is dependent on the level of TGE-specific secretory IgA antibody in the colostrum of the sow known as **'lactogenic immunity'**. When pregnant sows are infected orally with the virulent TGE virus, specific IgA precursor cells are sensitized in the intestine. These sensitized cells migrate to the mammary glands and differentiate into plasma cells that secrete IgA class, TGE virus antibody in colostrum and milk. This immune mechanism to induce protective antibody for suckling pigs is termed the 'gut–mammary

gland link' or the 'gut-associated lymphoid tissue' (GALT) system. Following natural infection with TGE during pregnancy, the recovered sow or gilt is capable of protecting her litter against the disease. After farrowing, the colostrum contains antibodies of the IgG, IgM and IgA isotypes derived from serum. After the third day, milk is produced and the only antibody it contains is the IgA antibody, which is synthesized at the mammary gland. The IgA antibodies of immune sows are the most critical in protection of mucosal surfaces such as the gastrointestinal tract, and this immunoglobulin is the most abundant isotype in porcine milk. These IgA antibodies are not induced after the parenteral administration of viral antigens, which explains the relative ineffectiveness of parenteral vaccines. Serum antibody induced by vaccination of the pregnant sow does not provide protection of piglets through colostrum or milk.

Secretory IgA is the predominant antibody class in milk and is responsible for lactogenic protection of pigs and active protection of the intestine. It is stimulated by oral inoculation with non-attenuated, but not attenuated TGE virus. Although high concentrations of IgA and IgG originating from the serum are present in colostrum, IgG does not persist in the milk, whereas IgA does persist because of local mammary secretion. After the first week of lactation, secretory IgA constitutes 50–60% of the total immunoglobulin concentration in swine milk and IgG makes up 20–30%.

Suckling pigs are protected from infection by continued ingestion of antibody of the IgA class secreted in milk. The level of serum IgA antibody as an indicator of immunity to transmissible gastroenteritis can be measured using the indirect immunoperoxidase antibody test. Young pigs, 6 weeks of age, which are exposed to experimental infection with the virus, develop both a humoral and cellular immunity which reach peaks at 21 and 28 days, respectively.

In recent years, less typical forms of the disease have been observed. With continuous farrowing and the continual introduction of susceptible pigs into an infective environment, outbreaks may be considerably prolonged, and this or recrudescence is more likely than when pregnant sows are kept in relative isolation on pasture or elsewhere. Atypical endemic forms of the disease with a low morbidity and mortality and frequently with the onset of clinical disease delayed until piglets are 2–4 weeks of age have been observed and may go unrecognized because of the atypical clinical findings. They are more likely to occur in large continuous farrowing units and may be associated with partial herd immunity and low virulence virus. Some sows do not develop a significant immunity following a single infection and in large herds there may be a sufficient number of these to allow the disease to perpetuate in a low-incidence, endemic form.

A recrudescence of the disease may occur after a period of several months and is thought to be due to inadequate exposure and immunity of some pigs, particularly dry stock during the initial outbreak followed by reinfection from a carrier pig. Recrudescence of clinical disease is usually of much shorter duration than the primary outbreak and commonly lasts only 6–10 days. The periods of recrudescence are commonly precipitated by the simultaneous farrowing of several susceptible gilts in the same farrowing room. Of greater long-term concern is that about 50% of some large herds continue to experience clinical recrudescences for almost 2 years or more. The endemic form of the disease appears to be correlated with herds of more than 100 sows and in herds where finishing pigs were kept. In large herds the virus may spread more slowly and replacement gilts entering the herd may take several months to become infected and to seroconvert. In large herds, the rapid turnover of breeding stock and continuous farrowing and early weaning also contribute to perpetuation of an endemic infection, thus endemic transmissible gastroenteritis can maintain itself by the slow and incomplete spread of the virus among adult pigs, particularly herd replacements. Joint infection with PRRS and TGE did not appear to enhance the clinical effects, shedding or persistence of either virus.[26]

Economic losses

A herd epidemic of TGE causes economic losses through:

- Death of pigs
- Increased downtime of the swine enterprise
- Increased labor
- Disturbance of the breeding program
- Subsequent reduced growth of young pigs destined for slaughter
- Curtailed performance of older pigs.

The economic losses can be very large. Simulation of the economic losses due to an outbreak of disease in Australia where the disease is exotic estimated a reduction in net revenue of 70% in the 6 months after a moderate outbreak (50% mortality of piglets under 1 week of age), and 100% for a severe outbreak (95% mortality of piglets under 1 week of age).[27] An analysis of the economic losses due to the disease in swine farms in some areas in the United States over a 2-year period estimated the average loss to be between 13% and 18% of the average return earned above total production costs. It has been assumed that the growth of surviving pigs was depressed by 10% and their feed conversion by 18%, but pigs surviving or born shortly after an epidemic of TGE are profitable to raise.

PATHOGENESIS

The S protein of the viral membrane of TGEv has four major antigenic sites and is the major inducer of neutralizing antibodies. The protein mediates the binding of the virus to the cell surface and the subsequent fusion of the viral and cellular membranes.[3] High titers of serum IgG and virus neutralizing antibody to TGEv probably reflect the amount of S spike protein the pig has received.[28] Two different ligands have been shown to interact with the S protein and binding to the porcine aminopeptidase N, the cellular receptor for TGEv is essential for infection of the cells.[29] The TGEv is also able to recognize sialic acid residues and attach to sialylated macromolecules.[30] A second binding site on the N-terminal division of the S protein allows TGEv to interact with terminal sialic acid residues on glycoproteins or glycolipids and to agglutinate RBCs. TGEv also recognizes a porcine intestinal brush border protein called MEP (mucin type glycoprotein and TGEv binds to this mucin produced by goblet cells. A mutant virus that has lost its sialic acid binding capability is not pathogenic as it is unable to attach to goblet cells.[31–34] Sialic acid binding activity is a pathogenicity factor for TGEv and it is important to note that the sialic acid binding sites for TGEv and *E. coli* are different.

The virus infects the upper respiratory tract and the intestines but the major clinical effects are due to intestinal infection.[35] Following oral challenge of susceptible piglets, the incubation period may be as short as 24 h. The virus infects mature differentiated columnar epithelial cells of the intestinal villi but not the undifferentiated cells of the crypts.[36] Replication occurs within 4–5 h with sloughing of the infected cells and release of virus, and after several replication cycles there is a marked reduction in villous size with villous atrophy. The loss of epithelial cells results in increased migration of undifferentiated cells from the crypts to line the shortened villi. With virulent virus, epithelial cells at all levels of the small intestine are infected with major lesions occurring at the proximal jejunum and to a lesser extent the ileum. The lesser virulence of attenuated strains of virus may be associated with their inability to infect and produce lesions in the villi of the more cranial portions of the jejunum. Gnotobiotic pigs inoculated orally with a TGE

vaccine will develop lesions similar to the naturally occurring disease.[37]

Diarrhea results from a combination of malabsorption and osmotic effects subsequent to the loss of intestinal surface area and disaccharidase activity, and impaired lumen-to-extracellular fluid flux of sodium consequent on the occurrence of undifferentiated cells lining the stunted villi. The virus invades the villus, but not the crypt epithelium of the small intestine within hours after experimental administration. The infected villus cells are quickly shed and replaced by relatively undifferentiated enterocytes. As infected cells are shed, the epithelium proliferates and migration of cells from the crypts accelerates. There are marked abnormalities in ion transport function in the jejunum and ileum at the height of the diarrhea. There is failure of the intestine to actively transport sodium and chloride and there is a defect of the glucose-mediated sodium ion transport. Macromolecular hyperpermeability of the small intestine also occurs but its significance is uncertain.[38] Experimentally induced infection of 3-week-old pigs with the virus results in villous atrophy and crypt hyperplasia, and a marked decrease in the secretory response of the villous epithelium to *Escherichia coli* enterotoxins. The disease is more severe in gnotobiotic pigs that are infected with *E. coli* in addition to the TGE virus, suggesting that bacterial factors also influence the severity of the diarrhea.

In the experimental disease in 2-day-old pigs, vomiting and diarrhea occur 12–24 h after oral inoculation of the virus and affected piglets are moribund 1 or 2 days later. Before becoming moribund most piglets become lethargic and comatose. In addition to dehydration and metabolic acidosis, there is a severe hypoglycemia due to a combination of inadequate glucose metabolism inherent to neonatal piglets and the acute maldigestion and malabsorption from the diffuse and severe villous atrophy. The high mortality may be due to a combination of dehydration, acidosis and severe hypoglycemia.

The age-dependent resistance to TGE can be explained in part by a decreased susceptibility of the epithelial cells of older pigs to infection and by an increased proliferative capacity of crypt cells with much more rapid regeneration of atrophic villi in pigs over 2 weeks of age. It may be that the virus has developed strategies to evade apoptosis in intestinal enterocytes by producing huge amounts of the virus.[39,40]

A recent experiment comparing a Korean strain with two US strains showed that the progression of the Korean virus was much slower, i.e. much less virulent, possibly because there was only replication in the ileum and jejunum whereas the US strains also replicated in the duodenum.[41] The more virulent strains attack a wider area of enterocytes. Most only attack the villous rather than the crypt enterocytes. An outbreak of reduced virulence TGE was associated with the presence on the farm of three strains of PRCV which had variable sequence changes in ORF3/3a/3b.[42]

CLINICAL FINDINGS

In a primary or epidemic outbreak the clinical findings of typical acute TGE are characteristic. The appearance of the disease is not significantly altered by a concurrent infection with PRRS.[43]

Piglets

After an incubation period of 24–48 h there is a sudden onset of vomiting and diarrhea. The diarrhea is profuse and frequent; the feces are watery and usually yellow-green in color. The feces may contain clots of white undigested milk and have an offensive odor. The vomitus is yellow, foamy and slimy. There may be a transitory fever but in most cases the temperature is normal. Depression and dehydration are pronounced, the hair coat is ruffled, and weakness and emaciation progress to death on days 2–5. Some piglets may continue to suck to within a few hours of death; those which survive are severely emaciated and gain weight slowly. The illness may commence as soon as 24 h after birth. It is not uncommon on an individual farm for the disease to become less severe and to spread more slowly with the passage of time. In the outbreak described by Pemberton there was an 80% mortality across two weeks of piglets[7] with 10% of 4 to 6-week-old freshly weaned pigs.

Older pigs

In older pigs there may be signs similar to those which occur in piglets but many animals become infected without clinical abnormalities. Diarrhea may occur first in the dry sows.[44] In older pigs, recovery is much more likely to occur, the illness lasting for up to 10 days. Lactating sows may or may not be affected clinically. Fever and inappetence occur, with or without diarrhea, and agalactia is a common complication in sows. In endemically affected herds with continuous farrowing and partial sow immunity, the disease is milder with diarrhea affecting piglets about 6 d of age or older and diarrhea in weaned pigs. Brief periods of clinical disease occur in some parts of the herd, mortality is low, and affected pigs subsequently grow poorly.

CLINICAL PATHOLOGY

Serum biochemistry

A severe dehydration with metabolic acidosis and a marked hypoglycemia are common.

Detection of virus

The virus can be detected in the mucosal scrapings and feces using an ELISA, immune electron microscopy, fluorescent antibody staining or by the immunoperoxidase test.[5] A capture-enzyme immunoassay has also been developed.[45] A reversed passive hemagglutination test for detection of the virus in feces is also available. A solid-phase immune electron microscopic technique for detection of the virus in feces is also useful for diagnosis in living animals. The PRCV can be isolated by tissue culture.[24]

DNA probe

DNA probes can differentiate the porcine respiratory coronavirus from the TGE virus.[46] PCRs were described quite early on for identifying TGE.[47]

In situ hybridization has been described[48] and a nested RT-PCR was developed[49] which was very sensitive. A multiplex RT- PCR for differentiating PED from TGEv in clinical samples has been described.[50] It has also proved possible to use formalin fixed tissue for multiplex PCR, nested-PCR and ISH with 100% conformity.[51]

Serology

Several serological tests can detect and measure antibody to the virus in live animals. The serum neutralization test is sensitive and reliable, but is time-consuming and requires facilities for cell culture techniques. Neutralizing antibodies appear in the serum 7–8 days after infection and persist for at least 18 months. An ELISA is more sensitive than the virus neutralization test and a competitive ELISA differentiates between TGE virus and PRCV.[35] A blocking ELISA to differentiate TGE and PRCV has also been described.[52]

NECROPSY FINDINGS

The lesions are confined to the intestine and stomach although in many field outbreaks and in the experimental disease the changes may be minor. The intestinal wall is thin and translucent and the intestine is distended with fluid ingesta. Despite the presence of milk in the intestine there is little evidence of fat absorption in the draining lymphatics. The important histopathological change is atrophy of villi with failure of epithelial cell differentiation in the small intestine. The atrophy is evident 24 h after infection and regeneration occurs 5–7 days later. The marked reduction in the size of intestinal villi may even be detected at low magnification on a stereomicroscope. In the stomach there may be engorgement of vessels and necrosis of the epithelium deep in mucosal crypts. No inclusion bodies are detectable. When secondary pathogens contribute to the disease there may be inflammatory lesions in

the intestines. In chronic cases a thickening of the intestinal wall identical with that seen in terminal (regional) ileitis has been described.

The disease, as it occurs in Europe, is characterized by more severe mucosal lesions, often including fibrin exudation. There is also degeneration of the heart muscle and, in some cases, of the skeletal muscle.

A simple test for the presence of intestinal lactase in intestinal washings may assist in the laboratory diagnosis. Examination of frozen sections of jejunum from acutely ill piglets by the fluorescent antibody technique is a rapid and effective method for the detection of virus in tissues. The intestine may be segmentally affected so multiple areas must be sampled. Viral antigen is detectable for only 24–36 h utilizing most fluorescent antibody (FA) conjugates. This makes selection of acute cases critical. Electron microscopy is often utilized to identify the presence of coronavirus but this method is not specific for the TGE virus. PCR methods for TGE virus detection are being developed and immunohistochemical techniques are available for use in formalin-fixed tissues.[53,54]

The use of apoptotic markers shows that most of the cells are undergoing apoptosis but are not infected with TGEV they are what is called bystander cells.[55] It has been previously suggested that apoptosis does not occur in the enterocytes of piglets infected with TGEv.[56] An accumulation of interferon alpha producing cells occurs in the GALT of TGEv infected piglets.[57] It has been suggested that these are the mucosal counterparts of the dendritic cells recently shown to produce IFN alpha after in vitro viral induction [57]. The TGEv challenge of pigs produces changes in $CD4^+/CD8^+$ cells which rise, natural killer cells and cytotoxic T-cells which also rise together with an increased expression of IL-2 receptors and a decrease in null cell phenotypes.[58]

Samples for confirmation of diagnosis

- **Histology** – several segments of jejunum and ileum, stomach (LM, IHC)
- **Virology** – several segments of jejunum and ileum (FAT), feces (EM).

DIFFERENTIAL DIAGNOSIS

The epidemiological and clinical characteristics of TGE should make possible a presumptive diagnosis, but confirmation must depend upon the finding of compatible histological lesions, the detection of antigen, transmission experiments and evidence of seroconversion. It is unusual to encounter outbreaks of diarrhea in piglets which appear to be typical of TGE, and either the virus can be demonstrated in the tissues by fluorescent antibody test (FAT) but serum antibodies cannot be detected in the breeding animals, or serum antibodies can be detected in the adults but the virus cannot be demonstrated in the tissues by either immunofluorescence or tissue culture.

Villous atrophy is not pathognomonic for the disease, since it occurs in 3-week-old piglets affected with diarrhea and steatorrhea, in rotavirus infections of piglets, and in some herds for undetermined causes immediately following weaning.

In piglets, TGE must be differentiated from the following:

- **Enteric colibacillosis** A common disease of piglets under 10 d of age with profuse diarrhea, no vomiting, dehydration and a good response to therapy if treated early
- ***Clostridium perfringens* type C** Enterotoxemia occurs in piglets under a few days of age and causes marked depression, diarrhea, dysentery, reddening of the anus and rapid death. Lesions at necropsy are characteristic
- **Coccidiosis** Affects newborn piglets 5–15 d of age, causing profuse diarrhea, depression, dehydration and unthriftiness. Affected piglets may continue to suck. There is a high morbidity, low mortality and oocysts in the feces
- **Rotavirus enteritis** Rotavirus causes diarrhea in suckling and weaned piglets with a high morbidity and low mortality. Most affected piglets recover in a few days and epidemics are commonly associated with continuous farrowing
- **Porcine epidemic diarrhea** A coronavirus-like virus causes diarrhea in pigs similar to TGE, except much less severe with less mortality. **Porcine epidemic diarrhea Type I** causes diarrhea only in pigs up to 4–5 weeks Porcine epidemic diarrhea Type II causes diarrhea in pigs of all ages. The morbidity may reach 100% but mortality is low. The disease may start in the finishing pigs and spread rapidly to pregnant sows and their nursing piglets. The diarrhea may persist in the 6–10-week-old pigs and seronegative gilts introduced into the herd may become infected and develop a profuse diarrhea lasting a few days
- **Vomiting and wasting disease** Vomiting and wasting disease affects piglets under 10 d of age in epidemics similar to TGE. However, vomiting is characteristic, diarrhea is not a feature and laboratory differentiation is necessary.

In adults (gilts, sows and boars, TGE must be differentiated from the disease listed below.

Diarrhea in gilts, sows and boars may be due to:

- **Swine dysentery**
- **Salmonellosis**
- **Porcine proliferative enteritis.**

TREATMENT

There is no specific treatment. Because dehydration and metabolic acidosis are severe and hypoglycemia occurs, treatment with fluids and electrolytes containing glucose is indicated. Because there is loss of intestinal villi and the enzyme lactase, the ideal treatment would be to reduce the intake of milk for up to 5 days and administer a glucose–glycine–electrolyte solution orally every few hours to maintain hydration. However, removal of affected piglets from the sow is impractical and not recommended. Oral fluid therapy should improve the survival rate, affected piglets recovering in a few days following treatment. In experimentally induced TGE, removal of the milk diet and the use of an oral glucose–glycine–electrolyte solution plus a 5% dextrose solution given intraperitoneally at the rate of 25 mL/kg BW once daily decreased the severity of the diarrhea, dehydration and metabolic acidosis but did not prevent or improve significantly the renal failure and severe hypoglycemia. A newborn piglet weighing 1.25 kg has an energy expenditure of about 170 kcal/d (711 kJ) if maintained at 30°C (86°F); 30 mL of a 5% dextrose solution supplies 1.5 g of glucose for a total of about 5.6 kcal/d (the gross energy of glucose is 3.74 kcal/g). Because the volume of 5% dextrose solution injected daily into piglets should not exceed 8% of their body weight, it is unlikely that the hypoglycemia can be prevented or treated.

The use of natural human interferon given orally to piglets 1–12 days of age affected with the disease increased survival rates compared to placebo-treated piglets.[59]

CONTROL

Control of the disease is complex because it is so highly contagious and because of the dynamics of infection between the different age groups of animals within large swine herds. While there is considerable information available about the biology of the virus and the nature of the disease, there is little documented reliable information about the control in a swine-breeding herd. Most of the recommendations for control are empirical and based on clinical experience without any controlled field trials to evaluate different control strategies. What follows are guidelines for the control of TGE based on some principles which are based on the some characteristics of the virus and the disease:

- The disease is highly contagious and spreads rapidly between groups of pigs in a herd. Most epidemics last 6 weeks
- Newborn piglets are highly susceptible to disease if the sow's

milk does not contain specific TGE secretory IgA antibody
- Infection of pregnant sows with the virulent virus results in protective immunity for their piglets. Recovered sows are immune, usually do not harbor or shed the virus, and need not necessarily be culled
- Weaned pigs are a major reservoir of infection in farrow-finish herds
- Vaccination of pregnant sows with any of the available vaccines is not as effective as natural infection in providing protection for piglets
- The disease is controlled either by elimination of the virus from the herd or by controlled natural immunization and use of the all-in all-out system of production.

Control during and after an outbreak

The highly contagious nature of the disease makes the immediate control of an outbreak in a herd virtually impossible. Epidemics usually last about 6 weeks, during which time many piglets die and the herd eventually becomes immune. Successful control depends on planning and implementation of certain strategies which must be understood and implemented by the producer, and monitored by the veterinarian. Failure of the producer to fully understand or accept the diagnosis and apply the principles of control will result in failure to control the disease and the persistence of an endemic form of the disease in the herd.[11] Several strategies are used to control the infection pressure and to enhance immunity where possible.

Isolation of sows due to farrow. To avoid further new infections of newborn piglets, sows due to farrow within 2–3 weeks should be isolated under strict hygienic conditions. However, this is usually impractical in most intensive swine production enterprises where isolation facilities are usually not available. The disease is so highly contagious that isolation is ineffective. There should be no movement of pigs between the farrowing or nursery rooms. An all-in all-out movement of pigs, especially in the farrowing rooms and nurseries, with complete cleaning and disinfection between groups is established (see all-in all-out practices discussed later).

Discontinuation of selling and purchasing breeding stock. Once a diagnosis of TGE has been confirmed in a breeding herd which sells breeding stock, all sales should be discontinued. Likewise, all purchases of breeding stock from other herds should be discontinued for a few months until the epidemic has subsided and future production plans of the herd, including disease control, are reviewed.

Partial depopulation and culling. If possible and feasible, all weaned pigs ready for finishing units should be moved off the farm to contract finishing units. This allows a general clean up of facilities, a break in the production cycle and an intensive all-in all-out system. All cull pigs should be destroyed to prevent a reservoir of pigs actively shedding the virus.

Planned exposure to virulent virus. To minimize the duration and severity of the outbreak, all pregnant sows due to farrow more than 3–4 weeks ahead should be given an inoculum of virulent TGE virus obtained from virus-infected intestines, ideally from piglets in which the disease began within the last 12–24 h. The piglets should be submitted for necropsy and TGE confirmed by a diagnostic laboratory. It cannot be assumed that all piglets which die in an epidemic of TGE will be infected with the virus. The intestines of the confirmed cases should be homogenized in special media, centrifuged and supernatants poured into capsules and frozen for storage. The contents of the capsules are thawed and poured onto the feed of the sows.[60] The inoculum is given daily for 3 days. Preparation and use of the inoculum insures adequate uniform inoculation of sows, compared to earlier recommendations to feed feces and intestines of piglets which died of the disease to the pigs. More inoculum can be prepared by inoculating weaned piglets in isolation and collecting their small intestines 1–2 h after onset of diarrhea, which is usually 16–21 h after inoculation. The boars are also fed the inoculum. An alternative to the inoculum is to mix the intestines from two affected piglets in 25 L water and feed 50 mL of the solution daily for 3 days.[61]

If there is sufficient time for immunity to develop, the piglets born 3–4 weeks later will be protected through the colostrum and milk which will contain the TGE virus-specific IgA antibodies. Piglets sucking such sows are resistant to infection while sucking, but become fully susceptible if transferred to a non-immune sow. Natural infection by mouth produces a high level of secretory antibody particularly IgA in the colostrum and milk whereas vaccination produces a good IgG response but a much lower IgA response. The newer recombinant vaccines have also been shown to be immunogenic but are still not able to produce lactogenic immunity.

An alternative to the feeding of infectious material to pregnant gilts and sows is vaccination using the available vaccines. The gilts, sows, replacement stock, boars and newborn piglets are vaccinated according to the indications of the vaccines used. However, the efficacy of the vaccines is questionable.

Biosecurity and acquisition of replacement breeding stock. Following recovery from an epidemic in a herd, replacement breeding stock should be introduced as a group at one time and exposed to animals in the herd, monitored for clinical disease and tested. Serological testing using paired sera at 30 and 60 days after entry will indicate seroconversion to the virus. The usual precautions to prevent transmission of infection between units of the herd and between herds are necessary, including:

- Washing of boots
- Sanitation of trucks
- Use of separate clothing for each unit of large herds
- Showering of personnel moving between units.

Washing hands and changing into clean outerwear or showering or changing into clean outerwear after being in contact with TGEv infected pigs was sufficient to prevent mechanical transmission of TGEv to susceptible pigs.[62]

All-in all-out management system. The all-in all-out management and production system is based on the principle of handling, feeding and housing pigs in small subgroups as they move through the various stages of production. These subgroups either remain free of certain infectious agents, if absent, or all animals in the group become infected and immune to the infectious agents which are present in some pigs and transmitted to others in the subgroup but not to other subgroups. With this system, breeding gilts and sows are handled and bred as subgroups, kept in the gestation units as subgroups, farrowed as subgroups, and nurse their pigs as subgroups. The pigs are weaned as subgroups at the same time, the weaned pigs are placed in the nursery facilities as a subgroup at the same time and all of the pigs are moved out of the nursery to the finishing facilities at the same time. The pigs are handled in finishing units as subgroups and all pigs are marketed as a subgroup. At each stage of production the housing facilities should be cleaned and disinfected following removal of the pigs, and left vacant for a few days before a new subgroup of pigs is introduced into previously cleaned rooms. The system avoids the mixing of pigs back and forth between groups and ages, which is often done to maintain uniformity of size and age of pigs. During an epidemic, the use of a strict all-in all-out system in the farrowing and nursery units will aid in the control of clinical disease. About 2 months after the epidemic and the absence of clinical disease, sentinel seronegative pigs 2–4 months of age can be introduced to each part of the herd and

monitored serologically for evidence of viral activity.

Complete depopulation and repopulation or establishment of new herd. In some situations where the disease cannot be controlled, complete depopulation of the herd is the best option. This should be followed by repopulation with breeding stock derived from specific pathogen-free herds or minimal disease-free herds which are known to be free of the virus. Serological testing can be used to test the animals before they are moved into the facilities. The establishment of new swine herds now commonly depends on the acquisition of breeding stock from disease-free herds.

TGE vaccines and vaccination

In many instances they do not provide a reliable complete protection for suckling pigs against a challenge exposure.[63] However priming piglets with PRCV was very beneficial in providing resistance to TGEv and also gave a much better maternal antibody response.[64]

Vaccination of pregnant sows. Because of the effectiveness of acquired immunity following natural infection, vaccination of the pregnant sow would appear to be the method of choice for control of the disease. However, the available vaccines have not been efficacious enough to be a reliable control strategy. Circulating VN antibodies acquired actively or passively, provide insufficient protection against clinical disease and parenteral vaccines have been relatively ineffective. Protection against the disease requires the presence of secretory IgA antibody, either actively or passively acquired, in the intestine (**see immune mechanisms**).

TGE vaccines. Several live-attenuated and inactivated virus vaccines are available for use in pregnant sows and neonatal pigs. Vaccines for oral and intranasal administration were developed on the basis that vaccination by the oral or intranasal route would induce the production of secretory IgA antibody. However, these vaccines have not been efficacious.

The vaccination of pregnant sows with attenuated strains of the TGE virus by either the parenteral or oral routes does not provide sufficient lactogenic immunity to protect their piglets against the virulent TGE virus. Some litters sucking vaccinated sows may achieve partial protection in which the onset of diarrhea is delayed, the diarrhea is less severe, and the case–fatality rate is decreased. Villous atrophy is inhibited to varying degrees in pigs sucking immunized sows, depending in part on the antibody titer in the colostrum and milk.

The severity of the losses in a vaccinated herd after exposure to the virus will vary, depending on:

- Herd management
- Environmental conditions
- History of previous exposure
- Severity of viral exposure.

After natural infection or experimental oral infection of pregnant sows with a virulent strain of the TGE virus, lactogenic immunity is highly protective for piglets and neutralizing antibodies in milk are mainly associated with the IgA fraction. Vaccination of sows orally with a non-attenuated vaccine provides greater levels of lactogenic protection than does orally or parenterally administered attenuated virus vaccine.[65] In vaccinated sows, the levels of colostral antibody correlate with the percentage of survivability of their piglets when challenge exposed at 3–5 days, whereas the serum antibody to TGE does not. There is also a significant relationship between milk antibody and percentage survivability when pigs were challenge exposed at 5, but not at 3 days of age. There is a need to develop an attenuated virus strain which is completely avirulent for pigs, but which also replicates sufficiently in the small intestine of sows after oral administration and induces secretory IgA antibody. It appears that no strains of the virus have been identified which are sufficiently attenuated and safe for pigs while yet able to provide a sufficient immune stimulus in the intestine of the sow. The Nouzilly strain, which is a mutant of the TGE virus resistant to acidity and proteases of the digestive tracts of adult pigs, is being evaluated as a vaccine.[66]

Vaccine schedule. If vaccines are used, it is generally recommended that the two vaccinations, 14 days apart, be given during the last trimester of pregnancy. Vaccines are available for vaccination of neonatal piglets, and weaner and finishing pigs but there is insufficient published information available on the efficacy of the vaccines based on randomized clinical trials using controls under field conditions.

Subunit TGE vaccine. Experimentally, a recombinant TGE virus S glycoprotein subunit vaccine given subcutaneously or intramammarily to pregnant sows induced colostral and milk IgG, but not IgA antibodies to the virus.[67] Piglets born from vaccinated sows were challenged at 4–5 days of age with the virulent virus and the morbidity was 100% with a mortality ranging from 20–80%.[67] The same vaccine given subcutaneously to 11-day-old piglets induced virus-neutralizing antibodies. This is consistent with the well-known observation that secretory IgA antibody in the milk is necessary for protection in piglets. Compared to VN antibodies, antibodies of the secretory IgA class are more effective at neutralizing the TGE virus because they are at higher titers in milk, more resistant to proteolytic enzymes, and bind to gastrointestinal enterocytes. Protective immunity to transmissible gastroenteritis correlates with milk whey secretory IgA antibody titer to the TGE virus when pigs are challenge exposed with the virulent virus at 3–5 days of age.

Immunity to PRCV

There is considerable cross-protection between the TGE virus and the PRCV.[68] There is indirect evidence that a bronchial-associated lymphoid tissue (BALT)– mammary gland link similar to the gut-associated lymphoid tissue (GALT)–mammary gland link described for the TGE virus may exist in pregnant, multiple PRCV-exposed sows. In herds infected with the PRCV, multiple exposures of pregnant sows are associated with higher IgA and IgG antibody titers to TGE virus in milk and these titers contribute to protection against the TGE virus.[68] The immunization of pregnant gilts with the PRCV induces lactogenic immunity and partial protection of piglets from challenge with the TGE virus.[69] An overall survival rate of 70% was found for piglets nursing PRCV-infected gilts, compared to a 16% survival rate for piglets nursing control gilts. The highest degree of protection occurs in sows primed with the PRCV, then given a booster vaccination with the TGE virus 2 weeks later.[70] Infection of pigs with the PRCV primes the systemic and mucosal humoral immune system against the TGE virus, so that subsequent challenge with the TGE virus results in a secondary antibody response and in a decreased duration of excretion of virus.[71] Protective immunity to TGE virus infection can also be induced in piglets exposed to the PRCV at 2–6 days of age.[72]

VOMITING AND WASTING DISEASE IN PIGS (HEMAGGLUTINATING ENCEPHALOMYELITIS VIRUS DISEASE IN PIGS)

Vomiting and wasting disease occurs in suckling piglets[1] and is characterized by vomiting and constipation with subsequent ill thrift. An acute encephalomyelitis may also occur following infection with the same virus.[2] A third possibility is inapparent infections in adults.[3]

ETIOLOGY

A coronavirus with hemagglutinating properties is the cause of both vomiting and wasting disease and an encephalomyelitis of piglets. The physical properties of the virus have been described.[4,5] The same isolate may be capable of causing either syndrome following experimental infection.[6]

EPIDEMIOLOGY

Vomiting and wasting disease was reported from Canada in 1958[7] and subsequently from the United States,[8] United Kingdom,[9] Europe,[10–12] and Australia.[13] Following its occurrence in Canada, a hemagglutinating virus was isolated from suckling piglets showing encephalomyelitis[14] and it has been subsequently demonstrated that both syndromes are associated with the same agent.[6,9] The encephalitic form has subsequently been reported in the United States.[15] Although clinical disease is comparatively rare, serological surveys suggest that infection is widespread even in countries that have not experienced the disease or where it has been absent for some years.[15–17] The infection is widespread in breeding swine herds.[18] Piglets suckled by immune sows will obtain maternal antibodies which disappear by 15 weeks of age. Active immunity begins between 8 and 16 weeks of age. Disease presumably occurs when the virus gains access to a susceptible herd but the reason for the age limitation is unknown. Transmission is by the oral or respiratory route.[6]

Both syndromes tend to occur in outbreak form affecting several litters within a short period of time. Morbidity approaches 100% and the case–fatality rate is high. The disease occurs in suckling pigs as early as 2 d of age but generally not in pigs older than 3 weeks of age. The encephalitic form tends to involve younger piglets than the gastroenteric form. The clinical course of the encephalitic form is usually 2–3 d whereas pigs with vomiting and wasting may survive several days to several weeks. The course of the outbreak is usually 2–3 weeks and subsequent litters are not affected. Area outbreaks may occur.

PATHOGENESIS

The pathogenesis is uncertain. Vomiting and wasting disease and encephalomyelitis are probably two clinical extremes of the same disease, and both syndromes may be observed in the same outbreak.[6,15] Differences in pathogenicity of the strain of virus, and age and litter susceptibility may influence the form that the disease takes. Virus may be isolated from the brain of pigs with acute encephalomyelitis but in cases of chronic vomiting and wasting disease, neither virus nor encephalomyelitis is demonstrable. It is possible that the vomiting and wasting syndrome is centrally mediated but that during the course of chronic illness the virus is eliminated and the inflammatory lesions resolved.[6] Localization of antigen in the stomach wall has been demonstrated in vomiting and wasting syndromes.[19] After experimental oral inoculation, the first site of multiplication is probably the nasal mucosa and then the virus replicates preferentially in the tonsils, lungs and small intestines.[19] This is followed by spread to the central nervous system via the sensory nuclei of the trigeminal and vagus nerves with subsequent spread to the brainstem, cerebrum, and cerebellum. The cause of the vomition is probably due to the replication of the virus in the *ganglion distale vagi*. The other sign wasting is due to disturbance of the vomiting centre with persistent vomiting resulting in malnutrition.

CLINICAL FINDINGS

In most cases these infections are not apparent clinically or go unrecognized and continue to cause morbidity.

In many instances the clinical signs are similar to those of poliencephalomyelitis associated with the porcine enteroviruses. Usually pigs under 2 weeks of age are affected. Mortality in young pigs is high but in older pigs they may survive and become stunted.

Vomition of yellow-green vomitus is the first sign and is accompanied by anorexia and thirst. Ineffective attempts to drink are characteristic. The temperature is usually normal or slightly elevated except for transient febrile reactions (up to 40.5°C; 105°F) for 24 h in the early stages in some pigs, and the feces are usually hard and dry. Diarrhea may occur but is not severe and occurs mostly in the older piglets. Vomiting may continue for some days but, in all affected pigs, there is severe, rapid emaciation and dehydration. They may continue in this state for some weeks and eventually die, apparently of starvation, or are destroyed by the owner.

The encephalitic form is manifest initially by depression. Piglets continue to suck for the first day but rapidly become inappetent and there is rapid loss of condition. Hyperesthesia, incoordination and muscle tremor with occasional vomiting is followed in 48–72 h by an acute encephalitis with paddling convulsions and death. Sows may show inappetence and mild fever for 1–2 d at the onset of the outbreak.

CLINICAL PATHOLOGY

Detection of virus

Infection may be demonstrated by the isolation of virus in primary tissue culture and growth detection is made by hemagglutination, fluorescent antibody or electron microscopic techniques.

Serology

The demonstration of rising antibody titers in surviving piglets is also satisfactory for diagnosis. Virus neutralization and hemagglutination inhibition tests are more sensitive than agar gel immunodiffusion.[20]

NECROPSY FINDINGS

Gross necropsy findings are generally negative. Non-suppurative encephalomyelitis with perivascular cuffing, gliosis and neuronal death are present in pigs dying with clinical signs of encephalitis but not necessarily in pigs with vomiting and wasting disease.

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed samples of above tissues, plus stomach and celiac/cranial mesenteric ganglia (LM)
- **Virology** – brain (including medulla and cerebellum), Gasserian and paravertebral ganglia (ISO)
- **Serology techniques** for RT-PCR and nested PCR have been described.[21]

TREATMENT AND CONTROL

There is no effective treatment. As yet there are no effective vaccines. The control of the disease must depend on prior exposure of sows to infection at least 10 d before farrowing, if necessary by purposeful exposure. The piglets will be protected by colostral antibody. Sows that have had affected litters will be immune to the disease and should not be discarded from the herd.

VIRAL DIARRHEA IN CALVES, LAMBS, KIDS, PIGLETS, AND FOALS

Synopsis

Etiology Rotaviruses, coronaviruses, toroviruses, parvoviruses
Epidemiology Common cause of diarrhea in newborn farm animals, most commonly in calves but also in lambs, kids, piglets and foals. Rotaviruses ubiquitous in environment and 50–100% of adults seropositive. Spread by feces. Protection dependent on specific antibody in colostrum in intestinal lumen. Bovine coronavirus is also pneumotropic and causes respiratory disease
Signs
Calves
Outbreaks of diarrhea at 5–14 d of age and older up to 3–4 weeks. Recover in few days
Piglets
Outbreaks of diarrhea at 1–4 weeks of age and following weaning. Porcine epidemic diarrhea Type I at 4–5 weeks of age; Type II at all ages. Recover in few days
Foals
Profuse diarrhea, slight fever, dehydration. Recover in few days
Lesions Fluid-filled intestine, dehydration. Villous and crypt atrophy
Diagnostic confirmation. Many diagnostic tests to identify viruses in fecal samples
Differential diagnosis list
Calves
Enteric colibacillosis, cryptosporidiosis, bovine virus diarrhea, coccidiosis
Piglets
Transmissible gastroenteritis, enteric colibacillosis, Porcine epidemic diarrhea Types I and II, coccidiosis, hemorrhagic enterotoxemia
Lambs
Enteric colibacillosis
Foals
Rotaviral diarrhea, foal heat diarrhea, salmonellosis, *Clostridium perfringens* Type B, and dietary diarrhea from excessive consumption of milk
Treatment Oral and parenteral fluid, electrolyte therapy
Control Reduce infection pressure, insure adequate colostral intake, vaccination of dam to provide specific colostral antibody

ETIOLOGY

Several families of viruses cause diarrhea in neonatal farm animals, and occasionally in adults. They include: Reoviridae, Coronaviridae, Toroviridae, Parvoviridae.

Rotaviruses

Rotaviruses of family Reoviridae are primary causes of diarrhea in calves, lambs, kids, piglets and foals. All members of the group of viruses share a common morphology and previously known as the reovirus-like viruses. Rotaviruses of human infants, calves, pigs, and foals are morphologically indistinguishable from each other and from the virus of infant mice; the lamb rotavirus is similar to both calf and pig viruses.

Atypical rotaviruses known as pararotaviruses have been isolated from pigs, cattle and lambs. They are morphologically similar to rotaviruses but do not possess the common group antigen and are characterized by their failure to be detected in serological tests such as immunofluorescence or ELISAs, which are based on the presence of the common group antigen.

Rotaviruses are assigned to serogroups with group members sharing distinctive common antigens. Currently, seven serogroups – A through G – are recognized.[1] Rotavirus serogroups are further classified into serotypes based on specificity of the outer capsid proteins VP7 (G types) and VP4 (P types). At least 14G and 12P serotypes of Group A rotavirus are recognized.[2] Group A rotaviruses are the most frequently detected viruses as a cause of diarrheal disease in farm animals and humans. Group B rotaviruses have been isolated from adult cows with diarrhea.[3]

Coronaviruses

Coronaviruses cause acute diarrhea in calves and piglets and perhaps foals.[7,8] The coronavirus-like virus of pigs is similar to, but distinct from, the virus of TGE and is the cause of porcine epidemic diarrhea type II.

Toroviruses

The family Toroviridae includes the Berne virus of horses and the Breda virus, which has been isolated from cattle.[4]

Parvovirus

Parvoviruses have been associated with diarrhea in calves but are not significant pathogens in cattle.[5]

Other viruses and mixed infections

While the rotavirus and coronavirus are the most common causes of viral diarrhea in newborn farm animals (other than TGE of piglets), the adenovirus and small viruses resembling astroviruses and caliciviruses have been isolated from diarrheic calves but their etiological significance is uncertain.

Multiple mixed viral infections are being recognized more frequently as diagnostic techniques are improved. Both rotavirus and coronavirus may occur in the same diarrheic calf with or without the presence of enteropathogenic *E. coli*.

EPIDEMIOLOGY

The general aspects of the epidemiology of viral diarrheas of newborn farm animals are described here followed by the specific epidemiological features in calves, lambs and kids, piglets, and foals. The rotavirus is used as a model.

Occurrence

The rotavirus is ubiquitous in the environment of domestic animals and serological surveys indicate that 50–100% of adult cattle, sheep, horses and pigs have antiviral antibody.

The rotaviruses from one species can infect members of only some other species and experimental infection of pigs, calves, and lambs with human rotavirus is possible. The calf rotavirus can infect pigs. However, the significance of interspecies infection under field conditions has not been evaluated. Cross-infection between species is not a property shared by all rotaviruses.

There are seven serogroups of rotaviruses recognized A–G,[2] and Group A rotaviruses are divided into serotypes defined by surface antigens which elicit neutralizing antibodies.

Methods of transmission

The intestinal tract is the site of multiplication of the rotavirus and the virus is excreted only in the feces. Infected feces may contain as many as 1010 virus particles/g. Because rotaviruses are stable in feces and relatively resistant to commonly used disinfectants, it is extremely difficult to prevent gross contamination of animal housing once infection has been introduced. The adult animal is the primary source of infection for the neonate. The survival of the bovine rotavirus in air and on surfaces is directly influenced by the level of relative humidity.[6] The rotaviruses in general survive well in an aerosol state and medium-range of relative humidity and air may be one of the vehicles for dissemination of the virus.

Immune mechanisms

An important epidemiological characteristic of rotavirus and coronavirus infections in newborn farm animals is that protection against disease is dependent on the presence of specific colostral viral antibody in the lumen of the intestine of the newborn. Colostral serum antibody in the newborn does not directly protect neonates against enteritis. The protective effect of colostrum depends on its antibody titer, the amount ingested and the amount available in the lumen of the intestine. The daily oral administration of colostrum containing specific antibody or hyperimmune serum to lambs will protect them against experimental enteritis. The protection is against clinical disease and not necessarily infection. Calves, lambs and piglets may still excrete virus in the feces while they are protected against enteritis by the presence of colostral antibody in the intestinal lumen. The protection lasts only as long as colostral antibody is present within the lumen of the intestine, which explains why rotaviral diarrhea occurs commonly after 5–7 d of age. Survival from rotavirus diarrhea in calves may be dependent on a high level of serum colostral immunoglobulin.

Protection against bovine rotavirus in calves with a high titer of maternal virus neutralizing antibodies is due to both lactogenic immunity and the intestinal serum-derived antibody.[7]

Calves

Many of the epidemiological characteristics of neonatal calf diarrhea associated with the rotavirus and coronavirus must be considered in the context of 'acute undifferentiated diarrhea of newborn calves' because mixed infections are more common than single infections.

Bovine rotavirus

Occurrence and prevalence of infection

In cattle, serogroups A, B and C are most commonly reported.[2] The bovine group A rotavirus was first isolated in the United States in 1969 as the cause of outbreaks of diarrhea in beef calves in Nebraska. Since then the virus has been recovered from calves affected with diarrhea and normal calves worldwide.[2,8] Diarrhea due to Group A rotavirus occurs in calves from 1–2 weeks of age.

The prevalence of infection with Group A rotavirus is high. An overall prevalence of approximately 30% in normal neonatal animals and 40% in diarrheic animals is common.[8] Within 14 d of age, 94% of dairy calves may be positive for Group A rotavirus and 80% may be positive for Group B.[9] Antibody to rotavirus is present in the serum of 90–100% of young adults, and clinically normal calves with high serum antibody may excrete the virus. The explanations include:

- Calves may be protected from disease but excrete the virus during the colostral feeding period
- Calves may be infected at a subclinical level but still excrete the virus although they may have been denied colostral antibody.

Non-Group A rotaviruses, which have Group B characteristics, have been found in normal and diarrheic calves in India.[10]

The prevalence of infection with Groups B and C bovine rotaviruses is less than A. Approximately 70% of adult cattle are seropositive to Group B and 50% of adult cattle are seropositive to Group C.[2] Serotypes G6 and G10 Group A rotaviruses are the most prevalent serotypes in dairy and beef calves with diarrhea in the United States.[11] Unusual Group A rotaviruses have been associated with epidemics of diarrhea in 3-month-old calves, which age is unusual.[11] The predominant G serotypes of bovine rotaviruses from outbreaks of diarrhea in dairy and beef calves in Australia have been determined.[13]

Rotavirus strains belonging to G10P11 constitute the largest proportion of bovine rotaviruses in cattle throughout India.[14] This has major zoonotic implications because this strain is related to those found in newborn children in India.

The prevalence of subclinical infection may be greater than that indicated by isolation of the virus from feces. Rotavirus–immunoglobulin and coronavirus–immunoglobulin complexes may be present in the feces of 44% and 70% of adult cattle, respectively, while the free rotavirus and coronavirus may be absent or present in only 6% of fecal samples, respectively. Clinically normal cows can shed the virus for several weeks in the presence of fecal and serum antibody. Repeated bovine rotavirus infection and re-excretion can occur in calves several months of age, even in the presence of serum antibodies. Clinically normal calves may also shed the virus and there may be histological evidence of lesions of the small intestine due to rotavirus infection.

In a longitudinal survey of calves in a herd over two successive calving periods, the rotavirus was first detected in calves at about 6 d of age. Diarrhea or excretion of abnormal feces was associated with rotavirus infection in 58% of infected calves while in the remaining 42% infection was subclinical. The overall prevalence rate of infection can vary from 16–80% among beef and dairy calves. In a random sample of dairy herds in Ohio in the United States, the prevalence of bovine Group A rotavirus detected in the feces of calves was 16% at an average of 14 d. Of all calves with liquid feces, 28% were shedding rotavirus, in comparison with 25% with semi-liquid feces, 23% of those with pasty feces, and 11% of those with firm feces.

Group C rotavirus, designated the Shintoku strain, has been isolated from adult cattle in Japan with diarrhea. A significant antibody response to the isolate was detected in convalescent-phase sera of cows which excreted the virus and no antibody response to bovine Group A was observed.

Concurrent infections. Rotavirus was detected in the feces of 43% of neonatal diarrheic dairy calves in Spain.[15] A concurrent infection was detected in 58% of the rotavirus infected calves, and the most common mixed infection was rotavirus-*Cryptosporidium*. The detection rates of the other enteropathogens with rotavirus infection were 20% for coronavirus, 85% for *Cryptosporidium*, 17% for F5+ *E. coli* and 2% for Salmonella. As age of calf increased, the detection rates of other enteropathogens decreased.

Risk factors

Animal risk factors

The factors which influence rotavirus infection and its clinical severity include:

- Age of the animal
- Immune status of the dam and absorption of colostral antibody
- Ambient temperature
- Degree of viral exposure
- Occurrence of weaning
- Presence of other enteropathogens.

Calves are most susceptible to rotavirus diarrhea between 1–3 weeks of age. This age occurrence is related in part to the rapid decline in specific colostral antibody to the rotavirus.

The mortality is highest in the youngest animals which have received insufficient colostrum and are subjected to severe weather conditions.

The occurrence and distribution of the virus in diarrheic and normal calves have been studied. The rotavirus has been found before, during and after the onset of diarrhea. It has been found along with the coronavirus and adenovirus in diarrheic calves. This serves to emphasize that while the virus can be considered as a primary pathogen in calves, the results of field and laboratory investigations indicate that multiple mixed pathogen infections are probably more common than single pathogen infections. There are also differences in the virulence between isolates. Earlier work suggested that most cases of naturally occurring rotavirus diarrhea in calves were also infected with *E. coli*. However, no attempt was made to determine if the *E. coli* possessed the virulence characteristics described under colibacillosis.

Environmental risk factors

While the rotavirus has been most commonly associated with outbreaks of diarrhea in beef calves raised in groups outdoors, it has also been recovered from dairy calves raised together in large groups in large dairy herds. The morbidity rate in beef herds has varied from herd to herd and from one year to another.

The survival of the bovine rotavirus in air and on surfaces is directly influenced by the level of relative humidity.[6] The rotaviruses in general survive well in an aerosol state and medium range of relative humidity and air may be one of the vehicles for dissemination of the virus.

Pathogen risk factors

There are differences in virulence among the bovine rotaviruses, which may explain the variability in the severity of disease in natural outbreaks and must be considered when developing vaccines.

Rotaviruses possess two outer capsid proteins: VP4 and VP7. The neutralization specificity related to VP7 is the G serotype and that associated with VP4 is referred to as P serotype. On the basis of G types, at least 14 serotypes of Group A rotaviruses have been described in animals and humans. The Group A rotavirus has been classified as 14 G serotypes, 11 P serotypes, and 20 P genotypes.

Specific G and P types have been associated with specific animal species. For example, human rotaviruses most commonly belong to G types 6, 8, and 10 and have P types. As more rotaviruses have been characterized from diverse locations worldwide, the host species specificity of P and G types has become less distinct. G types 6, 8, and 10, once thought to be specific to cattle, have been found in humans.

Determination of the serotype specificity is important for development and evaluation of more efficacious vaccines but it is complicated by the dual serotype specificity of the rotavirus. Strains of bovine Group A rotavirus have been isolated from beef herds which had been vaccinating the pregnant cows with the commercial vaccine containing Group A rotavirus.[16] The serological and genotypic characterization of strains responsible for the diarrhea were a bovine rotavirus reassortant with a P gene different from the vaccine virus. In the United States, commercially available rotavirus vaccines for cattle contain only strain NCDV-Lincoln.

G and P genotypes of Group A rotaviruses have been found circulating in calves in Brazil,[17] and in diarrheic calves born to cows vaccinated against the NCDV (P[1], G6) rotavirus strain.[18] The prevalence of the rotavirus G and P types in diarrheic calves in Japan changes in certain areas periodically.[19] A Group A rotavirus with G serotype 8 has been isolated from diarrheic calves in Japan.[20] A bovine Group 3 rotavirus has been identified and characterized which causes age-dependent diarrhea in cattle in the UK.[21]

In Sweden, in beef and dairy herds, several bovine rotavirus G-types (G3, G6, and G8, and G10) were detected.[22] In beef herds, G6 predominated, while G10 predominated or was the only G-type in dairy herds. In Sweden, the same strains of the virus persist for several years which is probably associates with the limited exchange of cattle between dairy and beef suckled herds which are characteristically small.

It is now becoming clear that in contrast to natural recovery from infection, which results in high titers of P-specific neutralizing antibodies, parenteral administration elicits primarily G-specific neutralizing antibodies. Thus, failure in passive protection with a monovalent vaccine for prevention of rotavirus-associated diarrhea in neonatal calves may be less than optimal due to diversity of P and G types occurring in nature.

Natural subclinical infections are common in calves in the second week of life, which raises doubts about rotavirus pathogenicity. Experimentally, the clinical outcome of infection is dependent on both age and rotavirus isolate. Age-dependent resistance to infection was not found. Bovine rotaviruses differ in virulence for calves in the second week of life and older calves are susceptible to rotavirus infection and disease.[23]

The calf rotavirus can be experimentally transmitted to piglets and has been isolated from natural outbreaks of diarrhea in piglets. The isolation of a rotavirus from neonatal deer affected with diarrhea in a zoo in Australia raises some interesting epidemiological possibilities.

Morbidity and case fatality

In some herds the disease starts at a low rate of 5–10% in the first year, increases to 20–50% in the second, and to 50–80% in the third year. In other herds, explosive outbreaks affecting 80% of the calves have occurred in the first year. The case-fatality rate has also been variable – in some herds as low as 5%, while in others as high as 60%. The mortality rate probably depends upon the level of colostral immunity in the calves, the incidence of enteric colibacillosis, and the level of animal husbandry and clinical management provided in the herd.

Method of transmission

The virus is excreted by both calves and adult cattle in large numbers (up to 10^{10}/g of feces) and excretion may last for several weeks. Even under open-range conditions, there is a rapid spread of the virus throughout calves which come into frequent contact with each other, particularly during the calving season. Calves are infected after birth from the dam's feces or from other infected diarrheic calves. Pregnant cows excrete the rotavirus intermittently throughout pregnancy, from one calving to the next, and provide a direct source of infection for the newborn calf. Both subclinically infected and diarrheic calves infected by rotavirus can be a source of infection for other in-contact calves.

Immune mechanisms

Newborn calves are protected from the rotavirus only during the first few days after birth, when colostrum contains specific rotavirus antibody which is active in the lumen of the intestine. This correlates well with the peak incidence of rotavirus diarrhea which is at 5–7 days of age, and coincides with a marked drop in colostral immunoglobulins by the third day after parturition and an incubation

period of 18–24 h for the disease to occur. The levels of serum and colostral antibody are lower in first-calf heifers, which explains the higher morbidity and mortality in their calves. The serum colostral immunoglobulins of the calf may also be transudated from the serum into the intestine and complement the role of colostral and milk antibodies in the lumen of the intestine.

Bovine coronavirus (calf diarrhea)

Bovine coronavirus causes diarrhea in both dairy and beef calves worldwide ranging in age from 1 day to 3 months of age but mostly between 1 and 2 weeks of age. Disease is more common during the winter months, which may reflect enhanced survival of the virus in a cool, moist environment. The virus is ubiquitous in cattle populations and the majority of adult cattle are seropositive. The coronavirus may be present in both diarrheic and healthy calves; the incidence rates range from 8–69% and 0–24% for diarrheic calves and healthy calves, respectively.

The virus can be shed by up to 70% of adult cows despite the presence of specific antibodies in their serum and feces. The peaks of shedding are during the winter months and at parturition in North America. Calves born to carrier cows are at a higher risk of diarrhea. Subclinical persistence and recurrent infections are also common in both neonatal and older calves and virus excretion from these animals may maintain a reservoir of infection.

Vaccination of the cows with a modified live rotavirus–coronavirus *E. coli* combination vaccine does not influence seasonal shedding, but in vaccinated cows the incidence of shedding does not increase at parturition as it does in non-vaccinated cows. The bovine coronavirus isolates all belong to a single serotype as polyclonal sera have detected only minor antigenic variations.

The **bovine coronavirus is also a pneumotropic virus** which can replicate in epithelium of the upper respiratory tract. In dairy calves, initial infections occur when the calves are 1–3 weeks of age but there are multiple episodes of shedding of viral antigens or seroconversion when the calves are several weeks of age. Clinical signs of respiratory disease occur between 2 and 16 weeks of age but are mild. A more severe lower respiratory tract infection causing minor lung lesions has been reported but is also not severe enough to warrant treatment. Such infections are probably common in closed herds with recurrent subclinical infections occurring in older calves. Persistence of infection or reinfection of the upper respiratory tract with the virus is also common. The amount and specificity of bovine coronavirus maternal antibodies in calves at the time of infection with the virus may interfere with the development of an active antibody response in serum and mucosal secretions. The fecal–oral route is the presumed method of transmission but aerosol transmission may also occur.

The bovine coronavirus has been isolated from wild ruminants with diarrhea.[24] Feces from diarrheic sambar deer, one waterbuck and one white-tailed deer in wild animal habitats contained coronavirus particles which were identified as bovine coronavirus. Gnotobiotic and colostrum-deprived calves inoculated with the isolates developed diarrhea and shed coronavirus in their feces and nasal discharge.[24] Thus wild ruminants may harbor coronavirus strains transmissible to cattle.

The bovine coronavirus of winter dysentery in adult cattle is closely related to the coronavirus causing diarrhea in young calves.[25] There is no evidence for serologic or in vivo antigenic differences between these two bovine coronaviruses.

Parvovirus

The parvovirus has been associated with outbreaks of postweaning diarrhea in beef calves but it pathogenicity is uncertain. Seroprevalence studies found 49–83% of adult cattle seropositive to the virus over a 2-year period.[5]

Bovine Torovirus (Breda virus)

Breda virus, a member of the genus *Torovirus*, has been isolated from the feces of neonatal calves with diarrhea in Iowa, Ohio, and several areas in Europe, and in Canada.[26] In Ohio, the virus was detected in 9.7% of fecal samples from cattle with diarrhea; it occurred in 26% of the total calf samples.[27] It is a common virus in the feces of calves with diarrhea on farms in Ontario. In veal calf operations in Ohio, 24% of calves shed the virus during the first 35 days after arrival and the shedding of the virus was associated with diarrhea. Calves shedding additional pathogens were more likely to have diarrhea than those shedding less than one pathogen.[28] Calves which were seronegative or had low antibody titer to the Breda virus on arrival were more likely to shed the virus than those calves which were seropositive on arrival.

More than 88% of adult cattle are seropositive to the Breda virus.[4] More than 90% of newborn calves have high maternal antibodies to the virus which wane at a few months of age, followed by active seroconversion between 7 and 24 months of age.

Bovine Norovirus

Noroviruses, formerly known as Norwalk-like viruses have been recognized as the most common pathogens involved in outbreaks of acute non-bacterial gastroenteritis in humans. The *Norovirus* genus, is one of four genera in the Caliciviridae family. Norovirus-specific DNA has been detected in the fecal samples of diarrheic calves in Michigan and Wisconsin.[29] The complete genomic sequence of an enteropathogenic bovine calicivirus isolated from Nebraska has been characterized and its enteropathogenicity documented.[30] The seroepidemiological prevalence of the Jena virus, a bovine enteric calicivirus, is 99% in some selected cattle populations in Germany.[31] In The Netherlands, the Norwalk-like virus (NLV) in endemic in veal calf operations and in a selected dairy herd.[32] The highest number of NLV positive veal calf farms were found in the regions with the highest number of veal calf farms. The virus is endemic in cattle populations and genetically distinct from the Norwalk-like virus in humans.

Lambs and kids

Rotavirus

The rotavirus has been isolated from the feces of lambs under 3 weeks of age with diarrhea. The disease is sporadic and no particular epidemiological characteristics have been described. Rotaviruses have been found in the feces of diarrheic lambs born in lambing sheds where about 1300 lambs were born on one sheep ranch and 3000–5000 on another ranch within 30 d. Clinical signs were noticed as early as 12–16 h after birth.[33] Morbidity approached 100% and mortality 10%. The virus was not classified as Group A but probably Group B.

In a series of fecal samples from diarrheic and normal lambs and goat kids from 1–45 d of age, the prevalence of Group A rotavirus infection in diarrheic lambs was very low (2.1%).[34] Group A and B rotaviruses were detected in 8.1% and 13.5% of diarrheic goat kids. Group C rotaviruses were detected in four normal goat kids. An association of diarrhea and infection was demonstrated only for Group B rotaviruses.

Atypical rotaviruses, possibly Group B, have been isolated from the feces of diarrheic goat kids.[35] Affected kids were 2–3 d of age and the disease was severe with marked dehydration, anorexia, and prostration.

The experimental disease in lambs is mild and characterized by mild diarrhea, abdominal discomfort and recovery in a few days. The mortality in lambs is much higher when both the rotavirus and enteropathogenic *E. coli* are used.

Piglets

Porcine rotavirus

Group A rotaviruses are a common cause of diarrhea in nursing pigs from 1–5 weeks of age with peak occurrence from 1–3 weeks of age, and weanling pigs at 3–5 weeks of age and within 3–5 d of

weaning. Groups A, B and C occur in diagnostic surveys with about 90% belonging to Group A.[36] Group C rotavirus has also been found to be the cause of enzootic neonatal diarrhea in a minimal disease herd. Multiple rotavirus G serotypes and P types have been detected in swine.[37] There is little or no cross-protection between porcine rotaviruses with distinct G and P types, but viruses which share common G and P types induce at least partial cross-protection in experimental studies.[38] Variant serotypes of porcine rotavirus such as G3 may cause severe outbreaks of diarrhea in piglets. Subclinical infections are common, and age resistance to rotavirus infection may not occur.

In an infected herd, piglets become infected between 19 and 35 d of age, and the virus cannot be detected in piglets under 10 d of age, presumably as a result of protection by lactogenic antibody. It is suggested that in an intensive piggery, with a constant shedding of viruses in feces of sows before and after farrowing leading to continuing cycle of rotavirus infection with a build-up of host immunity against a circulating strain in the pig population, a virus such as CRW-8 probably could undergo changes through mutations over a period of time leading to antigenic drift.

In piglets, rotaviral diarrhea is most common in pigs which are weaned under intensive management conditions and the incidence increases rapidly from birth to 3 weeks of age.[36] There is no age-dependent resistance up to 12 weeks of age. The disease resembles milk-scours, or 3-week scours of piglets. Mortality due to rotavirus varies from 7–20% in nursing pigs and 3–50% in weaned pigs depending on the level of sanitation. In the United States, the peak incidence occurs in February and a moderate rise occurs in August–September.[36]

A case–control epidemiological study examined the relationship between Group A rotavirus and management practices in Ontario over a 5-year period.[39] In rotavirus-positive herds, herd size was larger and weaning age was younger compared with rotavirus-negative herds.[39] Pigs raised in all-in all-out nurseries were 3.4 times more likely to have a positive Group A rotavirus diagnosis than in pigs in a continuous flow system. Pigs in the all-in all-out system were weaned at an earlier age.

The sow is the source of infection. Seropositive sows can shed rotavirus from 5 d before to 2 weeks after farrowing, when piglets are most susceptible to infection. There are increased secretory IgA and IgG antibodies to rotavirus in the milk of sows after natural rotavirus infection or following parenteral inoculation of pregnant or lactating sows with live attenuated rotaviruses.[38] The early weaning of piglets at a few days of age or at 3 weeks of age results in the removal of the antibody supplied by the sow's milk.

Continuous transmission of the virus from one group to another is an important factor in maintaining the cycle of rotaviral infection in a piggery. The virus can be found in dust and dried feces in farrowing houses which have been cleaned and disinfected. This suggests that the environment is also an important source of infection. The porcine rotavirus can survive in original feces from infected pigs for 32 months at 10°C.[40] Gilts and sows shed virus antigen prior to farrowing and during lactation, which makes it next to impossible to eliminate the infection from a herd. As sows increase in age they develop increasing levels of lactogenic IgA rotavirus antibodies but do not transfer increasing levels of protection to their piglets.

Different electrophoretypes of Group A rotavirus and different groups of rotaviruses may occur at the same time in a single piggery, which must be considered when developing vaccines. The subgroups of group A porcine rotaviruses have been classified and there are differences in virulence of isolates. Most isolates from outbreaks of diarrhea belong to Group A while a small percentage are atypical rotaviruses. Some porcine rotaviruses are related antigenically to human rotavirus serotypes 1 and 2. Porcine rotaviruses which display the typical bovine P[1], P[5], P[11], G[6], and G8 genotypes have been detected in pigs which indicates the high frequency of rotavirus transmission between cattle and pigs.[41] The various G and P types of the virus have been examined and compared in Poland and the US.[42]

Atypical rotaviruses and other enteroviruses are often present in preweaning and postweaning diarrhea in swine herds and should be considered as potential pathogens.[46] Some atypical rotaviruses are associated with villous epithelial cell syncytia in piglets with enteritis. Single and mixed infections of neonatal piglets with rotaviruses and enteroviruses have been described. Combined rotavirus and K99+ *E. coli* infection causes an additive effect when induced experimentally in gnotobiotic pigs.[32] The inoculation of calici-like viruses into gnotobiotic piglets can result in diarrhea and villous atrophy. Diarrhea in unweaned piglets 1–3 weeks of age has been associated with a combined infection of rotavirus and *Isospora suis*. The combined effect of a dietary change at weaning and rotavirus infection in gnotobiotic piglets is a temporary villous atrophy and there is no evidence of persistent atrophy of the small intestine.

Porcine coronavirus

The **porcine epidemic diarrhea virus** is a coronavirus-like virus which causes diarrhea in pigs, similar to TGE except much less severe and with less mortality. Two clinical forms of the disease have been described: porcine epidemic diarrhea types I and II. **Porcine epidemic diarrhea type I** causes diarrhea only in pigs up to 4–5 weeks of age. **Porcine epidemic diarrhea type II** causes diarrhea in pigs of all ages. The morbidity may reach 100% but mortality is low. The disease may start in the finishing pigs and spread rapidly to pregnant sows and their nursing piglets.[44] The diarrhea may persist in the 6 to 10-week-old pigs and seronegative gilts introduced into the herd may become infected and develop a profuse diarrhea which lasts a few days.

A porcine respiratory coronavirus with close antigenic relationship to the transmissible gastroenteritis virus has been identified as enzootic in the United Kingdom and some European countries.[45] A Canadian isolate of the virus inoculated into 8-week-old piglets caused polypnea and dyspnea and diffuse bronchiolo-alveolar lesions.[46] Seroprevalence studies in Spain reveal that 100% of large herds and 91% of small herds had animals with antibodies.[45] Only mild or inapparent respiratory signs occur and the growth of finishing pigs may be temporarily affected.

Foals

Equine rotavirus

Although rotavirus infection is a common cause of diarrhea in foals, there are surprisingly few epidemiological and microbiological data. Group A rotaviruses are a major cause of diarrhea in foals up to 3 months of age.[47] Most equine rotaviruses are distinct from those of other species with a distinctive electropherotype and subgroup reaction. Rotavirus serotype G3 and subtypes predominate in horses.[47] In Germany, G3 P[12] is the predominating type of rotavirus in the horse.[48]

The virus can be isolated from the feces of healthy foals and from diarrheic foals in outbreaks of diarrhea. Outbreaks of the disease occur on horse farms with a large number of young foals where the population density is high. A case–control study of foal diarrhea in the United Kingdom over a 3-year period revealed rotavirus was a significant pathogen associated with diarrhea in foals.[49] The other common pathogens were *Clostridium perfringens*, *Strongyloides westeri*, and *Cryptosporidium* spp. A survey of the enteric pathogens in diarrheic thoroughbred foals in the United Kingdom and

Ireland revealed a prevalence of 37% rotaviruses, and 8% in normal foals. In a United States survey of diarrhea in foals on 21 thoroughbred horse farms, rotavirus was detected only in diarrheic foals. A higher percentage of foals born to visiting mares developed diarrhea, compared to foals born to resident mares. Serological surveys indicate the presence of the rotavirus antibody in almost all of the mares whose foals are infected with the virus.[50]

PATHOGENESIS

Rotavirus

The rotavirus infects mature brush border villous epithelial cells in the small intestine and to a lesser extent in the large intestine. The infected cells are sloughed, leading to partial villous atrophy and the atrophic villi are rapidly recovered with relatively undifferentiated crypt cells which mature over a few days and result in the healing of the lesion. The activity of the mucosal β-galactosidase (lactase) in the brush border of the villous epithelium is less than that found in normal animals, which results in decreased utilization of lactose. This reduction in enzymes is associated with immature enterocytes on the villi during rotavirus infection. In vitro studies have suggested that lactase may be the receptor and uncoating enzyme for rotavirus, which may explain the high degree of susceptibility of the newborn with high levels of lactase. The net effect of the morphological and functional changes in the intestine is malabsorption resulting in diarrhea, dehydration, loss of electrolytes and acidosis. The diarrhea in milk-fed calves with the experimental disease ceases if the milk is withdrawn and replaced with glucose and water, which is similar to transmissible gastroenteritis. The D-xylose absorption test can be used to measure the degree of malabsorption in calves infected with rotavirus.

The pathogenesis is similar in calves, lambs, pigs and foals. Lesions occur within 24 h after infection, villous epithelial cells of the small intestine are infected and become detached, and regeneration occurs within 4–6 d after the onset of the diarrhea. The intestinal villi usually return to near normal within about 7 d after recovery from the diarrhea. However, calves and pigs may require 10–21 d to fully recover to a normal growth rate following rotavirus infection. Experimental rotaviral infection in 3-week-old piglets results in diarrhea, anorexia and vomiting. Villous atrophy of the small intestine is the most severe lesion which returns to normal in 6 d. Infection and clinical disease developed in the presence of serum-neutralizing antibody obtained from seropositive sows.

While it has been generally accepted that lactose malabsorption is an important factor in the pathogenesis of diarrhea, the experimental infection of gnotobiotic lambs with rotavirus did not result in lactose intolerance as assessed by the measurement of reducing substances in the feces or by the clinical effects and blood glucose levels after a lactose load. Lactose intolerance could be demonstrated by using extremely high doses of lactose, three to four times the normal dietary intake. Thus, lactose-containing feeds such as milk are not necessarily contraindicated in rotavirus diarrhea.

A combined infection with rotavirus and enterotoxigenic *E. coli* may result in a more severe disease than produced by rotavirus infection alone, particularly in calves several days of age when the rotavirus normally produces a mild disease and when calves are resistant to enterotoxigenic colibacillosis. The intestinal lesions of villous atrophy are also more severe and extend into the colon in dual infections. Naturally occurring cases of the dual infection in calves are considered to be more severe than single infections. Under field conditions more than one enteropathogen is likely to be involved in the pathogenesis of the diarrhea.

Experimentally, in gnotobiotic 1-day-old calves, concurrent infection with bovine virus diarrhea virus and bovine rotavirus results in a more severe enteric disease than that associated with either virus alone.[51] The BVDV potentiated the effect of the rotavirus. Severe lymphoid depletion was associated with BVDV infection regardless of the concurrent rotavirus infection. The clinical findings of induced combined BVDV and rotavirus infections in neonatal calves at 8 to 9 days of age are much more severe and the duration of diarrhea much longer than in rotavirus infection alone.[52]

Coronavirus

The pathogenesis of coronaviral enteritis in calves is similar to the rotavirus infection. The villous epithelial cells of the small and large intestines are commonly affected. The crypt epithelium is also affected, which makes regeneration of villous epithelial cells much longer, which in turn results in persistent diarrhea for several days and death from dehydration and malnutrition. Experimental infection of calves with virulent bovine coronavirus results in depletion of lymphocytes in the mesenteric lymph nodes and Peyer's patches, low levels of immunoglobulins and generalized immune suppression.[53] Experimental infection with the attenuated virus results in lower levels of intestinal immunoglobulin titers than with the virulent virus. Experimentally, newborn calves are capable of mounting an intestinal immune response to bovine coronavirus and vaccine failures may be the result of overattenuation of the virus.[53] The pathophysiological changes due to coronavirus-induced diarrhea in the calf have been described and are similar to the changes which occur in acute diarrheal disease in the calf associated with other enteropathogens.

Porcine coronavirus

This virus replicates in the villous epithelial cells of both the small and large intestine and clinically resembles TGE of piglets. There is no evidence that rotavirus infection in piglets is accompanied by increased permeability of the intestine to macromolecules.[54]

Calicivirus-like (Newbury) agent

This virus causes degeneration of the villous epithelial cells of the proximal part of the small intestine leading to villous atrophy, a reduction in disaccharidase activity and xylose malabsorption. In gnotobiotic calves experimentally infected with the Breda virus, the villous epithelial cells of the ileum and colon are affected, including the dome epithelial cells.

Parvovirus

Experimental infection of calves with the parvovirus results in lymphopenia and viremia and damage to the small intestinal crypt epithelium and the associated mitotically active lymphoid tissues. Villous atrophy occurs because of failure of replacement of villous epithelial cells. By 5 d after inoculation there was evidence of repair of the intestinal lesions. Following experimental challenge the tonsillar tissues, intestinal mucosa and mesenteric lymph nodes all become infected. Subsequent spread also results in greater involvement in the large intestine and the upper jejunum, Peyer's patches and mesenteric lymph nodes.

CLINICAL FINDINGS

Calves

The naturally occurring disease usually occurs in calves over 4 d of age and is characterized by a sudden onset of a profuse liquid diarrhea. The feces are pale yellow, mucoid and may contain flecks of blood. Recovery usually occurs in a few days. Explosive outbreaks occur and up to 50% of calves from 5–14 d of age in the affected population may develop the disease. If enterotoxigenic *E. coli* are present, the disease may be acute; dehydration is severe and deaths may occur. Multiple mixed infection with *E. coli*, coronavirus, and *Cryptosporidium* spp. are common in calves over 4 d of age and thus it may be impossible to describe a typical case of uncomplicated naturally occurring rotavirus or coronavirus-like diarrhea. There is a tendency for viral diarrhea in newborn calves to occur in explosive outbreaks; the

calves are usually not toxemic, but the character of the diarrhea cannot be differentiated clinically from that associated with the other common enteric pathogens of newborn calves.

A coronaviral enteritis affecting calves from 1–7 d of age has been described, but there are no distinguishing clinical characteristics. The diarrhea may be persistent for several days, followed by death in spite of fluid therapy and careful realimentation with milk. The feces are voluminous, mucoid and slimy, and may be dark-green or light-brown in color.

Lambs

Experimentally, newborn gnotobiotic lambs develop diarrhea 15–20 h following oral inoculation and show dullness and mild abdominal discomfort. There are only a few documented descriptions of naturally occurring rotaviral diarrhea in newborn lambs. Affected lambs under 3 weeks of age develop a profuse diarrhea and the case–fatality rate is high. It is not clear if outbreaks of uncomplicated rotaviral diarrhea occur in newborn lambs.

Piglets

Rotaviral diarrhea may occur in nursing piglets from 1–4 weeks of age and in pigs following weaning.[15] The disease in nursing piglets resembles milk-scours or 3-week scours. Most of the pigs in the litter are affected with a profuse liquid to soft diarrhea with varying degrees of dehydration. Recovery usually occurs in a few days unless complicated by enterotoxigenic *E. coli* or unsatisfactory sanitation, overcrowding and poor management. The disease is often most severe in herds in which there is continuous farrowing with no period of vacancy for cleaning and disinfection in the farrowing barn. The disease may also occur in pigs a few days after weaning and may be a major factor in postweaning diarrhea of piglets weaned at 3 weeks of age or earlier in the case of weaning pigs at 1–2 d of age.

Porcine epidemic diarrhea type I affects piglets only up to 4–5 weeks of age and is characterized by profuse watery diarrhea, high morbidity and low mortality.

Porcine epidemic diarrhea type II causes a profuse fluid diarrhea in pigs of all ages, including nursing piglets. Explosive outbreaks may occur and the morbidity may reach 100%. Mortality is usually restricted to piglets under 3 weeks of age.

Foals

Affected foals appear depressed, fail to suck and become recumbent. The temperature ranges from 39.5–41.0°C (103–106°F) and the respiration may be rapid and shallow. There is a profuse, watery, non-fetid diarrhea which results in severe dehydration and electrolyte imbalances. Recovery following treatment usually occurs within 2–4 d. Death may occur within 24 h after the onset of diarrhea.

CLINICAL PATHOLOGY

Detection of virus

Fecal samples (20–30 g) should be collected from affected animals as soon possible after the onset of diarrhea and submitted to the laboratory in a chilled state. Samples of intestinal mucosa from several sections of the small and large intestine should be submitted chilled for virus detection and possible isolation.

Because multiple mixed viral and bacterial infections are common, the request for a laboratory diagnosis must include consideration of all of the common pathogens. The viruses are much more difficult to detect than bacterial enteropathogens. In herd outbreaks, fecal samples from several affected animals and some normal animals should be submitted. The rotavirus will usually be present in both normal and diarrheic animals, which presents problems in interpretation and requires evaluation of the clinical and epidemiological findings.

Several laboratory tests are available for detection of rotaviruses and coronaviruses in the feces and intestinal contents and tissues. The particular test used will depend on the facilities and equipment available.

Electron microscopy. Demonstration of the virus in feces using electron microscopy has been a standard diagnostic technique. It is easier to see the virus if it has been concentrated by ultracentrifugation or clumped by immune electron microscopy using specific antiserum. With electron microscopy, the virus can be detected for up to 6–10 d after the onset of diarrhea. Protein A-gold immunoelectron microscopy is a valuable test to detect bovine coronavirus in the feces and nasal secretions of infected calves. However, since the equipment and expertise necessary for electron microscopy are not available in many laboratories, alternative diagnostic techniques have been developed.

Immunofluorescence. Several tests are based on immunofluorescence. These include immunofluorescent staining of fecal smears and cell culture immunofluorescence of fecal preparations. Immunofluorescent staining of a fecal smear is a more convenient test for diagnostic laboratories because a diagnosis can be made in a few hours and an electron microscope is not necessary. However, the immunofluorescence tests may not be as reliable as some other tests. The fluorescent antibody technique will only detect the virus within epithelial cells which are present in the feces for 4–6 h after the onset of diarrhea. In some studies the fluorescent antibody technique detects the virus in only 20% of samples while electron microscopy detected the virus in about 60% of the samples.

Immunodiffusion and electron microscopy. This test is superior to the fluorescent antibody technique. Treatment of the feces with chymotrypsin improves the detection rate. Monoclonal antibodies to porcine Group C rotavirus can be used in an immunofluorescent test and may have wider applications in the study of Group C rotavirus diarrheas in swine, cattle, and potentially, other species.

Testing immunofluorescent sections of spiral colon is the diagnostic method of choice for the detection of coronavirus in calves; fecal samples are unreliable. Isolation of coronavirus in tracheal organ culture is the most sensitive in vitro culture technique. A hemadsorption–elution–hemagglutination assay test for the detection of coronavirus in the feces of calves is a simple and rapid procedure. A counterimmunoelectrophoresis test is available for the detection of coronavirus in calves. An immunohistochemical technique can be used to detect the virus of porcine epidemic diarrhea in the small intestine.[55]

ELISAs. These tests are more sensitive and simple than immunoelectroosmophoresis, complement fixation, immunofluorescence on inoculated cell cultures or electron microscopy for the detection of rotavirus in calf feces. The ELISA is effective in detecting the presence of porcine rotavirus in feces and was confirmed in two-thirds of the samples tested using electron microscopy, immunofluorescence, and polyacrylamide gel electrophoresis (PAGE).[56] A blocking ELISA using monoclonal antibodies can detect the porcine epidemic diarrhea virus in feces and serum antibodies in both naturally and experimentally infected piglets and earlier than an indirect immunofluorescence test.[57]

A competitive blocking **ELISA (CB-ELISA)** is considered most suitable for routine detection of porcine epidemic virus in the feces of pigs.[58]

The **ELISA** or electron microscopy of feces are equally reliable in detecting the rotavirus and coronavirus in the feces of experimentally infected calves. The agreement between the two tests was 95% for coronavirus and 84% for rotavirus. There will always be borderline samples containing antigen in quantities near the detection limit for each test. Some samples will be positive for one test and negative for the other, and vice versa. This problem can be minimized if several individual samples from a disease outbreak are examined. The morphological

identification of rotavirus is usually straightforward but the pleomorphism of bovine coronavirus can present problems. The ELISA may also fail to detect viral antigen in feces which also contain antibody. The test can provide diagnostic results within 24 h after collection of the fecal samples.

Reverse passive hemagglutination (RPHA), ELISA and polyacrylamide gel electrophoresis **(PAGE).** Three techniques for the detection of rotavirus in fecal samples from diarrheic calves have been compared. The **RPHA** was at least as sensitive as the ELISA, and both were compared with the PAGE. The overall agreement between **RPHA** and **PAGE** was 96%; the ELISA was not as sensitive. The commercial ELISA has a slightly higher sensitivity than agglutination, **PAGE**, and concentrated **PAGE**, but the specificity of **ELISA** is lower. The latex agglutination test has a lower sensitivity than ELISA but its specificity is higher.[59] The latex agglutination test is easy to perform, more sensitive than electron microscopy and more specific for detection of rotavirus. A dot hybridization assay can detect and differentiate two serotypes of porcine rotavirus.

ELISA and RT-PCR. The fast and inexpensive ELISA combined with the highly specific and sensitive reverse transcriptase-polymerase chain reaction (RT-PCR) is a practical approach epidemiological studies of bovine rotavirus.[60]

PCR assays are now available for the detection of bovine rotaviruses in feces.[9]

Non-radioactive PCR-derived cDNA probe assays can be used to detect rotavirus serotypes.[61]

Rapid ELISA. A rapid **ELISA using monoclonal antibodies** can be used for the simultaneous detection of bovine coronavirus, rotavirus serogroup A and *E. coli* K99 antigen in the feces of calves.[35] The specificity of all of the components was more than 90% specific and the sensitivity for bovine coronavirus, K99 *E. coli*, and rotavirus, 77%, 93% and 100%, respectively.[35]

Immunochromatography. This is a test for the detection of Group A rotavirus in the feces of calves, piglets and foals, has a sensitivity of 89% and specificity of 99% compared to the ELISA, and its reproducibility is 100%.[62] It is a one-step procedure, simple to use, very rapid and can be carried out on the farm.

A field enzyme immunoassay test (Rotazyme test) is highly accurate and reliable for the detection of rotavirus in the feces of horses with and without diarrhea. The test is a simple, rapid and specific procedure which can take the place of a more expensive and slower procedure such as electron microscopy.

ImmunoCardSTAT Rotavirus [ICS-RV] is a human group A assay can be used as an on-site diagnostic test for bovine rotavirus with a sensitivity and specificity of 87.0% and 93.6%, respectively.[63] The assay is a 10-min one-step test with all the necessary reagents included in the kit and with no need for any laboratory equipment.

Serology

Several serological tests are available for the measurement of rotaviral antibody in serum and lacteal secretions. An ELISA is used to detect porcine epidemic diarrhea coronavirus antibodies in swine sera.[40] The radioimmunoassay is the most sensitive test compared to the agar gel immunodiffusion, complement fixation, hemagglutination and hemagglutination inhibition tests.

NECROPSY FINDINGS

The pathology of experimentally induced rotavirus and coronavirus diarrhea in colostrum-deprived and gnotobiotic calves, lambs, and piglets has been described. Grossly, the changes are unremarkable and consist of dehydration, fluid-filled intestinal tract and distension of the abomasum. The microscopic changes consist of shortening of the length of the villi and replacement of the tall columnar villous epithelial cells by cuboidal and squamous cells. Segments of the small intestine may reveal villous fusion, rounded absorptive cells, villous atrophy and exposure of lamina propria. Crypt hyperplasia occurs in response to the loss of columnar epithelial cells from the villi. Histological lesions due to previous rotavirus infection may be present in the upper small intestine of clinically normal calves. The rate at which enterocytes are affected in older disease-resistant calves is due to the slowing of the virus from entering the cells.[64]

In coronavirus enteritis in calves, there is commonly villous atrophy of both the small and large intestines and destruction of the crypt epithelium; destruction does not occur in rotavirus enteritis. The changes are more severe in field cases of acute diarrhea in calves in which both viruses and enteropathogenic *E. coli* can be isolated. Concurrent infection with BVDV has also been demonstrated to be synergistic in bovine rotaviral diarrhea.[51]

The histological appearance of the intestinal lesions of experimental infection of calves with Breda virus, calicivirus-like agent, and parvovirus have been described. In general, the lesions are similar to those associated with rotavirus and coronavirus infection.

The wide array of diagnostic tests available to confirm the presence of enteric viruses has already been discussed. Owing to the frequency of subclinical infection with these agents, it is important to histologically confirm concurrent atrophy of villi.

Samples for confirmation of diagnosis

- **Histology** – duodenum, jejunum, ileum, colon (LM, IHC)
- **Virology** – colonic content (EM, ELISA, LATEX AGGLUTINATION); colon, ileum, jejunum (FAT, ISO).

DIFFERENTIAL DIAGNOSIS

The cause of acute diarrhea in newborn farm animals cannot be determined clinically. All of the common bacterial and viral enteropathogens can cause an acute profuse fluid diarrhea with progressive dehydration and death in a few days.

When outbreaks of diarrhea are encountered, a detailed examination of the possible risk factors should be made and the appropriate fecal samples and tissues from affected animals should be submitted to the laboratory. The most reliable specimens include fecal samples obtained from animals within a few hours after the onset of diarrhea, and untreated affected animals which are submitted for necropsy and microbiological examination within a few hours after the onset of diarrhea.

The clinical and epidemiological characteristics of the common acute diarrheas of neonatal farm animals are as follows:

Calves

Enteric colibacillosis occurs primarily in calves under 4 d of age and is characterized clinically by an acute, profuse liquid diarrhea. Recovery following treatment usually occurs in 2 d. Outbreaks occur in beef and dairy calves. Rotavirus and coronavirus diarrhea usually occur in calves over 5–10 d of age and up to 3 weeks of age. Explosive outbreaks occur, characterized by an acute profuse liquid diarrhea with recovery in 2–4 d. Recovery is assisted by oral fluid therapy.

Cryptosporidiosis occurs in calves from 5–15 d of age and is characterized by a persistent diarrhea which may last for several days. The cryptosporidia may be detected by Giemsa stain of fecal smears or by fecal flotation.

BVD. Whether or not the BVDV causes clinically significant diarrhea with lesions of the small intestine of calves 3–6 weeks of age is unknown. Diagnostic laboratories report the presence of intestinal lesions such as villous atrophy and crypt cell destruction in calves 3–6 weeks of age which have been affected with an intractable diarrhea and from which the BVD virus was isolated from the feces. However, to date there is no evidence of a cause and effect relationship.

Piglets

TGE occurs most commonly in piglets under 1 week of age and explosive outbreaks are common. There is acute profuse diarrhea and vomiting. Affected piglets may continue to nurse for several hours after the onset of the diarrhea. The case–fatality rate is high in piglets under 7 d of age; older pigs commonly survive.

Porcine epidemic diarrhea type I affects piglets under 4–5 weeks of age and is characterized by profuse watery diarrhea, high morbidity and low mortality.
Porcine epidemic diarrhea type II causes a profuse fluid diarrhea in pigs of all ages, including nursing piglets. Explosive outbreaks may occur and the morbidity may reach 100%. Mortality is usually restricted to piglets under 3 weeks of age.
Enteric colibacillosis usually occurs in piglets under 3 d of age. There is acute diarrhea, dehydration and rapid death. Pigs with coliform septicemia may die without obvious diarrhea and usually appear cyanotic. Entire litters may be affected and the case–fatality rate may be 100%. Early treatment with antibiotics and SC fluids will result in recovery. Coccidiosis occurs in piglets from 5–10 d of age and is characterized by an acute diarrhea in which the feces are foul-smelling and vary in consistency from cottage cheese-like to liquid, and gray or yellow and frothy. The diarrhea is persistent for several days and non-responsive to antibiotics. Some pigs recover spontaneously, others die in 2–4 d. Coccidial oocysts can be detected in the feces. The morbidity rate varies from 50–75% and the case–fatality rate from 10–20%.
Hemorrhagic enterotoxemia due to *Clostridium perfringens* Type C affects entire litters of pigs under 1 week of age, is characterized clinically by severe toxemia, dysentery and rapid death, and at necropsy there is a hemorrhagic enteritis.

Lambs

Enteric colibacillosis occurs in lambs most commonly under 1 week of age and is characterized by dullness, failure to suck and acute diarrhea which responds to antibiotic and fluid therapy.
Coliform septicemia affects lambs under a few days of age and usually causes sudden deaths. Lamb dysentery occurs most commonly in lambs under 10 d of age and there may be sudden death or acute toxemia, tucked-up abdomen and a severe diarrhea and dysentery. At necropsy the characteristic finding is hemorrhagic enteritis.

Foals

Rotaviral diarrhea occurs in foals from 5–35 d of age, but most commonly in foals under 2 weeks of age. There is acute profuse watery diarrhea, failure to suck, recumbency, dehydration. Recovery is common within 1 week. A mild fever is common.
Foal heat diarrhea occurs in foals 6–10 days of age whose dams are in estrus 7–10 d after foaling.
Salmonellosis, *C. perfringens* Type B and dietary diarrhea from excessive consumption of milk are less common causes of diarrhea in newborn foals.

TREATMENT

The treatment of viral diarrheas in newborn farm animals is essentially the same as described for acute undifferentiated diarrhea of newborn calves. There is no specific therapy for viral diarrhea, but antimicrobial agents may be used both orally and parentally for the poss-ible occurrence of secondary enteric and systemic bacterial infections. In the absence of complications, recovery from viral enteritis usually occurs without specific treatment in 2–5 d, which parallels the replacement of the villous epithelial cells whose complete replacement and maturation requires several days after the cessation of diarrhea.

The **withholding of milk** for 24–48 h is beneficial, but often not possible or practical with nursing beef calves or litters of pigs. Milk can be easily withheld from hand-fed calves and replaced with oral fluids and electrolytes.

Oral and parenteral fluid therapy as indicated is essential and details are described in the sections on colibacillosis and fluid and electrolyte therapy). Affected foals may require fluid and electrolyte therapy for up to 72 h. A glucose–glycine electrolyte formulation is an effective fluid therapy for pigs affected with experimental rotaviral diarrhea. The formula is: glucose 67.53%, sodium chloride 14.34%, glycine 10.3%, citric acid 0.8%, potassium citrate 0.2% and potassium dihydrogen phosphate 6.8%. A weight of 64 g of the above is dissolved in 2 L water to produce an isotonic solution.

When possible, affected animals, particularly calves, should be **isolated from calving grounds** and other newborn calves, which are susceptible up to 3 weeks of age. When outbreaks of the disease occur in any species, the principles of good sanitation and hygiene should be emphasized to minimize the spread of infection.

CONTROL

The principles of control of viral diarrhea are similar to those described for acute undifferentiated diarrhea of newborn calves:

- Reduce infection pressure
- Insure adequate colostral intake
- Vaccinate the dam to induce specific immunity in the colostrum (passive immunization).

Management and colostral intake

The management of pregnant animals at the time of parturition must insure that the degree of exposure of the newborn to infectious agents is minimized. Control of population density to avoid overcrowding, and attention to sanitation and hygiene are important. Because infected neonates excrete large numbers of viral particles for several weeks, effective control is dependent on management of the environment of the newborn species with particular emphasis on hygiene. The ingestion of adequate quantities of good quality colostrum as soon after birth as possible is also important.

Vaccination

Two major approaches have been used to provide specific immunity for the control of rotavirus and coronavirus diarrhea in calves:

1. Stimulation of active immunity by vaccinating the newborn calf with an oral vaccine containing the modified live viruses (MLVs)
2. Enhancement of lactogenic immunity by vaccinating the dam during pregnancy (passive immunization).

Oral vaccines to newborn calves

A MLV rotavirus vaccine for oral administration to calves immediately after birth has been available commercially for many years. Initially, good results were claimed but vaccine field trials did not include contemporary controls and the efficacy of the vaccine was uncertain. The incidence of diarrhea in herds not vaccinated in the previous year was compared with the incidence during the year of vaccination, which is inadequate to assess the efficacy of the vaccine.

Field trials using the oral vaccine indicate a failure of protection of calves against rotavirus infection and rotavirus–coronavirus infection. Effective oral vaccination of calves may be hindered by the presence of specific antibodies in the colostrum – the colostrum barrier – and may explain the failure of the vaccine under field conditions. The intestinal antibody response of young calves to an enteric viral infection is associated with the production of IgM and IgA antibodies locally in the intestine. This response is absent or diminished in calves which have ingested colostrum with specific antibodies to the viruses. Most of the efficacy trials with the vaccine were carried out on colostrum-deprived gnotobiotic calves which were vaccinated orally at birth and experimentally challenged a few days after birth. It is probably futile to vaccinate calves orally immediately after birth, particularly in herds where the disease is endemic because the colostrum will contain high levels of specific antibodies.

Fecal shedding of oral vaccine rotavirus seldom occurs after oral inoculation of gnotobiotic calves with a commercial modified live bovine rotavirus-bovine coronavirus vaccine.[65] Because of low shedding of virus in gnotobiotic calves which do not have the interfering effects of colostral antibodies, it seems unlikely that vaccine rotavirus will be shed in quantities from orally vaccinated conventional calves which have ingested colostrum containing antibody. Thus detection of the

virus by negative stain electron microscopy in feces from orally vaccinated calves is most likely to be virulent field virus rather than vaccine virus.

Vaccination of pregnant dam (passive immunization)

Vaccination of the pregnant dam to enhance specific colostral immunity can provide passive protection against enteric viral infection of newborn farm animals. The success of this method depends on the continuous presence of a sufficient amount of specific antibody to the rotavirus and coronavirus in the intestinal lumen.[35] Normally, the colostral levels of antibody are high in the first few milkings after parturition. However, there is a rapid decline in colostral antibodies to below protective levels within 24–48 h following parturition. Most cases of rotavirus and coronavirus diarrhea occur from 5–14 d after birth when the antibody levels in the post-colostral milk are too low to be protective.

The parenteral vaccination of the pregnant dam before parturition with a rotavirus and coronavirus vaccine will usually increase the level and duration of specific antibody in the colostrums.[38] There is a need for a vaccine which when given to pregnant cattle will initially result in protective levels of specific antibody to the rotavirus and coronavirus in the colostrum, and then in the milk for a sufficient period such as 10 d to 3 weeks, the period in which animals are most susceptible to these viral diarrheas. The use of a modified live rotavirus–coronavirus vaccine stimulated a small but insignificant increase in colostral and milk antibodies. However, by 3 d after parturition, the rotavirus and coronavirus antibody titers in the milk of vaccinated heifers had declined to low or undetectable levels.

Inactivated rotavirus vaccines given to pregnant cows in the last trimester will significantly increase antirotavirus antibody in colostrum and milk from vaccinated dams compared to controls, but the severity of diarrhea may be the same in calves from both groups. The increased milk antibody delays the establishment of infection but does not reduce the severity of clinical disease which was experimentally induced. An inactivated oil-adjuvanted rotavirus vaccine given 1 month before calving to beef cattle significantly reduced the morbidity and mortality in 16 of 17 herds with a total of 4066 cows.[66]

Experimental studies of maternal bovine rotavirus vaccines

The use of an adjuvanted rotavirus vaccine given simultaneously intramuscularly and by the intramammary route significantly enhanced serum, colostrum and milk rotavirus antibody titers, whereas intramuscular vaccination with a commercial modified live rotavirus–coronavirus vaccine did not.[67] Colostrum supplements, from the cows vaccinated by the intramammary and intramuscular routes, fed to rotavirus-challenged calves at a rate of 1% of the total daily intake of milk, provided protection against both diarrhea and shedding. The 30-day milk antibody titers from these experimental cows were also considered to be protective for calves by which time the calves should have developed a high degree of age-specific resistance to rotavirus infection. The use of an inactivated rotavirus vaccine in an oil adjuvant given to pregnant cows 60–90 d before calving and repeated on the day of calving resulted in a significant increase and prolongation of colostral antibodies up to 28 d after calving. Diarrhea in calves from vaccinated cows was less common and less serious. Similar results were obtained with a combined inactivated adjuvanted rotavirus and *E. coli* vaccine. Similar results have been achieved by vaccination of pregnant ewes. Vaccination of ewes can result in an elevation of specific colostral antibody and prolong the period over which the antibody is present in the lumen of the intestines of the lambs. The vaccination of cows with a monovalent vaccine results in a heterotypic response to all serotypes of rotavirus to which the animals have been previously exposed, which suggests that single serotype vaccination may be sufficient.

The lactogenic antibody responses in pregnant cows vaccinated with recombinant bovine rotavirus-like (VLPS) of two serotypes or inactivated bovine rotavirus vaccines have been evaluated.[68] Bovine rotavirus antibody titers in serum, colostrum and milk were significantly enhanced by the use of triple-layered VLPs and inactivated vaccines but higher antibody responses occurred in VLP vaccinated cows.[68]

Bovine coronavirus vaccine

An oil adjuvanted vaccine containing bovine coronavirus antigen to enhance lactogenic immunity in the calf by vaccinating pregnant cows and heifers between 2 and 12 weeks before calving increased serum antibody in the dams which was reflected in a similar increase in the titer and duration of specific antibody in colostrum and milk for up to 28 days after calving.[69] The overall response was dependent on an adequate antigen payload being incorporated within the single dose vaccine.

Commercial bovine rotavirus-coronavirus and *E. coli* F5 (K99) vaccines

The original rotavirus and coronavirus vaccines for use in pregnant cows to provide passive immunization were not sufficiently efficacious because of the rapid decline in specific colostral antibodies, which renders the calves susceptible to the viral diarrhea several days after birth. The relative success of the enterotoxigenic K99+ *E. coli* bacterins has resulted in a shift of the epidemic curve for acute diarrhea in calves under 30 d of age from a few days of age to 2–3 weeks of age.

More recently developed vaccines are efficacious. An inactivated combined vaccine against rotavirus, coronavirus and *E. coli* F5 (K99+) administered 31 days before the first expected calving date has been evaluated and compared to controls.[70] There was a significant increase in serum antibody against all three antigens in vaccinated animals, which was accompanied by increased levels of protective antibodies to rotavirus, coronavirus, and *E. coli* in their colostrum and milk for at least 28 days. The levels of specific rotavirus and coronavirus antibodies in the milk of vaccinated cows were greater than a four-fold higher than in the control cows for at least 28 days after calving.

The primary vaccination of pregnant cows with a trivalent commercial vaccine containing live attenuated bovine rota- and coronavirus and *E. coli* F5 followed by an annual booster at 6 and 3 weeks before calving, or using the same protocol with an inactivated trivalent vaccine resulted in significant increase in the serum antibody of all vaccinated animals compared to controls.[71] The antibody titers were higher in cows receiving the live vaccine compared to those receiving the inactivated vaccine. The colostral antibodies against all three antigens increased in all live vaccinated groups whereas inactivated vaccinated animals had only significant increases in F5 titers. The colostrum of live vaccinated cows contained much higher specific antibody titers. Thus the modified-live virus vaccine can significantly enhance the specific response to rota-and coronavirus and *E. coli* F5 after a primary vaccination followed by a booster annually.

Feeding 2 liters of colostrum within 12 hours after birth, from cows vaccinated 8 weeks before calving with an inactivated vaccine containing rotavirus, coronavirus and E. coli K99+/F41 antigens, is efficient in raising the serum antibody titer of calves to a high level, and, thus, protecting them against rotavirus infections which occur in the first few weeks of life.[72]

Stored colostrum

The high levels of viral antibody in the colostrum of the first two milkings of cows can be used to advantage in hand-fed calves. The daily feeding of stored colostrum from the first few milkings of cows from the affected herd will reduce the incidence of clinical disease in the

calves. The colostrum must be fed daily because rotavirus antibody is not retained in the intestinal lumen for more than 2–3 d. In affected herds the specific antiviral antibody in the stored colostrum may be sufficient to prevent the disease if colostrum is fed daily for up to 20–30 d. If a large number of cows are calving over a short period of time, the colostrum from immunized cows can be pooled and fed to the calves daily. Even small amounts of colostrum from immunized cows are efficacious if mixed with cows' whole milk or milk replacer.[38] This supplemental feeding of colostrum may be required for only 3–4 weeks, since older calves generally possess a high degree of age-specific resistance to rotavirus infections.

Systemic colostral antibody

For many years it was uncertain if circulating colostral antibody in calves was transferred back into the intestinal tract. Evidence shows that passive immunity to calf rotavirus diarrhea can be achieved by adequate calf serum colostral antibody titers.[73] Calves fed colostrum on the first day of life had significant rotavirus-neutralizing antibody titers in their small intestinal lumina for 5 d and 10 d later. The intestinal antibody titers correlated with the serum antibody titers derived from colostrum and were predominantly of the IgG_1 isotype. Intestinal antibody titers were approximately equivalent in 5- and 10-day-old calves, suggesting that **antibody transfer to the intestinal tract is a continuing process for up to 10 days after birth.** Additional evidence that transfer of passive immunity occurs is that calves can be protected from rotavirus challenge by the administration of colostral immunoglobulins by parenteral injection. This protection was not due to lactogenic antibody, since the calves received no source of dietary antibody. The transfer of circulating antibody into the intestinal tract may be the mechanism which results in the decreased morbidity and case fatality due to diarrhea in calves with high concentrations of passive serum immunoglobulins.[73]

Porcine rotavirus vaccines

Oral porcine rotaviral vaccines have been unsuccessful. Maternal rotavirus vaccines used to induce passive immunity have been examined. In pigs, as in ruminants, IgG antibodies to rotavirus are predominant in colostrum and decline 8–32-fold in the transition to milk. However, secretory IgA is the primary isotype of rotavirus antibody in the milk of pigs. Increased levels of sIgA and IgG antibodies to rotavirus occur in the milk of sows after natural rotavirus infection of nursing piglets or following parenteral inoculation of pregnant or lactating sows with live attenuated rotaviruses.[38] But titers decline by the end of lactation, suggesting that repeated natural rotavirus infection of sows or parenteral revaccination may be necessary to maintain high sIgA antibody to rotavirus in milk. This observation may account for the higher prevalence of rotavirus infection during the first week of life in pigs born to gilts (38%) than in those born to sows (3%). There are few studies of maternal rotavirus vaccines for use in swine.

Equine rotavirus vaccine

An inactivated equine rotavirus vaccine given to mares at 8, 9, and 10 months of gestation was safe and immunogenic, and provided reasonable protection under field conditions.[74] Antibody titers were significantly increased at the time of foaling and 35 d after foaling in vaccinated, compared with control mares and for 90 d after birth in foals born to vaccinated, compared with foals born to control mares. The incidence of rotaviral diarrhea was lower in foals born to vaccinated, compared with foals born to control mares but the difference was not significant. Parenteral vaccination of mares with inactivated rotaviral vaccine stimulates production of high levels of specific IgG, and not IgA, in colostrum and milk.[75]

Subunit vaccines

Subunit rotaviral vaccines consisting of virus-like particles given parenterally can enhance bovine rotavirus antibody titers in serum, colostrum and milk.[76] These vaccines offer advantages over conventional modified-live or inactivated vaccines including:

- Exclusion of adventitious agents associated with live vaccines
- Consistent production of outer capsid proteins
- Genetic engineering to allow updating of efficacious vaccines for boosting lactogenic immunity. Field studies to evaluate the vaccine under naturally occurring conditions have not yet been carried out.

Chicken egg yolk immunoglobulin

Preliminary studies on the passive protection of anti-rotavirus chicken egg yolk immunoglobulins given orally to calves against experimental rotavirus infections in neonatal calves have been reported.[77] Treated calves had increased body weights and the number of calves shedding high titers of rotavirus in the feces was decreased compared to control calves.

WINTER DYSENTERY IN CATTLE

Synopsis

Etiology Bovine coronavirus
Epidemiology Northern climates. Adult lactating dairy cows, usually during winter months when housed. Immunity develops and lasts variable periods. High morbidity with outbreaks; no mortality. Transmitted by fecal–oral route
Signs Sudden onset of diarrhea affecting almost entire herd within several days. Mild fever, decline in milk production, inappetence. Recover in few days. Some coughing
Clinical pathology None routinely
Lesions None
Diagnostic confirmation Detection of virus in feces. Serology
Differential diagnosis list. All common causes of diarrhea in adult cattle (see Table 5.10)
Treatment None required
Control No specific control measures available. Hygiene. Minimize overcrowding in dairy housing
Winter dysentery is a highly contagious disease of adult cattle characterized by an acute onset of a short course of severe diarrhea and sometimes dysentery. Mild respiratory signs, accompanied by decreased milk production and variable depression and anorexia are also characteristic of the disease. Recovery is spontaneous within a few days

ETIOLOGY

The disease is associated with a bovine coronavirus (BCV) which is a member of family Coronaviridae, order Nidovirales.[1] The virus can be found in the feces of affected cows along with a serological response to the virus. The disease can be reproduced in bovine coronavirus seronegative lactating cows.[2]

Several studies have found a close serological relationship between the coronavirus causing winter dysentery and the coronavirus causing diarrhea in calves but there are antigenic differences between the different isolates.[1,3] The oral and intranasal inoculation of gnotobiotic and colostrum-deprived calves with the virus of winter dysentery results in diarrhea in the calves indistinguishable from that seen in calves inoculated with the calf diarrhea coronavirus.[4] The BCV has also been isolated from the diarrheic feces of adult wild ruminants (sambar deer, one waterbuck and white-tailed deer) affected with diarrhea in both England and the United States.[5] The BCV has tropism for both the intestinal and respiratory tracts.[6] The virus also causes respiratory tract infections in calves and feedlot cattle.[7,8]

EPIDEMIOLOGY

Occurrence and prevalence of infection

The disease occurs primarily in mature dairy cattle and has been reported in many countries including the United States, Canada, Sweden, Germany, France, Israel, Australia, and New Zealand. It is common in dairy cattle in Sweden.[2,9] A nationwide survey of antibodies to BCV in bulk tank milk in Swedish dairy herds found that 89% of samples were positive and 52% had very high levels of antibodies.[9] There were also higher antibody levels in larger herds.

Winter dysentery is most common in recently calved adult lactating dairy cows. Young cattle may be affected but with only mild clinical signs. The disease is most common in cattle in northern climates when they are housed from November to April. A moderate immunity, which persists for about 6 months, develops after clinical disease, and recurrent clinical disease seldom occurs in less than 2–3 years. In France, the frequency of epidemics in a herd vary from a few months to 10 years. In herds regularly exposed to the infection, epidemics are mild; when the intervals between recurrences are more than 3 years, the epidemics are more severe. Serological examination of paired serum samples from affected herds reveal that almost all cows seroconvert to bovine coronavirus and the BVDV.[2] The titers to the bovine coronavirus are still high 1 year after the outbreak and antibody is transferred to colostrum and to the calves in which it persists for up to 4–6 months of age.[2]

The disease has also occurred in adult beef cattle and in feedlot cattle 6 to 9 months of age.[8]

A coronavirus indistinguishable from BCV has been isolated from wild ruminants with diarrhea similar to winter dysentery in cattle.[10] The virus was isolated from the feces of sambar deer, waterbuck in a wild animal habitat, and from a white-tailed deer on a wildlife farm in Ohio. In a serological survey of coronaviruses among wild deer, 8.7% and 6.6% of sera from mule deer in Wyoming and from white-tailed deer in Ohio, respectively, were seropositive against the wildlife isolates and selected bovine coronaviruses. Thus coronaviruses exist in wild ruminants which may be a source of infection transmissible to cattle.

Morbidity and case fatality rates

The morbidity rate may be as high as 30–50% within a few days after the first case is encountered, and up to 100% after 1 week. The case–fatality rate is less than 1%. A typical outbreak may last for 1–2 weeks and in Sweden, 75% occur between November and January.[2] The disease is important in dairy herds because, although few animals die of the disease, it may cause serious loss of body condition and milk flow. In mild epidemics, the maximum decrease in milk production compared to a theoretical lactation curve ranges from 6–11%. The overall decrease in milk production may persist for 8–15 d, after which time milk production levels are regained. In severe epidemics, the maximum decrease in milk production may be as high as 30% and may last for up to 28 d.

Outbreaks of the disease diagnosed by farmers exhibit space–time clustering within a 30-day time and a 5.5 km radius. Large herds with more than 60 cows and a history of an outbreak in the previous year were at increased risk of an outbreak. In Sweden, one-third of the affected herds had experienced an outbreak within the previous 4 years and 18% had a least one further outbreak during the following 2 years.

Methods of transmission

Feces from clinical cases or clinically normal carriers are the source of infection, and contamination of feed or drinking water is the method of spread. In France, the disease occurs on small dairy farms where the surface area is smaller than 2.3 m^2/cow. The disease is highly contagious and is introduced to farms by human visitors, carrier animals and fomites. Infection of the respiratory tract with the bovine coronavirus may enhance the transmission of the infection in addition to the usual fecal–oral route of transmission of enteric pathogens.

Experimental reproduction

Both winter dysentery and calf diarrhea can be reproduced using the same strain of BCV.[2] Calf diarrhea and winter dysentery strains of the virus can cause diarrhea

in adult cows in conjunction with host or environmental factors.[3] Winter dysentery can be reproduced in seronegative lactating dairy cows by direct contact with an experimentally infected calf. All experimental cattle shed the virus in the feces at the onset of profuse watery diarrhea with small amounts of blood in the feces of the most severely affected animals including both cows and calves. The cows are commonly more depressed, and their appetites are decreased which is associated with a marked decrease in milk yield. Following infection all cattle will produce early interferon type 1 in serum and in nasal secretions and milk. All cattle develop high IgM antibody responses and long-lasting IgA antibody responses both systemically and locally. Prolonged IgM antibody responses occur in all infected cattle. The IgA antibody response in serum may be detectable for up to 17 months after infection. Bovine-specific IgG can be detected in all cattle during the experimental period of up to 22 months.

Risk factors

Host and environmental risk factors

The cow-level risk factors for the development of winter dysentery in dairy cattle have been examined.[11] The likelihood of developing disease increased as the ELISA value for bovine coronavirus (BCV) antigen detectable in feces increased. Pregnant cattle were less likely to develop the disease compared with nonpregnant animals. Cows with high acute antibody titers to BCV which seroresponded had greater odds of developing disease, compared with cows with lower titers.

Some herd-level risk factors have been identified in dairy herds which have been exposed to the BCV and have experienced outbreaks of the disease.[12] The factors which appeared to increase a herd's risk for the disease include: an increase in herd prevalence of adult cows that had a four-fold or more increase in BCV serum IgG antibody titer; increase in herd prevalence of adult cows that had a fourfold or more increase in bovine viral diarrhea titer; housing cattle in tie-stall or stanchion barns rather than free-stall facilities; and use of equipment to handle manure and subsequently handle feed. The adjusted population-attributable risk for these variables was 71, 43, 53, and 31$, respectively, and 99% overall, indicating that these variables had considerable effect on winter dysentery outbreaks.

Pathogen risk factors

Coronaviruses are divided into at least three antigenic groups, and antigenic cross-reactivity exists within an antigenic group.[10] Bovine coronavirus, mouse hepatitis virus, murine enteric coronavirus, rat coronavirus, human coronavirus, porcine hemagglutinating encephalomyelitis virus belong to the same group. Bovine coronavirus is an important cause of neonatal calf diarrhea, and winter dysentery. BCV also possesses tropism for the respiratory tract of young cattle.

Some BCV strains isolated from the respiratory tract of cattle had different biological, antigenic, and genetic properties compared with enteric strains of the virus. Strains isolated from feedlot cattle and compared to those with the originally described Mebus prototype (from neonatal diarrheic calves) reveal that the respiratory strains of BCV may differ genetically from the classical calf enteric and adult winter dysentery strains.[13]

Cross-protection studies between respiratory and calf diarrhea and winter dysentery coronavirus strains in calves have been examined using RT-PCR and nested PCR for their detection.[7] Calves inoculated with bovine respiratory coronavirus (BRCV), calf diarrhea coronavirus (CD), winter dysentery (WD) coronavirus strains of BCV and the challenged 3 to 4 weeks later with either BRCV, CD, or WD strains of BCV developed diarrhea, then recovered and were protected from BCV-associated diarrhea after challenge exposure with either homologous or heterologous BCV strains. Nasal and fecal shedding of BCV, which were detectable only by nested PCR, after challenge exposure confirmed field and experimental data documenting reinfection of the respiratory and enteric tracts of cattle, indicating that in closed herds, respiratory or enteric tract infections may constitute a source of BCV transmission to cows or young calves. The biological, serological and genome properties of cytopathogenic RBCV strains isolated in Quebec and Ontario, Canada, have been compared to the original Mebus strain. RBCV strains have also been compared to previously characterized enteric bovine coronavirus strains in order to identify specific strain markers which should be considered for diagnosis and development of vaccines.[1]

PATHOGENESIS

The disease is a mild enteritis affecting the small intestine. The virus also has a tropism for the respiratory tract and has been associated with respiratory disease in adult cattle and pneumonia in calves.

CLINICAL FINDINGS

Cattle

After an incubation period of 3–7 d there is an explosive outbreak of diarrhea which, in the course of the next 4–7 d, affects the majority of adult cattle. The youngest animals of the mature group may have only mild signs. A fever (39.5–40.5°C; 103–105°F) may precede the onset of diarrhea but when clinical signs are evident, the temperature is usually normal. There is a marked fall in milk yield which lasts for up to 1 week, anorexia of short duration, and some loss of body condition. The feces are liquid and homogeneous without much odor, and with no mucous or epithelial shreds; the color is dark green to almost black. Feces are often passed with little warning and considerable velocity. A nasolacrimal discharge and cough may precede or accompany the epidemic. The frequency of coughing may be higher in those herds which have not experienced a more recent outbreak. In most animals the course is short and the feces return to normal consistency in 2–3 d. In occasional cases the syndrome is more severe, dehydration and weakness are apparent, and dysentery – either with feces flecked with blood or the passage of whole blood – occurs. The disease in the herd usually subsides in 1–2 weeks but in some cases production may not return to normal for several weeks or a few months.[2]

In feedlot cattle, 6 to 9 months of age, the disease has been characterized by an acute onset of diarrhea with high morbidity and low mortality, dyspnea, coughing, and nasal discharge, and high body temperature (40 to 41°C in most severe cases.[8] The diarrhea is characterized by fluid dark (brown-black) feces sometimes containing frank blood.

Sheep

Diarrhea and unthriftiness in groups of sheep have been associated with the virus but no published information is available.

CLINICAL PATHOLOGY

The laboratory diagnosis is dependent on detection of the virus in feces and serology. Fecal and blood samples should be submitted from both affected and normal cows.

Detection of virus

Fecal samples can be examined for the presence of bovine coronavirus using the ELISA test and by electron microscopy for viral particles. For routine purposes, direct electron microscopy viral identification and/or ELISA is sufficient. This can be complemented by protein A gold **immune electron microscopy** because of its high sensitivity and specificity in the detection of viral particles. A reverse transcriptase PCR (RT-PCR) can be used to detect the BCV in the feces of experimentally inoculated cattle.[3] The 1-step RT-PCR and nested PCR assays were highly sensitive to detect BCV in nasal and fecal specimens and are useful for the etiological diagnosis of BCV in calves and adult cows.[7]

Serology

In addition to detection of the virus in feces, an increase in the antibody titer to coronavirus based on acute and convalescent sera collected 8 weeks apart is supportive evidence that the virus is the causative agent.[14] Attempts at diagnosing these infections serologically are often problematic because in adult cattle high BCV-specific IgG levels are often encountered in the acute samples, presumably due to reinfections with the virus, obscuring the detection of a possible increase in titer in paired samples.[14] In addition, adult cattle are usually seropositive and maternal antibodies frequently obliterate the detection of infection in calves. There is a need for serologic tests that do not require the cumbersome and expensive paired samples necessary for an Ig-G based diagnosis.

A capture ELISA test for BCV-specific IgA and IgM in milk and sera has been developed and is useful for discriminating between primary infection and reinfection.[14] In adult cattle, testing of paired serum samples using the antibody-capture ELISA may be a better indicator of recent BCV exposure than testing of serum samples with virus neutralizing assays.[15] Antigen–antibody binding in feces may interfere with results of the antigen-capture ELISA for BCV.

NECROPSY FINDINGS

In the rare fatalities available for necropsy, there is severe hemorrhage and hyperemia of the colonic and cecal mucosa. Frank blood may be present in the lumen of the large intestine.[8] Microscopically there is widespread necrosis and degeneration of the epithelium of the large bowel. Similar but less severe gross and microscopic changes have been observed in experimentally infected cattle.

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed cecum, colon (LM, IHC)
- **Virology** – colonic content (EM, ELISA), colon (FAT).

DIFFERENTIAL DIAGNOSIS

Winter dysentery must be differentiated from:

BVD/MD affects cattle 8–24 months of age in small outbreaks. Erosions of the oral cavity are present and the diarrhea and systemic effects are much more severe. The more recently recognized Type II BVD affects cattle of all ages including adult cattle and is a severe, highly fatal disease.

Coccidiosis affects cattle from 3–12 months of age and is characterized by frank blood in the feces and tenesmus, and the fecal sample is usually diagnostic.

Enteric salmonellosis is a severe toxemic enteritis with diarrhea and dysentery, fibrinous casts in the feces, a high fever, severe depression and rapid death. Culture of the feces is important.

Johne's disease. A chronic intractable diarrhea in mature cattle with loss of body weight and eventual emaciation.

Group B rotavirus. Rare cases of diarrhea in mature lactating dairy cows associated with Group B rotavirus have been described.[16] The onset of diarrhea is sudden, milk production decreased, the feces were liquid, and recovery occurred in 3 to 5 days.

Respiratory tract infections. The clinical findings of dyspnea, nasal discharge, coughing, and fever associated with the bovine respiratory coronavirus must be differentiated from acute undifferentiated bovine respiratory tract disease.

TREATMENT

Treatment is of doubtful value because affected cattle usually respond spontaneously in 24–36 h. Occasionally dehydration will become severe and is best treated with fluids and balanced electrolytes as indicated.

CONTROL

Management

Because of the explosive nature of the disease and the lack of information on possible precipitating causes, effective control measures cannot be recommended. Every effort must be made to avoid the spread of infection on inanimate objects such as boots, feeding utensils and bedding, but even the greatest care does not appear to prevent the spread of the disease within a herd.

Vaccination

Some preliminary studies have tested the potency of bovine coronavirus vaccine to induce serum antibodies but randomized controlled trials to test the efficacy of the vaccine have not been done.[17]

BLUETONGUE

Synopsis

Etiology Bluetongue virus, an orbivirus with several serotypes and considerable genetic heterogeneity
Epidemiology An infectious, noncontagious disease of sheep and occasionally cattle, transmitted by *Culicoides* spp. Cattle are the reservoir and amplification hosts. Severe disease is restricted to fine wool and mutton breeds of sheep. Infection, but not disease is endemic in tropical and subtropical regions. Disease occurs in epidemic and incursive areas when climatic conditions allow the expansion of vector occurrence
Clinical findings Fever, catarrhal stomatitis, rhinitis, enteritis and lameness due to coronitis and myositis
Clinical pathology Virus isolation, agar gel immunodiffusion and competitive or blocking enzyme-linked immunosorbent assay (cELISA) serological tests. Detection of nucleic acid
Necropsy findings Mucosal lesions, hemorrhage and necrosis of skeletal and cardiac muscles, hemorrhagic lesion at base of pulmonary artery
Diagnostic confirmation Detection of viral nucleic acid, virus isolation, riding titer with serology
Treatment None specific, supportive
Control Reduction of exposure to vector is attempted but major method of control in epidemic areas is by vaccination

ETIOLOGY

Bluetongue virus (BTV) is an arthropod-borne *Orbivirus* in the family Reoviridae. Within the BTV serogroup there are at least 24 serotypes of BTV worldwide. There is considerable **genetic variability** within the serogroup. This arises by genetic drift of individual gene segments as well as by reassortment of gene segments when ruminants or the vectors are infected with more than one strain. There is also debate of the biological validity of the classification of BTV into strict types.[1–3] All serotypes do not exist in any one infected area.

EPIDEMIOLOGY

Occurrence

Bluetongue virus infects domestic livestock populations in all **tropical and subtropical countries** and occurs on the continents of Africa, Asia, North America, South America, Australia and several islands in the tropics and subtropics, primarily between latitudes 40°N and 35°S.[4] **Incursive disease** has occurred in Portugal, Spain and Greece but until very recently bluetongue was not considered an endemic

infection in Europe. However, in an epidemic beginning in 1998, and persisting to date (2005), five serotypes have spread across and persisted in 12 countries in southern Europe occurring 800 km further north than ever previously recorded.[5] This persistence indicates overwintering of these infections in these new regions and is believed the result of climate change from global warming.

The distribution and intensity of infection in regions of the continents is determined by the climate, geography and altitude, as they affect the occurrence and activity of the *Culicoides* vectors, and by the presence of susceptible mammalian hosts. There is a **gradation** from continuous BTV activity in tropical areas to absence of virus transmission in colder areas. In large countries that span different lattitudes, such as the United States and Australia, there are areas that are free of infection.

In endemic areas, the infection is always present but clinical disease of the indigenous species is unusual. It can occur with new BTV strains and when non-indigenous susceptible species are introduced to the area.

Epidemic zones also exist, where infection and clinical disease occur every few years. Infection in these areas is highly focal and outbreaks occur when climatic conditions allow the vector to spread beyond its usual boundaries and to infect susceptible ruminants.

Incursive disease can occur in regions which do not normally experience infection and may occur when the virus is introduced by **windborne movement** of infected *Culicoides* with subsequent insect breeding in the summer before 'die out' in the autumn and winter. This method of spread is believed to have been the genesis of several serious outbreaks of bluetongue in countries normally free of the disease and of the outbreaks in Portugal in 1956, in Cyprus in 1977, in Turkey and Greece in 1979–1980 and in Israel in 1960–1980.[4–6] Polymerase chain reaction-based procedures can be used to determine the serotypic and geographic origin of infection with BTV.[7]

In the **United States**, the prevalence of seropositive cattle varies from high in the southern and western states to low in the northern states, especially the northeastern states. In the northwest region, there are epidemics of infection in the summer and fall every few years, associated with movement of infected vectors from the south. **Canada** is free of infection except for periodic incursions into the Okanagan Valley in British Columbia from windborne infected *Culicoides* from south of the border.[8] In **Australia**, there has been a sequential introduction of bluetongue serotypes from Indonesia by windborne *Culicoides* spp. but endemic infection is limited to northern cattle areas with extension down the east coast.[7,9–11]

Host occurrence

Infection occurs in a number of animals but significant disease occurs only in sheep. Cattle are the major **reservoir host** for sheep. Under natural conditions infection occurs in sheep and cattle, but it is also recorded in elk, white-tailed deer, pronghorn antelope, camels and other wild ruminants. Natural infection rarely occurs in goats but the infection can be transmitted experimentally.[12]

Method of transmission

The disease is not contagious and is **transmitted biologically** by certain species of ***Culicoides.*** There are over 1400 species of *Culicoides* worldwide but only a limited number have been associated with BTV.[10,13–15] Female *Culicoides* feed on cattle and horses and also sheep, deer, and goats, requiring at least one blood meal for the completion of the ovarian cycle. They feed nocturnally on animals in open pens and fields and the optimal temperatures for activity lie between 13°C and 35°C.

Virus in ingested blood infects cells of the midgut by a **receptor-mediated process**,[16] replicates and subsequently is released to the salivary gland. Once infected, they are infected for life – a period of several weeks.[14] They may feed twice or more and on different hosts, and achieve their greatest transmission potential 6–14 d after feeding on a viremic animal. BTV is maintained in nature by alternating cycles of infection between the midge and ruminant species. In many areas the disease is **seasonal** because *Culicoides* are killed by the first hard frost.

Culicoides breed in damp, wet areas including streams, irrigation channels, muddy areas and fecal runoff areas around farms, and habitats for them exist on the majority of farm environments. Species that are **cattle associated**, such as *C. brevitarsis*, breed in cattle dung. The generation time in the summer is about 14 d. Different species have different geographic occurrence and their distribution in a country is determined by climatic factors and the presence of a preferred host.

Culicoides species

In the **United States**, *C. variipennis* var *sonorensis* is the vector except in the southeast where it is *C. insignis*. This species and *C. pucillus*, *C. insignis*, *C. pusillus* and *C. filarifer* are also important in transmission in the **Caribbean** and Central and **South America**. There are other subtypes of *C. variipennis* in the United States which have different distributions to *C. variipennis* var. *sonorensis*. In **Africa**, *C. imicola* (*pallidipennis*) is a major vector and in the **Middle East and Asia** *C. fulvis*, *C. imicola*, *C. obsoletus*, *C. nudipalpis* and *C. orientalis*. In **Australia**, *C. wadai*, *C. actoni*, *C. brevitarsis*, *C. peregrinus*, *C. oxystoma*, *C. brevipalpis* and *C. fulvus* are vectors or potential vectors. They have different distribution in the country which oscillates, depending on climate. *C. brevitarsis*, *C. brevipalpis* and *C. wadai* are **obligate parasites** of cattle (dung breeders), but the others can complete their lifecycle in the absence of cattle. *C. brevitarsis* is the most extensively dispersed vector.[10] *C. imicola* has been involved in the recent expansion of bluetongue in **southern Europe,** but *C. obsoletus* and *C. pulicaris* have been implicated as new vectors in these regions.[5,17]

Other vectors

Other vectors may transmit the disease mechanically but are unlikely to be of major significance in disease epizootics. The argasid tick *Ornithodoros coriaceus* has been shown experimentally to be capable of transmitting the virus and be a potential vector. The sheep ked (*Melophagus ovinus*) ingests the virus when sucking the blood of infected sheep and can transmit the infection in a mechanical manner. Mosquitoes may play a role in transmission and *Aedes lineatopennis* and *Anopheles vagus* have been suspect.

Over-wintering

The life span of an adult culicoides is usually less than 10 days and at the most a few weeks. Cold winters kill virtually all of the adult vectors and there can be no transmission during these cold periods. Despite this there is an annual recrudescence of bluetongue in several temperate areas. The reason for the **persistence** of the infection from season to season is not fully understood. There is the possibility of the virus over-wintering in the insect vector but there is little evidence in support of this. *Culicoides* survive winter periods as larvae but there is no evidence of transovarial transmission of BTV in these insects.[5,18]

With infected animals bluetongue viruses can be isolated after initial infection for only a short period of time in infected sheep and only slightly longer in cattle. Infection of *Culicoides sonorensis* that were allowed to feed on infected animals occurred for only 11 days after initial infection in sheep and 49 days following infection of cattle although bluetongue virus nucleic acid can be detected for longer periods.[19] An analysis, in 2001, of published data indicated that the duration of viremia in cattle ceased by 63 days after

infection in adult cattle and a slightly longer period in infected colostrum-deprived calves.[20] Infection, as detected by routine isolation if virus, can also persist in wild ruminants.

However, none of these periods adequately explain the recrudescence and apparent over-wintering of infection in some areas. It has been recently shown that infectious BTV can be recovered from ovine skin biopsies for more than 9 weeks after infection and it is postulated that infection can be covertly present in seropositive and aviremic ruminants as a result of a persistent infection established in γδ T-cells. This covert but persistent infection is believed to allow perpetuation of BTV through the winter.[21] It is suggested that the occurrence of new vectors in the following spring with biting activity results in skin inflammation with recruitment of inflammatory cells including γδ T-cells and that interaction of these infected cells with skin fibroblasts results in a conversion of a persistent infection of the γδ T-cells to a productive lytic infection that allows subsequent infection of biting vectors.[5,21]

Venereal transmission

Bluetongue virus has been found in the **semen** of infected bulls during the initial viremic period, and infection has been transmitted through bull semen to susceptible cows,[22] but it is unlikely that this is a significant mechanism of transmission. Transplanted **embryos** from infected services are free of the virus and this is regarded as a minimal risk technique for obtaining offspring from cattle and sheep in infected areas.[23,24]

Persistent infection

Persistent infection in immunotolerant animals following in utero infection, once thought to be of importance, is now believed not to occur.[12,25]

Pathogen and vector risk factors

The geographical occurrence of bluetongue serotypes varies and is changing with time. There are differences in virulence between serotypes and between strains within serotypes and virulence is also related to virus dose and dependent on vector species, distribution and competence. Different *Culicoides* species **vary in susceptibility** to infection and some known vectors are resistant to infection with some serotypes, which in part explains regional differences in serotype occurrence.[10] Different *Culicoides* species have **different host preferences** and some have a distinct preference for cattle and little host preference for sheep.[10]

Climate

Climate is a major risk factor as culicoides require warmth and moisture for breeding and calm, warm, humid weather for feeding. A cold winter or a dry summer can markedly reduce vector numbers and risk for disease. Moisture may be in the form of rivers and streams or irrigation but rainfall is the predominant influence and rainfall in the preceding months is a major determinant of infection.[26–29]

Precipitation affects the size and persistence of breeding sites and the availability of humid microhabitats to allow shelter from desiccation during hot summer and autumn periods. Optimal temperature is also essential and in endemic areas temperatures for survival of the adults and larvae require temperatures sustained above a mean of 12.5°C for the cooler months and temperatures in the range of 18 to 30°C in the summer and autumn for optimum recruitment to adults and for optimal adult activity.[30,31] Temperature also affects the rate of virus production in culicoides.[32] Geographic information systems (GIS) can be used to predict area risk.[28]

Serotype occurrence

Genetic studies indicate that BTV tends to exist in discrete, stable ecosystems and that BTV serotypes that circulate in one region of the world are largely different from those in other regions. In the **United States**, five serotypes – 2, 10, 11, 13, and 17 – have been isolated. Serotype 2 is a relatively recent isolate and is restricted to the habitat of *C. insignis*, but the latter four are endemic throughout much of the south and west. Serotype 13 is probably a reassortment virus with a gene segment derived from a vaccine virus parent[33] and other reassortments between live vaccine virus and wild-type virus are a concern for the emergence of virus types that could posses enhanced virulence characteristics or novel antigenic properties.[34] In the **Caribbean** Region and **South** and **Central America**, serotypes 1–4, 6, 8, 12, 14, and 17 are reported.[4,13,35] In **Australia**, eight serotypes – 1, 3, 9, 15, 16, 20, 21, and 23 – have been isolated. Six of these (3, 9, 15, 16, 20, and 23) have only been found in the north of the Northern Territory, while two serotypes (1 and 21) are widely distributed across the northern and eastern coast of Australia. The introduction appears to have been sequential and five have been introduced since 1981. The virus has been isolated from infected *Culicoides* and sentinel animals and although there is serological evidence of infection in Queensland and New South Wales, there has been no clinical disease. In **Africa**, serotypes 1, 16, 18, 19, and 24 are the major serotypes isolated and in **Asia**, serotypes 1, 4, 7, 9, 10, 12, 16, 17, 20, 21, and 23.[4,36] Serotypes 1, 2, 4, 9, and 16 are associated with disease in the current expansion in southern Europe.[5]

The bluetongue viruses are stable and resistant to decomposition and to some standard virucidal agents, including sodium carbonate. They are sensitive to acid, inactivated below pH 6.0, and susceptible to 3% sodium hydroxide solution and organic iodides.

Host risk factors

Cattle

Cattle are the **reservoir and amplifying host** and have a high titer viremia. Cattle appear to be much more attractive to *Culicoides* spp. and this may enhance the importance of cattle as carriers. A **critical density** of cattle in a region may be required to sustain bluetongue in regions where the *Culicoides* vector is strongly cattle associated.[10]

Bos taurus breeds are more likely to be seropositive than *Bos indicus* and bulls have a greater risk for infection than females or castrated males. Seroprevalence increases with age, probably a reflection of increased duration of exposure.

Sheep

All breeds of sheep are susceptible but to varying degrees. **Merinos and British breeds** are more susceptible than native African sheep. There are also differences in **age** susceptibility to clinical disease which, inexplicably, vary with different outbreaks. With Australian serotypes, disease occurs only in sheep 3 years of age or older.[11] Exposure to **solar radiation** can increase the severity of the disease, as can excessive droving, shearing, poor nutrition and other forms of stress.

Morbidity and case fatality

When the disease occurs in a flock for the first time the incidence of clinical disease may reach 50–75% and the mortality 20–50%. Outbreaks in Cyprus and Spain were accompanied by mortality rates of 70% in affected flocks[2] but most outbreaks result in much lower mortality. Mortality rates of 2–30% are reported under field conditions in South Africa and from 0–14% in field outbreaks in the United States. High mortality can occur when a new strain of BTV emerges in an area.

Immunity to BTV tends to be strain specific and in epizootics, more than one strain may be introduced into an area. Infections caused by different serotypes may follow one another in quick succession in a sheep population. The serotypes vary widely in their virulence with a corresponding variation in the severity of the disease produced. However, sequential infection with more than one type of BTV results in the development of heterotypic antibody and may result in protection

against heterologous serotypes not previously encountered.

Experimental reproduction

Infection is readily produced by experimental infection of sheep and cattle but it is common for the clinical presentation of the experimental disease to be **very mild** despite the fact that the isolate might have been associated with severe disease in the field.[12,37] In many cases experimental infection produces viremia, fever, leukopenia and an antibody response but the localizing, identifying lesions are often minimal, with erythema of the coronary bands as the only visible abnormality in some cases.[38]

Fetal infection

Congenital defects of the nervous system of lambs occur when pregnant ewes are vaccinated with **attenuated vaccine** virus, and when calves and lambs are inoculated experimentally before midgestation, but **occur rarely with natural** infection. Unadapted virus does not readily cross the placenta.[39] Experimental inoculation of pregnant ewes is more likely to lead to fetal death with a generalized hepatic necrosis and suppressed hepatic hematopoiesis. Infection of the ewe in midpregnancy can result in infection of the lamb which is unaffected and born normally, but viremic so that it may remain as a source of infection for a further 2 months.[40] However, such lambs are not expected to have a major role in the spread of the disease.

The location and the nature of the lesions in the lambs of ewes injected with attenuated vaccine virus is related to the level of maturation and migration of nerve cells at the time infection occurs. The degenerative nature of the lesions results from the presence of immature neural cells with enhanced viral susceptibility combined with an inability to mobilize an effective immunological response.[22] In older fetuses, a typical inflammatory response develops and there is also a generalized retardation of growth and lymphoreticular activity.[41]

Experimental inoculation of cows at 60–120 d of pregnancy with virulent viruses can cause **congenital defects**, including excessive gingival tissue, agnathia (tilted mandible), arthrogryposis, ataxia and head pressing. Hydranencephaly or porencephaly may also be a sequel to infection with more virulent strains. The severity of the brain lesions decreases with increasing fetal age and infection at 243 d results in a mild encephalitis and the premature birth of calves which are still viremic but poorly viable.

Economic importance

Mortality varies with the serotype but can be significant and it is estimated that the incursion of the disease in Europe since 1998 has caused has death of over 1 million sheep.[5,34] However, production loss is also of great importance. Adults either lose their fleece from a break in the growth of the staple or develop a weakness (tender wool) that causes breaks in processing and markedly reduces the value of the fleece. Pregnant ewes commonly abort. There is a severe loss of condition and convalescence is prolonged, particularly in lambs. The loss from clinical disease and from reduced wool quality and suboptimal production following infection in sheep are significant.

A further major indirect cost of the disease is the restriction in **international trade**. The severe disease that occurred in the outbreaks in Cyprus and the Iberian peninsula in the 1940s and 1950s resulted in bluetongue being placed on **list A** of veterinary diseases by the Office International Des Epizooties (OIE). As a result there are restrictions on the international movement of cattle and sheep and their products from countries that have this infection to those that do not. The validity of these restrictions imposed by countries where bluetongue is unlikely to transmit is questionable. It is estimated that the United States has an annual loss of $144 million because of the inability to trade with BTV-free countries.[42]

Movement restrictions within an affected country, even though having limited scientific reason for imposition with bluetongue, can have a significant economic effect on a country's tourist-related income. In the year 2005 movement restrictions for cattle in Spain threaten the quality of bullfights and functions such as the running of the bulls in the Pamplona festival.

PATHOGENESIS

Sheep

The pathology of bluetongue can be attributed to vascular endothelial damage resulting in changes to capillary permeability and fragility, with subsequent disseminated intravascular coagulation and necrosis of tissues supplied by damaged capillaries. These changes result in edema, congestion, hemorrhage, inflammation and necrosis. Following infection into the skin, there is replication in the local draining lymph node and dissemination in mononuclear cells to secondary sites of replication in lymphoid tissue and lung. Viremia is detectable by day 3 and peak viremia, associated with fever and leukopenia, usually occurs 6–7 d after infection. Circulating virus concentrations subsequently fall with the appearance of circulating interferon and specific neutralizing antibodies.[38,43] With the viremia, there is localization of the virus in **vascular endothelium** which causes endothelial cell degeneration and necrosis with thrombosis and hemorrhage. There is also the development of a hemorrhagic diathesis and coagulation changes consistent with disseminated intravascular coagulation.[44] The distribution of the lesions is believed to be influenced by mechanical stress and the lower temperatures of these areas in relation to the rest of the body.[12]

Cattle and wild ruminants

With infection in cattle and wild ruminants, infection of endothelial cells is minimal. The viremia in cattle is highly cell associated, particularly with **erythrocytes and platelets.**[38,44,45] Although the virus does not replicate in the erythrocytes, it is protected from circulating neutralizing antibody and infected erythrocytes are likely to circulate for their lifespan. BTV antigen can be detected in erythrocytes of cattle 140 d after infection.[45] The severe clinical disease that occurs in only a few infected cattle is possibly a type 1 hypersensitivity reaction dependent upon virus-specific IgE from repeated exposure.[44]

The presence of the bluetongue virus in the **semen** of bulls is accompanied by structural abnormalities of the spermatozoa and by the presence of virus particles in them.

CLINICAL FINDINGS

Sheep

Naturally occurring, florid bluetongue in sheep has the following clinical characteristics. After an incubation period of less than a week, a severe febrile reaction with a maximum temperature of 40.5–41°C (105–106°F) is usual, although afebrile cases may occur. The **fever** continues for 5 or 6 d. About 48 h after the temperature rise, nasal discharge and salivation, with reddening of the buccal and nasal mucosae, are apparent. The **nasal discharge** is mucopurulent and often blood stained and the saliva is frothy. Swelling and edema of the lips, gums, dental pad and tongue occur and there may be involuntary movement of the lips. **Excoriation** of the buccal mucosa follows, the saliva becomes blood stained and the mouth has an offensive odor.

Lenticular, necrotic ulcers develop, particularly on the lateral aspects of the tongue, which may be swollen and purple in color, but more commonly is not. **Hyperemia** and ulceration are also common at the commissures of the lips, on the buccal papillae and around the anus and vulva. Swallowing is often difficult for the animal. Respiration is obstructed and stertorous and is increased in rate up to 100/min. Diarrhea and dysentery may occur.

Foot lesions, including **laminitis** and **coronitis**, and manifested by lameness and recumbency, appear only in some animals, usually when the mouth lesions begin to heal. The appearance of a dark red to purple band in the skin just above the coronet, due to coronitis, is an important diagnostic sign. **Wryneck**, with twisting of the head and neck to one side, occurs in a few cases, appearing suddenly around day 12. This is apparently due to the direct action of the virus on muscle tissue as is the pronounced muscle stiffness and weakness which is severe enough to prevent eating. There is a marked, rapid loss of condition. There is **facial swelling** with extensive swelling and drooping of the ears and hyperemia of the non-wooled skin may be present. Some affected sheep show severe conjunctivitis, accompanied by profuse lacrimation. A break occurs in the staple of the fleece. Vomiting and secondary aspiration pneumonia may also occur. Death in most fatal cases occurs about 6d after the appearance of signs.

In animals that recover, there is a **long convalescence** and a return to normal may take several months. Partial or complete loss of the **fleece** is common and causes great financial loss for the farmer. Other signs during convalescence include separation or cracking of the hooves and wrinkling and cracking of the skin around the lips and muzzle. Although the subsequent birth of lambs with porencephaly and cerebral necrosis is usually recorded after vaccination with attenuated virus, it also occurs rarely after natural infections.

In sheep in **enzootic areas**, the disease is much less severe and often inapparent. Two syndromes occur: (i) an abortive form in which the febrile reaction is not followed by local lesions and (ii) a subacute type in which the local lesions are minimal, but emaciation, weakness and extended convalescence are severe. A similar syndrome occurs in lambs which become infected when colostral immunity is on the wane.

Cattle

Most infections are inapparent, although a few animals may develop a clinical syndrome not unlike that seen in severely affected sheep. Clinical signs which have been recorded include:

- Fever (40–41°C, 104–106°F)
- Stiffness and laminitis in all four limbs
- Excessive salivation
- Edema of the lips
- Inappetence
- Nasal discharge
- Fetid breath.

Many affected cattle also have ulcerative lesions on the tongue, lips, dental pad, and muzzle. A severe **coronitis**, sometimes with sloughing of the hoof, may occur. Some cows have **photodermatitis** and lesions on the teats. Serosanguineous exudate may appear in the nostrils and a discharge from the eyes. Contraction of the infection during early pregnancy may cause abortion or **congenital deformities** including hydranencephaly, microcephaly, curvature of the limbs, blindness and deformity of the jaw.

Goats

Infected goats show very little clinically. There is a mild to moderate fever, and hyperemia of the mucosae and conjunctivae. BTV infections in deer produce an acute disease that is clinically and pathologically identical to epizootic hemorrhagic disease of deer and characterized by multiple hemorrhages throughout the body.

CLINICAL PATHOLOGY

There is a fall in packed cell volume and an initial leukopenia followed by a leukocytosis. In severe disease there is a marked leukopenia, due largely to lymphopenia. Infected cattle show a similar leukopenia. The skeletal myopathy which occurs in this disease is reflected by a rise in creatine phosphokinase.

Specific diagnosis is either by isolation of the virus, detection of viral antigen or nucleic acid, or detection of specific antibodies in serum. Serological assays can detect prior exposure to BTV but cannot establish if the animal is viremic, which is currently still important for movement decisions concerning cattle.

Virus isolation

Virus isolation commonly is carried out by tissue culture or culture in developing chick embryos. The virus can be isolated from blood during the febrile period and it, or detection of viral nucleic acid, is the most reliable **confirmation** of BTV infection because there are difficulties with the interpretation of serological test results. However, traditional isolation methods require 2–4 weeks.

Less commonly, diagnosis is by inoculation of blood into susceptible sheep. A positive test depends on the appearance of diagnostic clinical signs and resistance to subsequent challenge with the bluetongue virus, or a significant increase in virus-neutralizing antibodies in the recipient sheep.

Detection of antigen or nucleic acid

Immunohistochemical tests including immunofluorescence, immunoperoxidase and immunoelectron microscopic techniques using monoclonal antibody can be used for rapid sensitive and specific detection of antigen.[46,47] In situ nucleic acid hybridization and **PCR** can be used for detection of the virus and have the advantage of speed over tissue culture virus isolation and can also differentiate between wild-type isolaytes and vaccine strains.[19,46,48,49] Tests that detect viral RNA do not necessarily indicate that an infectious virus is still present.

Serological tests

A number of serological tests are available based on the detection of group-reactive antibody or serotype-specific antibody. Bluetongue diagnosis by serology is imprecise, unless a rising titer is demonstrated in acute and convalescent serum samples. The commonly available tests include complement fixation, the AGID, a number of different ELISA tests and virus neutralization.[46] In most laboratories the complement fixation test has been replaced by the AGID test. The **AGID test** is easy to perform and inexpensive. Antibody appears 5–15 d after infection and persists for 2 or more years.[50] The test is relatively **insensitive** and detects cross-reacting antibodies to other orbiviruses. Also, in epizootics a significant proportion of antibody-negative animals may be viremic.

There are a number of ELISA tests that have been developed using group-specific monoclonal antibodies and that have been suggested as alternates to the AGID for routine diagnosis and international trade.[42,46,51] The **competitive ELISA** appears more sensitive than most and is highly specific and may replace the AGID test as the preferred test for serodiagnosis of bluetongue.[42,46,52]

NECROPSY FINDINGS

The mucosal and skin lesions have already been described. Other consistent lesions include generalized edema, hyperemia and hemorrhage and necrosis of skeletal and cardiac muscles. There is a most distinctive hemorrhage at the base of the pulmonary artery. Animals with damage to esophageal or pharyngeal musculature may have lung consolidation due to aspiration pneumonia. Hyperemia and edema of the abomasal mucosa are sometimes accompanied by ecchymoses and ulceration. Microscopically there is thrombosis and widespread microvascular damage leading to myodegeneration and necrosis. Aborted bovine fetuses should be examined for evidence of hydranencephaly or porencephaly. As previously discussed, there are numerous tests available to confirm the presence of BTV in blood and tissue samples.

SAMPLES FOR CONFIRMATION OF DIAGNOSIS

- **Histology** – fixed oral and mucocutaneous lesions, abomasum, pulmonary artery, skeletal muscle from a variety of sites, left ventricular

papillary muscle. Brain from aborted fetus. (LM, IHC)
- **Virology** – chilled lung, spleen. CNS tissues, thoracic fluid from aborted fetus (ISO, PCR, in situ HYBRID, ELISA, etc.)

DIFFERENTIAL DIAGNOSIS

- Foot-and-mouth disease
- Epizootic hemorrhagic disease
- Contagious ecthyma
- Sheep pox.

TREATMENT

Local irrigations with mild disinfectant solutions may afford some relief. Affected sheep should be housed and protected from weather, particularly hot sun, and fluid and electrolyte therapy and treatment to control secondary infection may be desirable.

CONTROL

Reduction of infection through vector abatement

Attempts to control bluetongue through a reduction of infection consist of reducing the risk of exposure to infected *Culicoides* and reduction in *Culicoides* numbers. Neither are particularly effective.

Reducing the risk of exposure is attempted by spraying cattle and sheep with repellents and insecticides and housing sheep at night. Biweekly application of permethrin was found not to be effective in preventing infection.[53]

During transmission periods avoidance of low, marshy areas or moving sheep to higher altitudes may reduce risk. Because of the preference of some *Culicoides* for cattle as a host, cattle have been run in close proximity to sheep to act as vector decoys.[54] Widespread spraying for *Culicoides* control is not usually practical and has only a short-term effect.

There is a high mortality in *Culicoides* that fed on cattle that have been treated with a standard anthelmintic dose of ivermectin and also a larvicidal effect in manure passed for the next 28 d for *Culicoides* that breed in dung.[55]

Vaccination

Vaccination is the only satisfactory control procedure once the disease has been introduced into an area. Vaccination will not prevent or eliminate infection but it is successful in keeping losses to a very low level provided immunity to all local strains of the virus is attained.[56,57] Current vaccines are usually **polyvalent attenuated** virus vaccines and are in use in South Africa and Israel and available in other countries. These vaccines have been used in South Africa for more than 50 years and they are known to induce effective and long lasting immunity. Currently they are produced in cell culture and freeze-dried. The present Onderstepoort Bluetongue Vaccine comprises three bottles (Vaccines A, B, and C) and includes the following serotypes of BTV:

- Bottle A: BTV serotypes 1, 4, 6, 12, and 14
- Bottle B: BTV serotypes 3, 8, 9, 10, and 11
- Bottle C: BTV serotypes 2, 5, 7, 13, and 19.

The three bluetongue vaccines are administered separately at 3-week intervals.

Reactions to vaccination are slight but ewes should not be vaccinated within 3 weeks of mating as anestrus often results. **Annual revaccination** 1 month before the expected occurrence of the disease is recommended. Immunity is present 10 d after vaccination so that early vaccination during an outbreak may substantially reduce losses. Lambs from immune mothers may be able to neutralize the attenuated virus and fail to be immunized, whereas field strains may overcome their passive immunity. In enzootic areas, it may therefore be necessary to postpone lambing until major danger from the disease is passed and lambs should not be vaccinated until 2 weeks after weaning. Rams should be vaccinated before mating time.

Live attenuated vaccines should not be used in **pregnant ewes** because of the risk of deformity in the lambs or embryonic death.[54] The danger period is between the 4th and 8th weeks of pregnancy with the greatest incidence of deformities occurring when vaccination is carried out in ewes pregnant for 5–6 weeks. The incidence of deformities may be as high as 13%, with an average of 5%. Abortions do not occur although some lambs are stillborn.

The preparation and use of **attenuated vaccines** against BTV is **problematic**. The neutralizing epitopes are highly conserved on some serotypes but they are highly plastic on others [1]. It is therefore necessary to continually monitor the identity and prevalence of the serotypes that need to be in the vaccine.

There are also concerns for the use of live vaccines to control insect-borne diseases because of the risk of the vaccine strain being transmitted, of being exalted in virulence by passage, and of recombinants resulting in the development of new virus strains with unwanted characteristics. There is evidence for the emergence of a **reassortment strain** from a vaccine virus in the United States[33] and suspicion of occurrence elsewhere.[5] However, living vaccines are used for practical reasons, including the fact that inactivated vaccines do not provide protection against infection.[58] The difficulty in obtaining safe vaccines may be overcome by the use of recombinant DNA technologies. There is also good reason to suggest that cattle should be a major target of vaccination for bluetongue control.

International movement of livestock

Countries that are free of BTV infection have traditionally erected barriers to avoid its introduction by **prohibiting** the importation of any ruminant animals from countries where the disease occurs. Others have less severe restrictions and several procedures aimed at permitting limited movement are in force; their stringency varies with the importing country. Some countries only require a negative serological test or series of tests prior to movement. Others require a negative test in conjunction with a period of quarantine. The introduction of bovine **semen** from low-risk areas after suitable tests of donors and a prolonged storage period is accepted by most countries. Most countries allow the importation of **embryos**.

A more enlightened understanding of the epidemiology of bluetongue will probably result in a re-evaluation of these requirements in the future including regionalization within a country to allow exports from areas where there is no prevalence or transmission.[42]

EPIZOOTIC HEMORRHAGIC DISEASE

Epizootic hemorrhagic disease virus (EHDV) is a serogroup of *Orbivirus* closely related to bluetongue virus. There are at least 10 serotypes and some have antigenic relations with serotypes of bluetongue virus.[1] The serotypes infect deer and cattle naturally; sheep can be infected experimentally but not goats or pigs. In deer, the serotypes produce clinical disease. The pathogenesis of epizootic hemorrhagic disease is similar to that of bluetongue and infection of ruminants with either virus is characterized by extensive vascular injury, disseminated intravascular necrosis and tissue necrosis.[2]

The **geographic occurrence** of epizootic hemorrhagic disease viruses is similar to that of bluetongue virus. The virus, or serological evidence of infection, occurs on the North American, Australian, Asian and African continents.[3] In North America, there are two serotypes (EHDV-1, EHDV-2) and infection occurs in all areas of the United States, except the northeast and the arid southwest, and in southern Canada. In Australia, five serotypes are identified and the virus has been predominantly isolated from sentinel cattle in the north.[4] **Transmission** is by species of *Culicoides* and some species of gnats and mosquitoes.[3] There are also geographic differences in the severity of disease following EHDV infection with clinical disease in cattle being of rare occurrence in the United States but capable of causing outbreak of disease in cattle in Asia.

Infection in deer

In North America, epizootic hemorrhagic disease is considered one of the most important diseases of deer, particularly of white-tailed deer (*Odocoileus virginianus*) but also mule deer (*O. hemionus*, and pronghorn antelope (*Antiocarpa americanna*).[5] There are areas of enzootic stability, where seroprevalance in deer is high but clinical disease rare, and areas with low seroprevalance where clinical disease is severe.[6,7] All ages are susceptible, morbidity can be as high as 90% and **mortality** as high as 60% in some deer herds. The virus infects endothelial cells and the pathogenesis, clinical signs and postmortem lesions are similar to those of acute bluetongue in sheep with fever, hemorrhage and death.

Infection in cattle

Seroprevalence studies suggest that infection of cattle is common but **clinical disease is very rare**. An exception is infection with a genetically distinct strain of EHD-2, which was initially associated with an epizootic of disease of cattle in Japan in 1959, called **Ibaraki disease**, and which resulted in 39 000 sick cattle and 4000 deaths.[8] Disease with this agent was subsequently observed in other Asian countries. Clinically, the disease was characterized by fever, hyperemia and edema of the mucosae, a hemorrhages ulcerative stomatitis with laryngeal and pharyngeal paralysis salivation and dysphagia. At postmortem there were hemorrhages in the pharynx and esophagus and animals commonly died with aspiration pneumonia. Infection of pregnant cattle with Ibiraki virus can also result in abortion and stillbirths and currently this seems a more common clinical manifestation. There is evidence of genetic change in isolates from different outbreaks and the clinical manifestations of infection with different strains can vary.[9,10]

Occasional disease associated with infection with EHDV is recorded in cattle in the late summer in the United States and is also recorded in a recent outbreak on the island of Reunion.[11] It is similar to bluetongue and manifest with fever, lameness, reddening and swelling of the oral mucosa with necrotic ulceration of the dental pad and behind the incisor teeth, cracking and sloughing of the skin of the muzzle and hyperemia of the skin of the teats and udder.[3] Morbidity has ranged from 1–20%.

Diagnosis of infection is by virus isolation, nucleic acid identification and serology. AGID will detect antibody but will also detect cross-reacting antibodies with bluetongue. The c-ELISA is specific and sensitive.[12]

Diseases associated with viruses and *Chlamydia* – II

22

Viral diseases characterized by respiratory signs

VIRAL INFECTIONS OF THE UPPER RESPIRATORY TRACT OF HORSES

Viral respiratory tract disease is considered by veterinarians in the United States to be second only to colic among medical diseases in importance to the health and welfare of horses.[1] The situation is likely similar in most developed countries and especially those in which equine influenza is endemic. Episodes of upper respiratory tract disease characterized by fever, nasal discharge and cough are common in horses, especially young animals and horses housed in groups in stables and barns. An estimated 17% of equine operations in the United States have one or more horses affected by upper respiratory disease each year, and 1.5% of horses develop the disease every 3 months.[2] Upper respiratory disease is most common in spring and least common in winter.[2] Strangles was an uncommon cause of disease, occurring in only three horses per 1000 per 3 months.[2] Viral respiratory disease is approximately three times more common in horses less than 5 years of age.[2]

With the exception of *Streptococcus equi* and possibly *Mycoplasma* spp., the known causes of infectious upper respiratory disease of horses are viral and include: equine herpesvirus types 1, 2 and 4, equine influenza virus, equine rhinitis virus types A and B (ERAV and ERBV), equine adenovirus, equine viral arteritis, and equine parainfluenza 3 virus. Equine hendra virus and African horse sickness cause signs of severe respiratory disease. Both strangles and equine viral arteritis can be mild and lack outstanding clinical signs, thus closely resembling disease associated with other viral causes of upper respiratory tract disease. Therefore, differentiation among diseases associated with these agents based on clinical signs and epidemiological characteristics is difficult and definitive diagnosis is only achieved through serological or microbiological examination of blood or nasal discharge.

Isolation and identification of a causative organism from nasopharyngeal swabs or airway washings of acutely affected horses provides a definitive diagnosis, although on occasion more than one potential pathogen may be isolated. Demonstration of **seroconversion** or a three- to four-fold increase in titer from serum samples collected during the acute and convalescent (usually 3 weeks after onset of clinical signs) phases of disease is persuasive evidence of infection. Immunofluorescence, enzyme-linked immunosorbent assay (**ELISA**) and polymerase chain reaction (**PCR**) tests may provide

rapid diagnosis through detection of viral particles in nasal swabs and tissue specimens. The ability to determine the cause of an outbreak of upper respiratory disease in horses is enhanced by the use of multiple diagnostic tests and obtaining samples from more than one horse in an outbreak.[3] However, definitive diagnosis of the cause of nasal discharge, cough, and fever is often not achieved.[4]

All the agents known to cause upper respiratory disease in horses are relatively sensitive to environmental influences, and spread of the agent is dependent on **transmission from infected horses**, either directly or on fomites. Introduction of an infected horse into a susceptible population of horses may result in an explosive outbreak of upper respiratory tract disease. Such events are common on stud farms and in racing stables, where relatively closed bands of horses are maintained for much of the year. The movement of horses over long distances may facilitate the introduction of pathogens to which the local population of horses is naive.

The opposite situation occurs when young horses are introduced into larger bands of mixed aged animals, such as happens in racing stables or barns of pleasure horses. The younger, possibly naive, horse is then exposed to endemic pathogens to which the resident horses have developed resistance.

Young horses are at particular risk of developing infectious disease of the upper respiratory tract. The diseases are usually a problem only in yearlings and 2-year-olds; young foals acquire a passive immunity from the dam and adults have acquired a permanent immunity through exposure or vaccination. In a horse population it is the average age and the mix of ages which largely determine its herd resistance, and when 30–40% of that population has not previously been exposed to infection then major outbreaks are likely. All of the diseases are transmitted by droplet infection, and over long distances so that limitation of their spread is possible only by rigid isolation and intensive sanitary precautions, and even the best protected studs are likely to be invaded from time to time.

Equine rhinitis virus (ERV)

There are two, and possibly three, strains of equine **rhinitis virus**, (ERAV, ERBV) that infect horses. ERV is more closely related to foot-and-mouth disease than to other picornaviruses.[5] Almost all the information available on ERV infection of horses is for ERAV. The virus has been well characterized.[6–8] Serologic evidence of infection with ERAV is present in 50–100% of horses.[9,10] The virus is present in nasal discharges, feces and urine of a large proportion (17%) of clinically normal horses. The importance of urine shedding of the virus in transmission of infection is unclear, although the inhalation of aerosols of infected urine might transmit the virus.[4] ERAV might be an important but under recognized cause of acute upper respiratory disease in horses.[9] The **disease** thought to be associated with ERAV is characterized by an incubation period of 3–8 days, fever, pharyngitis, pharyngeal lymphadenitis, and a copious nasal discharge which is serous early and becomes mucopurulent later. **Viremia** is a consistent feature of the early stages of the disease. A cough persists for 2–3 weeks. The uncomplicated disease is mild and self-limiting. Among a group of susceptible horses, there is rapid spread of infection and disease.[11] Studies in England have not identified the virus as an important cause of inflammatory airway disease in race horses.[12] Virus neutralizing antibody develops within 7–14 days of infection and persists for long periods. **Immunity** after natural infection is said to be solid and long-lasting. **Diagnosis** is based on serological testing and tissue culture of the virus, which is environmentally resistant. There is no commercial vaccine available. Planned exposure of young horses to infection has been recommended, but should be reconsidered in light of current knowledge of the prolonged shedding of the virus in urine and feces.[9] The virus appears to have minimal zoonotic potential.[10,13]

Equine rhinitis virus B has been characterized and approximately 24% of horses in Australia and 86% of horses in Austria have serum neutralizing antibodies to the virus.[10,14] The role of ERBV in causing disease in horses is unknown.

Parainfluenza-3 virus

Upper respiratory tract disease associated with equine parainfluenza-3 (PI-3) is characterized by a mild self-limiting disease which is not clinically distinguishable from the others in the group.[15] The epidemiology and economic importance of disease associated with this agent is unknown.

Equine adenovirus infection

Two antigenic types of equine adenovirus, EAdV-1 and EAdV-2, are recognized that cause **respiratory disease** in foals and adult horses and **diarrhea** in foals, respectively.[16,17] Infection with EAdV is worldwide, based on seroepidemiological studies using virus neutralization and complement fixation tests, and affects up to 70% of horses. Horses less than 1 year of age are most likely to not have serological evidence of exposure, and are therefore presumably at risk of infection and disease. EAdV usually causes a mild respiratory disease with fever, coughing, nasal discharge and conjunctivitis, although its association with fatal pneumonia in thoroughbred foals is reported. Foals usually acquire the infection from their dams, which secrete the environmentally stable virus in nasal discharge, urine and feces. In Arab foals with inherited combined immunodeficiency adenovirus infection is usually fatal. The virus is not associated with inflammatory airway disease in race horses in England,[12] but has been associated with small outbreak of upper respiratory tract disease.[17]

Diagnosis can be made on cell smears taken from conjunctiva or nasal mucosa that reveal characteristic adenoviral intranuclear inclusion bodies **Serological methods** include serum neutralization, hemagglutination inhibition, complement fixation, or precipitating antibody tests. The serum neutralization test is most accurate, but the hemagglutination inhibition test is most suitable for a screening test No specific **control measures** are indicated for normal foals.

Reovirus

A reovirus, or a series of serotypes, cause mild upper respiratory tract disease of horses.[18] Infection with these agents appears to be of little clinical or economic importance.

Equine coital exanthema

Equine coital exanthema is a **venereal disease** manifested by papular, then pustular, and finally **ulcerative lesions** of the vaginal mucosa, which is generally reddened. The ulcers may be as large as 2 cm in diameter and 0.5 cm deep and are surrounded by a zone of hyperemia. In severe cases the lesions extend onto the vulva and the perineal skin to surround the anus. In the male, similar lesions are found on the penis and prepuce. Many mild cases are unobserved because there is no systemic disease and affected horses eat well and behave normally. The effect on fertility is equivocal although there may be a loss of libido during the active stage of the disease in stallions.[19] **Transmission** is usually venereal from affected or clinically normal carrier animals in which the infection is thought to be latent in sciatic ganglion.[19] The **incubation period** is 2–10 days and the course up to complete healing of ulcers is about 14 days. Diagnosis can be achieved by use of virus isolation or demonstration of viral DNA in skin lesions.[20] Secondary bacterial infection may lead to suppurative discharge and a longer course. In some outbreaks lesions occur on the skin of the

lips, around the nostrils, and on the conjunctiva. They may also be present on the muzzle of the foal. Ulcerative lesions of the pharyngeal mucosa also occur in infections with EHV-2 and with EAdV. Ulcerative lesions of the oral mucosa are of great importance because of the necessity to diagnose vesicular stomatitis early. Control can be achieved by use of artificial insemination.[10]

EQUINE HERPESVIRUSES

Five herpesviruses have been associated with various diseases of horses and foals (equine herpesvirus 1-5, EHV-1 to 5). EHV-1, EHV-3 and EHV-4 are alphaherpesviruses, whereas EHV-2 and EHV-5 are slow-growing gammaherpesviruses. Common names are 'equine abortion virus' for EHV-1, 'cytomegalovirus' for EHV-2, 'equine coital exanthema virus' for EHV-3, and 'rhinopneumonitis virus' for EHV-4 (although this term is sometimes used, confusingly, for EHV-1). EHV-1 and EHV-4 show extensive antigenic cross-reactivity and were previously considered subtypes of the same virus (EHV-1), but restriction endonuclease fingerprinting has demonstrated them to be different viruses. EHV-1 is closely related to asinine (donkey) herpesvirus 3, which is suggested to be its progenitor.[1] Related herpesviruses (asinine herpesvirus 1–5) infect and some cause disease in donkeys.[1–3] The recently identified asinine herpesviruses ASV-4 and ASV-5 cause a fatal interstitial pneumonia in donkeys.[3]

The disease syndromes attributed to equine herpesvirus infection, which are discussed in the following pages, and the viruses associated with them are:

- **Upper respiratory tract disease** of adult horses, weanlings and older foals is caused principally by EHV-4, although disease attributable to EHV-1 occurs. EHV-2 causes respiratory disease, including pneumonia, of foals, and rarely upper respiratory disease of adults
- **Abortion** is almost always associated with EHV-1, although rare sporadic cases are associated with EHV-4
- **Perinatal disease** of foals, including birth of sick and weak foals and development of viral septicemia within 48 hours of birth, is associated with EHV-1
- **Myeloencephalopathy** is associated with EHV-1 and rarely EHV-4
- **Genital disease** is an unusual manifestation of EHV-1 infection
- **Coital exanthema** is associated with EHV-3.

Disease associated with EHV-5 has not been identified, although it is suspected to have a role in interstitial pneumonia of adult horses. The diseases associated with EHV-1–4 are discussed below.

EQUINE VIRAL RHINOPNEUMONITIS (EQUINE HERPESVIRUS 4 INFECTION)

Synopsis

Etiology EHV-4, an alphaherpesvirus
Epidemiology Transmission between horses and by mediate contagion. Lifelong latency of infection with putative periodic reactivation of virus shedding. Respiratory disease occurs as sporadic disease and as outbreaks. Younger animals more commonly affected by disease. Immunity following vaccination or infection is apparently short lived
Clinical signs Upper respiratory disease, rarely abortion or myelencephalopathy
Clinical pathology Seroconversion or increase in titer detected by ELISA able to differentiate EHV-1 from EHV-4
Diagnostic confirmation Virus isolation from, or polymerase chain reaction test on, blood, nasopharyngeal swabs or tissue. Seroconversion or increase in titer detected by ELISA able to differentiate EHV-1 from EHV-4
Treatment There is no specific treatment
Control Vaccination (of minimal efficacy). Quarantine. Hygiene

ETIOLOGY

Upper respiratory disease of foals and adults is associated with equine herpesvirus 4 (EHV-4), an alphaherpesvirus. The DNA sequence of EHV-4 has been determined.[1] There appear to be strains of EHV-4 that vary in virulence, based on severity of clinical disease, but at present it is not possible to differentiate between strains of low and high virulence by laboratory methods.[2]

EPIDEMIOLOGY

Occurrence

Infection with EHV-4 is endemic in horse populations worldwide. The serologic surveys of prevalence of serologic evidence of infection are of limited value as earlier studies used techniques that were unable to differentiate between antibodies to EHV-1 and EHV-4. The few recent serologic surveys using ELISA tests capable of differentiating between antibodies to EHV-1 and EHV-4 demonstrate that almost all horses and foals >60 days of age have evidence of infection by EHV-4.[3–6] Young foals can be seropositive as a result of transfer of immunoglobulins from seropositive dams, making determination of the time of first infection, and active seroconversion, difficult. Furthermore, serologic tests are also unable to differentiate between responses to natural infection and to vaccination.

EHV-4 can be isolated from both clinically normal foals and those with signs of upper respiratory disease with similar frequency.[7] Shedding of virus is more likely in foals with nasal discharge.[7] There is a marked seasonal distribution to the pattern of shedding, with the most frequent detection of shedding being in early autumn (March).[7]

Upper respiratory tract disease attributable to EHV-4 is very common and probably affects almost all horses during the first 2 years of life.[8] EHV-4 rarely causes abortion in mares, septicemia in newborn foals, or myelencephalopathy in adult horses.[9]

Method of transmission

EHV-4 is highly infectious, and transmission probably occurs by the inhalation of infected droplets or by the ingestion of material contaminated by nasal discharges. Foals infected with EHV-4 have prolonged and profuse shedding of virus in nasal secretions. Mediate infection may occur, the virus surviving for 14–45 days outside the animal.

Infections always arise from other horses, both by direct contact and via fomites. Horses and foals are infectious during the active stage of disease and, because horses become latently infected, presumably during subsequent periods of viral reactivation and shedding. The duration of latency is unknown but is

assumed to be lifelong.[10] EHV-4 establishes latency in the trigeminal ganglion, which is the origin of the maxillary branch of the trigeminal (5th cranial) nerve that provides sensory innervation to the nasal mucosae.[11,12] It is assumed that reactivation of the virus and subsequent virus shedding poses a risk to in-contact, susceptible animals, but this has not been definitively demonstrated in field situations. If this were the case, then clinically normal animals harbor latent virus that during periods of reactivation can infect susceptible animals. If true this feature of the disease has obvious importance in the prevention, control, and management of outbreaks of disease.

Risk factors

Immunity

Immunity resulting from natural infection of the respiratory tract is of short duration despite the persistence of serum virus-neutralizing (VN) antibodies.[10] If similar to EHV-1, immunity to EHV-4 is likely associated with cytotoxic T-cell responses because of the importance of cell-associated virus in dissemination of infection throughout the horse. Because of the short duration of immunity an animal can become clinically affected a number of times during its life, although subsequent disease tends to be milder. Foals born to mares with serum antibodies to the virus acquire a protective passive immunity that persists for up to 180 days, provided that they ingest sufficient high quality colostrum. Unfortunately, VN antibodies are not necessarily an indication of resistance to infection.

Age

Foals are infected by EHV-4, presumably from the dam or other mares in the band of mares and foals, early in life and excrete large quantities of virus in nasal secretions.[8,13] Horses are infected repeatedly throughout life, with episodes of disease being less frequent and milder with increasing age. EHV-4 is isolated more frequently from younger than from older horses,[8] suggesting an age-associated decrease in susceptibility to disease.

Economic importance

Disease associated with EHV-4 is apparently of considerable economic importance because of the loss of training time and opportunities to perform during convalescence and quarantine. Although the upper respiratory disease is a mild inflammation of the respiratory tract of horses, characterized by coughing and nasal discharge, the importance of the disease is the large numbers of animals affected in an outbreak. Fatalities in uncomplicated cases of rhinopneumonitis are rare.

PATHOGENESIS

The pathogenesis of EHV-4 infection and disease is assumed to be similar to that of EHV-1, with the exception that the virus does not commonly cause abortion, neonatal septicemia, or myeloencephalopathy.[14] The virus is inhaled and binds to epithelium of the upper respiratory tract, enters epithelial cells and reproduces. The infection then spreads throughout the respiratory tract, including trachea and bronchioles, and to lymphoid tissues associated with the respiratory tract. There is a viremia, though this may be of short duration. There is cell death and development of intranuclear inclusion bodies in the respiratory tract and associated lymphoid tissues. The EHV-4 virus then becomes latent as evidenced by isolation of virus from lymph nodes associated with the respiratory tract,[15,16] and detection of viral genome in trigeminal ganglia, although this has not been a consistent finding.[17] The factors causing viral recrudescence from these latent sites have not been determined. It should be noted that definitive evidence of viral recrudescence of EHV-4 as a cause of outbreaks of disease is lacking, and experimental induction of recrudescence is achieved only by administration of large doses of corticosteroids.[16]

CLINICAL FINDINGS

The classical respiratory tract form of the disease (rhinopneumonitis) is virtually indistinguishable on the basis of clinical signs from the other respiratory tract diseases of horses. There is an incubation period of 2–20 days. Fever, conjunctivitis, coughing and mild inflammation of the upper respiratory tract are the cardinal manifestation of the disease, but inapparent infection is common. The temperature varies from 39 to 40.5°C (102.5 to 105.5°F). There is enlargement, but not abscessation, of the submandibular lymph nodes, especially in foals and yearlings. These signs are more likely to occur in young horses or when horses are assembled in sale barns. Edema of the limbs and diarrhea occur rarely. The length of the illness is usually 2–5 days, although the nasal discharge and cough may persist for 1–3 weeks. Secondary bacterial invasion, usually *Streptococcus equi* subsp. *zooepidemicus*, may exacerbate the clinically inapparent viral pneumonia. Young foals can develop primary viral pneumonia.

EHV-4 only rarely causes abortion or neurologic disease.[9]

CLINICAL PATHOLOGY

Results of hematological and serum biochemical examinations are neither specific nor diagnostic. In adult horses with rhinopneumonitis there may be a pronounced leukopenia, due largely to depression of neutrophils.

Serological tests are of critical importance in diagnosis and control of equine herpesvirus infections. Serum antibody levels to EHV-1/4 may be determined by ELISA,[18] virus neutralization (VN),[14] or complement fixation (CF) tests. The CF and VN tests are not able to differentiate between seroconversion associated with EHV-1 and EHV-4, whereas an ELISA using recombinant antigens specific for EHV-1 and EHV-4 is able to differentiate infection by each of these types of equineherpesvirus.[19] Many, if not all, adult horses have serum antibodies to EHV-4 as a result of previous infection or vaccination. Thus the demonstration of antibodies is not in itself sufficient to confirm a diagnosis of the disease. **Complement-fixing antibody** appears on the 10th–12th day after experimental infection but persists for only a few months. Demonstration of a three- to four-fold increase in the serum concentration of specific complement-fixing antibodies in acute and convalescent serum samples provides persuasive evidence of recent infection, albeit by either EHV-1 or EHV-4. Complement-fixing antibodies persist for only a short time (several months) while VN antibodies persist for over a year, and testing for them is therefore a more reliable means of determining that previous infection with the virus has occurred. Until recently, serological differentiation of antibodies to EHV-1 and EHV-4 was not possible. However, highly specific **ELISA** tests based on the variable region of the C terminus of glycoprotein G, at least one of which is commercially available, have been developed that can differentiate between antibodies to EHV-1 and EHV-4 in horse serum .[19–22] The ELISA is reported to be more sensitive, easier to perform, more rapid and more reproducible than the virus neutralization test. Importantly, the ELISA test is able to differentiate between infections associated with EHV-1 and EHV-4.[19]

Identification of the virus in nasal swabs, or blood buffy coat by culture or a PCR test provides confirmation of infection.[23] The use of seminested or multiplex PCR provides rapid identification of EHV-4 viral genome in pharyngeal swabs.[23] The test is at least as sensitive as viral isolation in identifying presence of virus. However, the use of rapid and innovative diagnostic techniques based on enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), immunohistochemical staining with peroxidase, or nucleic acid hybridization probes is often restricted to specialized reference laboratories. Therefore the method of choice for diagnosis of

rhinopneumonitis by diagnostic virology laboratories handling many routine samples continues to be the traditional methodology of cell culture isolation followed by sero-identification of the isolated viruses.[21] The virus can be isolated in tissue culture, chick embryos and hamsters, from either nasal washings or aborted fetuses.

Samples of nasopharyngeal exudate for virus isolation are best obtained from horses during the very early, febrile stages of the respiratory disease, and are collected via the nares by swabbing the nasopharyngeal area with a 5 × 5 cm gauze sponge attached to the end of a 50 cm length of flexible, stainless steel wire encased in latex rubber tubing. A guarded uterine swab devise can also be used. After collection, the swab should be removed from the wire and transported promptly to the virology laboratory in 3 mL of cold (not frozen) fluid transport medium (serum-free MEM [minimal essential medium] with antibiotics). Virus infectivity can be prolonged by the addition of bovine serum albumin or gelatine to 0.1% (w/v).[21]

NECROPSY FINDINGS

Fatalities are extremely rare in the respiratory forms of EHV-4 infection.

Samples for confirmation of diagnosis

- **Virus isolation or identification** by fluorescent antibody testing or PCR of nasal swabs or blood.

DIFFERENTIAL DIAGNOSIS

The upper respiratory diseases of horses are listed in Table 16.4. There is no specific treatment although antibiotics are often administered to horses with respiratory tract disease to prevent or treat secondary bacterial infection. There is, however, no evidence that antibiotic treatment shortens the duration of the disease or prevents complications.

CONTROL

Principles of a control program include:

- Enhancing the immunity of individual horses by vaccination
- Minimizing the risk of introducing EHV-4 infection to the farm or stable
- Hygiene to prevent spread of virus on fomites such as clothes and tack
- Rapid isolation of any horse with disease that could be attributable to EHV-4.

Vaccination

Vaccines for protection against rhinopneumonitis contain both inactivated EHV-1 and EHV-4 virus,[24] presumably because both viruses cause respiratory disease in horses. None of the currently available vaccines consistently prevent infection of vaccinated horses or provide complete protection against disease associated with EHV-4 although a combined EHV-1/EHV-4 inactivated virus vaccine attenuated the clinical signs of disease in experimentally infected foals.[25,26] The development of modified live virus vaccines administered intranasally holds promise for effective control of both EHV-1 and EHV-4 in foals and adults.[24]

Hygiene

Standard hygienic procedures should be adopted to avoid spread of the disease, with particular attention being given to the isolation of introduced horses.

EQUINE HERPESVIRUS 1 INFECTION OF HORSES (RESPIRATORY DISEASE, MYELOENCEPHALOPATHY, ABORTION AND NEONATAL SEPTICEMIA)

Synopsis

Etiology Equid herpesvirus-1 (EHV-1) causes respiratory disease of adults, abortion, neonatal septicemia, and myeloencephalopathy

Epidemiology Transmission between horses and by mediate contagion. Lifelong latency of infection with periodic reactivation of virus shedding. Respiratory disease, abortion and myeloencephalopathy occur prominently as outbreaks, but can affect sole animals

Clinical signs Upper respiratory disease, abortion, neonatal septicemia, and neurologic disease with incontinence, ataxia and recumbency

Clinical pathology Seroconversion or increase in titer using an ELISA able to differentiate between EHV-1 and EHV-4

Diagnostic confirmation Virus isolation from, or polymerase chain reaction test on, blood, nasopharyngeal swabs or tissue. Seroconversion or increase in titer

Treatment There is no specific treatment although acyclovir, an antiviral agent, has been administered. Symptomatic treatment of neurologic signs in horses with myeloencephalopathy

Control Management including quarantine, maintaining mares in small bands, and education of staff about importance of control measures. Vaccination for prevention of abortion. Quarantine. Hygiene

ETIOLOGY

EHV-1 is an alphaherpesviruses, a DNA virus.[1] EHV-1 and EHV-4 show extensive antigenic cross-reactivity and were previously considered subtypes of the same virus (EHV-1), but restriction endonuclease fingerprinting has demonstrated both the propinquity and difference of the two virus species. There are two recognized strains of EHV-1, although this designation does not appear to have any association with virulence. Currently, it is not possible to differentiate EHV-1 strains of varying virulence based on in vitro characteristic.[2] Virulence is associated with presence of a functional gp2 protein, which is apparently responsible for viral egress from infected cells,[3] and glycoprotein D and cell surface glycosaminoglycans that are needed for efficient entry of EHV-1 into cells.[4]

The most important clinical syndromes associated with EHV-1 infection are abortion, neonatal septicemia, and myeloencephalopathy. Upper respiratory tract disease of adult horses, weanlings and older foals is caused principally by EHV-4, although outbreaks attributable to EHV-1 occur. Genital disease is an unusual manifestation of EHV-1 infection. Infection with EHV-1 causes retinitis and fatal disease in camelids.[5,6] EHV-1 also causes disease in wild equids including zebras.[7]

EPIDEMIOLOGY

Occurrence

Infection with EHV-1 is endemic in horse populations worldwide and many adult horses have serologic evidence of

infection.[8,9] Serologic surveys, which provide an index of the extent of infection in the sampled population, performed before 1995 were hindered by the lack of an assay able to differentiate immune responses to EHV-1 from those to EHV-4. Furthermore, the advent of vaccines eliciting serum antibodies against EHV-1/4, and the inability of diagnostic tests to differentiate between antibodies induced by vaccination or natural infection, complicates assessment of the prevalence of serum antibodies to EHV-1/4. Seroprevalence of EHV-1 specific antibodies is 9–28% in adult Thoroughbred horses, 26% of Thoroughbred brood mares, 11% of Thoroughbred foals, and 46–68 % of 1 and 2-year-old Thoroughbred race horses in Australia.[8–11] Sixty-one percent of 82 normal horses and horses with upper respiratory tract disease had antibodies to EHV-1 in New Zealand.[12]

Upper respiratory tract disease associated with EHV-1 infection has been suggested to occur as outbreaks[13] although this is not well documented. Signs of infectious upper respiratory disease affected 20% of Thoroughbred race horses at one race track in Canada over a 3-year period, and seroconversion to EHV-1 occurred in 5–18% of these horses whereas the vast majority of horses seroconverted to influenza.[14] However, all horses that seroconverted to EHV-1 also either seroconverted to influenza virus or had been recently vaccinated with a vaccine containing EHV-1. These results suggest that the stress of influenza disease may have triggered reactivation of latent EHV-1 infection in some horses,[14] suggesting that EHV-1 did not have a primary role in the outbreak of respiratory disease. Similarly, in England, EHV-1 was not associated with clinical respiratory disease in Thoroughbred race horses.[15] EHV-1 was isolated from foals with purulent nasal discharge and respiratory disease concurrent with neurologic disease among the dams in Australia.[16]

Abortion due to EHV-1 occurs as both sporadic cases and as epizootics (abortion storms). Approximately 3% of abortions in mares are attributable to EHV-1 infection, although the actual incidence probably varies widely among years and geographical regions.[17] Outbreaks of EHV-1 abortion and birth of nonviable foals occurs sporadically on farms with sometimes catastrophic losses. Loss of foals through abortion or birth of nonviable foals can be as high as 28% of pregnant mares on the farm.[18] Initial cases can, in the absence of appropriate control measures, rapidly spread the infection.[18] Vaccination with killed EHV-1 vaccine during late gestation does not reliably prevent the disease[18] although conventional wisdom is to ensure that mares are well vaccinated (see 'Control' below). EHV-4 rarely causes abortion in mares. Disease of neonates associated with EHV-1 occurs both sporadically and as outbreaks in which up to 25% of foals may be affected.[19] Foals infected in utero usually die soon after birth, while those infected in the period after birth may have milder disease and a lower mortality rate (6%).[19] One-third of viremic foals may not seroconvert, based on the complement fixation test.[19]

Myeloencephalopathy occurs as sporadic cases but more often presents as an epizootic within a stable or barn or within a localized area.[16,19–22] Morbidity rates in exposed horses range from 1 to 90% with mortality rates of 0.5–40%.[16,19–22] Pregnant or nursing mares are suggested to be at greater risk of this disease,[8] but outbreaks occur on premises, such as riding schools or race tracks, where there are no foals or pregnant mares.[20–22]

Method of transmission

EHV-1 is highly infectious, and transmission probably occurs by the inhalation of infected droplets or by the ingestion of material contaminated by nasal discharges or aborted fetuses. The virus gains access to the body after binding to respiratory mucosal epithelium Other routes of infection are not recognized.

The virus is efficiently transmitted to in-contact animals and rapid spread of infection results from close contact of an infected animal with susceptible horses. Infection can be spread over short distances in the absence of physical contact or fomite transmission. This likely occurs by airborne spread of virus in droplets of aerosolized nasal secretions.

Infections always arise from other horses, either by direct contact or via fomites. Mediate infection from virus on fomites such as tack, veterinary equipment, vehicles, and housing occurs because the virus survives for 14–45 days outside the animal. The source of the virus is always on of the following:[23]

- a horse or foal with active infection
- a fetus, fetal membranes, or reproductive tract secretions of a mare immediately after abortion or birth of a weak foal
- virus shed by horses in which latent infection has reactivated.

Horses and foals are infectious during the active stage of disease and, because horses become **latently infected**, during subsequent periods of viral reactivation and shedding. There is good circumstantial evidence, such as the occurrence of abortion, neonatal disease, or myeloencephalopathy in closed herds, to support a role for latency and reactivation in the genesis of the disease. The duration of latency is unknown but is assumed to be lifelong.[1] Latent EHV-1 virus is detectable in the trigeminal ganglion and CD5/CD8 lymphocytes.[24–26] Reactivation of the virus might not result in clinical signs in the host animal but there is shedding of virus in nasal secretions. Consequently, clinically normal animals harbor latent virus that can infect susceptible animals during periods of reactivation. This feature of the disease has obvious importance in the prevention, control, and management of outbreaks of disease.

Abortion storms are usually attributable to an index case that is:

- A latently infected mare that sheds virus from the respiratory tract, but does not abort
- A mare that aborts an infected conceptus
- A mare that sheds virus from the respiratory tract, and then aborts.[1]

Mares usually, but not always, abort from EHV-1 infection only once in their lifetime.[1] A likely scenario in abortion storms is the reactivation of latent virus in a resident horse with subsequent shedding of virus in nasal secretions or, if the mare aborts, fetal tissues and uterine fluids. Contamination of the environment or horse-to-horse contact spreads infection to susceptible cohorts (primary transmission). The infected cohorts then further spread the virus to other horses in that band of mares (secondary transmission), which then spread infection among other bands of mares and foals, paddocks or fields of horses, or farms (tertiary transmission).[18,23]

Out breaks of **myeloencephalopathy** likely occur through similar mechanisms. Most outbreaks are associated with an index case or introduction of a horse with signs of infectious respiratory disease, with subsequent development of new cases in horses that have either direct or indirect (aerosol or fomite) contact with the index case.[16,19,21] It has recently been recognized that horses with clinical signs of myeloencephalopathy can spread the disease, contrary to previous supposition.[22] This has important implications for handling and care of affected horses, especially those severely affected horses that may be referred for intensive or specialized care.

Cycling of infection

Studies on Thoroughbred stud farms in Australia have demonstrated the temporal sequence of events that contribute to spread of EHV-1 infection in that region[9]

and these studies likely have relevance to other regions of the globe. There is a cyclical pattern in which horses are infected at a young age and the source of infection is, depending on the age of the foal, either its dam or other foals. Foals are infected by EHV-1 and shedding virus in nasal secretions as young as 11 days of age,[27] often without development of clinical signs but usually associated with mucopurulent nasal discharge.[28,29] Peak incidences of cases of respiratory disease associated with EHV-1 are late during the foaling season before weaning, and again after weaning when foals from several groups are housed together. The source of infection in foals before weaning is mares and, as the number of foals in the herd increases over the course of the foaling season, other foals.[9] Weanlings spread the disease among their herd during the period shortly after weaning when foals from more than one group are mixed. The incidence density of new cases among weanlings can be as high as 13 new cases per 1000 foal weeks.[30] The disease associated with these outbreaks is mild and without long term consequences to the foal or weanling. However, the presence of foals excreting large quantities of EHV-1 has the potential to increase the risk of viral abortion in late term mares in contact with these foals.[9] Furthermore, presence of respiratory disease associated with EHV-1 and shedding of virus by foals is associated with development of myeloencephalopathy in mares.[16]

Risk factors

Immunity

Immunity against respiratory disease and resulting from natural infection of the respiratory tract is of short duration despite the persistence of serum virus-neutralizing (VN) antibodies.[1] The cell-associated nature of the viremia and lack of expression of viral antigens on the surface of infected cells contributes to the poor efficacy of humoral immunity. Immunity to EHV-1 is mediated by cytotoxic T cells, which explains the limited efficacy of inactivated virus vaccines that have minimal effect in stimulating cytotoxic T cells despite being capable of inducing a humoral immune response.[31] The presence of EHV-1 cytotoxic T cell precursors correlates well with protection from experimental infection,[32] and some of the EHV-1 antigens ('early proteins') responsible for this resistance have been identified.[33] Because of the short duration of immunity an animal may become clinically affected by respiratory disease a number of times during its life, although subsequent disease tends to be milder. Mares usually only abort from EHV-1 infection once in their lifetime and there are no reports of horses developing myeloencephalopathy more than once.

Lack of antibodies to EHV-1 was identified as a risk factor in an outbreak of EHV-1 myeloencephalopathy in a herd of mares with foals at foot.[16] Mares with strong antibody responses to EHV-1 did not develop disease.

Economic importance

Disease associated with EHV-1 is of considerable economic importance because of the loss of training time and opportunities to perform during convalescence and quarantine, the loss of pregnancies during abortion storms, and deaths due to myeloencephalopathy and infection of neonates.

PATHOGENESIS

The three organ systems involved in clinical disease associated with EHV-1 infection are the respiratory tract, uterus and placenta, and central nervous system. The common final pathway for injury in each of these body systems is damage to vascular endothelium with subsequent necrosis, thrombosis, and ischemia.

Following EHV-1 exposure to the upper respiratory tract, virus can be detected in the soft palate and main stem bronchus within 12 hours, and at all levels of the respiratory tract by 24 hours.[34] In the respiratory tract there is an initial phase after infection in which there is rapid proliferation of the virus in the nasal, pharyngeal and tonsillar mucosae, with subsequent penetration and infection of local blood vessels.[34] This is followed by a systemic, viremic phase in which the virus is closely associated with blood lymphocytes, from which it can be isolated. Infection induces increased production of interferon gamma by T-lymphocytes.[35] Absence of viral antigens on the surface of EHV-1 infected peripheral blood mononuclear cells explains their ability to avoid complement-mediated lysis.[36] This activity, combined with the immunosuppression that accompanies EHV-1 infection, allows dissemination of the infection to the reproductive tract and central nervous system. Immunosuppression is mediated by production in EHV-1 infected cells of an 'early protein' that interferes with peptide translocation by the transporter associated with antigen processing.[37] Immunosuppression is evident as reduced in vitro proliferation of peripheral blood monocytes and down regulation of expression of major histocompatability complex class I molecules on the surface of infected cells.[38,39] It is from this point that the invasion of lungs, placenta, fetus and nervous tissue occur. Movement of infected mononuclear cells into target tissues is associated with expression of adhesion molecules by endothelium in the gravid uterus and in leukocytes.[40]

Viral infection of endothelium results in death of endothelial cells, inflammation, activation of clotting factors and formation of blood clots in small vessels. This thrombotic disease causes ischemia of neighboring tissues with subsequent necrosis and loss of function. Another theory is that deposition of antigen–antibody complexes in small vessels results in an Arthus reaction with subsequent ischemia, necrosis and loss of function. However, recent demonstration that mares with no antibody titer to EHV-1 were at increased risk of developing myeloencephalopathy does not support a role for type III hypersensitivity in this disease.[16] Regardless of the underlying mechanism, clinical signs are a result of vasculitis and necrosis of tissue in the central nervous system and reproductive tract. This is in contrast to neurologic disease associated with herpesvirus in other species, in which the nervous system disease is a direct result of infection of neural tissues.

Abortion is caused by damage to the placenta, endometrium or fetus. Placental lesions include vasculitis, focal thrombosis and infarction of the microcotyledons of the pregnant uterus.[41] The fetus is infected and there are diagnostic lesions present in many aborted foals, including massive destruction of lymphocytes in the spleen and the thymus. In those abortions in which there is no lesion or evidence of virus infection in the foal, there may be extensive damage to the endometrium due to an endothelial lesion and its attendant vasculitis, thrombosis and secondary ischemia.[42,43]

Foals that are infected in utero but survive to full term may be stillborn or weak and die soon after birth with pulmonary, hepatic, and cardiac lesions. EHV-1 infection in foals not infected before or at birth is usually a self-limiting, mild infection of the upper respiratory tract with an accompanying leukopenia and a transitory immune suppression, although uveitis and occasionally death occur in a small number of foals.[19] Virus can be isolated from the nasal mucus and the buffy coat of the blood for some time after clinical signs have disappeared.[44]

The pathogenesis of **myeloencephalopathy** in horses contrasts with herpesvirus encephalitis of other species in which there is viral infection of neuronal tissue.[1,16] The myeloencephalopathy in horses is, as discussed above, the result of vasculitis, thrombosis and subsequent ischemia of neural tissue. Impairment of blood flow results in hypoxia and dysfunction or death of adjacent neural tissue.

CLINICAL FINDINGS

EHV-1 infection manifests as several forms of disease on a farm such that nervous system involvement can occur in an outbreak in which abortion and respiratory disease also feature[19] although more commonly one form of the disease (myeloencephalopathy or abortion) occur alone or with mild respiratory disease. Foals, stallions and mares can be affected with one or other form of the disease, although the disease is most commonly seen in adult horses. Onset of neurologic signs is usually, but not invariably, preceded by cases of respiratory disease, fever, limb edema, or abortion.

Respiratory disease

The classical respiratory tract form of the disease (rhinopneumonitis) is virtually indistinguishable on the basis of clinical signs from the other upper respiratory tract diseases of horses and is identical to that associated with EHV-4.

Abortion

Outbreaks of abortion might not be preceded by clinically apparent respiratory disease.[18] The incidence of abortion is highest in the last third of pregnancy, particularly in the 8 to 10-month period but can occur as early as the 5th month. Abortion occurs without premonitory signs and the placenta is usually not retained. There is frequently no mammary development. Affected mares sometimes prolapse the uterus. Some foals are stillborn whereas others are weak and die soon after birth.

Abortion storms are often long lasting, with a period of 17–22 days separating the index case from cases caused by secondary transmission of the virus,[18,45] suggesting an incubation period of 2–3 weeks. Experimental infections induce abortion 15 to 65 days after intranasal inoculation of the virus.[46] While most abortions then occur within one month of the first secondary cases, abortions on a farm can continue for many months.[18,45]

Neonatal viremia and septicemia

In-utero EHV-1 infection causes abortion or the birth of infected foals, some of which are nonnal at birth, but become weak and die within 3–7 days of birth with signs of respiratory distress and septicemia. A less severe form of the disease, characterized by pyrexia, nasal discharge and chorioretinits, occurs in slightly older foals that are apparently infected after birth.[19,47] Affected foals that survive sometimes do not have serum antibodies to EHV-1.[19] Death may be associated with secondary bacterial infection with *Escherichia coli* or *Actinobacillus equuli*, although EHV-1 infection alone is sufficient to cause death.

Myeloencephalopathy

The disease initially occurs in an index case, which might or might not have had signs of infectious respiratory disease alone or with signs of neurologic disease.[16,19–21] Signs of neurologic disease develop in other horses approximately 2 weeks after disease in the index case. Disease then develops in a number of horses over a short period of time (3–10 days).[16,20,21]

Fever, without signs of respiratory disease, often precedes signs of neurologic disease by 24–72 hours.[21] The onset of neurologic signs is usually rapid, with the signs stabilizing within 1–2 days. Signs are variable but usually referable to spinal white matter involvement. Affected horses have variable degrees of ataxia and paresis manifest as stumbling, toe dragging, pivoting and circumduction that is most severe in the hind limbs. Signs are usually symmetrical. There is often hypotonia of the tail and anus.

Fecal and urinary incontinence are common and affected horses often dribble urine, have urine scalding of the skin of the perineum and legs, and require manual evacuation of the rectum. The severity of signs can progress to hemiplegia or paraplegia manifesting as recumbency and inability to rise. Less commonly, cranial nerve deficits, such as lingual or pharyngeal paresis, head tilt, nystagmus or strabismus, are present. Affected horses are usually alert and maintain their appetite.

Severity of neurologic disease varies among horses within an outbreak, and the prognosis is related to the severity of disease. In general, horses that become recumbent have a poor prognosis for both short-tenn and long-tenn survival despite intensive nursing care.[16,19–21] However, less severely affected horses have a good prognosis for survival, with case fatality rates are low as 2–3% in some outbreaks.[21] Horses with mild signs of neurologic disease often recover completely and return to their previous level of performance,[20,21] although some have persistent neurologic deficits after one year.

CLINICAL PATHOLOGY

Results of hematological and serum biochemical examinations are neither specific nor diagnostic. EHV-1 infection of adult horses results in leucopenia that is attributable to both neutropenia and T-cell lymphopenia, with B-cell lymphocytosis occurring during the recovery period.[48] EHV-1 septicemia of foals is characterized by profound leukopenia, neutropenia with a left shift and lymphopenia.

Cerebrospinal fluid (CSF) of horses with EHV-1 encephalomyelopathy is characteristically xanthochromic and has an increased total protein concentration (>1 g/L) with a normal white cell count.[49] The interpretation of EHV-1 antibody in CSF is uncertain, although normal horses are not expected to have detectable antibodies to EHV-1 in the CSF.[49]

Serological tests are of critical importance in diagnosis and control of equine herpesvirus infections. Many horses have serum antibodies to EHV-1 and EHV-4 as a result of previous infection or vaccination. Thus the demonstration of antibodies is not in itself sufficient to confirm a diagnosis of the disease. Complement-fixing antibody appears on the 10th–12th day after experimental infection but persists for only a limited period. Demonstration of a three- to four-fold increase in the serum concentration of specific complement-fixing antibodies in acute and convalescent serum samples provides persuasive evidence of recent infection. Complement-fixing antibodies persist for only a short time (several months) while VN antibodies persist for over a year, and testing for them is therefore a more reliable means of determining that previous infection with the virus has occurred. Until recently, serological differentiation of antibodies to EHV-1 and EHV-4 was not possible. However, highly specific **ELISA** tests based on differences between EHV-1 and EHV-2 in the variable region of the C terminus of glycoprotein G, at least one of which is commercially available, have been developed that can differentiate between antibodies to EHV-1 and EHV-4 in horse serum.[50–53] The ELISA is reported to be more sensitive, easier to perform, more rapid and more reproducible than the virus neutralization test. Importantly, the ELISA test is able to differentiate between infections associated with EHV-1 and EHV-4.[53]

Identification of the virus in nasal swabs, or blood buffy coat by culture or a PCR test provides confirmation of infection.[54] The use of seminested or multiplex PCR provides rapid identification of EHV-1 viral genome in pharyngeal swabs.[54] The test is at least as sensitive as viral isolation in identifying presence of virus. However, the use of rapid and innovative diagnostic techniques based on enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), immunohistochemical staining with peroxidase, or nucleic acid hybridization probes is often restricted to specialized reference laboratories. Therefore the method of choice for diagnosis of EHV-1-associated disease by diagnostic virology laboratories handling many routine samples continues to be the traditional methodology of cell culture isolation followed by sero-identification of the isolated

viruses.[51] The virus can be isolated in tissue culture, chick embryos and hamsters, from either nasal washings or aborted fetuses.

Samples of nasopharyngeal exudate for virus isolation are best obtained from horses during the very early, febrile stages of the respiratory disease, and are collected via the nares by swabbing the nasopharyngeal area with a 5 × 5 cm gauze sponge attached to the end of a 50 cm length of flexible, stainless steel wire encased in latex rubber tubing. A guarded uterine swab devise can also be used. After collection, the swab should be removed from the wire and transported promptly to the virology laboratory in 3 mL of cold (not frozen) fluid transport medium (serum-free MEM [minimal essential medium] with antibiotics). Virus infectivity can be prolonged by the addition of bovine serum albumin or gelatine to 0.1% (w/v).[51]

NECROPSY FINDINGS

Fatalities are extremely rare in the respiratory forms of EHV-1 infection. Macroscopic findings in **aborted fetuses** include petechial and ecchymotic hemorrhages, especially beneath the respiratory mucosae. The most consistent finding is an excess of clear yellow fluid in the pleural and peritoneal cavities. Focal hepatic necrosis and slight icterus may also be present. In some aborted fetuses the cut surface of the spleen reveals unusually prominent lymphoid follicles, which are swollen due to necrosis and edema. Acidophilic intranuclear inclusion bodies may be evident histologically in a variety of cell types, including the bronchiolar and alveolar epithelium, hepatocytes and dendritic cells of the lymphoid tissues. Although the microscopic pathology is unimpressive, examination of the placenta via immunohistochemical techniques can be a useful aid in the diagnosis of EHV-1 and EHV-4 Induced abortions.[55,56] In foals that are alive at birth but die soon afterwards there is usually massive pulmonary congestion and edema, with collapse of the lung and hyaline membrane development in those that survive longer.

In the **nervous or paralytic form** of the disease there is an acute disseminated myeloencephalopathy. Hemorrhages may be visible grossly but often there are no macroscopic changes. Disseminated vasculitis occurs in the experimental disease[57] and the malacic lesions present in the nervous tissue are the result of leakage from these damaged vessels. The virus can be isolated from the brain and the isolation is facilitated by use of an indirect peroxidase stain[58] to establish the location of the virus. The virus infects endothelial cells within the central nervous system (CNS) but has also been demonstrated within neurons and astrocytes and has been linked to chorioretinitis in a foal.[59] In rare cases the virus may cause lesions in other tissues, such as the intestinal mucosa and spleen[60] or pharynx.[61]

The laboratory examination of aborted fetuses should include a search for virus by tissue culture and immunohistochemical or PCR techniques, as well as a histological examination of the lung and liver for the presence of inclusion bodies. A direct fluorescent antibody test has also been used.[62] A serological examination of the foal may provide useful information in those cases where attempts at isolation are negative but seroconversion has occurred. However, a recent study found that fetal serology was an unreliable means of diagnosing EHV-1 abortion and that IHC was slightly more sensitive than virus isolation.[63]

Samples for confirmation of diagnosis

- **Virology** – chilled lung, liver, spleen, thymus and thoracic fluid of aborted fetuses or neonates. Spinal cord or brain of horses with nervous disease (VI, PCR, FAT, serology)
- **Histology** – fixed lung, liver, spleen, thymus, trachea from fetuses or neonates
- Fixed brain and spinal cord from several sites, as well as Bouin's-fixed eye should be examined in adults with nervous disease (LM, IHC).

DIFFERENTIAL DIAGNOSIS

Respiratory disease may be associated with a variety of agents (Table 16.4).

Abortion can be associated with leptospirosis, *Salmonella abortusequi*, placentitis associated with *Streptococcus zooepidemicus* or *Escherichia coli*, associated with mare reproductive loss syndrome, or congenital abnormalities, among other causes. When other pregnant mares are at risk abortion in a late-term mare should always be considered to be due to EHV-1 until proved otherwise.

Neurologic diseases with clinical presentations similar to that associated with EHV-1 include rabies, equine protozoal myeloencephalitis, neuritis of the cauda equina (equine polyneuritis), trauma, acute spinal cord compression (cervical stenotic myelopathy) and equine degenerative myelopathy. Fever is rare in other neurologic diseases of horses and any horse with neurologic disease and fever or a history of fever within the previous week should be considered to have EHV-1 myeloecephalopathy. Outbreaks of posterior paresis or ataxia, especially in horses without fever, should prompt consideration of ingestion of intoxicants such as *Astragalus* spp., *Swainsonia* spp., or sorghum. Rye grass staggers can produce similar signs of ataxia.

Neonatal septicemia may be associated with *E. coli*, *Streptococci* spp. and other bacteria, especially in foals with failure of transfer of maternal immunoglobulins.

TREATMENT

Because of the highly contagious nature of EHV-1 infections, horses with respiratory disease, abortion or neurologic disease, especially if these occur as an outbreak, should be isolated until the cause of the disease is identified.

There is **no specific treatment** for the diseases associated with equine herpesvirus infection although acyclovir was used to treat horses in recent outbreaks of myeloencephalopathy. The drug is effective against EHV-1 in vitro and pharmacokinetic studies suggest that administration of 10 mg/kg orally every 4–6 hours (five times daily) or 10 mg/kg IV every 8 hours results in acceptable concentrations of drug in the blood.[64] However, other studies have not demonstrated adequate concentrations of the drug in blood after oral administration of 20 mg/kg.[77] The efficacy of this drug in treatment of EHV-1 myeloencephalopathy has not been determined.

Antibiotics are often administered to horses with respiratory tract disease to prevent or treat any secondary bacterial infection. There is, however, no evidence that antibiotic treatment shortens the duration of the disease or prevents complications.

Horses with EHV-1 **myeloencephalopathy** require intense supportive care.[65] Administration of corticosteroids to these horses is controversial,[19,65] but many clinicians administer dexamethasone sodium phosphate (0.05–0.25 mg/kg IM every 12–24 h) or prednisolone (1–2 mg/kg orally or parenterally every 24 h) for 3–5 days. Administration of corticosteroids may be contraindicated because of the presence of replicating virus in affected horses. Nursing care to prevent urine scalding, pressure sores and pneumonia is important in horses with myeloencephalopathy. Recumbent or severely ataxic horses should be supported to stand if at all possible. While a rope tied to the tail and slung over an overhead beam may be used to assist the horse to stand, a sling may be necessary to support more severely affected horses.

Neonatal foals with septicemia should be treated aggressively with **antibiotics** and **supportive care**, including enteral or parenteral nutrition and fluid administration (see 'Principles of providing care to the critically ill neonate'). Treatment with acyclovir has been reported.[47] Failure

of transfer of passive immunity should be rectified with oral or intravenous administration of colostrum or plasma, respectively.

CONTROL

Recommendations for programs to prevent introduction of infection and to control disease outbreaks are available from several sources.[12,66]

Prevention of infection

The principles are:[12]

- enhanced immunity, currently attempted by vaccination
- subdivision and maintenance of the farm population in groups of horses to minimize spread of the infection
- minimize risk of introduction of infection by new horses
- minimize risk of reactivation of latent infection in resident horses
- develop plans for implementation of these routine control measures, and for actions in the event of an abortion
- educate management and staff as to the importance of strict adherence to these procedures.

The relative importance of each of the above measures has not been determined, but implementation of control measures, including allocation of mares to small bands based on anticipated foaling date, quarantine of new introductions, and vaccination of pregnant mares has reduced the incidence of EHV-1 abortion in central Kentucky. The most striking association has been an apparent reduction in the incidence of abortion storms. It must be emphasized that vaccination does not replace any of the other management procedures in control of this disease and that abortions have occurred among vaccinated mares on farms on which the other management procedures have been ignored.

Vaccination

Vaccination against respiratory disease and abortion associated with EHV-1 is widely practised despite lack of clear cut evidence that vaccination reduces the incidence or severity of either of these diseases. Information regarding field efficacy of equine herpesvius vaccines is lacking, and that derived from experimental challenge models is often contradictory or incomplete.[67] Give these caveats, the following recommendations are made based on generally accepted practices.

None of the currently available vaccines consistently prevent infection of vaccinated horses or provide complete protection against disease associated with EHV-1. The principal objective of vaccination has been to protect mares against abortion associated with EHV-1, although vaccines intended to prevent rhinopneumonitis and containing both EHV-1 and EHV-4 are available. Additionally, vaccination of mares is intended to reduce transmission of EHV-1 to foals in an attempt to interrupt the cyclical nature of infection on stud farms.[9,68] Vaccines consisting of a modified live EHV-1, inactivated EHV-1, or a mixture of inactivated EHV-1 and EHV-4 are available for intramuscular or intranasal administration to horses.[69] Both inactivated and modified live EHV-1 vaccines elicit virus-neutralization and complement fixation antibody responses in horses,[1] although high antibody titers are not necessarily related to resistance to infection.[69]

Resistance to infection might be more closely related to cytotoxic T-cell responses.[33] Widespread use of a combined EHV-1 and EHV-4 killed virus vaccine in Australia has not reduced serologic evidence of infection in foals on farms where mares are vaccinated,[68] although the vaccine was effective in preventing disease induced by experimental infection. Complicating assessment of vaccine efficacy is the variable response to vaccination by some mares and foals, with certain animals having minimal responses to vaccination which in other horses elicits a strong immune response.[70] Efforts are underway to develop modified live vaccines that can be administered intranasally.[67] Intranasal administration of one such EHV-1 vaccine induced protection against experimentally induced EHV-1 (and EHV-4) respiratory disease and abortion in mares, and prevented infection of foals even when administered in the presence of maternally-derived antibodies.[71–73] An alternative approach is the development of subunit vaccines using the envelope glycoprotein D which has been shown to elicit protective immunity in laboratory animal models of EHV-1 disease and administration of which induces virus neutralizing antibody and glycoprotein D-specific ELISA antibodies in horses.[74] However, at the time of writing these products are not commercially available nor has their efficacy in field situations been demonstrated.

Despite the incomplete protection afforded by vaccines, vaccination against EHV-1 is an important part of most equine herd health programs in the vaccination of pregnant and nonpregnant mares, foals, and adult horses. The intent of vaccination of mares is to prevent abortion associated with EHV-1. One inactivated virus vaccine is reported to decrease the incidence of abortion by 65%, although others have not been able to replicate this success and there are reports of abortion storms on farms of well vaccinated mares[1,18,75] An inactivated virus vaccine containing EHV-1 and EHV-4 prevented abortion in five of six mares exposed experimentally to EHV-1, whereas all six non-vaccinated mares aborted.[46] Mares are vaccinated with the inactivated vaccine during the 5th, 7th, and 9th months of gestation. Additional vaccinations at breeding and 1 month before foaling are recommended by some authorities.

Foals are an important source of infection (see 'Infection cycling' above) and control of infection in foals is considered critical to control of infection on a farm.[9] Consequently, attention has been paid to the responses of foals to vaccination at various ages, given the risk of passive immunity interfering with vaccination and the early age at which foals are infected by EHV-1.[9] Current recommendations vary with some authorities recommending vaccination of foals after 5 months of age, to avoid the interfering effect of passive immunity on response to vaccination.[76] However, vaccination of foals at this age likely misses the period of time when foals are first infected by EHV-1 from their dam or other mares in the band.[9] One recommendation is that foals be vaccinated in their 3rd month, with revaccination 1 month and 6 months later. Modified live virus vaccine is given to foals at 3–4 months of age, nonpregnant mares and other horses as two doses administered 3 months apart, followed by revaccination every 9 months. Because of the short duration of immunity following vaccination, frequent vaccination, perhaps at intervals as short as 3 months, of horses at high risk is recommended. However, the efficacy of such a program is uncertain.

The efficacy of vaccination in preventing myeloencephalopathy appears to be minimal and there is concern that well vaccinated horses might be at increased risk of the disease, although this has not been conclusively demonstrated and there is evidence to the contrary.[16]

Subdivision of horses on a farm

Maintenance of small groups of horses of similar age and reproductive status is recommended to minimize the chances of spread of infection.[12] Pregnant mares, after weaning of foals, should be maintained in a herd that does not have access to foals, weanlings, nonpregnant mares or other equids (donkeys). Similarly, weaned foals should be separated from horses of other ages in recognition of the high rate of infection and viral shedding in weanlings.[9] Failure to adhere to these procedures can result in rapid spread of infection and abortions among at risk

mares.[18] Pregnant mares should be combined into small groups (~10) early in pregnancy based on their anticipated foaling dates.[12,66] Multiparous mares should not be mixed with mares that are pregnant for the first time.

Management practices should be introduced that minimize the opportunities for viral spread. Ideally, pregnant mares are handled using facilities separate to those used to handle mares with foals or weanlings. If common facilities must be used, pregnant mares should be handled first, after thorough cleaning of the facility, followed by mares with foals and finally weanlings and other horses.

Minimize risk of introduction of infection

The only sources of virus are recrudescence of latent infection and introduction by newly arrived horses shedding virus. All horses must be considered as potentially shedding EHV-1 on arrival at a farm and should be isolated from resident horses. Introduction of new horses to the small groups of pregnant mares should be avoided if at all possible, or if absolutely necessary preceded by a 21 day isolation period.[23,66] If at all possible, avoid mingling resident and non-resident mares even after quarantine of non-resident animals.

Prevention of reactivation of latent infection

The factors inciting reactivation of latent infection and viral shedding are unknown. However, stressful events, such as transportation or other disease, have the potential to cause reactivation of latent infection. For this reason pregnant mares should not be shipped within 8 weeks of expected foaling and all efforts, including vaccination, should be made to prevent other infectious diseases.[66]

Control of outbreaks

The principles underlying control of abortions due to EHV-1 include:[12,66]

- early and rapid diagnosis
- prevention of spread of infection
- treatment of individual cases

Rapid diagnosis

Every abortion in a late term mare should be considered to be associated with EHV-1 until proven other wise. Therefore, rapid and early diagnosis of the abortion in important to instituting control measures. Means of diagnosing EHV-1 abortion are detailed above. In regions with large numbers of breeding mares, **all** abortions in mares should be investigated by detailed post mortem examination of the fetus and serologic examination of the mare.

Prevention of spread

Diligent and concerted efforts must be made to prevent dissemination of infection from the initial focus. Infected fetal tissues and fluids, and contaminated materials such as bedding, should be placed in impervious containers and either transported to a laboratory for examination or destroyed by incineration. Samples for laboratory examination should be handled in a manner to prevent spread of infection. Facilities and equipment that might have been contaminated should be disinfected by thorough cleaning followed by application of a phenolic or iodophor disinfectant.[23]

The mare should be isolated until results of laboratory examination are negative for EHV-1 or until the second estrus, at which time it is unlikely that there is shedding of virus from the reproductive tract.[66] Other mares in the same band as the mare that aborted should be considered exposed and at risk of abortion. These mares should be held in strict isolation until the results of laboratory examination are negative for EHV-1, or until they foal or abort. Other recommendations for horse movement include:

- When an abortion occurs on the stud, no mares should be allowed to enter or leave it until the possibility of EHV-1 infection is excluded. However, maiden and barren mares, i.e. mares that have foaled normally at home but that are not in foal, coming from home studs where no signs of the disease are occurring, may be admitted because they are considered to be not infected
- If EHV-1 infection is identified on the stud, all pregnant mares due to foal that season (i.e. late pregnant mares) should remain at the stud until they have foaled. The incubation period for EHV-1 abortion ranges between 9 and 121 days
- All non-pregnant animals and mares that have foaled should remain at the stud for 30 days after the last abortion.

The main problem that arises in this program is in deciding what to do with mares that come into contact with the respiratory disease but not the abortion disease. This may occur very early in pregnancy and prolonged isolation would be onerous. The decision usually depends on the owner's risk aversion and the availability of facilities to maintain long-term isolation.

Control of outbreaks of myeloencephalopathy

Outbreaks of EHV-1 induced neurologic disease often occur in riding schools and similar situations where there is constant movement of horses on and off the property. As such it is exceedingly difficult to institute control measures that prevent introduction of the disease and that are compatible with the use of the horses. Having said that, the principles outlined above for preventing introduction of infection on to breeding farms also apply for prevention of myeloencephalopathy at riding stables.

Outbreaks of neurological disease attributable to EHV-1 should be handled as follows:[12]

- Affected horses should be isolated as there is strong evidence that these horses are infectious[22]
- The diagnosis should be confirmed by virus isolation, PCR, or histological examination of tissues from affected horses that die or are euthanized
- There should be no movement of horses on or off the premises for at least 21 days after the last case has occurred[12]
- Movement among bands of horses on the farm should be avoided
- Bands of horses should be monitored for clinical, serological or virological evidence of infection
- Animals should leave or move between bands only when there is no evidence of continued active infection in their group
- Vaccination in the face of an outbreak of EHV-1 myeloencephalopathy is not recommended
- Prophylactic use of acyclovir has been reported although the efficacy of this practice is unknown.[64]

EQUINE HERPESVIRUS 2 (CYTOMEGALOVIRUS)

ETIOLOGY

EHV-2 is a slow-growing gamma-herpesviruses.[1] The viral genome has been elucidated.[2] There is considerable antigenic, genetic and biologic heterogeneity among EHV-2 isolates which might reflect variations in pathogenicity.[3]

EPIDEMIOLOGY

Almost all adult horses and foals over 2 months of age have serologic evidence of infection by EHV-2.[3–6] EHV-2 was cultured from bronchial or other lymph nodes in 97% of horses sampled at an abattoir and from blood of 31–76% of live adult horses (clinically normal or with respiratory disease) in Europe and New Zealand.[3,7,8] Virus was isolated from blood of 76 of 77 normal foals examined in the United States[6] and in all of 16 foals from a stud with endemic respiratory disease in New Zealand.[5] Viral genome was detected in blood of ~70% of live, adult horses in Europe and in trigeminal ganglion of 6 of 12 seropositive ponies.[8,9] Thirty-four virus isolates were obtained from peripheral blood leukocytes of 139 horses in Poland.[10] Viral DNA was detected in blood samples of all foals examined in Europe.[11] These data demonstrate the ubiquitous nature but uncertain clinical significance of EHV-2 infection of horses worldwide.

The frequency with which disease attributable to EHV-2 occurs in horses is uncertain. In one report, 10 of 16 foals naturally infected with EHV-2 developed respiratory disease, and two died.[5] EHV-2 is isolated from tracheal aspirates of foals with respiratory disease much more often than it is isolated from tracheal aspirates of foals without respiratory disease.[6] Isolation of EHV-2 is statistically associated with upper respiratory disease in horses,[8] and experimental infection causes conjunctivitis, lymphadenopathy, and coughing.[12] The virus is isolated more frequently from eyes of horses with keratoconjunctivitis than from eyes of normal horses, suggesting a role for EHV-2 in this disease.[13] The observation that EHV-2 can be isolated more frequently from the blood of horses with upper respiratory disease, ataxia or abortion might indicate a causative role for the virus, or that intercurrent disease induces reactivation of EHV-2 infection.[3]

EHV-2 is highly infectious, and transmission probably occurs by the inhalation of infected droplets or by the ingestion of material contaminated by nasal discharges. Virus is secreted in nasal and ocular discharge of recently infected horses, and in nasal secretions and tracheal fluid of foals with respiratory disease associated with natural infection.[5,6,12] If survival ex vivo is similar to that of the other equine herpesviruses, mediate infection may occur for 14–45 days, although this has not been specifically investigated for EHV-2.

Infections always arise from other horses, both by direct contact and by fomites. Horses and foals are infectious during the active stage of disease and, because horses become latently infected, during subsequent periods of viral reactivation and shedding. The duration of latency is unknown but is assumed to be lifelong.[1] Latent EHV-2 virus is detectable in the trigeminal ganglion, lymph nodes, and peripheral blood monocytes of clinically normal horses .[3,7–9] Reactivation after experimental infection can be triggered by administration of dexamethasone.[12] Factors influencing reactivation of the virus and the importance of reactivated infections in dissemination of infection and induction of disease is unknown, but is likely important as for other equid herpesviruses.

It appears that foals are infected at a young age and that infection is persistent into adulthood .[5,6,11] EHV-2 can be isolated by 25 days of age from foals that were seronegative at birth and there is a progressive increase in virus neutralization from 1 to 5 months of age.[6] Viral shedding is persistent until development of high antibody titers at 6–9 months of age.[5]

PATHOGENESIS

The pathogenesis of EHV-2 has not been defined. However, it is apparent that infection occurs at a young age, as early as several weeks of age, and becomes latent in lymph nodes, especially those draining the respiratory tract, peripheral blood mononuclear cells, and nervous tissue including the trigeminal ganglion. As with EHV-1, there is evidence that EHV-2 causes immunosuppression[14] and it is speculated that this might play a role the development of other infections, including pneumonia associated with *Rhodococcus equi* or other bacteria.[5]

CLINICAL FINDINGS

EHV-2 or equine cytomegalovirus causes a long-term infection in foals, some of which develop clinical signs of purulent nasal discharge, fever and lymphadenopathy in a syndrome which lasts about 1 week. Affected animals rarely die although deaths of foals from pneumonia have been recorded.[5,6,8] EHV-2 was isolated from 20 of 30 foals with signs of lower respiratory disease including fever, abnormal lung sounds and radiographic abnormalities.[6] Bacteria were isolated from tracheal aspirates of 29 of these foals.

EHV-2 is statistically associated with keratoconjunctivitis in horses of varying ages.[13]

CLINICAL PATHOLOGY

Results of hematological and serum biochemical examinations are neither specific nor diagnostic. A blocking ELISA has been developed that detects serum

antibody specific for EHV-2, and is useful to detecting new infection in foals.[15] Identification of the virus in nasal swabs, blood buffy coat or fetal tissue by culture or a PCR test provides confirmation of infection.[16]

NECROPSY FINDINGS

Necropsy findings for diseases associated with EHV-2 infection are poorly reported. Two foals that died of respiratory disease associated with EHV-2 infection had pneumonia, chronic pharyngitis and lymphoid depletion in the thymus and spleen.[5]

DIFFERENTIAL DIAGNOSIS

Differential diagnosis includes other causes of respiratory diseases in horses (Table 16.4).

TREATMENT

There is no specific treatment for the diseases associated with equine herpesvirus-2 infection. Antibiotics are often administered to horses with respiratory tract disease to prevent or treat secondary bacterial infection.

CONTROL

Control is difficult given the ubiquitous nature of infection and uncertain importance of disease associated with EHV-2. There is currently no commercial vaccine to prevent infection or disease associated with EHV-2.

EQUINE COITAL EXANTHEMA (EQUINE HERPES 3 INFECTION)

Equine coital exanthema is a **venereal disease** associated with infection by equine herpesvirus 3 and manifested by papular, then pustular, and finally **ulcerative lesions** of the vaginal mucosa, which is generally reddened. The ulcers may be as large as 2 cm in diameter and 0.5 cm deep and are surrounded by a zone of hyperemia. In severe cases the lesions extend onto the vulva and the perineal skin to surround the anus. In the male, similar lesions are found on the penis and prepuce. Many mild cases are unobserved because there is no systemic disease and affected horses eat well and behave normally. The effect on fertility is equivocal although there may be a loss of libido during the active stage of the disease in stallions.[1] **Transmission** is usually venereal from affected or clinically normal carrier animals in which the infection is thought to be latent in sciatic ganglion.[1] The **incubation period** is 2–10 days and the course up to complete healing of ulcers is about 14 days. Diagnosis can be achieved by use of virus isolation or demonstration of viral DNA in skin lesions.[2] Secondary bacterial infection may lead to suppurative discharge and a longer course. In some outbreaks lesions occur on the skin of the lips, around the nostrils, and on the conjunctiva. They may also be present on the muzzle of the foal. Ulcerative lesions of the pharyngeal mucosa also occur in infections with EHV-2 and with equine adenovirus. Ulcerative lesions of the oral mucosa are of great importance because of the necessity to diagnose vesicular stomatitis early. Control can be achieved by use of artificial insemination.

EQUINE VIRAL ARTERITIS (EVA)

Synopsis

Etiology Equine arteritis virus
Epidemiology Outbreaks of disease due to lateral transmission by infected body fluids. Venereal transmission by persistently infected, clinically normal, stallions with subsequent lateral spread among mares
Clinical signs Abortion. Upper respiratory disease with systemic signs including edema and respiratory distress
Clinical pathology Serology. No characteristic changes in hemogram or serum biochemistry
Diagnostic confirmation Virus isolation from blood, sperm-rich fraction of semen, nasopharyngeal swabs or tissue. Seroconversion or increase in complement fixation titer
Differential diagnosis:
- The systemic disease – viral respiratory disease
- Abortion – EHV-1, mare reproductive loss syndrome
- Similar disease in neonates – EHV-1 or other septicemia

Treatment There is no specific treatment
Control Vaccination, especially of stallions and seronegative mares to be inseminated by seropositive stallions, and to control outbreaks at racetracks. Quarantine. Hygiene

ETIOLOGY

Viral arteritis of horses, donkeys and mules is associated with an **arterivirus**, formerly classified as a non-arthropod borne togavirus but now recognized as a member of the coronavirus-like superfamily.[1] The virus is single-stranded RNA. There is considerable genomic variation among isolates with EAV of North American and European origin clustering in geographically distinct viral clades.[2,3] Although different isolates of EAV vary in virulence, consistent variations in virulence among clades have not been demonstrated.[2] Novel phenotypic variants of EAV can emerge during persistent infections in stallions and this might be an important feature in the development of disease in exposed mares and foals.[3–5] A strain recently isolated from donkeys and mules in South Africa causes only mild disease in horses.[6] The virus resists freezing but not heat.

EPIDEMIOLOGY

Occurrence

Serologic evidence of infection by equine arteritis virus (EAV) is found in horse populations in North and South America, Europe, Africa, Asia, and Australia.[7] Recent disease outbreaks have been identified in North America, Britain, Spain, Italy, France, Poland, The Netherlands, South Africa, and Germany.[7] It is probable that the disease is now present in most countries with substantial populations of horses. International shipment of horses and frozen semen contributes to the spread of the EAV.[8]

The proportion of seropositive horses varies considerably among populations, with there being marked differences among breeds. Overall, 2% of horses in the United States are seropositive to EAV (serum neutralization titer >1:4) with 8.4% of horse operations having seropositive horses.[9] Twenty-five percent of operations whose principal activity was breeding had at least one unvaccinated seropositive horse, whereas 4% of racing operations had a least one unvaccinated seropositive horse.[9] The prevalence of titers to EAV is higher in mares and in horses used for breeding.[9] The frequency with which horses in the United States have serum titers >1:4 varies with breed with 24% of Standardbreds, 4.5% of Thoroughbreds, 3.6 % of Warmbloods and 0.6 % of Quarter horses being seropositive.[9] Approximately 19% of Warmblood horses imported into the United States have antibodies to EAV, with horses from Germany and the Netherlands having the highest prevalence (21 and 25% respectively).[10] Between 55–93% of Warmblood and Lipizzan breeds in Austria have serologic evidence of exposure to EAV.[11] Disease in Great Britain and North

America has been associated with importation of infected stallions or semen.[8,10] Horses of all age groups are susceptible. The disease spreads rapidly in a group of susceptible horses, and although the course of clinical disease is short, an outbreak in a group of horses may persist for a number of weeks. Naturally acquired infections in newborn foals can occur as an outbreak and cause severe disease.[12]

Origin of infection and transmission

EAV is spread in two ways:

1 **Horizontal transmission** of virus by predominantly nasal fluid, but also by urine, feces, lacrimal fluid and vaginal discharge of infected horses
2 **Venereal transmission** from stallions to susceptible (seronegative) mares.

Horizontal transmission through infected nasal discharge and body fluid is effective and is the means of disease spread in outbreaks in racing stables, and among mares and foals at breeding farms. Virus is found in the respiratory secretion for 7–14 days and in other tissues for 28 days.[11] Close contact between horses is probably required for transmission of the virus – it has been reported to spread after contact of horses across a fence.[8] Duration of viability of the virus in the environment has not been reported, but the potential for spread of infection on fomites includes clothing and tack should be considered when dealing with an outbreak.

Venereal transmission: Stallions are infected by horizontal transmission of the virus, subsequently excrete the virus in semen and infect susceptible mares at the time of mating. Clinically normal stallions are also capable of transmitting the virus horizontally to other stallions in a breeding operation, demonstrating the potential for horizontal spread of infection from stallions in the absence of clinical disease or sexual contact.[13] Between 30 and 60% of infected stallions excrete the virus in semen for weeks to months.[14] Some stallions excrete virus for years, and lifelong infection and virus excretion can occur.[11] Prolonged infection of stallions is associated with mutation of the virus and secretion by the stallion of viral strains that vary over time. However, disease resulting from transmission of infection from a stallion to a mare, and subsequent spread of infection to other horses, is associated with a single viral strain.[5] In other words, stallions can excrete a variety of strains of the virus during their life, but outbreaks of disease are associated with a single viral strain; multiple viral strains are not detected during outbreaks of disease.[5]

Prolonged excretion of the virus in semen is likely important in the maintenance of the virus in populations of horses. Introduction of a **persistently infected stallion** into a naive population or insemination of seronegative mares with semen from an infected stallion have been implicated as the cause of outbreaks of viral arteritis.[8] The carrier stallion infects mares at mating, the mares develop disease and shed virus in nasal and other body fluids and infect in-contact susceptible horses and foals by horizontal transmission.

Immunity

Vaccination or recovery from natural infection results in the development of a strong serum antibody virus neutralizing response which is believed to be important in clearance of the virus and resistance to infection.[15] Naive, pregnant mares infected by horizontal transmission may abort or, less commonly, give birth to infected foals that subsequently die.

Foals of immune mares are resistant to infection, and viral neutralization antibodies are present in mare's colostrum and foal's serum after sucking, with persistence of the antibodies to the age of 2–6 months in the foals.[16] Persistence of passive immunity in foals has important implications for resistance to infection and for timing of administration of modified live vaccines.

Economic importance

The chief impact of the disease on breeding farms is the loss of foals through abortion and the cost of quarantine and control measures. The systemic illness may be severe, but the mortality rate is low. During outbreaks at race tracks the economic impact is a result of lost opportunities for training and racing sick or convalescing horses, and the effect of quarantine and control measures. Additional costs are incurred by the inconvenience and cost of vaccinating mares to be bred to stallions infected with the virus and import regulations controlling movement of horses and semen including the inability to export mares, fillies and non-carrier stallions that are seropositive (perhaps as a result of vaccination), and the limited opportunities for export of semen from infected stallions or export of the stallions themselves.

PATHOGENESIS

The pathogenesis of disease associated with horizontal transmission of EAV has been elucidated.[17] After inhalation of the virus it binds to the respiratory epithelium and infects alveolar macrophages and is detectable in bronchial lymph nodes by 48 hours after infection. Three days after infection the virus is detectable in circulating monocytes with subsequent systemic distribution of infection. The virus localized in vascular endothelium and medial myocytes by days 6–9 and there is significant damage to blood vessels by day 10. The virus infects renal tubular epithelium and can persist there for up to 2 weeks. Medial necrosis of blood vessels might cause anoxia of associated tissues. Virus is not detectable in any tissue by 28 days after infection, with the exception of accessory sex glands in intact male horses.

Abortion is caused by a severe necrotizing myometritis and presumed consequent reduction in fetal blood flow. The are usually no lesions in the fetus, although the fetus is sometimes infected with the virus.

CLINICAL FINDINGS

Infection by EAV is usually **clinically inapparent**, especially after venereal infection of mares. **Abortion** is not necessarily associated with clinical disease in the mare. Systemic disease is usually mild to moderate and self-limiting with recovery in 5–9 days in the vast majority of horses.

Systemic disease is characterized by an incubation period of 1–6 days followed by the appearance of fever (39–41°C, 102–106°F). A serous nasal discharge which may become purulent and be accompanied in some horses by congestion and petechiation of the nasal mucosa, urticaria, conjunctivitis, excessive lacrimation developing to purulent discharge, keratitis, palpebral edema, and blepharospasm. Opacity of the aqueous humor and petechiation of the conjunctiva may also occur. Signs of pulmonary disease, such as respiratory distress and coughing are attributable to pulmonary edema and congestion, but are uncommon. The appetite is reduced or absent and, in severe cases, there may be abdominal pain, diarrhea and jaundice. Edema of the limbs is common and more marked in stabled horses than those at pasture. In stallions, edema of the ventral abdominal wall may extend to involve the prepuce and scrotum. Depression is usual and varies in degree with the severity of the syndrome. The disease is acute and severe, and deaths may occur without secondary bacterial invasion. In these cases dehydration, muscle weakness and prostration develop quickly. It must be emphasized that the disease may be much milder than that described above.

Clinical disease in neonatal foals is characterized by fever, profound depression, weakness, limb and facial edema, and respiratory distress. Severely affected foals usually die. Foals can be affected at birth, or be born apparently normal and develop disease 1–19 days after birth.[12]

Abortion occurs within a few days of the onset of clinical illness, although it

is not usually associated with clinically apparent disease. Abortions may occur in 10–60% of at-risk mares during an outbreak and during the 3rd–10th months of gestation.[11] Abortion occurs 12–30 days after exposure. The abortion is not foreshadowed by premonitory signs, and the placenta is not retained.

CLINICAL PATHOLOGY

Hematological examination of adults and foals during the acute phase of the systemic disease is characterized by leukopenia and thrombocytopenia.[12]

Serological confirmation of infection is achieved using complement fixation, serum neutralization and ELISA tests.[7] Seroconversion occurs within 1 week of infection, and demonstration of a rising antibody titer, based on acute and convalescent serum samples, or seroconversion is considered evidence of recent infection. False-positive results for the virus neutralization test have occurred using OIE prescribed rabbit kidney (RK-13) indicator cells when testing serum from horses vaccinated with an EHV-1/4 tissue cultured derived vaccine.[18] The false-positive results are likely a result of vaccine-induced anticellular antibody response against the RK-13 cells.

Virus isolation from blood, body fluids, fetal or placental tissue is readily achieved during the acute phase of the disease. Appropriate samples for virus isolation include nasopharyngeal or conjunctival swabs and anticoagulated whole blood (heparin, EDTA or citrate are suitable anticoagulants).[11] Virus is continuously excreted in the semen of infected stallions and is readily isolated from the sperm-rich fraction of the semen. A nested PCR can detect the presence of virus in naturally infected semen at concentrations as low as 2.5 plaque forming units per mL with a specificity of 97% and a sensitivity of 100%, and may be useful for the rapid diagnosis of EVA shedding stallions.[19]

Antemortem diagnosis of EAV disease can be achieved by examination of skin samples using monoclonal antibody immunoperoxidase histochemistry. Examination of skin samples obtained by biopsy reveals edema and vasculitis and presence of intracytoplasmic EAV antigen.[20]

NECROPSY FINDINGS

Gross lesions include edema of the eyelids and petechiation of the upper respiratory tract, and the serosae of the abdominal and thoracic viscera. There is an abundant serofibrinous pleural and peritoneal effusion with generalized edema of the lungs, mediastinum, and abdominal mesenteries. A hemorrhagic enterocolitis, as well as hemorrhage and infarction in the spleen may be noted. Characteristic histological changes are found in the small arteries and include **fibrinoid necrosis of the tunica media and karyorrhexis of the infiltrating leukocytes**. Fluorescent antibody or immunohistochemical staining demonstrates viral antigen within the endothelial cells of these blood vessels. An immunoperoxidase method has also revealed viral antigen within endothelial cells and macrophages of an aborting mare and her fetus and within skin biopsies of animals exhibiting a maculopapular rash.[20] Serological tests performed on samples collected at necropsy can also be used to confirm that exposure to the virus has occurred.

The virus can be isolated from the lung and spleen of aborted fetuses, but no consistent, specific lesions are present. Necrotizing arteritis, similar to that in the mare, may be detectable.[21]

Samples for confirmation of diagnosis

- **Virology** – chilled lung, spleen and thymus (VI, PCR, FAT)
- **Serology** – heart-blood serum or fetal thoracic fluid (VN, ELISA, CF)
- **Histology** – fixed lung, spleen, adrenal, jejunum, colon and heart (LM, IHC).

DIFFERENTIAL DIAGNOSIS

Definitive diagnosis is based on isolation of EAV from affected cases, or the demonstration of seroconversion or an increase in serum antibody titer.

The systemic disease must be differentiated from that associated with EHV-1 or EHV-4 infection, equine influenza, strangles (see Table 16.4), infection with Getah virus in Japan, equine infectious anemia, African horse sickness, and purpura hemorrhagica.

Abortion should be differentiated from that associated with EHV-1, *Salmonella abortusequi*, leptospirosis, mare reproductive loss syndrome, and congenital malformations.

Similar disease in neonates can be associated with EHV-1, immaturity or premature birth, and bacterial septicemia.

TREATMENT AND CONTROL

There is no specific treatment for equine viral arteritis. Most horses recover without specific care. Severely affected foals require intensive care.

Control of EAV infection is based on the strong **immunity** induced by natural infection or vaccination with a modified live virus, and an understanding of the role of carrier stallions in the disease. The following practices are suggested:[9]

1. Isolate all new arrivals (and returning horses) to farm or ranch for 3 to 5 weeks
2. If possible, segregate pregnant mares from other horses
3. Blood test all breeding stallions for EAV antibodies
4. Check semen of any unvaccinated, antibody-positive stallions for EAV to identify carriers before breeding
5. Once tested negative for EAV antibodies, vaccinate all breeding stallions annually
6. Physically isolate any EAV carrier stallions
7. Restrict breeding EAV carrier stallions to vaccinated mares or mares which test positive for naturally acquired antibodies to the virus
8. Vaccinate mares against EVA at least 3 weeks prior to breeding to a known carrier stallion
9. Isolate mares vaccinated for the first time against EVA for 3 weeks following breeding to an EAV carrier stallion
10. In breeds or areas with high rates of EAV infection, vaccinate all intact males between 6 to 12 months of age.

Testing of mares and stallions permits identification of serologically negative, and therefore at-risk, animals. Seronegative mares should not be mated with infected stallions nor inseminated with fresh or frozen semen from infected stallions because of the risk of transmission of infection to the mare.[8] Seropositive mares, or mares that have been vaccinated at least 3 weeks, can safely be bred to stallions that have serological evidence of infection. Seropositive mares should be separated from seronegative mares for at least 3 weeks after mating to a seropositive stallion. Seropositive stallions that have not been vaccinated should have their semen cultured to determine if they are excreting the virus. Stallions excreting virus in their semen should be kept isolated from susceptible horses but can be bred to seropositive mares, as described above. Because the virus survives cooling and freezing, similar principles should be applied to the use of artificial insemination in horses. One control program requires that all stallions be vaccinated with a modified live virus vaccine 28 days before the beginning of each breeding season.[11]

Vaccination with a modified live virus vaccine induces strong immunity, although revaccination is necessary to insure continuing immunity.[7,11] The vaccine protects mares exposed to stallions shedding the virus in semen and has been used to control outbreaks of the respiratory form of the disease at racetracks.[22] The modified live virus vaccine is

regarded as safe,[11] although there is mild fever and leukopenia, and evidence that the vaccine virus replicates in the vaccinates.[23] A killed virus vaccine has limited availability and its efficacy in the field has not been reported.[21] Antibodies induced by the vaccine cannot be differentiated from those resulting from natural infection, a situation that may be problematic when import restrictions require the horse to be seronegative, presumably as proof of lack of exposure to virulent EAV.

Vaccination of foals from immune mares results in good protection provided that the timing of vaccination is delayed until maternal antibodies to EAV are no longer present in the foal.

EQUINE INFLUENZA

Synopsis

Etiology Influenza virus H3N8 (previously A/equine 2) of two lineages and numerous, evolving, strains. Historically, H7N7 virus
Epidemiology Short incubation period and highly contagious nature of the virus result in explosive outbreaks of disease. Viral shedding by subclinically affected horses is important for introduction of infection to populations. Prolonged carrier state is not recognized
Clinical signs Upper respiratory disease complicated by pneumonia. Abortion is not a feature of the disease
Clinical pathology None characteristic
Lesions Rhinitis, pneumonitis. Rarely causes death
Diagnostic confirmation Demonstration of virus in nasopharyngeal swab either by culture, ELISA, PCR, or membrane bound immunoassay
Treatment Supportive care. There is no specific treatment
Control Vaccination, often every 4 months, quarantine and hygiene

ETIOLOGY

Equine influenza is associated with infection by equine **influenza A/H7N7** (previously referred to as equine influenza A1) or **equine influenza A/H3N8** (previously referred to as equine influenza A2) virus, members of the influenzavirus A genus of the family Orthomyxoviridae. Of the two serologically distinct subtypes, all reported outbreaks in the past two decades have been associated with strains of EIV-A/H3N8. There are no reports of disease associated with EIV-A/H7N7 in the past 25 years and reports of seroconversion might be related to use of vaccines containing EIV-A/H7N7 antigen.[1] There are no reports of other influenza viruses, such as the H1N1 avian virus, causing disease in horses, although the avian-like influenza A/I/Jilin89 (H3N8) caused severe disease and high mortality among horses in China in 1989.[2] Equine influenza H3N8 virus can infect dogs and cause serious disease and death.[3]

Currently, two major lineages of EIV-H3N8 circulate in horse populations – a Eurasian lineage and an American lineage. The terms Eurasian and American do not denote geographical isolation of these lineages, and viruses of American lineage circulate in Europe and North America, although to date the only virus of Eurasian lineage isolated in North America was the Saskatoon isolate (1/90).[4] Within the American lineage there is further division of the virus into three distinct lineages (South American, Florida and Kentucky) with the predominant lineage varying from year to year with evidence of cycling.[4,5] Cycling is the predominance of one lineage one year, and the other lineage in the subsequent year, with reversion to the initial lineage in the third year, and so on.[5] This is believed to be a mechanism for viral perpetuation, allowing avoidance of eradication of the virus by changing the immunological target from year to year without viral evolution.[5]

The predominating virus lineage or strain varies from year to year and from region to region. The important point is that there is continual change in the viral strain in some populations of horses and that constant monitoring of viral strains is vital for appropriate composition of vaccines and for molecular epidemiology. For instance, the majority of viruses from Europe (France, Italy and the UK) and North America characterized antigenically and/or genetically between January 2003 and April 2004 were of the American lineage. Based on hemagglutination inhibition (HI) testing most viruses isolated in Europe, represented by A/equine/Newmarket/5/03, were antigenically closely related to the vaccine strains, A/equine/Newmarket/1/93 (American lineage), A/equine/Kentucky/97 and A/equine/Kentucky/98 (American lineage). Viruses recently isolated in South Africa and the USA were distinguishable from these three vaccine strains and were more closely related to A/equine/South Africa/4/03.[6] The South African strain was identical to an American lineage strain originally isolated in Wisconsin in 2003 (A/Equine/Wisconsin/1/03).[7,8] The HA1 sequences of 2003 American-like viruses fall within a single phylogenetic subgroup referred to as the 'Florida' lineage.[5] In 2003 and 2004 a few viruses, isolated in Benelux, were of the 'European' lineage,[6] and were antigenically similar to some viruses circulating in Europe during 2002, represented by A/equine/Lincoln/1/02, and were distinguishable from the prototype vaccine strain A/equine/Newmarket/2/93.[6] The European lineage viruses circulating in 2002 were heterogeneous in their antigenic and genetic characteristics. Information about EIV strains changes constantly and is available at the equiflunet website.[6]

The existence of lineages and strains of virus is important in the epidemiology of the disease because the antigenic differences among strains can be sufficient to prevent cross-protection provided by natural infection or vaccination. Cross-protection refers to the ability of one antigen (virus strain) to produce immunity in the horse against infection with another type of antigen (virus strain). Infection or challenge with the same type of antigen is referred to as homologous challenge, whereas that with a different antigenic type is referred to as heterologous challenge.[9] Strains of influenza virus circulate between and among populations of horses, with more than one strain of virus circulating at any one time in some horse populations,[10] although individual disease outbreaks are associated with a single viral strain. Many, but not all, of these virus strains are constantly evolving and evolution of the viruses is necessary for perpetuation of cycles of infection

through the emergence, or reemergence by cycling, of heterologous strains.[5,11] Evolutionary stasis, the continued circulation of older strains of virus, occurs and has importance for vaccine composition.[11] However, emergence of new strains is common and of great importance for control of the disease. Evolution of strains of equine H3N8 virus occurs through antigenic drift. **Antigenic drift**, the accumulation of point mutations in the gene coding for the major surface protein hemagglutinin, occurs continuously in virus circulating in horse populations. Antigenic drift occurs most rapidly in hemagglutinin protein but also occurs in M and NS genes.[12] Antigenic drift, by producing heterologous viral strains, contributes to the continuing susceptibility of horses to infection and the reduced efficacy of some vaccines.

Influenza virus is an RNA virus that has eight segments to its genome which encodes ten proteins. The hemagglutinin and neuraminidase proteins are used for antigenic characterization of virus strains. Mutations in these genes or poor fidelity RNA copying results in changes in amino acid composition of viral proteins that may be detected by serological tests (see 'Clinical Pathology') and that might have, as discussed above, important consequences for infectivity and pathogenicity of the virus. **Antigenic shift** is an event in which there is a dramatic alteration in the viral genome occurring by reassortment of viral genes during co-infection of a cell by two different types of virus (for example infection of a pig by both avian and human influenza viruses). Antigenic shift, which has not been documented for influenza viruses infecting horses, has the potential to produce new viruses with markedly different host infectivity and pathogenicity to either parent virus.

EPIDEMIOLOGY

Occurrence

Worldwide, the only large horse populations in which **influenza virus infection** does not occur are in Australia and New Zealand. Widespread use of aircraft to move horses between countries in short periods has increased the spread of equine influenza viruses, as exemplified by the 2003 outbreak of equine influenza in horses in South Africa associated with a virus from North America, and an earlier outbreak in Hong Kong. In both cases virus was introduced by imported horses.[8,13,14]

Epidemics of equine influenza have occurred in Europe or North America in 1956 (H7N7), 1963 (H3N8), 1969, 1979, and 1989, although this does not represent a comprehensive listing of large scale outbreaks.[15,16] Epidemics affecting >1 million horses occurred in China in 1989 (associated with the novel H3N8 Jilin virus) and 1993/1994 (associated with a conventional H3N8 virus closely related to 1991 European isolates).[16] Epidemics in Europe and North America have been associated with introduction of a novel virus (for example the 1963 appearance of H3N8 virus in Miami) or antigenic drift of existing viruses and resultant inefficacy of extant vaccines.[15]

Localized outbreaks of disease in stables or race courses occur almost annually in countries in which the disease is endemic, likely related to the movement of horses into the training and racing populations, with subsequent introduction of virus and development of disease in at risk horses (see 'Animal Risk Factors'). Disease associated with equine influenza virus usually occurs as outbreaks associated with the introduction of virus into a population of susceptible horses. Virus may be introduced by clinically affected horses or, more commonly, by horses that are not noted to be clinically ill. Vaccinated horses may become infected and shed influenza virus while not becoming ill, especially if vaccinated with heterologous strains, and this is likely a common method of introduction of virus into susceptible populations.

Outbreaks of influenza virus infection may cause clinical disease in nearly all (98%) horses in a susceptible population, although in populations of horses of mixed age and with varying serum titers to equine influenza the morbidity rate may be much lower (16–28%).[17] The incidence of disease in one race track population was approximately 130 cases per 1000 horses at risk per month[18] although this rate likely varies widely among outbreaks. The mortality rate is usually very low (<1%) with most deaths associated with secondary bacterial infections. However, a recent outbreak of disease in China associated with a novel H3N8 (Jilin virus) strain was associated with a morbidity rate of 80% and mortality rate of 20–35%.[2]

The disease in populations of vaccinated or previously exposed horses is associated with a lower morbidity and mortality, and slower spread, due to the milder disease induced by influenza virus infection of immune or partially immune horses. In an outbreak among vaccinated racehorses in Hong Kong, 75% of horses had serological evidence of infection, 37% had clinical signs of infection, and 0.2% died.[14] Horses imported from Australia and New Zealand, where the disease does not occur, had a morbidity rate of 52%, while horses from the northern hemisphere had a morbidity rate of 20%, likely reflecting the effect of previous exposure to influenza virus or repeated vaccination.[14]

The profile of an epidemic can vary from explosive with a large proportion of a small group of susceptible horses housed in close proximity, such as a small band, developing clinical disease within 24–48 hours, to much more prolonged outbreaks lasting several weeks in larger groups of horses of varying susceptibility housed in multiple barns. During larger outbreaks among horses of varying susceptibility there is a characteristic three phase pattern.[18] The first stage is associated with the first cases of disease and slow spread over 10–14 days. This stage is followed by one of rapid spread of the disease to horses clustered in stalls around horses affected during the first phase of the outbreak. The third phase is characterized by declining numbers of cases.[18]

Origin of infection and transmission

Equine influenza virus is relatively susceptible to environmental conditions, and during an outbreak infection must originate from an infected horse although the proximate source of virus can be contaminated equipment or other fomites. **Transmission** of equine influenza virus occurs by direct contact, inhalation of aerosols of infected material, and on fomites. Survival of the virus on clothing and surfaces, including vehicles used to transport horses shedding the virus, can result in transmission of infection in the absence of horse to horse contact.[8] **Fomite transfer** on veterinary clothing, equipment or vehicles was likely responsible for the spread of infection from quarantined horses in both South African outbreaks.[8,19] However, in most instances, horses are infected by other horses that are in close proximity or have physical contact, for instance exercise ponies (horses or ponies used to accompany race horses from the stable to the track in preparation for racing or training gallops) or stable mates.[17] Aerosol spread occurs over distances of 35 meters, possibly further, and is enhanced by the frequent coughing characteristic of the disease. Equine influenza virus in aerosols survives longer (24–36 hours) than human or porcine strains (15 hours).

Clinically affected horses excrete more virus than do horses in which the infection is inapparent. The duration of infectivity of clinically affected horses is 3–8 days and with the short incubation period of 2–3 days combine to produce the potential for a very rapid new infection rate and a characteristic explosive outbreak.

Risk factors

Animal factors

All age groups of horses, including newborn foals, are susceptible. The greatest

risk appears to be between the ages of 2 and 6 months,[20] serum levels of passively acquired antibodies being lost by foals at 2 months of age.[21] A recent survey of >8000 horses in the United States revealed that only 20.2% of horses aged 6 to 12 months had a detectable influenza antibody titer (HI), as compared to 89.0% of horses aged 20 years or more.[22] The percentage of horses that had a high equine influenza antibody titer increased as the horse's age increased such that 45–51% of horses older than 5 years had high titers. This observation is consistent with most cases of the disease occurring in 2-year-old or younger horses, probably because older horses are immune through either natural exposure or vaccination. Thoroughbred race horses ≤2 years were 5–8 times more likely to develop influenza than were horses ≥5 years of age in a well characterized series of outbreaks.[17] Seronegativity to a H3N8 virus (Saskatoon/90) was associated with a 13–38 fold increase in likelihood of developing influenza, independent of the effect of age.[17] It is probable that outbreaks occur as a result of a natural accumulation of young animals which have not been previously exposed, the co-mingling of these susceptible animals with older infected ones at race and show meetings, and to the significant level of antigenic 'drift'. This capacity of the virus to change slightly and continuously in antigenic composition leads to the frequent appearance of new strains which are likely to breach existing natural and induced immunological barriers.

Outbreaks can occur at any time of year, and their timing probably depends on husbandry and management practices, such as yearling sales, transport of horses for racing and sale, and movement of show and breeding animals. These events often provide the combination of a population of susceptible animals housed in crowded, poorly ventilated barns that facilitate transmission of the virus.[23]

Immunity depends on the means of exposure (vaccination or natural infection), the strain of the virus, and the time since exposure. After infection, protective immunity to homologous strains of the virus is present and persists for 1 year, possibly up to 2 years. Field studies of disease outbreaks indicated that the concentration of antibodies in serum that provide some resistance to disease might be less than that suggested from experimental studies.[17] Protective immunity induced by natural infection is characterized by production of IgA in nasal secretions and IgGa and IgGb in serum, whereas administration of an inactivated, alum-adjuvanted commercial vaccine induces only a serum IgG(T) response that is not protective against challenge.[24] Immunity after vaccination lasts for a much shorter period of time, 3–4 months, and is specific for the subtypes, and their strains, of virus included in the vaccine. Immunity following infection or vaccination is less protective against infection by a heterologous strain.[23] Similarly, vaccination exposure to a heterologous virus may induce only a poor anamnestic immune response.[23] These observations are consistent with the concurrent circulation of multiple viral strains influenza virus in horse populations, and the cycling of virus strains causing disease in consecutive years.[5]

Management factors

Housing of large numbers of horses in close contact, or in enclosed environments such as large barns or stables, provides optimum conditions for facilitating contact and aerosol spread of the virus. Shed barns, which characteristically have poorer ventilation and greater stocking density than pole barns, are associated with a 4-fold increase in risk of influenza.[17]

Presence of small numbers of horses with access to large numbers of at risk horses might impact the course of an epidemic. Track ponies, which have close contact with large numbers of horses on a daily basis, are important in spread of influenza in racing barns.[17]

Economic importance

Influenza causes minimal loss through death of horses, but it causes much inconvenience in racing stables because it occurs in explosive outbreaks and affected horses have to break training. Such outbreaks have the capacity to close down the racing industry in a country for a period of months.[14] An additional cost is incurred because of restrictions on international movement of horses and associated quarantine periods.

Zoonotic potential

Equine influenza A viruses can infect humans although such infections are unusual and subclinical [25]

PATHOGENESIS

The disease is principally one of inflammation of the upper respiratory tract, although pulmonary lesions are common in adult horses and the disease can cause severe, fatal pneumonia in foals.[7,26,27] The virus is inhaled, attaches to respiratory epithelial cells with it hemagglutinin spikes, fuses with the cell, and is released into the cytoplasm where it replicates. New virions are released from the cell surface and infect other cells or are expelled into the environment. Initial viral infection and replication occurs mainly in the nasopharyngeal mucosa, but by 3–7 days after infection, virus can be recovered from cells throughout the respiratory tract. Infection of the respiratory mucosa results in death of epithelial cells, inflammation, edema, and loss of the protective mucociliary clearance. Death of cells is a result of influenza virus-induced apoptosis of respiratory epithelial cells and local and systemic increases in interferon and interleukin-6.[28,29] Proliferation by opportunistic bacteria, commonly *Streptococcus zooepidemicus*, occurs because of the disruption of normal clearance mechanisms, and can exacerbate the inflammation and cause bronchopneumonia. Viremia, if it occurs, is mild and brief, although it may be related to some of the systemic signs of the disease. Some speculate that myocarditis, myositis and encephalitis occur occasionally in response to influenza virus infection, but definitive proof is lacking.[23] Influenza virus has not been isolated from tissues other than those of the respiratory tract.[23] Enteritis was reported in horses in the 1989 Chinese outbreak (Jilin/89), but is not reported for disease associated with conventional virus strains.

CLINICAL FINDINGS

Outbreaks of equine influenza are characterized by a sudden onset and rapid spread of disease. Typically, in a large group of susceptible horses the incidence of the disease peaks about 1 week after the first case is noticed and new cases do not develop after 21–28 days.[14,17,30] The disease may have an attenuated clinical course in a population of vaccinated or previously exposed horses. The milder disease in immune animals may be clinically indistinguishable from upper respiratory diseases associated with other common agents such as EHV-4, equine rhinitis virus and arteritis virus.

Clinically, the disease starts with a fever (38.5–41°C, 101–106°F) after an incubation period of 24–72 hours. Horses may be depressed, refuse feed, and reluctant to move. The dominant sign is cough, which is dry and hacking in the beginning and moist later, and which commences soon after the temperature rise and lasts for 1–3 weeks. It is easily stimulated by manual compression of the upper trachea. During the early stages of the disease, nasal discharge is not a prominent sign and, if it occurs, is watery. There is no marked swelling of the submaxillary lymph nodes but they may be painful on palpation in the early stages of the disease, especially in younger horses. Limb edema or swelling is unusual in horses with influenza. Abnormal lung sounds, characterized by crackles, wheezes, and increased intensity of normal breath

sounds may be apparent in both uncomplicated disease and in horses with secondary bacterial pneumonia. Ultrasonographic examination of lungs of horses with influenza, even clinically mild disease, reveals pulmonary consolidation, fluid bronchograms, and peripheral irregularities.[27,31] Tracheal aspirates are neutrophilic, yield heavy growth of *S. zooepidemicus*, and are consistent with bronchitis and pneumonia.[31] Horses, unwisely, forced to exercise have reduced endurance. Horses that are protected against environmental stress pursue an uncomplicated course with most horses have complete recovery in 7–14 days, although a mild cough can persist for weeks.

The above is a description of the classical disease. However, in outbreaks there is a range of disease severity.[17] Mucopurulent nasal discharge is observed in 75–90% of horses, cough in approximately 60%, fever in 20–50%, inappetance in 20–30%, and signs of depression in 20–40%.[17] Undoubtedly, the proportion of horses showing each of these signs will vary from outbreak to outbreak depending on the age and susceptibility of horses in the population, among other factors.

Complications and a more severe disease occurs in a small number of horses. Horses that are worked, transported, or exposed to adverse climatic conditions can experience a worsening of the cough, and severe bronchitis, pneumonia and edema of the legs may develop. Complications are usually associated with secondary bacterial infection, usually *Strep. zooepidemicus*, that results in a mucopurulent nasal discharge, persistent fever, and markedly abnormal lung sounds. Icterus, encephalitic signs, incoordination and myoglobinuria are reported as rare complications.[23] Electrocardiographic abnormalities have been reported in horses with influenza, and were attributed to myocarditis. However, there is no objective evidence of myocarditis secondary to influenza infection of horses nor is there a clear association between influenza infection and electrocardiographic abnormalities.

A more severe form of the disease, associated with an antigenically distinct strain of equine influenza 2, is reported from China. The mortality rate is 35%, and death is due to pneumonia and enteritis.[2]

A severe form of the disease is also reported in young foals. Foals develop fever, severe respiratory distress and acute interstitial pneumonia that is commonly fatal.[10,26,32] The disease is not invariably associated with failure of transfer of passive immunity.

CLINICAL PATHOLOGY

There are no characteristic changes on hematologic or serum biochemical examination of horses clinically affected by equine influenza virus infection.

Confirmation of the diagnosis of infection by equine influenza virus is achieved through virus isolation, indirect demonstration of virus in nasopharyngeal swabs, and/or serology.[33]

Measurement of antibody concentrations against the viral hemagglutinin antigen is important in determining susceptibility to infection, vaccine efficacy, and exposure – factors important in implementing control measures (see below). Documentation of seroconversion, a three- to four-fold increase in **hemagglutination inhibition** (HI) antibody titer, or a doubling in antibody titer measured by the **single radial hemolysis test**, in paired sera collection 14–21 days apart provides retrospective confirmation of the diagnosis. The single radial hemolysis test is more reproducible than the hemagglutination inhibition test and is the preferred test for determining concentrations of antibody against the hemagglutinin antigen.[34] For the single radial hemolysis test virus is coupled to red blood cells that are then included in agarose. Wells are punched in the agar plate filled with test sera. Influenza antibodies then cause lysis of red cells, with the diameter of the zone of hemolysis proportional to the concentration of the strain specific antibody in the serum.[25] Antibodies against the non-structural protein (NS1) are detectable in horses after natural infection, but not after vaccination with an inactivated virus thereby permitting differentiation of immunologic responses to vaccination and infection.[35]

However, because **rapid identification** of the cause of the outbreak is important when instituting control measures, timely demonstration of virus in nasopharyngeal swabs is desirable. Rapid demonstration of viral shedding can be accomplished by use of tests for rapid diagnosis.

Directigen Flu A test (Becton Dickinson) is a rapid test designed for use with humans, that identifies influenza viral nucleoprotein by a membrane-bound enzyme immunoassay. It has been validated for use in horses and is effective because of the conserved nature of the target antigen across influenza A strains.[36] Results are available in as little as 15 minutes. The test had sensitivity of 83%, specificity of 78%, positive predictive value of 70%, and negative predictive value of 88% compared to virus culture. Sensitivity was 54%, but specificity and positive predictive value were 100% when compared with serological diagnosis. The low sensitivity compared to serology was ascribed to inadequate collection of nasopharyngeal swabs, or collection of samples when horses were not excreting virus.[36] The high specificity and positive predictive value of the test mean that a positive result confirms the diagnosis of influenza infection. The relatively low specificity means that samples should be collected from a number of horses in various stages of the disease. Nasopharyngeal swabs should be collected by inserting a cotton gauze swab approximately 30 cm (12 inches) into the nostril or, preferably, nasopharynx of an adult horse and leaving it in place for 60 seconds.[25] The swab should then be transferred to specialized transport media and shipped to the laboratory.[33]

Other rapid diagnostic tests include the **Flu OIA (Biostar)** assay for influenza A and B viral antigen. The test cross reacts with equine herpesvirus 2 and is therefore not useful for diagnosis of upper respiratory disease of horses.[6] The test is more sensitive than the Directigen test, possibly because it detects nonviable viral material present in exfoliated epithelial cells.[37] Other tests include the **ZstatFlu** (ZymeTx), **QuickVue Influenza** (Quidel) and **NOW Flu** (Binax) assays, none of which have been validated for use in horses at the time of writing.[6]

Use of rapid tests is not a substitute for viral isolation, which is important for typing of the isolate and subsequent epidemiological studies and vaccinal applications. Isolation of the virus provides a definitive diagnosis.

Material for viral culture should be collected as early as possible during the illness and inoculated into the transport medium quickly. The transport medium should contain phosphate buffered saline, glycerol, and antibiotics, among other constituents.[25]

Virus can be detected rapidly in clinical specimens by a reverse transcription PCR (RT-PCR) test for nucleoprotein gene, hemaglutinin gene of H3N8 viruses and hemaglutinin gene of H7N7 virus.[33] RT-PCR and viral isolation are more sensitive than use of Directigen assay in detection of virus.[38]

NECROPSY FINDINGS

Necropsy material is rarely available and the lesions in these fatalities are usually complicated by other pathogens. Histologically, a necrotizing bronchiolitis accompanies widespread pulmonary edema. Foals dying of acute respiratory distress associated with influenza infection have severe diffuse interstitial pneumonia which is characterized histologically by necrotizing bronchitis and bronchiolitis and multifocal interstitial pneumonia.[10]

Samples for postmortem confirmation of diagnosis

- **Nasal swabs** in viral transport media, and sections of lung and trachea should be submitted for virus isolation or demonstration by fluorescent antibody or PCR testing
- **Formalin-fixed nasopharynx, trachea, and lung** should be submitted for light microscopic examination.

DIFFERENTIAL DIAGNOSIS

See Table 16.4.

TREATMENT

Currently, there is no specific treatment of influenza virus infection of horses.

Amantadine is used in humans for prophylaxis and treatment of influenza infection in high-risk populations, and it has been investigated for use in horses.[39] Amantadine administered intravenously caused transient neurologic abnormalities in experimental horses.[39] Rimantidine (30 mg/kg PO q 12 hour) administered 12 hours before experimental inoculation of horses with equine influenza KY/91 mitigated signs of disease but did not eliminate viral shedding.[40] However, the safety and efficacy of amantadine and rimantidine in horses with naturally occurring disease have not been demonstrated at this time. Until these issues are resolved, and because the infection has such a low case fatality rate, the use of these drugs in horses cannot be recommended.

Antibiotic treatment of uncomplicated cases is probably not warranted but horses that develop prolonged fever (greater than 5 days), signs of pneumonia, or a profuse mucopurulent nasal discharge should be treated with broad-spectrum antibiotics, such as potentiated sulfonamides (15–30 mg/kg, PO, IM, or IV, every 12 h), ceftiofur (2.2 mg/kg, IM, every 12 h), or procaine penicillin (20 000 IU per kg, IM, every 12 h) with or without gentamicin (6.6 mg/kg, IM, every 24 h). The usual cause of secondary bacterial infection is *S. zooepidemicus*, which is susceptible to penicillin.

Supportive treatment includes rest, provision of a dust-free environment and, on occasion, administration of non-steroidal anti-inflammatory drugs (NSAIDs). However, NSAIDs should be used judiciously, as their analgesic properties may mask signs of complications, such as pleuritis. Corticosteroids are contraindicated in the treatment of this disease. Cough suppressants are also contraindicated, as coughing is a normal protective mechanism that aids in the clearance of material from the airway. Mucolytics can be administered but their efficacy is unknown. Clenbuterol administration does not alter the course of the disease and is not recommended.[41]

CONTROL

The fundamental aims of a control program are to:

- Increase the immunity of both individual animals and the population to infection
- Reduce the opportunities for spread of infection between horses
- Prevent the introduction of novel strains of the virus into a population.

These aims are achieved by vaccination, hygiene and quarantine.

Immunity and vaccination

Immunity to influenza through administration of inactivated vaccines can be assessed by measurement of serum antibody concentrations against hemagglutinin, using the single radial hemolysis test, whereas immunity gained through natural infection is independent of serum antibody concentration.[34] However, serum antibody concentration is currently used as an indicator of susceptibility of individual horses to infection, and as a guide in the development and application of vaccination protocols, including monitoring of need for vaccination in individual horses. Serum antibody concentrations to hemagglutinin measured by single radial hemolysis are specific for the strain of virus and are strongly predictive for resistance to disease associated with that virus in both experimental and field challenge.[34,42,43] Failure of a commercial inactivated virus multivalent vaccine to induce detectable increases in antibody concentration in Thoroughbred race horses was associated with lack of protection against natural infection by a heterologous influenza virus.[44] It is important to reiterate that resistance to disease after vaccination or natural infection is greatest for homologous virus and minimal for challenge by heterologous virus.[45] Thus, horses with antibody concentrations protective to disease associated with homologous virus are susceptible to disease associated with heterologous virus.[34,42,43]

Vaccination against equine influenza is now in general use in countries where the disease occurs, and use of efficacious vaccines is effective in limiting the severity of clinical illness and morbidity during an outbreak[14,46] Vaccine efficacy is limited by the short duration of immunity induced by vaccination, the presence in horse populations of multiple viral strains and of antigenic drift in these strains, and the poor immunity induced by vaccines (and natural infection) to challenge by heterologous virus.[34,46] Furthermore, the immune responses induced by administration of inactivated virus or subunit vaccines, which are primarily an increase in serum IgG(T) antibody titer, differ markedly from the immune responses to natural infection, which are production of IgA in nasal secretions and IgGa and IgGb in serum.[24]

Multiple factors are important in determining the efficacy of a vaccine in protecting against disease. Factors include efficacy of the vaccine in stimulating an immune response, viral strains included in the vaccine amount of antigen in a dose of vaccine adjuvant, and timing and frequency of administration of the vaccine.

Vaccines

A complete listing of current commercially available vaccines, the viral stains or antigens included, and the adjuvant used is available at the equiflunet website.[47] This site should be consulted for up to date information on equine influenza vaccines as this is a rapidly developing field. For instance, during the period January 2003 to April 2004, H3N8 viruses of the American lineage caused widespread outbreaks in Europe, with well-vaccinated horses frequently affected. Furthermore, viruses responsible for recent outbreaks in South Africa (2003) and circulating in North America were antigenically distinguishable from the currently recommended vaccine strains. On the other hand, viruses of the European lineage were associated with limited, more localized, outbreaks in Europe and were antigenically and genetically similar to some viruses circulating during 2002. Based on these observations, it is recommended that vaccines are updated to contain an A/equine/South Africa/4/03 (H3N8)-like virus (American lineage) and an A/equineNewmarket/2/93 (H3N8)-like virus (European lineage). A/eq/Suffolk/89 and A/eq/Borlänge/91, currently used vaccine strains, continue to be acceptable.

There are several forms of vaccine available including those that contain one of inactivated virus, modified live virus, hemagglutinin and neuraminidase subunits, or hemagglutinin proteins.[47] Furthermore, the type of adjuvant varies among vaccines with carbomer, aluminum hydroxide, carbopol, saponin, immune-stimulating complex (ISCOM), and various proprietary products (Meta-stim, PureVax) being used.[47] A comparison of each vaccine is beyond the scope of this text, but several principles should be considered when selecting a vaccine: the vaccine should induce a measurable immune response and demonstrable

protection against disease (natural or experimental), it should contain pertinent viral strains, it should be safe, and it should be practical (i.e. readily administered).

Most vaccines are comprised of inactivated or subunits of virus combined with an adjuvant. Inclusion of an adjuvant is important in maximizing the immune response to vaccination. The important factor in vaccine composition is the inclusion of adequate amounts of antigen of pertinent strains of virus. H7N7 virus is no longer a cause of clinical disease and it should not be included in contemporary vaccines.[34] Inclusion of antigen from both American and Eurasian lineages of H3N8 virus is essential, and vaccine composition should be regularly updated to reflect those viruses currently circulating in the horse population.[34,46,47] The vaccine must include an adequate amount of antigen, measured by the single radial diffusion assay, preferably, the single radial hemolysis assay, as there is a clear relationship between dose of antigen and magnitude and duration of antibody response.[46] There is increasing concern, and some evidence,[45] that inclusion of multiple antigens in vaccines (for example, tetanus toxoid, equine herpesvirus, encephalomyelitis virus) reduces the efficacy of influenza vaccines. While this concern has yet to be proved conclusively, it should be borne in mind when formulating vaccine programs for horses at high risk of influenza.

A modified live virus vaccine is available in North America and has proven to be effective in experimental studies in preventing disease against heterologous virus challenge (both American and Eurasian lineages).[48] Furthermore, the duration of protection is at least 6 months after completion of a course of vaccination. Vaccinated ponies had had significantly lower clinical scores, smaller increases in rectal temperature, and shed less virus over fewer days than did the unvaccinated controls in response to challenge 6 months after vaccination.[49] After challenge at 12 months, vaccinates had rectal temperatures, duration and concentration of virus shed significantly reduced to that in unvaccinated animals. The results of this study showed that 6 months after a single dose of vaccine the duration and severity of clinical signs were markedly reduced amongst vaccinated animals exposed to a severe live-virus challenge. Appropriate use of this vaccine should lead to a marked reduction in the frequency, severity and duration of outbreaks of equine influenza in North America.[49]

A live recombinant canary pox vector vaccine has been introduced in Europe.[46] The vaccine uses the viral vector to introduce influenza hemagglutinin genes into host cells. The recombinant virus expresses the hemagglutinin gene of both A/eq/Newmarket/2/93 (European lineage) and A/eq/Kentucky/94 (American lineage).[50] The canary pox infection of the host cell is abortive, with no virus produced, but influenza viral gene is expressed and presented through MHC class 1 by the host cell, with subsequent induction of an immune response.[34] In preliminary reports it provides protection against infection by homologous virus, or by A/eq/Newmarket/05/03, the cause of the 2003 outbreak of influenza in Britain, 2 weeks after vaccination.[50] The vaccine was used to aid in the control of the 2003 influenza outbreak in South Africa.

Other novel vaccine strategies include use of DNA or vector vaccines. Although effective in inducing a protective response, technological issues currently limit the widespread use of DNA vaccines.[51,52]

Objective

The objective of a vaccination program is to insure that horses have maximal immunity at the times of greatest risk of exposure to influenza virus. Therefore, young horses should be adequately vaccinated before being introduced into larger populations of horses. Older horses should receive frequent booster vaccinations before, and during, the racing or show season. Mares should be revaccinated before being shipped to breeding farms. It is important in any control program that all horses in a herd be vaccinated so that the population immunity to infection is maximal.

Timing

Foals

Timing of vaccination of foals depends on the immune status of the mare, and consequent acquisition of passive immunity by the foal. The presence of even small amounts of maternally derived antibody interferes with the immune response of foals to vaccination.[53,54] Furthermore, vaccination of foals while they continue to have passive immunity can result in impaired responses to subsequent vaccinations.[53,54] The practical significance of this latter observation is unknown but because of its potential importance should be considered when developing vaccination protocols for foals. Therefore, vaccination of foals born to mares vaccinated more than once yearly should be delayed until the foals are at least 24 weeks of age when the immunity resulting from the vaccination is much better; this might leave some foals unprotected because passively acquired immunity is shortlived and some foals of recently vaccinated dams are seronegative by 4 weeks of age.[21] Foals of unvaccinated mares can be vaccinated at less than 1 month of age. Vaccinations are carried out at 6 to 12-week intervals for at least two injections. Subsequently, booster injections are given at least once a year, although more frequent vaccination confers a greater immunity.

Race and show horses

Yearlings and young horses are at increased risk of disease, and careful attention to their vaccination status is important in reducing the incidence of disease in this group. Yearlings and 2 year olds in racing stables in Great Britain typically have antibody concentrations against influenza prior to vaccination on arrival at the stable that are not protective.[55] Vaccination increases antibody titer such that approximately three quarters of yearlings and 2 year olds have protective titers.[55] For yearlings entering training the important predictors of antibody titer prior to vaccination on arrival at the stable were the time since a previous vaccination, total number of previous vaccinations, and the age at first vaccination.[55] This study demonstrates the need for appropriate vaccination of young horses before they enter larger populations of horses, both to protect the young horse from disease and also to confer herd immunity on the population that they are entering.

Vaccination of race and show horses and other horses at increased risk of exposure should be frequent. Booster vaccines should be timed to maximize immunity at the time of greatest exposure, such as introduction to a new stable or at the beginning of the show season. For maximal protection subsequent booster injections should be administered at intervals of 6, or even 4, months. Measurement of antibody concentrations by single radial hemolysis can be useful in determining the need for booster vaccination. Previously, vaccination during the racing season was disliked by trainers because of transitory swellings at injection sites and an infrequent mild systemic reaction, however administration of contemporary vaccines is rarely associated with these adverse effects. In general, vaccination appears to have no adverse effect on performance.

Schedule

Various schedules have been proposed for influenza vaccinations of horses, with different regulatory bodies having specific recommendations.[6] The FEI requires all horses competing in FEI competition to provide evidence of sufficient vaccination against equine influenza. This involves regular six monthly booster vaccinations following a primary vaccination course. All horses and ponies for which an FEI

Passport or a National Passport approved by the FEI has been issued must have the vaccination section completed and endorsed by a veterinarian, stating that it has received two injections for primary vaccination against equine influenza, given between 1 and 3 months apart. In addition, a booster vaccination must be administered within each succeeding 6 months (± 21 days) following the second vaccination of the primary course. None of these injections must have been given within the preceding 7 days including the day of the competition or of entry into the competition stables.

The UK Jockey Club has strict vaccination requirements which must be complied with to enter horses in their competitions or onto their premises. The program includes a 1st equine influenza vaccination to be followed by a 2nd vaccination 21 to 92 days later, with a 3rd vaccination 150 to 215 days from the 2nd vaccination.[6] Thereafter vaccinations should be annually, with the last permissible day being the same date as the previous year's vaccination. Horses may not race until the 8th day after the day of vaccination.

A schedule proposed for control of influenza in a large area includes the following rules:

- Mandatory vaccination for all horses entering racing premises
- Horses not to race in the 10-day period following vaccination
- Horses coming from international locations must be vaccinated before departure
- All horse events, including shows, sales and gymkhanas, should apply the same restrictions.

The recommended vaccination program using inactivated or subunit vaccine is:

- Mares should be vaccinated during the final 4–6 weeks of gestation to ensure adequate passage of passive immunity to the foal
- Vaccination of foals at 6 months of age
- Two vaccinations initially at 21 days, and not more than 92 days apart
- A booster vaccination 5–7 months later
- Annual boosters or, in the face of increased infection pressure or when the risk of infection is high, boosters should be at 6-month or even 4-month intervals
- When vaccination schedules break down and a horse goes longer than 12 months without a booster, recommence with a two-vaccination schedule
- Yearlings and 2-year-olds may require an additional vaccination between the second vaccination of the primary series and the booster at 6 months.[53]

Control measures

Hygienic precautions can be of value in limiting the spread of the disease. Vehicles used for the transport of horses are thought to play a large part in transmission and should be thoroughly disinfected between shipments.[19]

Quarantine is imperative to prevent introduction of virus by animals in the incubation period of the disease or subclinically infected horses. The most common introduction of infection, especially internationally, is through importation of subclinically infected horses.[23] Also, because vaccinated animals can be infected and be shedding virus but not have signs of infection, isolation of introduced animals is an essential precaution, especially when an outbreak is in progress. The period of isolation should be at least 21 days. The degree of isolation required cannot be specified because of lack of basic information, but it is suggested that droplet infection can occur over a distance of 32 m and that maximum security with regard to clothing, utensils and personnel must be practised. Additional measures are a requirement for recent (4–8 weeks) vaccination, measurement of antibody concentrations in imported horses to ensure that they have protective immunity, and testing of imported horses on arrival for viral shedding.[34] The later can be accomplished through use of rapid diagnostic tests (see above).

Control measures during an outbreak are intended to eliminate sources of infection, reduce transmission of virus, enhance the resistance of at-risk horses, and decrease the number of horses at risk.[23] Infected horses (identified by stallside or rapid laboratory tests) and clinically affected horses should be removed from the group and isolated for 3–4 weeks. Ventilation of shed rows and barns should be optimal to minimize aerosol spread of the virus. No horses should be introduced or allowed to leave until the outbreak is over, probably about 4 weeks after the first case is identified. Movement of horses between barns or paddocks should be avoided. Training and racing should be suspended. The opportunity for fomite transfer on clothing, tack, feed utensils or vehicles should be minimized by strict hygiene. Vaccination of clinically normal horses in the face of an outbreak can enhance the immunity of at-risk horses, and is probably safe.

EQUINE HENDRA VIRUS INFECTION (FORMERLY EQUINE MORBILLIVIRUS)

ETIOLOGY

An acute disease of horses transmissible to humans and characterized in horses by fever and respiratory distress occurs uncommonly in northeastern Australia.[1] The disease is associated with the recently recognized equine Hendra virus (Henipavirus in the family Paramyxoviridae, formerly equine morbillivirus) which is closely related to Nipah virus and more distantly related to Menangle virus, both of which cause disease in pigs and humans.[2,3]

EPIDEMIOLOGY

The disease in horses is uncommon, with four known occurrences between 1994 and 2004 affecting 23 horses with death of 17 horses and 2 humans.[4,5] Serologic evidence of infection in horses is similarly rare – no seropositive horses were detected among 2000 horses examined on 166 properties.[6] Similarly, no serologic evidence of infection was detected in samples from 500 pigs at 100 piggeries.[7]

Transmission

The source of the virus is a wildlife host, the frugiverous pteropoid bats (fruitbats and flying foxes, *Pteropus* spp.).[3,8] Bats are seropositive for antibodies to the virus, the only seropositive mammals of 34 wildlife species sampled, and the virus can be isolated from pteropoid postpartum uterine fluid and fetal tissue.[3] The mechanism of spread from bats to horses is uncertain, but it is speculated that ingestion by horses of infected bat fetal fluids and tissues might transfer infection from bats to horses. Fruit bats were consistently present in all four occurrences of the disease which occurred during the fruit bat birthing season.[4]

Dissemination of infection between horses by mechanical spread of infected nasal discharge likely occurred in the largest outbreak, and may have been the route of infection of the human fatality.[5] The virus is present in nasal discharges and urine of infected horses and spread from horse to horse might also occur through inhalation of infected urine.[9] Mosquitoes do not appear to be important in the spread of infection.[4] Human to human transmission of infection has not been reported.

Disease occurs in horses, humans, cats, and guinea pigs, though in the latter two species the disease was a result of experimental infection.[10,11] Fruit bats do not develop clinical disease when experimentally infected.[11]

Zoonotic potential

The disease has important zoonotic implications as two human deaths, one of encephalitis and the other of pneumonitis and respiratory failure, occurred in people who had close contact with clinically ill or dead horses.[12,13] However, the virus does not appear to be easily transmitted to humans as most people in contact with clinically affected horses did not develop antibodies to the virus.

CLINICAL SIGNS

The **incubation period** of the spontaneous disease is 8–11 d, but is much shorter in experimentally-induced disease[1,12] **Clinical signs** of the disease in horses include depression, loss of appetite, fever, ataxia, tachycardia, tachypnea and copious frothy nasal discharge.[12] Horses may show aimless pacing, hemorrhagic nasal discharge and swelling of the head.[14] Death in acutely affected horses is associated with severe respiratory distress. Two of the four horses that survived the initial disease displayed localized myoclonic twitches involving the upper forelimb and the lower lip, face and upper hindlimb muscles.[14] Clinically inapparent infections of horses occur.

CLINICAL PATHOLOGY

Characteristic changes in the hemogram or serum biochemical profile are not reported. If infected animals survive more than a few days after the onset of clinical signs they develop serum neutralizing antibodies. Antibodies are detectable by immunofluorescence[1,12] or a rapid immune plaque assay.[15] Viral genome can be detected by RT-PCR that is highly specific.[16] Viral isolation in Vero cells or imaging using electron microscopy demonstrate presence of the virus. Details of diagnostic tests are available from the OIE.[17]

NECROPSY

Necropsy examination reveals pulmonary edema with hemorrhage and froth in the airways.[1] Histologic examination reveals an interstitial pneumonia characterized by extensive vascular damage as well as necrosis of alveolar macrophages. Pulmonary vascular changes include edema and hemorrhage within alveoli, plus necrosis and thrombosis of alveolar capillaries and small arterioles. The distinctive histologic feature is the presence of syncytial giant cells within blood vessels of the lungs and other organs.[1] Although only a small number of cases have been examined, it appears unlike most other morbillivirus infections, intracytoplasmic or intranuclear inclusion bodies are not visible using conventional light microscopy.[18] Retrospective diagnosis of the disease can be documented using an immunohistochemical technique or demonstration of viral nucleic acid in tissue by a test based on the PCR.[19]

TREATMENT AND CONTROL

There is **no specific treatment** for this disease. The **control measures** in the described outbreaks included slaughter of all infected horses, extensive serological testing and control of movement of horses within a defined disease control zone. The disease in index cases is likely attributable to contact of susceptible horses with infected fluids of pteropoid bats and interventions that prevent or reduce the frequency of this occurrence are sensible, although the efficacy of this control technique has not been determined. A vaccine is not available.

CAPRINE HERPESVIRUS-1 INFECTION

Synopsis

Etiology Caprine herpesvirus-1
Epidemiology Most infections subclinical. High seroprevalence in Mediterranean countries. Latent infection common and outbreaks of abortion and neonatal mortality with no known precipitating cause
Clinical findings Abortion, neonatal disease, vulvovaginitis, balanoposthitis
Clinical pathology Leukopenia in systemic disease in kids
Lesions Ulceration and necrosis. Multifocal necrosis in intestine and organs. Aborted fetusus and young kids
Diagnostic confirmation Virus isolation, PCR
Treatment and control No effective treatment. Herd biosecurity. Experimental vaccine shows protection

ETIOLOGY

Caprine herpesvirus-1 (CpHV-1), an alphaherpesvirus within the family Herpesviridae. Restriction endonuclease

analysis indicates that there are different strains but these are not geographically clustered.[1]

EPIDEMIOLOGY

Occurrence

The disease is recorded in the United States, Canada, Australia, New Zealand, and some countries in Europe and probably has worldwide distribution. Within the countries where it occurs there is serological evidence that the **infection is widespread**. Seroprevalence is particularly high in Mediterranean countries with high goat populations.[1–3]

In adults, the systemic disease is clinically inapparent, but a genital form of the disease can be transmitted sexually. The virus mostly causes latent or subclinical infections, such as vulvovaginitis and balanoposthitis, which may sometimes present as very serious forms. It is also associated with occasional but severe outbreaks of **abortion** where the abortion rate may approach 50%.[4,5] CpHV-1 is also associated with severe systemic disease in 1- to 2-week-old kids.[6,7] This may occur in herds where does are also aborting or occasionally in herds without accompanying abortion.

Transmission and experimental reproduction

Transmission is thought to be by inhalation and ingestion because of the presence of the virus in nasal, pharyngeal and vaginal discharges and in the feces. The virus is excreted for 7 days after infection. The transmission rate is high, especially in the genital form. Only goats are affected, lambs and calves not succumbing after intranasal instillation although lambs may be infected by IV injection. After primary infection CpHV-1 establishes latent infection. Sites of latent infection sites have been identified as the third and fourth sacral ganglia but it is difficult to reactivate these infections either by experimental or natural means.[8,9] Reactivation has been observed at the time of estrus[10] and outbreaks of vulvovaginitis occur in the post mating period.[2]

However, the factors that precipitate the occasional outbreaks of abortion and disease in young kids are not known.

Abortion has been reproduced by experimental challenge occurring 1–7 weeks after challenge. Challenge of females in early pregnancy is followed by fetal stunting and death but with challenge in mid pregnancy the there is no fetal growth impairment and the fetus carried to term but born dead.[11]

Economic importance

Causes of loss include deaths of young goats, in which the morbidity and case fatality rates are high, and abortion and stillbirths in ewes. Although the disease is not common abortion rates are high in herds that experience disease.

PATHOGENESIS

In 1- to 2-week-old unweaned kids a septicemia occurs, with infection developing in various organs, especially the alimentary and respiratory tract. With fetal infection the virus crosses the placenta and infects it, causing placentitis and invading the fetus.

CLINICAL SIGNS

Adults

In both the experimentally produced and the natural disease there is no prodromal clinical disease preceding abortion and aborted kids appear full term. Where there are twins one may be born dead and the other alive.[5] In cases of genital disease there is vulvar erythema and edema, and shallow erosions and ulcers on the vulvar and vaginal mucosae. The vaginal discharge is clear to mucopurulent. The lesions heal in approximately a week's time. Outbreaks occur in the post-mating period and are not necessarily followed by abortion. In males, there is hyperemia and ulceration of the penis and prepuce with a purulent exudate.

Newborn kids

Consistent signs include weakness, anorexia, cyanosis and dyspnea, increases in heart and respiratory rates, abdominal pain, fluid gut contents accompanied by diarrhea and dysentery, in some cases. Vesicles and ulcers may also be present on the coronets. Some show conjunctivitis, a seropurulent nasal discharge, erosions of the oral mucosa, and petechial hemorrhages in the skin.

CLINICAL PATHOLOGY

Leukopenia is a consistent finding in sick newborn kids. The virus can be isolated from all secretions and can be identified by PCR and restriction endonuclease analysis. In serum, antibodies can be demonstrated by a serum neutralization test, ELISA tests and radioimmunoassay.

NECROPSY FINDINGS

Adults

Ulceration and necrosis of the vaginal and vulvar mucosae, and placentitis, are standard findings in ewes. Males show inflammation and **ulceration of the penis and prepuce**. A few adults develop an acute pneumonia with thick fibrinous exudate in the pleural cavity. **Miliary foci of hepatic necrosis** may or may not be grossly visible in aborted fetuses but at the microscopic level multifocal necrosis is a common change in this tissue, and in adrenal glands, lung and kidney.[4,7] Herpesviral intranuclear inclusions can be found in some of these tissues.

Newborn kids

Prominent lesions include ulceration and necrosis of the mucosae of rumen, abomasum, intestine, cecum and colon. Lesions are particularly severe in the large intestineVesication and ulcers of the skin of the feet may also be seen. Microscopically, foci of necrosis are often also seen in the adrenal glands, urinary bladder, spleen, liver, lungs, and various other tissues. Characteristic **intranuclear inclusion bodies** may be seen in mononuclear cells associated with these lesions.[6]

Samples for confirmation of diagnosis

- **Virology** – *Kids, fetuses* – liver, lung, adrenal gland. *Adults* – genital ulcers, vesicles. Chilled samples (VI, PCR) It may be difficult to isolate from aborted fetuses but can be it can be demonstrated by PCR
- **Histology** – formalin fixed samples of the above tissues.

DIFFERENTIAL DIAGNOSIS

The systemic disease needs to be differentiated from the severe mycoplasmal infections and bacterial septicemias. Ulcerative dermatosis may be a confusing diagnosis in the genital form.

Causes of abortion for differential diagnosis are in Table 18.8.

TREATMENT AND CONTROL

There is no treatment, although NSAIDs may ease the discomfort in the genitals caused by the disease. Quarantine and serological examination of all introduced goats seems the only effective control measure that can be adopted at the present time. An inactivated vaccine has been shown to engender protection,[12] but the disease is probably not common enough that this would be commercially available.

SWINE INFLUENZA

Synopsis

Etiology Influenza A virus subtypes H1N1, H1N2 and H3N2 of *Orthomyxovirus*
Epidemiology United States, England, Japan, Canada, Belgium. Young pigs. High morbidity, low mortality. During cold months. Antigenic diversity of virus. Aquatic birds natural reservoirs. Spread between pigs
Signs High incidence of anorexia, fever, thumps, muscle stiffness; recovery in several days
Clinical pathology PCR test to detect virus. Hemagglutination test and ELISA
Lesions Marked congestion of upper respiratory tract. Exudate in bronchi. Atelectasis. Suppurative bronchiolitis
Diagnostic confirmation Demonstrate virus in tissues
Differential diagnosis list
- Enzootic pneumonia
- Hog cholera
- Inclusion body rhinitis
- Atrophic rhinitis

Treatment Antimicrobials for secondary infection
Control No effective measures available. Vaccines are in use in certain parts of the world

INTRODUCTION

Swine influenza is an important cause of bronchointerstitial pneumonia throughout all pig keeping areas of the world. Real problems are associated with the changing viruses that cause disease.

ETIOLOGY

Classical swine influenza is associated with influenza A virus subtypes H1N1, H1N2 and H3N2 belonging to the *Orthomyxovirus* genus of the Orthomyxoviridae family. Other types have been isolated from pigs but as yet have not established as widespread endemic strains.

EPIDEMIOLOGY

The segmented nature of the viral genome is a critical structural feature that enables them to be reassorted. Since 1998, H, N and PB1 polymerase genes from human viruses, M, NS and NP genes from classical swine viruses and PA and PB2 polymerase genes from avian viruses have also been found.[1,2]

Occurrence

There are three groups of viruses but only influenza A viruses are important in pigs. They occur in a large number of species including humans, primates, pigs, horses, sea mammals, and birds.[3] When new variants occur in pig husbandry they are usually found in the pig population before they acquire the ability to spread rapidly and become associated with disease. They are named using the following convention: A/species/localization/isolate number/year of isolation, e.g. A/Wisconsin/125/98. If no species is indicated it is a human virus. They are described with reference to the hemagglutinin (HA or H) and the neuraminidase (NA or N) that project from the surface of the viral envelope. There are 15H and 9N forms that can be distinguished antigenically and genetically and all of these have occurred in waterfowl and shore birds. They provide a permanent source of infection as does the water on which they float.[4] The H binds to sialic acid and mediates the virus infection of the host. It also contains most of the antigenic sites. The N protein catalyses cleavage of sialic acid.

Swine influenza first appeared in the United States immediately following the 1918 pandemic of human influenza, and it was generally believed that it was caused by adaptation of the human influenza virus to swine. Nucleotide sequencing of the genes coding for the internal virus proteins indicates that the human pandemic H1N1 strain and the classic swine strain H1N1 have a common avian ancestor. It is suggested that a virulent avian strain H1N1 entered the human population in 1918 causing the pandemic. The pandemic virus was then introduced into the swine population where it has persisted unchanged. In contrast, swine influenza was seen in the UK in 1941 but then disappeared until it was seen in Czechoslovakia in 1950 and Germany in 1959. Influenza was not seen again until observed in swine in Europe in 1979 possibly following importation of pigs from North America, associated with a virus antigenically related to contemporary avian H1N1 strains found in ducks.[5] These avian like strains have been the most common since 1979.[6]

Swine influenza still occurs in the United States and viruses of the H1N1 lineage were the dominant cause of SIV from 1930 to the 1990s.[2] These were highly conserved (relatively unchanged) but new antigenic and genetic variants did occur.[2,7] Classical H1N1 viruses have also been isolated from pigs from South America, Europe, and Asia. Wild pigs also have H1N1.[8] In the 1980s there were many genetic mixings between avian-like H1N1 and human-like H3N2 viruses.[9] In 1992, many outbreaks of classical swine influenza occurred in England, associated with a group of H1N1 viruses that were distinguishable from classical swine viruses, the European swine viruses, and human H1N1 viruses, all of which are known to be circulating in pigs.[10] Influenza A virus subtypes H1N1 and H3N2 are endemic in pigs in Great Britain.[11] Two distinct antigenic variants of H1N1 viruses have been associated with outbreaks of swine influenza, one of which was probably transmitted from birds to pigs in the early 1990s.[6] The H1N2 subtypes isolated from pigs in Great Britain appear to have originated from a human H1N1 virus, which was circulating in the pig population in the 1980s, and from swine H3N2. It is suggested that the H1N1 viruses have disappeared from the human population, and the pig population provides a reservoir for the virus.[11] Serological surveys indicate that a swine H1N1 influenza virus has circulated in the swine population in North America for many years.[10] Recent isolates from Quebec posses a hemagglutinin distinguishable from subtype H1N1.[12]

Epidemics of swine influenza have also occurred in Japan, Canada, Belgium, and France. In North America, human H3N2 have been found much less often than in the rest of the world but the very recent introduction of H3N2 from humans to pigs was probably the major factor in the emergence of the recent strains.[1]

Mixtures of human and classical virus genes have been isolated from pigs in Asia and the USA.[13] H3N2 viruses with human H and N genes and avian internal protein genes have been isolated from pigs in Asia[14] and H3N2 has been found in Korea[14] and are currently the dominant H3N2 viruses in pigs in Europe.[15] Since 1998 double and triple re-assortants have been isolated from pigs in the USA. The N. Carolina virus had three human genes and five swine genes.[16] They include human H and N genes, genes from swine H1N1 viruses and two others from avians.[17–19]

Soon after the occurrence of the H3N2 viruses, new H1N2 viruses arose in the USA where the human H3 had been replaced by a porcine H1[20] and then spread.[21,22] They had been known elsewhere in the world for some time: Japan[23]; France[24]; Germany[25]; Taiwan.[26] They were described in the UK where they were found to be the most severe cause of pathology associated with the SIV viruses.[27] These were all re-assortants between human H3N2 and classical H1N1.

Human H3N2 and avian H1N1 were isolated in the UK[3,6] and were then found to have spread to Europe.[28–32] They are usually human H and N and the rest avian genes but one Italian virus has an avian H1.[28] They have shown considerable genetic drift in Europe.[33]

Subtype H3N2 has been isolated in Canada from pigs with severe proliferative and necrotizing pneumonia (PNP),[34] although this PNP is probably associated with PRRS and PCV2. Serological surveys indicate the infection is widespread in the swine populations in some countries.

The first unusual virus to be found in pigs was an H9N2 introduced to pigs in SE Asia probably from land-based poultry.[35]

Further problems occurred in the autumn of 1999 when an avian H4N6 was found in pigs with pneumonia on a commercial swine farm in Canada.[36] Since then the avian H5N1 has appeared in pigs in China and is being carried west by bird migrations into Russia. The potential of avian viruses to spread to pigs and persist in pigs is unknown. Even if the viruses do not replicate they can contribute viral genes to other pig viruses. This is the reason for continual surveillance of SIV viruses. These were wholly avian viruses that were of North American lineage. It was the first report of an interspecies transmission of an avian H4 virus to domestic pigs under natural conditions.

The disease usually affects young pigs, but all ages may be affected. Typically, sudden onset epidemics occur with a high morbidity rate but with a low case fatality rate of less than 5%. Loss of body condition is marked, which is usually the important cause of financial loss, although occasionally death losses may be extensive if the pigs are kept under inadequate conditions or if secondary bacterial infections occur. Abortions and deaths of newborn pigs have also been reported as causes of loss in this disease.

Risk factors

Animal risk factors

Young, growing pigs are most susceptible. The viral infection is commonly complicated by bacterial infection due to *Haemophilus parasuis, A. pleuropneumoniae,* and possibly other opportunists of the upper respiratory tract of the pig. When an epidemic occurs, most of the pigs in the herd are affected within a few days, which suggests that all animals are previously infected and that some risk factor, such as inclement weather, precipitates the epidemic.

The agent also contributes to the Porcine Respiratory Disease Complex. In a recent study in Korea 14 of 105 cases had SIV,[37] whereas in Iowa it has been reported in 19% of the case of PRDC.[38]

Environmental risk factors

Epidemics occur mainly during the cold months of the year, commencing in the late autumn or early winter and terminating with a few outbreaks in early spring. Several days of inclement weather often precede an outbreak. Three risk factors for SIV were identified on a survey of Belgian finishing farms[39] were H1N1 were found in 71% and H3N2 were found in 22%. There was a close association between H1N1 and H3N2. H1N1 appeared to be associated with fully slatted floors, increasing numbers of pigs in the locality and dry feeding. H3N2 was associated with the purchase of pigs from more than two herds, increasing numbers of pigs locally, and natural ventilation.

Pathogen factors

Molecular microbiology has now revealed the antigenic diversity of the virus. Several different H and N antigens have been identified and grouped on the basis of serological tests, which refine the diagnosis and reveal more about the epidemiological relationships. The H3N2 strain similar to H3N2 strains found in the human population has been isolated from an outbreak in England.[2,3]

Two antigenically distinct H1N1 influenza A viruses were isolated during an outbreak of respiratory disease in swine in Canada in 1990/91.[40,41] One is a variant of the swine H1N1 influenza virus that is widespread in the American Midwest, whereas the other is similar to the virus isolated from swine in 1930. This suggests that influenza viruses can be maintained for long periods in swine herds, especially in certain geographical areas. It is proposed that the antigenic diversity of these viruses may be due to the result of drifts in the population of circulating swine influenza viruses in an area.[7] The antigenic diversity oligonucleotide analysis of strains isolated from outbreaks in Sweden indicated a similarity with the Danish strain. One of the Swedish strains was closely related to the US strain.

The H1N1 strain of the virus can be found in pig tissues at slaughter but it does not persist for more than 2–3 weeks in deep frozen or refrigerated storage.

Methods of transmission

The natural reservoir of influenza A virus is aquatic birds. Various subtypes have been established in other species, such as influenza A H1N1 viruses, which infect human and different animal species. The influenza viruses may be transmissible between humans and pigs. Swine are the sole animals known to be susceptible to influenza A viruses of human, swine, and avian origin. Swine may become infected with related type A human influenza strains during epidemics of human influenza, but show no clinical signs of infection. The human strains have been isolated from pigs in Hong Kong, and pigs may serve as a reservoir for pandemics in humans as well as a source of genetic information for recombination between human and porcine strains. In Japan, pigs may be seropositive to the H1N1 human viruses relative to human H1N1 influenza epidemics, and seropositive to human H3N2 viruses unassociated with human epidemics of disease.[42] In Czechoslovakia, influenza A viruses are brought into pig herds by carrier people.

Pigs can be naturally infected with a range of avian influenza viruses. There have been at least three independent introductions of distinct wholly avian viruses into pigs.[43,44] The virus in the late 1970s spread throughout Europe and the UK and became a major cause of SI.[45] These viruses also undergo drift.[45,46]

Elsewhere in the world antibodies against H4, H5, and H9 viruses have been isolated from Asian pigs[47] and avian H4N6, H3N3 and H1N1 viruses have been recovered from pigs in Canada.

Swine are susceptible to both human and avian viruses because they have receptors on their respiratory epithelial cells for both avian (receptor SA α 2, 3 Gal) and human (receptor SA α 2, 6 Gal).[48] Several re-assortants have been isolated from pigs in the USA and other parts of the world.[49,50]

Thus, swine have an important role in the ecology of influenza A viruses and are regarded as a 'mixing vessel' for the introduction of reassorted viruses into the human population.[40,43,51]

There is a report claiming that outbreaks of influenza in turkeys followed outbreaks of swine influenza in pigs from nearby swine herds.[52] Swine and other influenza viruses have also been isolated from cattle, and experimental inoculation of calves has been successful. The swine influenza virus may cause natural infection in cattle and the virus can be transferred to uninoculated calves.

The primary route of infection is through pig to pig contact via the nasopharyngeal route. Peak shedding occurs 2–5 days post-infection (>10^7 infectious particles/mL at a peak).[53,54]

The rapid spread of infection from pig to pig occurs by inhalation of infective droplets. The disease may appear almost simultaneously in several herds within an area following the first cold period in late autumn. The virus can persist in infected swine, which can act as convalescent carriers and be the reservoir of the virus between epidemics. However, the experimental inoculation of a swine influenza virus into specific pathogen-free (SPF) pigs resulted in a mild disease and the period of viral shedding was shorter than 4 weeks.

Immunity

Both cell-mediated immunity and humoral responses are important. They do not prevent infection but they can mediate the killing of infected cells. The immune response is rapid and completes elimination

of the virus within 1 week. Antibodies decline by 8–10 weeks.[55] The IgA levels in nasal washes are the most important defence.[56] There is limited cross-protection between different viruses[31] and protection after vaccination is more virus specific.[54]

Maternal protection will last from 4–14 weeks with no pigs being completely protected from nasal virus shedding upon challenge but at least the lung is protected.[57,58] Pigs with a high maternal antibody level did not develop an immune response.[58] Maternal antibody does not cross protect between subtypes.[57,59]

ZOONOTIC IMPLICATIONS

Swine influenzas pose a significant health risk to humans ever since the first human and porcine outbreaks in the USA in 1918.[60] By 1970 there was evidence that people who came into contact with pigs through their jobs became infected with the viruses and a virus was isolated from pigs and stockman.[61,62] There is very little evidence of maintenance of human H1N1 in the pig populations[44] but human H3N2 have been recovered regularly from pigs in Asia and Europe.[44,63] The drift that has taken place in pigs of former human H3N2 has also been minimal compared to the rate of drift in the human population. The viruses from pigs found in humans have been reviewed.[3,49,62]

PATHOGENESIS

Classical swine influenza was originally described as a disease of the upper respiratory tract, the trachea and bronchi being particularly affected, with secondary bacterial pneumonia due to *Pasteurella multocida*. However, recent descriptions of the lesions in naturally occurring cases and in the experimental disease indicate that the primary lesion is a viral interstitial pneumonia.[64] Viral replication takes place in the epithelial cells of the nasal mucosa, tonsils, trachea, lungs and tracheobronchial lymph nodes.[65] No other sites have been detected[66] and viremia is of low titer. Inoculation of the H1N1 strain of influenza virus isolated in England from pigs with clinical disease into 6-week-old pigs caused fever, coughing, sneezing, and anorexia.[64] A widespread interstitial pneumonia, with lesions in the bronchi and bronchioles, and hemorrhagic lymph nodes was characteristic. The H3N2 swine influenza virus isolated in Canada is associated with a proliferative and necrotizing pneumonia (PNP) of pigs, and there is evidence the strain may be related to A/Sw/Hong Kong/76H3N2 swine influenza virus.[34] There is recent evidence that this PNP is more a feature of PRRS and PCV2 than SIV. A new antigenic variant of H1N1 swine influenza A virus isolated in Quebec has been associated with proliferative and necrotizing pneumonia of pigs.[7,12]

In the United Kingdom there has also been recorded an H1N7 which included both equine and human influenza genes. It was of low pathogenicity for pigs, found on only one farm, and did not establish in the pig world.[67] Re-assortant H3N1 viruses from human and classical swine H1N1 have also been seen in the UK and also in Taiwan.[26]

The virus causes an acute infection with shedding beginning on day 1 and finishing by day 7.[66] Infected cells in the respiratory tract are reduced by 2–3 days post-inoculation. Most of the effects of the infection are caused by the production of proinflammatory cytokines (IFN-α, TNF-α IL-1, and IL-6.) These produce inflammation, fever, malaise, loss of appetite. The depth of infection in the lung probably determines how much of these cytokines are produced.[68,69]

Contrary to widespread belief there is no evidence that the virus causes reproductive failure in swine. The experimental inoculation of seronegative pregnant gilts did not reveal any evidence of transplacental transmission of the virus to the fetus.

CLINICAL FINDINGS

It is essentially a herd disease.[1,13,17,44] The signs have not changed over the 80 years. After an incubation period of 1–7 days, (usually 1–3), the disease appears suddenly, with a high proportion of the herd showing fever (up to 41.5°C, 107°F), anorexia and severe prostration. The animal is disinclined to move or rise because of muscle stiffness and pain. Labored, jerky breathing ('thumps') is accompanied by sneezing and a deep, painful cough which often occurs in paroxysms. There is congestion of the conjunctivae with a watery ocular and nasal discharge. Sometimes there is open mouthed breathing and dyspnea especially if the pigs are forced to move. Morbidity is usually 100% but mortality is rarely above 1%. In general, the severity of the illness appears greater than, in fact, it is and after a course of 4–6 days signs disappear rapidly depending, in part, on the level of colostral antibody. However, there is much loss of weight, which is slowly regained. Clonic convulsions are common in the terminal stages in fatal cases. The condition may continue to affect the herd for several weeks as the disease spreads, especially so if the herd is outdoors and the population dispersed. The new H3N2 re-assortants in the USA have been associated with respiratory disease but also spontaneous abortion in sows and death of adult pigs.[13,17] The clinical signs are dependent on immune status, but are also influenced by age, infection pressure, concurrent infections, climatic conditions, housing and most of all on the secondary infections particularly bacteria. There is some question as to whether other viruses can predispose to SIV but experimentally infection with PRCV and H1N1 or H3N2 SIV has not shown this.[70] Pigs with both *M. hyopneumoniae* and SIV coughed more and had more pneumonia than either of the two agents on their own.[71]

CLINICAL PATHOLOGY

Within 24 hours of the onset of clinical signs there is a switch of cells in the bronchial lavage from macrophages to over 50% neutrophils.[68]

Serological tests

After infection has ceased to circulate in the herd SIV AB could still be demonstrated after 28 months post-infection.[72]

It is extremely important to make sure that the antigens that are used in the serological tests are contemporary to the viral strains that may be found in the country.[22,33,67,73,74]

Diagnosis of acute SIV infections requires the use of paired serum samples. The **hemagglutination inhibition test** has been the recommended test for many years and still remains so. However, it is tedious and has only moderate sensitivity but high specificity. It has been adapted and modified.[75] One HI test for H1N1 will detect other H1N1 strains,[76] but this is not true for H3N2 when the Midwest strains are compared with the N. Carolina strains as they differ considerably.[77] Above 1:80 is usually considered positive and within 5–7 days the titers may reach 1:320-I:640 by 2–3 weeks post-infection. An **ELISA**-based test is now available to estimate the hemagglutination titer[5] and can be used at the herd screening level.[78]

Detection of virus

Virus is likely to be found in the nasopharyngeal area during the acute phase of the disease. Swabs should be taken on Dacron, placed in transport medium stored at 4°C for no more than 48 hours but if for longer freeze at –70°C. Viruses can also be isolated from trachea or lung tissues of pigs. They can be grown in hens' eggs or increasingly in tissue culture. Samples need to be cool and moist. The virus is then detected by hemagglutinating activity in egg fluids about 5 days after inoculation. There are some strains that may not grow in hens' eggs or require more than one cell line to isolate and identify the virus which may require 1–2 weeks.[79]

Antigen detection

A **PCR** test can be used to detect virus in nasal swab specimens[80] and give results similar to virus isolation.[53,66,81,82] Recently, a gel based multiplex RT-PCR assay was

developed to detect H1 and H3 subtypes of SIV.[83]

The virus can be detected by direct immunofluorescence of lung tissue or lavage fluids.

Immunohistochemistry on fixed tissue is also useful. The positivity is mainly in the bronchial and bronchiolar epithelial cells and less intense in the interstitial cells and alveolar macrophages.[84]

NECROPSY FINDINGS

Swelling and marked edema of cervical and mediastinal lymph nodes are evident. There is congestion of the mucosae of the pharynx, larynx, trachea, and bronchi. A tenacious, colorless, frothy exudate is present in the air passages. Copious exudate in the bronchi is accompanied by collapse of the ventral parts of the lungs. This atelectasis is extensive and often irregularly distributed, although the apical and cardiac lobes are most affected, and the right lung more so than the left. It may reach 50% by 4–5 days post-infection.[85,86] The affected tissue is clearly demarcated, dark red to purple and often reminiscent of enzootic pneumonia. Surrounding the atelectatic areas the lung is often emphysematous and may show many petechial hemorrhages.

Histologically, in acute swine influenza the major feature is necrotizing bronchiolitis.[87] There is a suppurative bronchiolitis and widespread interstitial pneumonia characterized by the early appearance of neutrophils followed by the accumulation of macrophages and mononuclear cells in the alveolar walls.[64] After a few days there is a peribronchial and peribronchiolar infiltration of lymphocytes.[87] In the variant of H1N1 swine influenza in Canada, there is more diffuse damage to the respiratory epithelium, resulting in firm to meaty lungs that appear thymus-like on cut surface.[12]

Microscopically, there is marked proliferation of type II pneumocytes, in addition to the presence of macrophages and necrotic inflammatory cells in the alveoli. The influenza type A virus can be demonstrated by indirect immunofluorescence staining using monoclonal antibody directed to certain protein parts of the human type A influenza virus.[12] The influenza type A virus can be detected and differentiated from the virus of porcine reproductive and respiratory syndrome in formalin-fixed, paraffin-embedded lung tissue using immunogold staining.[88]

Samples for confirmation of diagnosis

- **These are best collected** from animals with high fevers and clear nasal discharge. Most pigs may excrete virus for 5–7 days post-infection but the peak load may be around 24 hours post-infection
- **Histology** – formalin-fixed lung, trachea, turbinate (LM, IHC). After 72 hours there is little IFA or IHC positivity. Histopathology may help in the diagnosis for 2 weeks post-infection
- **Virology** – nasopharyngeal swab in viral transport media; lung and trachea (ISO, FAT, PCR) fresh chilled but not frozen. Keep cool. Do not use cotton.

DIFFERENTIAL DIAGNOSIS

The explosive appearance of an upper respiratory syndrome, including conjunctivitis, sneezing, and coughing, with a low mortality rate, serves to differentiate swine influenza from the other common respiratory diseases of swine.

Enzootic pneumonia of pigs is most commonly confused with swine influenza, but it is more insidious in its onset and chronic in its course.

Hog cholera is manifested by less respiratory involvement and a high mortality rate.

Inclusion body rhinitis in piglets may resemble swine influenza quite closely.

Atrophic rhinitis has a much longer course and is accompanied by characteristic distortion of the facial bones.

TREATMENT

No specific treatment is available. Treatment with penicillin, sulfadimidine, or preferably a broad-spectrum antibiotic, may be of value in controlling possible secondary invaders. The provision of comfortable, well-bedded quarters, free from dust, is of major importance. Clean drinking water should be available, but feed should be limited during the first few days of convalescence. Medication of the feed or water supplies with a broad-spectrum antibiotic for several days is a rational approach to minimizing secondary bacterial pneumonia.

CONTROL

There are only two options vaccination and biosecurity. Biosecurity is difficult as there is always the possibility of aerosol infections and wild fowl/poultry infections.

All in/all out systems may remove infection with each group of pigs and the subsequent disinfection may kill out the virus. Good housing and protection from inclement weather help to prevent the occurrence of severe outbreaks. Once the disease has appeared little can be done to prevent spread to other pigs. Recovered animals are immune to subsequent infection for up to 3 months.

Vaccines, both commercial inactivated and adjuvanted SIV for IM use are available in the USA and Europe. Active immunization occurs in the face of maternal derived antibody when titers are <10 for H1N1 and <40 for H3N2.[63] Some of the vaccines contain the original H1N1 viruses but others such as in the USA contain a monovalent H1N1 virus. Following the outbreaks of H3N2 in the USA in 1998 both monovalent and bivalent H1N1/H3N2 SIV vaccines became available. Autogenous vaccines are used in the USA.

In Europe although the viruses have changed the old vaccines are still used as they produce high antibody titers.[89,90] There is a need to add H1N2 to the vaccines however as there is no cross protection between the European H1N2 and H1N1 and H3N2 viruses and because it was shown[33] that there is no current vaccine protection against H1N2. Evidence from the USA shows that there is cross protection with their strain of H3N2.[91] Most animals with titers >160 are probably protected against viral replication in the lungs and disease.[70,90] Sow vaccination is important in controlling infection in suckling pigs and often controls the infection in nursery pigs. Intranasal or IN/IM vaccination of pigs with formalin inactivated SIV induces very specific IgM, IgG and IgA antibodies in their nasal secretions and sera resulting in complete protection.[92]

A recent trial of a new H1N1/H3N2 vaccine was successful,[93] with reduced viral shedding, and reduced clinical signs and pneumonia.

Experimental vaccines continue to be produced including a human adenovirus 5 recombinant expressing the hemagglutinin and nucleoprotein of H3N2 SIV has been used experimentally to provide protection against challenge with H3N2.[94] Complete protection was shown by lack of nasal shedding and by lack of lung lesions following subsequent challenge.

PORCINE CYTOMEGALIC VIRUS (INCLUSION BODY RHINITIS, GENERALIZED CYTOMEGALIC INCLUSION BODY DISEASE OF SWINE)

Inclusion body rhinitis, associated with a beta herpesvirus (family Herpesviridae), is an extremely common, but generally minor, disease in young pigs. It was first recognized in 1955. The virus is now called porcine herpesvirus 2. The disease has probable worldwide occurrence[1–5] and has also been described in Canada[6] and Japan[7] and clinical and serological[8,9] observations suggest that it is present in most pig herds. SPF herds established by hysterectomy techniques are not necessarily exempt and congenital transmission of the virus has been demonstrated.[10] When the virus first enters a susceptible herd then both trans-placental and horizontal virus transmission takes place. Antibody responses start quickly so there are often no clinical signs but widespread infection.

The virus is present in the upper respiratory tract of pigs and the major infection site is the conchal (turbinate) epithelium. High excretion occurs predominantly in the 2–4-week period after infection.[10] Transmission is via the respiratory route through direct contact and aerosol infection, and possibly also via urine. The virus invades epithelial cells, especially those of the nasal mucous glands, to produce destruction of acinar cells and metaplasia of the overlying epithelium and the major clinical manifestation is that of upper respiratory disease. Following infection, the virus may become generalized. In older pigs, generalization is restricted to epithelial cells of other organ systems, especially those of the renal tubules, and is clinically inapparent. However, in very young pigs the virus also shows a predilection for reticuloendothelial cells, and generalization may result in further clinical abnormality.[11]

Clinically, the disease affects piglets up to approximately 10 weeks of age but the age at manifestation in any herd can depend upon the method of husbandry. In the UK, it is assumed that approximately 50% of the herds are infected. Within the individual herd there may be up to 98% affected. The disease usually occurs when the virus is introduced into the susceptible herd or if for some reason there is a huge increase in the number of susceptible pigs. A wide age-spectrum of involvement may be seen initially when the disease is introduced into the herd for the first time. In most herds the disease affects pigs in the late suckler and early weaner stage. It is at its most severe in pigs under two weeks of age. Sneezing is the most prominent sign and frequently occurs in paroxysms and following play fighting. There is a minor serous nasal discharge which rarely may be blood-stained, and also sometimes muco-purulent with a brown or black exudation around the eyes. There may be coughing. The clinical course varies approximately from 2–4 weeks. All pigs within the group are affected but there is usually no mortality.

The virus also crosses the placenta so it is possible for intra-uterine infection to produce fetal death, and runting after birth as well as very early pneumonia, rhinitis and poor piglet weights at weaning.

Generalized cytomegalic inclusion body disease may occur in pigs exposed to intra-uterine infection and usually occurs as an outbreak involving several litters. The syndrome is characterized by sudden death and anemia. There is often a history of scouring within the group within the first week of life, and affected pigs show skin pallor and often superficially appear plump and well-developed due to edema, especially in the neck and forequarter regions. Death, resulting primarily from anemia, occurs during the 2nd–3rd week of life, and mortality within the group may approach 50%. Petechial hemorrhages have been a feature of the experimentally produced disease in gnotobiotic pigs[11] but do not necessarily occur in field outbreaks. A moderate anemia producing a check to growth, but without significant mortality, may also be seen in recently weaned pigs experiencing the disease. Many survivors may be stunted.

More serious effects from generalized infection are seen when piglets are exposed to heavy infection at a very young age. It also occurs when there are new imports and when intercurrent disease and poor nutrition reduce resistance. This commonly occurs in large herds with high

density continual throughput farrowing and weaning houses. In addition to upper respiratory disease, infection at this age may result in enteric disease, sudden death, anemia and wasting, with a marked unevenness of growth within the litters.

There may be complete blockage of the nasal passages. It is believed that the olfactory epithelium may be damaged so that there is no sense of smell and that piglets may not then eat and that is the reason so that so many die.

Inclusion body rhinitis is not a primary cause of atrophic rhinitis. However, it is probably contributory in lowering local resistance to infection and in predisposing to more severe infection with *Bordetella bronchiseptica* and other respiratory pathogens.

The diagnosis of inclusion body rhinitis is commonly made following the demonstration of typical intranuclear inclusion bodies in histological sections from electively slaughtered piglets.[12] Large basophilic inclusion bodies are found in the mucous gland cells of the turbinate mucosa and may also be demonstrated in exfoliated cells obtained via nasal swabs from live pigs. Small intra-nuclear inclusion bodies are found in the reticulo-endothelial cells. These are best taken from several pigs at the height of clinical infection. Diagnosis by virus isolation is uncommon, as the virus has proved difficult to grow, but it will establish in porcine lung macrophage cultures.[13] Antibody to infection may be detected by indirect immunofluorescent techniques.[8,9] An ELISA is also a sensitive reproducible and practical test.[6] Recently, a PCR has been developed[14] and this showed that 59% of pigs tested positive. However only 59% of PCR positive pigs had clinical signs and lesions consistent with inclusion body rhinitis.

There is no effective treatment and in most herds none is warranted. With severe rhinitis, antibiotics may temporarily reduce the severity of secondary bacterial infection. Control of severe disease rests with managemental procedures that avoid severe challenge to very young piglets. It is also possible to produce virus-free pigs from hysterotomy-derived pigs but it is necessary to monitor.

ENZOOTIC PNEUMONIA OF CALVES

Synopsis

Etiology *Mycoplasma* spp., parainfluenza-3 virus, bovine respiratory syncytial virus, and other viruses; secondary bacterial infection
Epidemiology Housed dairy calves under 3–5 months; high morbidity low mortality; veal calves; beef calves crowded in calving grounds; poor colostral immunoglobulin status; inadequately ventilated calf barns; excessive infection pressure on newborn calf because of close proximity to adult cattle in barns; economically important
Signs Mild to severe dyspnea, fever, loud breath sounds over cranioventral lungs (consolidation), coughing, high morbidity; low case fatality rate, secondary bacterial pneumonia with toxemia
Clinical pathology Isolate pathogens from nasal swabs, transtracheal aspirates. Serology for seroconversion to viruses
Differential diagnosis:
- Pneumonic pasteurellosis due to *Pasteurella haemolytica*
- *Haemophilus somni* pleuropneumonia
- Aspiration pneumonia
- Dyspnea of enzootic muscular dystrophy
- Chronic cases may resemble congenital cardiac defects

Treatment Antimicrobials to prevent and treat secondary bacterial pneumonia
Control Insure adequate colostral intake. Good housing and ventilation. Prevent crowding in calf barns. Raise dairy calves separate from adult cattle or in calf hutches

ETIOLOGY

The cause is multifactorial, associated with various species of viruses, bacteria, mycoplasma, and environmental and host risk factors contributing to the pathogenesis, severity and nature of the pneumonia. Pathogens like mycoplasma and viruses may act as primary pathogens, and certain bacterial species may cause secondary complications.

Mycoplasma spp.

The mycoplasma are considered as primary pathogens and probably the most important and most common etiological agents of calf pneumonia. *Mycoplasma bovis* is a major cause of calf pneumonia.[1] In addition, *Ureaplasma diversum*, *Mycoplasma dispar*,[2] and *M. bovirhinis* are isolated with a high frequency from the lungs of pneumonic calves.[3] *M. canis* is being isolated with increased frequency. *Acholeplasma laidlawii* and *M. arginini* are also found but of dubious significance.[1] *M. bovis* produces clinical pneumonia experimentally in calves and has been isolated from severe epidemics of pneumonia in calves imported into one country from others.[1] The prevalence of nasal mycoplasmal flora in healthy cows and calves in the same herds is much lower.[4]

Parainfluenza-3 paramyxovirus

The evidence for viruses as primary etiological agents is based on virus isolation, serological evidence of active infection, lesions of viral pneumonia, and experimental infection. The parainfluenza-3 (PI-3) virus has been isolated most commonly from affected calves and inoculation of the virus into colostrum-deprived calves results in a pneumonia that resembles the naturally occurring disease.

Bovine respiratory syncytial virus

Bovine respiratory syncytial virus (BRSV) causes pneumonia in both dairy and beef cattle of all ages, but primarily in dairy calves under 6 months of age.[5,6] BRSV isolates belong to an antigenic grouping different from that of human respiratory syncytial virus (HRSV), and two distinct antigenic subgroups of BRSV exist.[5,6]

Mixed viral and other pathogen infections

A survey of viral infections of the respiratory tract of calves over a 3-year period revealed that only BRSV, the PI-3 virus and bovine virus diarrhea virus (BVDV) were significantly associated with disease. Seroepidemiological and clinical surveys of calves raised as herd replacements in dairy herds commonly reveals evidence of PI-3 virus and BRSV infections associated with respiratory disease. The rhinoviruses, adenoviruses, reoviruses, and enteroviruses were also isolated but in much lower frequency, and were considered not to be important. *Chlamydia* spp. have been associated with respiratory disease in calves and usually as part of a mixed infection with viruses and bacteria. Bovine coronaviruses have been isolated from calves with respiratory disease but their significance is uncertain.[7]

Bacteria

Mannheimia haemolytica and *Past. multocida* may also be recovered from the lungs of calves with pneumonia and may act synergistically with the *Mycoplasma* spp. to cause a more severe and fatal pneumonia. Several different bacterial species including *Streptococcus* spp., *Staphylococci* spp., *Arcanobacterium pyogenes*, *Histophilus somni* and *Fusobacterium* spp. may also be recovered from pneumonic lungs.[5]

EPIDEMIOLOGY

Occurrence

Dairy calves

Enzootic pneumonia occurs most commonly in housed dairy calves from 2 weeks to 5 months of age being raised as herd replacements. Pneumonia can be responsible for up to 30% of all deaths of calves in dairy herds from birth to 16 weeks of age,[8] second to enteritis which can account for 44% of all deaths. Some farms report cases of pneumonia, while others have none.

Pneumonia can be the single largest cause of death in veal calf farms.[9] The calves are purchased at about 10 days of age, assembled into large groups of 25–50 per group and fed a milk substitute diet for about 16 weeks and then sent to slaughter. The peak incidence of disease occurs about 5 weeks after arrival in the calf house during which time PI-3 and BRSV are recovered most often.

BRSV appears to have assumed major importance as a causative agent of herd epidemics of pneumonia in housed dairy calves[5,6] weaned beef calves, and even adult cows. Serological surveys indicate that the prevalence of infection is high and varies from 60 to 80% of the cattle populations examined . Most mature cattle in some populations have seroconverted to the virus. However, the incidence of clinical respiratory disease associated with BRSV is much lower. Respiratory disease in weaned beef calves 6–8 months of age in North America has also been attributed to BRSV and is characterized by a sudden onset, commonly after the cold weather begins in the fall of the year.[5,6] Affected animals are commonly in good bodily condition and well-nourished. BRSV was the most commonly isolated viral agent in a series of 14 epidemics of pneumonia in housed dairy calves. The disease may be mild, moderate, or severe.

In dairy herds, clinical disease attributed to BRSV may appear initially in the youngest calves from 2 to 8 weeks of age in which the mortality will be highest, followed by disease in the mature lactating cows in which milk production will drop.

Beef calves

Enzootic pneumonia occurs in nursing beef calves and can account for significant reductions in weaning weight and a significant cause of economic loss due to disease in the neonatal period.[10] In cow–calf herds in northwestern Quebec, one of the major causes of a low percentage of weaned calf crop was the occurrence of diarrhea and pneumonia in calves under 2 weeks of age.[11] Pneumonia can also occur after beef calves have been housed.[12]

Morbidity and case fatality

Morbidity rate and case fatality rates vary depending on the quality of housing and management provided, and the kind and concentration of viruses and bacteria that predominate in the environment at any one time. The morbidity rate may reach 100%, and the case fatality rate is usually less than 5%. In dairy calves under 3 months of age, the morbidity rate and case fatality risk for pneumonia were 25.6% and 2.25, respectively.[13] The cumulative risk incidence of respiratory disease in dairy heifers from birth to 8 weeks of age was 8.4%.[14] In acute respiratory syncytial viral pneumonia of calves there may be an unexpected acute onset of respiratory disease in which 80–90% of calves are affected, with a case fatality rate that may reach 30% or higher.

On veal calf farms, pneumonia can be the largest single cause of death, with mortality rates up to 3.7% and culling rates at 5.1%. Peak death and cull losses occur during the 7th and 8th week of production.[9]

In Ontario Holstein dairy herds, 15% of calves were treated for pneumonia before the age of weaning.[15] Treatment rates for pneumonia increased slightly until about the 6th week of life and then declined until weaning. Calves that had pneumonia during the first 3 months of life had an increased risk of mortality before they reached calving age.[16] In Holstein herds in New York, the crude incidence rate for respiratory disease within 90 days of birth was 7.4%.[17] In those same herds, dullness of calves and unspecified diagnosis within 90 days of birth increased the hazard rate of death after 90 days of age 4.3-fold above that for heifers without dullness within 90 days of birth.[18] These data indicate pneumonia in dairy calves in the first 3 months of age can have an adverse effect on long-term survival and subsequent growth rate.[19,20]

Methods of transmission

Aerosol infection and **direct contact** are the methods of transmission and both are accentuated in crowded, inadequately ventilated conditions. The principal mode of transmission of *M. dispar* among calves reared in dairy farms is the airborne route up to several meters in distance.[21] Newborn calves raised in individual pens may become infected within 5–15 days after an experimentally infected calf is placed in the calf house.[21]

M. bovis has been isolated from calves exhibiting severe fibrinonecrotic bronchopneumonia that were imported directly from continental Europe into Northern Ireland.[2]

Risk factors

Because most of the pathogens described under etiology can be found in the respiratory tract of normal calves, it has been generally accepted that environmental risk factors, such as ambient temperature, relative humidity, air quality, and population density, are necessary to precipitate the disease. In addition, several animal risk factors make calves susceptible to the pathogens in their environment. There are also pathogen risk factors that determine the disease outcome.

Animal risk factors

The onset of calf pneumonia occurs between 2 and 4 weeks of age when the concentration of serum IgG_1, IgG_2 and IgA in the nasal secretions are lowest.[22] When the concentrations of serum IgG_2 begin to increase at about 2–4 months of age, the incidence rate of new cases of pneumonia begins to decline. The spectrum of colostral antibodies present in home-raised calves will depend on the spectrum of infection in the adult cows. Most calves that recover from clinical enzootic pneumonia are resistant to further attacks of the disease associated with the same infectious agents. Herd immunity to one or more viruses develops, and severe outbreaks of disease usually occur following the introduction of animals that may be carriers of infectious agents to which the resident animals are non-immune. In commercial veal calf units where market-purchased calves are being introduced on a regular basis, there is commonly a succession of minor epidemics of enzootic pneumonia. The incidence is highest in the recently introduced calves and the disease will occur in a small percentage of resident calves.

In a study of range beef calves from birth to 45 days of age, respiratory disease accounted for a total mortality of 1% and was associated with twins, which may result in a less viable calf at birth that may be neglected and abandoned.[23] The risk of respiratory disease was also higher for male calves. The recent advancement of calving dates of beef cattle herds in the cold areas of North America from April–June to January–March results in crowded conditions in calving yards, which creates the environmental conditions similar to those of housed dairy calves. This has increased the incidence risk for enzootic pneumonia in beef calves.

In herds infected with BRSV, newborn calves acquire colostral antibodies to BRSV, which declines to undetectable levels in an average of about 100 days with a range of 30–200 days.[24] It appears that colostral immunity does not protect calves from experimental or naturally occurring clinical disease, but active

immunity from natural infection with or without evidence of clinical disease will protect the animals from clinical disease but not from reinfection upon later exposures to BRSV.

Environmental and management risk factors

Environmental risk factors, such as inadequate housing and ventilation are major contributors to the disease process.[25] These include calving area, calf housing, spatial separation between calves, mixing calves of different age groups, and seasonal effects. Dairy herds that do not house calves in groups prior to weaning, or that house calves in groups of seven or fewer calves per group, are less likely to be affected with high mortality rate due to respiratory disease.[26] The calving area and environment can affect calf health through stress and the degree of exposure to infectious agents. Inadequate ventilation, improper climate control, and poorly constructed facilities can induce stress in calves. Crowding results in close contact and promotes spread of infection, and also results in excess moisture which, in the presence of inadequate ventilation (movement of air) and supplemental heat, causes a high relative humidity and chilling of calves. Many calf barns are old, adapted barns which are occupied for several months without depopulation and disinfection. Monitoring 48 dairy herds over 1 year in the National Animal Health Monitoring System, revealed that mortality was lower in herds that used calf hutches compared to those that did not.[27] In commercial veal units, the longer the disinfection and vacancy break, up to 6–7 days, the lower the incidence of disease in new calf crops entering the unit. Ventilation is commonly inadequate because of poor design of the building.

Rapid changes in weather, particularly during the winter months, are often followed by outbreaks of acute pneumonia because of inadequate ventilation. A common practice during cold weather is to close the air inlets and turn off the ventilating fans in an attempt to maintain the inside temperature at a comfortable level. This results in increased relative humidity, condensation of moisture on walls and on the calves, leading to wet conditions, and the reduced ventilation results in an increase in the concentration of droplet infection.[17] Attempts to correlate meteorological data with the daily morbidity rate have not yet provided evidence for the hypothesis that climatic factors have an influence on incidence. This may be due to the difficulties associated with accurately monitoring meteorological data, and the lack of a direct relationship between the environment outside a calf barn and the microclimate of the calf inside the barn. The disease appears to be most common during the winter months when calves are housed continuously and when ventilation is commonly inadequate.

Humid weather results in a marked increase in the percentage of bacterial colony-forming particles of less than 4–7 μm in size. This provides the beginnings of a sound physical framework for the explanation of this and other, as yet empirical, relationships between the microenvironment in calf barns and the etiology and epidemiology of calf pneumonia.

The management risk factors that can influence the incidence rate and mortality of calves with pneumonia include:

- Colostrum feeding practices
- General feeding practices
- Quality of perinatal care provided by the personnel
- Age at weaning
- Use of prophylactic antimicrobials
- Health management of the dams.[28]

The feeding of a coccidiostat to preweaned calves may be associated with an increase in the risk of pneumonia because herds with a history of disease would be more likely to feed a coccidiostat.[29]

Factors associated with mortality to 21 days of life in dairy heifers in the United States include:

- First colostrum-feeding method, timing and volume
- Time of separation from dam
- Calving ease
- Twin birth.[30]

Up to 31% of mortality is associated with ineffective colostrum feeding. The longer the calf is left with the dam after birth, the greater the mortality, presumably due to greater exposure of the calf to pathogens harbored by the dam. Difficult calving also may interfere with the optimum ingestion of colostrum and absorption of immunoglobulins.

A path model of individual-calf risk factors for calfhood morbidity and mortality in New York Holstein herds indicated that management appeared to affect, directly and indirectly, the risk of respiratory disease within 90 days of birth.[31] Being born in loose housing is strongly related to development of clinical signs of calf diarrhea within 14 days of birth, which in turn increases the risk of respiratory disease within 90 days of birth.

Calves reared as herd replacements may be born inside and raised indoors until they are about 6 months of age and then turned out to pasture for the summer. In the case of veal calf-rearing units, the calves are kept and fed indoors under intensive conditions from a few days of age until they reach 150 kg body weight (BW) at 12 weeks of age. In the barley-beef units, the calves are fed indoors on an intensive basis from weaning until they reach market weight at 10–12 months of age. In all of these situations, young, growing calves are raised together under confined conditions, which promotes the spread of bovine respiratory disease associated with several viruses, *Mycoplasma* spp., and *Pasteurella* spp. Based on serological surveys, most calves raised in close confinement will have become infected by several viruses, including the PI-3 virus, adenoviruses, bovine respiratory syncytial virus, infectious bovine rhinotracheitis, and bovine viral diarrhea. If natural exposure to these viruses, *Mycoplasma* spp., and bacteria is so widespread and inevitable, it raises serious questions about the rationale for vaccination. In most cases the effects of the viruses and *Mycoplasma* spp. are minimal. The stress factors associated with inadequate ventilation, high relative humidity and chilling, and the secondary bacterial complications are responsible for the onset of clinical disease.

Pathogen risk factors

The infectious agents are ubiquitous in the respiratory secretions of the animals and in their environment, and more numerous in crowded poorly ventilated conditions. The spectrum of infectious agents that are present and acting in a calf population and the severity of clinical disease will vary between farms, between countries, and from season to season. It has been assumed that the older calves and mature animals in a herd are the source of infection for the young calves. this assumes major importance in control measures that are commonly designed to rear calves separate from older animals.

Mycoplasma dispar colonizes the respiratory tract of experimentally infected young calves for several months and can be isolated from nasal swabs and transtracheal samples throughout the period of colonization. *M. dispar* and *Past. multocida* have been cultured from transtracheal aspirates of dairy calves with pneumonia under 3 months of age.[11] In calves aged 1–5 months in calf-rearing farms that purchase calves from dairy farms, the prevalence and level of colonization of the respiratory tracts with *Mycoplasma* spp. can be more than 90% over a 2-year period.[21] *M. dispar*, *M. bovirhinis*, and *Acholeplasma laidlawii* have all been isolated from such calves. A high degree of colonization with *M. dispar* among 1 to 2-month-old calves on these rearing farms indicates the ability of the pathogen to spread among the calves and colonize

the respiratory tract. *M. dispar* is able to spread very rapidly among groups of calves, and airborne transmission is considered to be an important mode of transmission in addition to direct contact. The infection rate in the calves at the farms of origin is small.

The number and types of *Mycoplasma* spp. that colonize the nose and trachea of calves are influenced by the age of calves and not by the environmental temperature or relative humidity. *Mycoplasma* spp. start to colonize the upper respiratory tract of calves within days after birth, and the peak isolation rate from their nasal cavities occurs at about 2–6 weeks of age, and from the trachea at 6–8 weeks of age.[32] Over 92% of calves collected from farms and reared in a controlled environment can harbor *Mycoplasma* spp. in their noses when they are 2 weeks of age. The rate of recovery falls gradually thereafter.

Parainfluenza-3 virus is commonly subclinical in a group of calves, and clinical disease may not occur until other pathogens are present or when adverse environmental conditions precipitate clinical disease. Following natural infection of young calves, the PI-3 virus may persist for several weeks. However, the presence of PI-3 infection may predispose to respiratory disease by interfering with normal pulmonary clearance mechanisms and allowing secondary invasion by bacteria or mycoplasmas.

Bovine respiratory syncytial virus. Infection with BRSV may be subclinical, mildly clinical, or highly fatal. Raising calves in close proximity to older cattle may result in constant exposure to infectious agents to which the mature animals are immune. The disease may be endemic on particular farms in which almost every calf experiences clinical disease. Herd epidemics may occur following the introduction of a different virus, such as BRSV, or following a breakdown in the ventilation system. The disease occurs specifically in nursing beef calves from 1 to 4 months of age while on pasture.

Mixed flora. While a mixed flora of viruses, mycoplasma and bacteria can be isolated from the respiratory tract of calves with pneumonia, and the unpassaged respiratory material can cause disease similar to the naturally occurring disease, the inoculation of pure cultures of *M. dispar*, *M. bovis*, and *Ureaplasma* spp., or pure cultures of BRSV or PI-3, into calves does not produce the severe clinical disease seen in the field. The failure of pure cultures of a pathogen to produce a severe pneumonia may be for one of three reasons:

- Combinations of organisms are required for disease
- Laboratory passage of the pathogens, necessary for purification causes their attenuation
- Material in the respiratory secretion other than the pathogens identified is required for disease, which may include agents that were not detected by routine culture techniques.

Economic importance

The economic losses associated with enzootic pneumonia may be considerable. One estimate reports that the disease accounts for 50% of all calf mortality and a reduction of 7.2% in liveweight gain. In commercial veal units, the presence of enzootic pneumonia may be associated with a prolonged time in the unit because of reduced daily liveweight gain.

The economic loss due to calfhood morbidity and mortality is well-recognized by the dairy industry. However, the long-term effects of morbidity from diseases such as enzootic pneumonia on health and performance may constitute an even greater economic loss to the herd. Calfhood diseases occurring in the first 3 months of life may have serious long-term consequences. Heifer calves that are treated for pneumonia during the first 3 months of life are 2.5 times more likely to die after 90 days of age than heifers that are not treated for pneumonia.[16] Heifer calves without respiratory disease are twice as likely to calve, and calved for the first time 6 months earlier, when compared to calves with respiratory illness as calves.[33] Some studies have found no significant independent association with calfhood disease status with first lactation milk production.[34] However, the population selected did not include all heifers affected as calves; a heifer could have a suboptimal rate of growth or unthrifty appearance and would be removed from the herd before milk production was measured.

PATHOGENESIS

Mycoplasma

The endobronchial or intratracheal inoculation of gnotobiotic calves with *Mycoplasma* spp. does not usually result in significant clinical disease. However, 2 or 3 weeks following inoculation, there is microscopic evidence of pneumonia. The lesions produced by experimental inoculation of calves with *M. bovis*, *M. dispar* or *Ureaplasma* spp. are characterized by **peribronchiolar and perivascular 'cuffing'**, catarrhal bronchiolitis, and atelectasis.[1] Intranasal inoculation of *Ureaplasma diversum* into SPF calves results in thick cuffs of round cells surrounding the bronchi, bronchioli and blood vessels, and a lobular catarrhal pneumonia.[35] However, clinical signs of pneumonia are not observed. Inoculation of *M. canis* results in only a slight pathological change which disappears 9 days after infection. *M. dispar* produces an alveolitis without cuffing lesions. It is thought that the *Mycoplasma* spp. are synergistic with each other, viruses, and bacteria in producing the lesions of subclinical and clinical enzootic pneumonia.

M. bovis pneumonia in calves is characterized by coagulative necrosis and accumulation of catarrhal exudate in the airways resulting in a sudden onset of marked dyspnea, fever, and poor response to therapy. The coagulative necrosis does not cross the interlobular septa, which is in contrast to *Mann. haemolytica* which crosses the septa.

Viruses

The respiratory viruses can cause a viral interstitial pneumonia affecting the cranial lobes of the lung which may be subclinical, mildly clinical or severe and highly fatal.

Parainfluenza-3

Subclinical viral pneumonia associated with the PI-3 virus uncomplicated by secondary bacterial invasion is usually of minor importance. In subclinical PI-3 infection in calves, seroconversion will occur and at necropsy there are microscopic lesions consisting of bronchiolitis, bronchial and bronchiolar epithelial hyperplasia, alveolar epithelialization, and giant cell syncytial formation. In the mild form there are slight clinical signs such as coughing and polypnea. In the severe form of viral pneumonia, such as in respiratory syncytial viral infection, there is severe dyspnea, with mouth-breathing and an expiratory grunt, but a marked absence of toxemia compared with a bacterial pneumonia. Death can occur without secondary bacterial bronchopneumonia. Atelectasis and consolidation of the anterior lobes of the lungs are characteristic and account for the loud bronchial tones audible on auscultation over the anterior ventral aspect of thorax.

The experimental intranasal inoculation of the PI-3 virus into colostrum-deprived calves results in a pneumonia that is grossly and histologically similar to the naturally occurring disease. Within 2–4 days following infection there is bronchiolitis and bronchitis and cellular exudate in the bronchiolar lumina. These lesions become more severe and are accompanied by alveolar cell thickening and hyperplasia. Beginning at about 14 days following infection, there is healing of the bronchiolar and alveolar lesions. The bronchiolar exudate becomes organized by fibroblasts, and mononuclear cells predominate in the alveolar exudate. Bronchiolitis obliterans is

widespread but re-epithelialization of damaged bronchiolar mucosa and alveoli occur.

Experimentally, the PI-3 virus can affect alveolar macrophages, which may impair the lung clearance mechanisms and allow *Mann. haemolytica* to produce a secondary bacterial bronchopneumonia. However, aerosols of PI-3 followed by *Mann. haemolytica* 7 days later do not necessarily result in significant pulmonary disease.

After the primary viral pneumonia is established, bacterial invasion may occur and the resulting pneumonia will vary with the species of bacteria which are present. Secondary bacterial pneumonias usually respond to treatment, although relapses are common if the viral pneumonia is extensive. Viruses are capable of reducing the resistance of mucous membranes, allowing bacteria such as pasteurellae to invade tissues. They are also capable of destroying the cilia on the bronchial mucosa which act as an escalator and help to keep the lower respiratory tract free of potential pathogens. In animals where there is an uncomplicated viral pneumonia with very extensive lesions there may be minimal clinical signs and almost complete resolution.

Bovine respiratory syncytial virus

Infection with BRSV in calves causes rhinitis, tracheitis, bronchitis, proliferative and exudative bronchiolitis, with accompanying alveolar collapse and multinucleated syncytial giant-cell formation in the epithelial lining and in the lumen of the bronchioles and alveoli.[36] The pulmonary function changes observed during the acute phase of the disease are consistent with a diffuse obstructive disease. This lesion could impair the lung clearance mechanism and predispose to bacterial bronchopneumonia. Experimental inoculation of gnotobiotic calves with BRSV produces macroscopic lesions of the lungs without clinical signs. The lesions consist of proliferative and exudative bronchiolitis, with accompanying alveolar collapse and mononuclear cellular infiltration of the peribronchiolar tissue and alveolar walls. Infected calves respond serologically by 11 days after inoculation. The experimentally induced lesions are commonly resolved by about 30 days after inoculation.

The effects of BRSV on bovine pulmonary alveolar microphage function have been studied and there is only limited impairment at the in vitro level.[37] In experimentally infected calves the virus can be detected in the epithelial cells of bronchioli and alveoli by immunofluorescence.[38]

BRSV can replicate and induce cytopathological changes in airway epithelial cells which include bronchial ciliated and mucous cells and bronchiolar ciliated and non-ciliated epithelial (Clara) cells.[39] Syncytial epithelial cells may be observed in bronchi, bronchioles, alveoli, and in alveolar macrophages. However, syncytial cell formation is not unique to infection with BRSV since it may also occur in other viral infections of the lung. Whether or not BRSV can predispose to bacterial pneumonia is unknown, but the changes in lung tissue associated with the virus may affect lung clearance mechanism and predispose to secondary bacterial infection and inflammation.

The pathogenesis of acute fatal pneumonia due to the BRSV is not well-understood. The characteristic lesions are exudative or necrotizing bronchiolitis, atelectasis, interstitial edema, and emphysema. field observations have recorded that the acute fatal disease is commonly preceded by a mild respiratory disease several days previously, which suggests that hypersensitivity may be an important pathogenetic mechanism causing lung injury. The second stage may follow initial improvement or recovery from the first stage, and is associated with the onset of extreme respiratory distress. However, these observations have not yet been validated. The acute fatal disease attributed to BRSV has been reproduced experimentally in colostrum-fed, conventionally reared 1-month-old calves.[40]

CLINICAL FINDINGS

Regardless of the identity of the causative pathogen, the clinical findings in almost all enzootic pneumonias of calves are similar. In the **experimental viral pneumonia**, a febrile reaction occurs on about the 5th day and is followed by the appearance of rhinitis, pneumonia, and mild diarrhea. The fever is only moderate (40–40.5°C, 104–105°F). A harsh, hacking cough, easily stimulated by pinching the trachea, is characteristic.

In **naturally occurring cases**, the clinical findings are similar, although the fever is usually higher. This may be due to bacterial invasion in the early stages. The nasal discharge is only moderate in amount and is mucopurulent. On ausculation of the thorax the major abnormalities can be detected over the ventral aspects of the apical and cardiac lobes. The breath sounds are loud and harsh and represent breath sounds transmitted through consolidated lung. The intensity of the heart sounds is increased because of shrinkage of lung tissue in the cardiac area. The usual course ranges from 4 to 7 days. Some peracute cases of uncomplicated viral pneumonia die within 1 day after the onset of signs. Infections with the PI-3 virus generally cause mild respiratory disease characterized by coughing, nasal discharge, slight fever, and recovery in a few days.

M. bovis pneumonia in young calves is characterized by the sudden onset of severe dyspnea, fever, and rapid deterioration in spite of therapy.

In **BRSV pneumonia** there may be a sudden onset of acute pneumonia in 80–90% of a group of calves. The clinical findings are characteristic of a severe viral pneumonia. Affected calves are usually mentally alert and there is only a mild fever. There is polypnea and dyspnea which in a few days become worse with mouth-breathing and an expiratory grunt. Loud breath sounds, indicating consolidation, are audible over the anterior lobes of the lung. Squeaky, wheezing sounds due to the bronchiolitis are also commonly audible over the periphery of the consolidated areas. Loud, crackling sounds due to interstitial emphysema may also be audible over the dorsal aspects of the lungs. Death may occur in 2–4 days in spite of intensive therapy.

When secondary bacterial bronchopneumonia occurs, the fever, dyspnea, and toxemia are usually more severe. When secondary infection with *Pasteurella* spp. occurs, the temperature rises to 41–41.5°C (106–107°F), the area of lung affected is much increased, and loud harsh breath sounds due to edema are followed by crackles and a pleuritic friction rub. These cases usually respond rapidly to adequate treatment. When *Arcanobacterium pyogenes* is the secondary invader, consolidation is marked, there is a profound toxemia and loud breath sounds. In cases where *Fusobacterium necrophorum* is present, the clinical findings are similar and pulmonary abscesses are likely to develop. Necrotic lesions are often present in the mouth and pharynx in these cases and the pulmonary infection probably originates from here. With both of these latter infections there may be some response to antibiotic treatment, but there is a predisposition to relapse soon after treatment is terminated. Coughing, dyspnea, anorexia and emaciation continue, and the animal eventually has to be destroyed.

CLINICAL PATHOLOGY

Isolation of pathogens

Nasopharyngeal swabs, transtracheal aspirates, and lung lavage samples[3,13] may be taken for isolation of viruses, mycoplasmas, and bacteria. Special laboratory media are required to isolate *Mycoplasma* spp.[35] Determination of drug sensitivity to the bacteria may be valuable, particularly

when a number of calves are involved in an outbreak. The isolation of BRSV from natural infections is difficult due to the labile nature of the virus. The immunofluorescent antibody test for antigen detection is one of the most rapid, reliable, and sensitive tests for BRSV from tracheal aspirates, nasal swabs, and lung samples.

Serology

Serological tests have been more extensively used for confirmation of suspected BRSV infections. The standard serological test is a virus-neutralization test using microtiter plates.[41] Others include a modified indirect fluorescent antibody test,[6] indirect hemagglutination, and an ELISA test, the latter of which is considered to be sensitive and specific and has the advantage of giving test results within several hours whereas the virus-neutralization test requires 5–6 days for completion. The complement fixation test is less specific and less sensitive than the ELISA test.

NECROPSY FINDINGS

In uncomplicated viral pneumonia, irrespective of the specific cause, there are areas of atelectasis and emphysema in the apical and cardiac lobes, with little macroscopic involvement of the diaphragmatic lobes. In the later stages, a dark red consolidation featuring a hobnail appearance of the pleural surface affects most of the ventral portions of the apical and cardiac lobes. The lesions are always bilateral. Histologically, there is a bronchointerstitial pneumonia. Acute inflammation of the nasal mucosa, particularly on the turbinate and ethmoid bones, is usually accompanied by a marked, mucopurulent exudation. In PI-3 infection, intracytoplasmic inclusion bodies are widespread in the lungs; and after experimental infection, are present on the 5th day, but have disappeared by the 7th day after infection.

In respiratory syncytial viral pneumonia there is severe interstitial pneumonia and interstitial emphysema. Histopathologically, there is severe bronchiolitis, alveolitis with multinucleated syncytia (which often contain eosinophilic intracytoplasmic inclusion bodies), and alveolar epithelial cell hyperplasia.

When bacterial or mycoplasmal invasion has occurred, the lesions vary with the agent present. Extensive hepatization with mottled red and gray lobules, and considerable interlobular aggregations of serofibrinous fluid, often accompanied by a fibrinous pleuritis, is characteristic of *Past. multocida* infection. Extensive consolidation and suppuration occur with *A. pyogenes* and *F. necrophorum* infections. In the latter case there may be necrotic lesions in the mouth and upper respiratory tract.

Confirmation of this diagnosis at necropsy is somewhat awkward, as the population of pathogens responsible may change between the time of disease onset and the death of the calf. In severe outbreaks it may be necessary to euthanize animals early in the course of the disease, or to perform serological surveys for respiratory pathogens among surviving herdmates.

Samples for confirmation of diagnosis

- **Histology** – lung (several sections), trachea, turbinate (LM, IHC)
- **Virology** – lung (several sections), trachea (FAT, ISO)
- **Mycoplasmology** – lung (MCULT, FAT)
- **Bacteriology** – lung (CULT).

DIFFERENTIAL DIAGNOSIS

Clinically, the diagnosis of pneumonia is usually readily obvious, but the causative agents are usually not determined. Young calves raised indoors and affected with a cough, nasal discharge, and pneumonia are usually affected with enzootic pneumonia associated with the agents described under etiology. The common diseases of the respiratory tract of young calves which may resemble enzootic pneumonia include the following:

- Bacterial pneumonia due to *Mann. haemolytica*, *Klebsiella pneumoniae* or *H. somni* in young calves characterized by severe toxemia, fever, dyspnea, grunting, and a poor response to therapy
- *M. bovis* pneumonia is characterized by sudden onset of dyspnea, fever, depression, and poor response to therapy in a group of calves
- Calf diphtheria usually affects a single calf and is characterized by inspiratory dyspnea, stridor, toxemia, fever, and obvious lesions of the larynx
- Lungworm pneumonia occurs in young calves at pasture, and marked dyspnea, coughing, and a few deaths are characteristic. A fever is common in lungworm pneumonia and there are loud breath sounds over the ventral aspects of the lungs, and loud and moist crackles over the dorsal aspects
- Acute myocardial dystrophy in young calves, following turn out on pasture, is characterized by sudden onset of weakness, polypnea and dyspnea due to pulmonary edema and lesions of the diaphragm, tachycardia and arrhythmia, and skeletal muscular weakness
- Aspiration pneumonia occurs occasionally in calves that have been force-fed colostrum or milk. There is a sudden onset of marked dyspnea, anxiety and distress, and death may occur within a few minutes. However, some calves survive and there is marked dyspnea with abdominal breathing, and loud breath sounds and crackles over the dorsal and ventral aspects of both lungs. Some calves will recover completely in a few days
- BRSV interstitial pneumonia in weaned beef calves must be differentiated from pneumonic pasteurellosis. In BRSV pneumonia there is a sudden onset of marked dyspnea, fever, anxiety but not toxemia, mouth-breathing in advanced cases, loud breath sounds and wheezes over both lung fields especially over the ventral aspects, and subcutaneous emphysema. Several animals are usually involved. Affected animals fail to respond to treatment with antimicrobials and the case fatality rate is usually over 75%. There may be a history of mild respiratory disease in the affected group about 10 days previously. In pasteurellosis, depression, toxemia, fever, loud breath sounds over the ventral aspects of the lungs, and a favorable response to treatment are characteristic
- Chronic enzootic pneumonia is characterized by bronchiectasis and pulmonary abscessation, causing unthriftiness and a poor response to therapy.

TREATMENT

Antimicrobial therapy

Uncomplicated enzootic pneumonia associated with mycoplasma or viruses is unlikely to respond to treatment, but antimicrobial therapy daily for 3 days is indicated because of the high probability of secondary bacterial pneumonia. Any of the antimicrobials used commonly for the treatment of acute undifferentiated bovine respiratory disease are effective. The short-acting or long-acting oxytetracyclines, the trimethoprim-potentiated sulfonamides, and florfenicol are efficacious and are recommended. Penicillin, tilmicosin, and ceftiofur are also effective for the treatment of secondary bacterial pneumonia. Danofloxacillin has excellent in vitro activity against several field isolates of *Mycoplasma* spp. from cattle,[42] and has potential for the treatment of respiratory infections associated with *Mycoplasma* spp.[42] Early treatment is necessary to avoid the development of incurable secondary complications, such as pulmonary abscesses, pleuritis, bronchiectasis, and suppurative pneumonia. In commercial veal calf units, the case fatality rate can be kept to a low level by early and adequate treatment. In some cases it may be sufficient to treat animals once only, but a proportion of cases are likely to relapse after an initial response. Such cases require repeated daily therapy for 3–5 days. If the number of relapses in an area or on a farm is excessive, all cases should receive multiple treatments.

M. bovis strains in Europe are becoming resistant to antibiotics traditionally used for mycoplasma infections in particular oxytetracyclines, florfenicol, tilmicosin, and spectinomycin[2,43]; only danafloxacin showed any antimycoplasma activity.[44] Spectinomycin had only partial therapeutic effect in calves experimentally infected with *M. bovis*.[24] The fluoroquinolones are still effective but their use in animals in controversial.[25]

Valnemulin, a pleuromutilin antibiotic with high activity against mycoplasmas had some beneficial effect when added to the milk from four days of age for 3 weeks of one-month-old calves with respiratory disease from which *M. bovis* was isolated in about 80% of cases.[45] Treated animals had less severe clinical disease but individual treatment was still necessary.

Adjunctive therapy

Bronchodilators and NSAIDs as adjunctive therapy for enzootic pneumonia in calves are used but their efficacy is questionable.

Correction of adverse environmental conditions

The clinical management of an outbreak of enzootic pneumonia in calves must include correction of adverse environmental conditions, which may have precipitated the disease.

CONTROL

Environmental and managemental

Control of the disease in housed calves is dependent on effective animal and environmental management. Overcrowding, drafty or inadequately ventilated housing, exposure to inclement weather, and sudden changes in environmental temperatures are major risk factors. Recently purchased calves should be isolated for several weeks before being introduced to the group.

Ideal environmental conditions

Control is especially difficult and expensive in countries where the calves are housed for several months during the winter months in northern climates. The most comfortable ambient temperature for young calves ranges from 13 to 21°C (55–70°F) with a relative humidity of 70%. To achieve these environmental conditions requires a suitable insulation material in the walls and ceilings, ample bedding to absorb moisture from feces and urine, and adequate movement of air to remove aerosol particles that may be infectious. This requires an adequate air inlet and outlet system, adequate capacity fans, and supplemental heat during very cold periods. The installation of recirculating air filter units can lead to a substantial reduction in the concentration of airborne bacteria to which calves are exposed. field studies in veal calf units indicate that mean aerial bacteria concentration in filtered barns can be reduced by 45%, the number of calves requiring treatment reduced by 19%, the number of repeat courses of treatment and the total antibiotic usage reduced by 29% and 35%, respectively. At slaughter, the average area of lung consolidation in calves from filtered barns can be reduced by 35%. In general, air filtration can result in a reduction in both the incidence and severity of clinical and subclinical pneumonia in calves and in improved weight gain.

In spite of ideal hygiene and management it may not be possible to prevent the development of new cases if the infection already exists in a herd, or if cattle from other herds are moved into the herd. At present, it is feasible only to be vigilant and treat new cases urgently and vigorously, because a strict hygiene program may not be feasible in the average commercial herd. If management is inadequate and the general resistance of the animals is low, losses due to calf pneumonia with significant bacterial or mycoplasmal invasion can be sufficient to make calf-rearing unprofitable.

Calf barns or hutches

Where economics permit, the ideal situation is to construct a calf barn completely removed from the main adult cow barn to minimize the spread of infection from adults that may be symptomless carriers. After the colostral feeding period, calves are removed from the calving barn and placed in individual pens in the calf barn. The raising of young calves outdoors in calf 'hutches' or 'igloos' is highly satisfactory and economical, even in countries where the outside temperatures go well below freezing. With adequate bedding, protection from the prevailing winds and adequate nutrition, calves will grow satisfactorily. Dairy herds that have had difficulty controlling enzootic pneumonia of calves have found this system to be an excellent alternative to the construction of a stand-alone, well-ventilated calf house. Nutritional deficiencies, usually of energy and protein, are common in young calves and often accentuate the severity of the pneumonia. Young calves should receive a balanced calf starter grain ration supplemented with essential vitamins and minerals, and good quality hay beginning by at least 3 weeks of age.

Vaccines and immunization

There is **insufficient information** available from field trials to make recommendations for the use of vaccines for the control of enzootic pneumonia in calves. It is difficult to evaluate the results of vaccination trials because investigators use so many combinations of vaccines, different vaccination schedules, and there are many different management variables and differences in methods of evaluation. In addition, most vaccination trials are not randomized controlled trials.

Any successful vaccine would have to be multivalent and would have to be effective when given before 2 months of age or earlier to coincide with the decline in immunity and the occurrence of enzootic pneumonia in calves. A study of vaccination of calves in a commercial calf-rearing unit that compared the use of no Vaccine intranasal infectious bovine rhinotracheitis (IBR), intranasal IBR–PI-3, and intranasal IBR–PI-3 plus BRSV on three occasions at 7, 10, and 16 weeks did not have a significant effect on growth rates during a 10-month period to slaughter.[46] There is good field evidence that the colostral immunological status of the calf has a significant effect on the susceptibility of the calf to pneumonia.[47] There is a clear association between low levels of IgG_1, IgG_2 and IgA of calves at 2–3 weeks of age, and subsequent susceptibility to pneumonia at 2–3 months of age. Calves with signs of pneumonia had low levels of IgG_1 compared with non-pneumonic calves which had relatively higher levels. In addition, calves with high levels of serum immunoglobulin do not respond normally to vaccine and any vaccine for enzootic pneumonia would have to be administered during this relatively refractory period. However, for veal calves, which are purchased at a few days of age and with low levels of immunoglobulin, this may not be a problem.

The intranasal inoculation of calves with virulent or a modified strain of PI-3 virus stimulates the development of both serum antibody and nasal secretion antibody. The nasal secretion antibody is dose-dependent. Challenge exposure of these calves provides protection against clinical disease. These factors should be considered in the development and administration of PI-3 viral vaccines if the objective is to establish an optimal concentration of antibody in the nasal secretion. The parenteral administration of two sequential doses, 2 weeks apart, of an inactivated PI-3 virus vaccine with adjuvant will induce high levels of serum antibody and prevent virus excretion in nasopharyngeal secretions after challenge. Successful immunization of calves against PI-3 infection may be useful for protection against pneumonic pasteurellosis if PI-3 precedes the bacterial infection. This is presented in greater detail in the section on pneumonic pasteurellosis.

A quadrivalent vaccine containing the inactivated antigens of BRSV, PI-3, *M. dispar*, and *M. bovis*, or a vaccine containing only BRSV, given to two vaccinated groups respectively, and compared to controls, provided protection against naturally occurring pneumonia and non-fatal respiratory disease in a large beef-rearing unit over a period of 2 years in the United Kingdom.[48] Calves were collected from farms in the first few weeks of life and reared in the unit in groups of 100 until slaughter at about 18 months. The proportion of calves receiving treatment for respiratory disease was 38% in the control group, 25% in those vaccinated with the quadrivalent vaccine and 27% in those vaccinated with the BRSV vaccine. Mortality in the control group was 9%, 2% in the quadrivalent vaccine group, and 3% in the BRSV-vaccinated group.

A single dose of an experimental vaccine for *M. bovis* pneumonia, inactivated with saponin, given subcutaneously to 3 to 4-week-old calves followed by experimental challenge 3 weeks later with a virulent strain of *M. bovis* provided protection against clinical pneumonia.[22] Unvaccinated calves developed clinical signs of disease due to lung lesions. The vaccine also reduced the spread of *M. bovis* to internal organs. Calves tested 6 months after immunization had high levels of humoral immunity. The successful use of saponin in vaccines has been demonstrated for other mycoplasma infections such as contagious caprine pleuropneumonia (CCPP) and contagious agalactia. The saponin may preserve the major antigens seen in untreated whole cells.[49]

The evaluations of BRSV vaccines are currently in progress and the preliminary results are inconclusive. A combined vaccine containing *Mann. haemolytica*, *H. somni*, and a modified live-virus for the control of enzootic pneumonia in young beef calves vaccinated at 3 and 5 weeks of age reduced the number of calves requiring treatment.[50]

VIRAL PNEUMONIA IN OLDER CALVES, YEARLINGS AND ADULT CATTLE (BOVINE RESPIRATORY SYNCYTIAL VIRAL PNEUMONIA)

Synopsis

Etiology Bovine respiratory syncytial virus (BRSV). Subtypes A, B
Epidemiology Prevalence of infection high; disease most common in cattle under 6 months of age but adult cattle also affected; recurrent infections and disease in herds common; persistent infection in few seropositive cows. Immunity following natural infection or vaccination short-lived. Antibodies following natural exposure are different than those following experimental infection or vaccination. Maternal antibody does not prevent infection but high levels decrease severity of clinical disease
Signs Mild, moderate, or severe dyspnea, fever, agalactia, coughing, wheezes of lungs, most animals recover, small percentage develop severe fatal viral interstitial or bacterial pneumonia. Outbreaks occur in cattle under 6 months of age and also in adult cattle
Clinical pathology Difficult to isolate or detect virus in tissues. Immunohistochemical tests of nasopharyngeal swabs and lung tissue. Serology
Differential diagnosis Pasteurella pneumonia. Other viral interstitial pneumonias. Infectious bovine rhinotracheitis. Lungworm pneumonia
Treatment Nothing specific
Control Minimize stressors. Control by natural exposure and treat secondary bacterial pneumonia. Modified live-virus and inactivated virus vaccines available but efficacy uncertain because lack of field trials

ETIOLOGY

The bovine respiratory syncytial virus (BRSV) is a cause of a viral pneumonia primarily in cattle under 6 months of age, and also yearlings and adult cattle. The BRSV is a pneumovirus in the family Paramyxoviridae.[1] Isolates of the virus from calves with severe respiratory disease in a region of Britain are more closely related by genetic analysis sequences to US isolates than to earlier British and mainland European isolates.[2] Importation of live cattle from North America to Britain may explain the relatedness of the isolates. The literature of the history and taxonomy of the virus has been reviewed.[1]

EPIDEMIOLOGY

Occurrence

Prevalence of infection

The virus is ubiquitous in the cattle population and new infections occur most commonly in autumn and winter annually and may result in severe respiratory disease. In longitudinal studies in dairy herds, 90% of primary infections occur in calves and heifers; very few occur in cattle over 2 years of age, and all cattle in the herds are seropositive when they are over 3 years of age.[1,3] Recurrent infections occurring annually at the same time, and in cows of all ages, without new introductions into the herd, are characteristic of BRSV infections in a herd.[3] There is evidence that the virus circulates during spring or summer at very low levels or not at all. Persistent BRSV infection in some of the cows in a herd might be a means for the virus to survive during the summer, but a steady state of reinfection of seropositive cows throughout the year at a low level might also maintain a reservoir of infection. Monthly data on the prevalence of BRSV antibodies in dairy herds suggest that persistent infection in seropositive cows is more likely than population persistence.[3]

While the prevalence of infection in the cattle population is high, the incidence rate of clinical disease is much

lower.[3] It can be assumed that most mature cattle have been exposed to the virus. Surveys in the United States, England, Denmark, Sweden, and France found seropositive rates in herds ranging from 50 to 80%. Cattle entering feedlots may seroconvert to the virus, which may be associated with an increased risk to subsequent treatment for respiratory disease.[3] A high percentage of young beef bulls aged about 6 months and entering performance test stations may seroconvert to BRSV and adenovirus, both of which may be associated with clinical respiratory disease.

Occurrence of clinical disease

In general, calves under 6 months of age are most commonly affected and some BRSV infections are undoubtedly associated with enzootic pneumonia of housed dairy calves. In **dairy herds**, recent introductions of young cattle purchased from public saleyards may introduce the infection to home-farm cattle that have had no previous exposure to the viruses, or in which their immunity to a previous infection with the virus has declined. Thus, adult dairy cows may be affected with a highly fatal pneumonia due to the virus.[4] A high prevalence of infection exists in Swedish cattle and annual outbreaks of disease have occurred in adult cattle, pregnant or recently calved cows being most severely affected.[5] Outbreaks have occurred in beef cattle on pasture.[6] The disease occurs in **nursing beef calves** 1–8 months of age on pasture with their dams without any history of previous stress. A common occurrence is in **weaned beef calves** 6–8 months of age within 2–3 weeks following weaning and commingling in confinement.[6] Yearling cattle in feedlots are also susceptible.

In North America, herd epidemics of clinical disease usually occur during the **fall** and **winter months.**[3] However, nursing beef calves may be affected with clinical disease during the summer months. Some outbreaks have occurred in nursing beef calves between 1 and 2 months of age while they are still in nursery pastures or in the calving areas.

A spontaneous outbreak of respiratory disease in goats due to the BRSV has been described,[7] and sheep can be infected with the virus.[8]

An epidemic of acute respiratory disease associated with the BRSV occurred during the winter and spring of 1995 in Norway.[9] Data from 431 cattle herds were collected. The risk of acute respiratory disease occurring in cattle was related to herd size and type of production and an expressed interaction between these two variables. The risk of a herd outbreak in a mixed herd of 20 animals was estimated to be 1.7 times greater than in a dairy herd, and 3.3 times greater than in a beef herd of comparable size. On increasing herd size to 50 animals, the risk increased 1.3 fold for a mixed herd, 3.3 fold for a dairy herd, and 2.1 fold for a beef herd, compared to a risk for a corresponding type of herd of 20 animals. The disease spread initially from one location to another during the first 6 to 9 weeks, where the rate of transmission between neighboring farms seemed to be higher than for the other districts included in the study. It was hypothesized that one common source of infection was involved in the outbreak and the case herds were clustered in time as well as spatially.[10] The average daily milk loss was estimated to be 0.70 kg per cow for 7 days after a herd outbreak compared with the period one week before.[11]

Morbidity and case fatality

The morbidity rate in herd epidemics of clinical disease can vary from 30 to 50% or higher. The case fatality rate is usually low, 3–5%, but may be higher.[3]

Methods of transmission

The mode of transmission has not been defined but aerosol infection and direct contact are probable. Infection spreads rapidly among susceptible cattle.

Risk factors

Animal risk factors

Naturally occurring BRSV infection affects both dairy and beef cattle and those under 6–10 months of age are most susceptible to clinical disease. Nursing beef calves with colostral BRSV antibody are not protected from infection but the incidence and severity of clinical disease is inversely related to the level of maternal antibodies in calves younger than 3 months.[2] The highest percentage of reinfections occurs most commonly in cows during their first lactation.[12] Older animals may have a more effective immunity because of previous exposure.

Seroepidemiological surveys in **feedlot cattle** found that seroconversion to the virus may occur in up to 70% of animals within 1 month after arrival.[13] Animals with low titers to the virus on arrival are at increased risk of subsequent treatment for respiratory disease, which suggests that the virus may be a factor in bovine respiratory disease. In some situations in feedlot cattle, high BRSV serum antibody levels on arrival were related to a lower risk of respiratory disease.[6]

Environmental risk factors

The highest incidence of clinical disease occurs in autumn and winter months. Outbreaks have been associated with changes in weather, especially declining ambient temperatures and atmospheric pressure.

Pathogen risk factors

BRSV has a narrow host range, affecting primarily cattle. Important antigenic differences between BRSV isolates have been described. Subgroups A and AB are associated with severe respiratory disease and circulate in the Dutch cattle population.[1] In natural outbreaks of infection in closed dairy cattle herds and veal calf units in Denmark, using DNA sequence data, identical viruses were isolated within a herd during outbreaks, but viruses from recurrent infections varied by up to 11% even in closed herds.[14] It is possible that a quasispecies variant swarm of BRSV persisted in some of the calves in each herd and that a new and different highly fit virus type (master and consensus sequence) became dominant and spread from a single animal in connection with each outbreak.

Antigenic subtypes may have relevance both in explaining differences in virulence between subtypes and in the development of new vaccines for the control of clinical disease.[15] The production and characterization of monoclonal antibodies to a vaccine strain of BRSV has been described.[16] The respiratory syncytial virus of goats and sheep, caprine respiratory syncytial virus and ovine respiratory syncytial virus are antigenically related, but not identical, to BRSV.

The BRSV may act synergistically with a concurrent experimental challenge of the virus and 3-methylindole to produce more severe pulmonary disease similar to BRSV pneumonia seen in feedlot cattle, than either agent alone.[15] But vaccination of cattle with BRSV vaccines does not protect the potential synergism between the 3-MI and BRSV infection.[17]

Whether or not the virus persists in individual animals in spite of the presence of maternal or naturally-acquired antibodies has been a major question. Serological findings indicate persistence of the virus but the virus could not be detected in lung lavage fluid or nasal swabs.[18] Experimentally, the virus persisted in tracheobronchial and mediastinal lymph nodes for up to 71 days after infection.[19] In vitro, the virus was still able to replicate in bovine B-lymphocyte cell lines 6 months after infection. This may explain the absence of the virus between epidemics, recurrent infections in the same individuals and inapparent reinfection of adults.

Immune mechanisms

After a natural BRSV infection, the protection is short-lived and multiple reinfections are common.[1,3] In endemic

areas, the absence of BRSV-associated disease in adult cattle is possibly due to repeated infections. This places a constraint on vaccine development, because one or two vaccinations would have to induce immunity that only repeated natural infections can provide. BRSV infections can occur in the presence of high to moderate levels of maternal antibodies.[3] Maternal antibodies, which are directed against the F, G and N proteins of BRSV, are commonly present in calves, but do not protect against infection.[1,3] However, the incidence and severity are inversely related to the level of specific maternal antibody,[3] and natural infection does not prevent reinfection but appears to offer good protection against clinical disease after infection.

The BRSV colostral antibody of dairy calves varies dependent on season of the year the calves are born.[20] Dairy calves born during the winter months in the Netherlands have lower BRSV colostral antibody titers than those born during the summer months. This may be due to the seasonal periodicity of BRSV circulation or by other factors influencing antibody development or colostrum intake is uncertain. Calves born in the summer have higher antibody titers at 14 to 19 weeks of age most likely attributable to BRSV exposure. Calves born during the season of infection may be primed with BRSV field virus during the period of maternally derived immunity and may be better protected against disease by cellular immunity during the next season of infection.

IgM and IgA are the predominant antibody isotypes in the respiratory tract after BRSV infection, with IgA especially prominent after reinfection.[3] Both serum antibody responses and local antibody responses are suppressed by maternal antibodies.[3] After natural BRSV infection of cattle, antibodies are predominantly directed against the epitope A, whereas after experimental infection, or vaccination with an inactivated vaccine, the antibody responds against epitope B and non-neutralizing epitope C are markedly increased compared with the same epitopes in naturally infected cattle.[1]

The subgroups of the virus are based on antigenic differences of the G protein, and BRSV infection protects against reinfection by homologous strains of the virus. It is also known that a complete BRSV can partially protect against a BRSV infection with a strain that contains an antigenic dissimilar G protein.[1] Therefore, incorporation of representative viruses of different BRSV subgroups in vaccines for cattle does not seem necessary to achieve cross-protection. A gE-negative bovine herpesvirus-1 (BHV-1) strain can successfully be used as a vector for development of combination vaccines against bovine respiratory disease, and the G protein can induce significant protection against BRSV infection in calves.[21]

Vaccination of calves with a formalin-inactivated BRSV vaccine followed by challenge exposure to virulent virus increased the severity of clinical disease and lesions compared to calves non-vaccinated and challenged.[21] Vaccination did not induce neutralizing antibodies, but IgG antibodies were detected with ELISA. Immunization with formalin-inactivated BRSV vaccine mainly primes a Th2-like inflammatory response characterized by a significant eosinophilic influx in the bronchia alveolar lung field and lung tissues and high levels of immunoglobulin E serum antibodies.[22]

PATHOGENESIS

BRSV causes rhinitis, tracheitis, bronchitis, bronchiolitis, and mild interstitial pneumonia. In naturally occurring cases, the principal lesions are bronchitis and bronchiolitis in the cranioventral portions of the lungs combined with widespread emphysema and edema throughout the lungs.[1,3] BRSV infection causes airway obstruction and hyperactivity that may persist for up to 30 days following viral exposure.[3] In naturally occurring cases, the cranioventral lung fields are particularly poorly ventilated and there is arterial hypoxemia associated with mismatching of ventilation and perfusion.[3] Radiographic and radionuclide lung perfusion imaging reveals the presence of bullous emphysema and areas of marked atelectasis.

The pathogenesis of acute fatal pneumonia due to BRSV is not clear. The characteristic lesions are exudative or necrotizing bronchiolitis, atelectasis, interstitial edema, and emphysema. The acute fatal disease is commonly preceded by a mild respiratory disease several days previously, which suggests that hypersensitivity may be a pathogenetic mechanism causing lung injury. The second stage may follow initial improvement or recovery from the first stage and is associated with the onset of extreme respiratory distress. The virus-specific IgE antibody may play a role in the pathogenesis of the severe disease as part of a hypersensitivity reaction.[23] The IgM and IgA antibodies are not involved in a hypersensitivity reaction. In experimentally induced infection in calves, there is considerable injury to bronchiolar epithelium including hypertrophy, hyperplasia, and formation of syncytia.[24] In the alveoli, BRSV infection results in necrosis of type I pneumocytes; the response of type II pneumocytes includes hypertrophy, hyperplasia, and syncytial formation. It is suggested that an immune-mediated mechanism may be responsible for the widespread lesions over the entire lung.

The severe highly fatal form of the disease, also known as the 'malignant' form, or the paroxystic respiratory distress syndrome (PRDS) is associated with extensive pulmonary mast cell degranulation.[25] In a series of naturally-occurring paroxystic respiratory disease in calves, paired serum samples were taken three weeks apart, and lungs examined at necropsy. The serum concentration of tryptase was used as a marker of mast cell degranulation. Tryptase is a preformed serine protease stored in mast cell granules and causes significant changes in the respiratory tract smooth muscle tone and vascular permeability. The substances released by the mast cells are at least partially responsible for the pulmonary edema, in particular by means of venoconstriction and the increase in the vascular permeability induced by the histamine. (In neonatal calves and young adult cattle, histamine affects respiratory function by contraction of the trachea and pulmonary veins which increases total pulmonary resistance and induce venous hypertension.[26] This would likely result in increased pulmonary capillary pressure and the development of alveolar edema. The main physiopathologic target of pulmonary mast cells in cattle is the pulmonary vein.)

The edema and bronchoconstriction caused by the mast cell leucotrienes impede bronchiolar flow, which causes ventilatory asynchronism. The mechanical constraints caused by the asynchronism are aggravated because the bovine lungs consist of a number of compartments, which prevents any collateral ventilation and any dissipation of interlobular pressure gradients. The breaking point is reached when the level of the mechanical constraints exceeds the level of tissue resistance causing interstitial emphysema.

Calves which die from the BRSV-associated PRDS have a uniform pattern of gross lesions. The trachea and bronchi are filled with a white-to-pink froth and the lungs are heavy and voluminous and fail to collapse. The most characteristic lesions were the dramatic lung distension by edema, alveolar hyperinflation and severe interstitial and subpleural emphysema, often with large dissecting bullae on the dorsal edge of the diaphragmatic lobes.

Microscopically, the most characteristic lesions are bronchitis, bronchiolitis, and alveolar edema, mononuclear cell infiltration, hyaline membrane deposition

and scattered hyperplasia of type-2 pneumocytes. There is a clear gradient in the severity of inflammatory changes in the airway along a cranio-caudal axis, lesions being more frequent and severe in the cranial parts except for hyperinflation and emphysema. Extensive mast cell degranulation occurs in the diaphragmatic lobes where neither the virus nor the epithelial syncytia, nor the bronchiolitis, typically observed in cranio-ventral zones are found.

Experimental reproduction of BRSV pneumonia

Experimental reproduction of the disease has been difficult; in most cases, infection results in only mild clinical disease with limited lesions.

Severe respiratory tract disease and lesions can be reproduced experimentally in conventionally reared calves and the virus can be recovered from tissues.[24] Severe disease similar to the naturally-occurring disease can be induced with a single aerosol of a low-passage clinical isolate of the virus.[24] Moderate to severe BRSV-induced pneumonia can be reproduced in colostrum-fed calves, and nasal shedding of the virus and demonstration of the antigen in the lungs at necropsy provides evidence that the virus causes the disease.[27]

In neonatal calves with experimental acute infection with BRSV, there is increased pulmonary resistance and decreased compliance, which explains the severe dyspnea observed in some calves. There is no evidence that transplacental infection occurs.[3] Experimental infection of young lambs with BRSV can result in severe pathological changes with only mild clinical disease.[28]

In experimentally infected calves, the virus can be detected in the bronchiolar epithelial cells and in alveolar cells, including bronchial ciliated and mucous cells, and bronchiolar ciliated and non-ciliated epithelial (Clara) cells. Syncytia are often observed in the bronchiolar walls and in the alveoli, and such syncytia were always replicating the virus.[29] However, syncytial cell formation is not unique to infection with BRSV since it may also occur in other viral infections of the lung.

Ultrastructural studies of experimental BRSV pneumonia reveal that ciliated and non-ciliated bronchiolar epithelial cells and alveolar type II pneumocytes are targets of the virus.[1,3] BRSV infection of ciliated cells in the airway can result in the loss of cilia and ciliated cells, which may interfere with lung clearance mechanisms and predispose to bacterial pneumonia. The experimental inoculation of lambs with both BRSV and *Mannheimia haemolytica* results in a more severe acute respiratory disease than that produced by either agent alone, and the severity of the disease may be a result of synergistic action of the two agents.

Experimental BRSV infection in calves, induces an acute phase protein response.[28] Strong and reproducible acute phase proteins haptoglobulin and serum amyloid A will peak at 7–8 days after inoculation of the virus. The pro-inflammatory cytokine, tumor necrosis factor (TNF-α), can be detected in the broncho alveolar lung lavage fluids and high levels appear on the days when severe lung lesions and clinical signs are obvious.[30] It may be involved in mechanisms leading to increased permeability of endothelium.

CLINICAL FINDINGS

The clinical findings vary considerably from herd to herd and from year to year. In dairy cattle, disease occurs most commonly in young calves under 6–10 months of age, although outbreaks of severe disease in mature dairy cattle also occur. Clinical signs of infection in older cattle, particularly those with previous exposure to the virus, are less severe. In large dairy herds, episodes of infection are usually mild and often unnoticed, despite cattle having a fever, slight inappetence, and a corresponding decrease in milk production which lasts 3–5 days.[31] Primary infections in lactating dairy cattle may cause a considerable decrease in daily milk production. However, reinfections are not associated with an important loss of milk production.

A **sudden outbreak of acute respiratory disease** in a group of animals is a characteristic of a primary BRSV infection. The disease is more severe in animals with no previous exposure to the virus. A dry, non-productive cough, severe dyspnea and polypnea, and bilateral nasal discharge are characteristic. A fever of 40–42°C (104–108°F) is common and milk production in lacatating cows declines markedly. Feed consumption in the affected group declines for a few days. The fever usually persists for 3–5 days in spite of therapy with antimicrobials. Toxemia is not a feature unless there is secondary bacterial pneumonia. On auscultation of the lungs there are loud breath sounds over the ventral aspects indicating consolidation, and wheezes indicating bronchiolitis. These are the findings of a viral interstitial pneumonia. Most animals recover within 5–7 days. About 1–2% of affected animals will develop a fatal viral pneumonia characterized by severe dyspnea with abdominal breathing and an expiratory grunt, mouth-breathing with foamy salivation, marked anxiety, persistent fever, and death within 2–5 days after onset.[4,5] Feed and water consumption are decreased because of severe dyspnea, which results in a gaunt abdomen and dehydration. Affected animals are reluctant to move or lie down. The loud breath sounds audible over the ventral two-thirds of both lung fields, indicating that extensive consolidation is becoming pronounced. Subcutaneous emphysema over the withers may also occur. Occasionally, some animals that are not being observed closely will die with peracute pneumonia within a few days and represent the index case of an outbreak.

In outbreaks of BRSV infection in **young dairy cattle** under 12–16 months of age, the first clinical abnormalities usually noticed by the owner are coughing and a mild nasal discharge in 50–75% of the animals. Inappetence with a fever of 40°C (104°F) or higher lasts for about 3 days followed by recovery in most cases. Coughing, nasal discharge, and conjunctivitis may persist for several days or a few weeks in 10–30% of the animals with no long-lasting complications. Abdominal breathing, and loud and abnormal lung sounds may occur in about 50% of the animals but these commonly resolve within 10 days.

In an outbreak of BRSV in **recently weaned beef calves** 6–8 months of age, nasal and lacrimal discharge, polypnea and dyspnea, fever of 40–42°C (104–108°F) decreased feed intake, coughing, and lethargy are common. In a small percentage of affected animals, within a few days the dyspnea becomes marked with mouth-breathing and the production of frothy saliva created by the labored respirations. Subcutaneous emphysema over the withers due to severe, interstitial emphysema also occurs. Loud breath sounds, wheezing, and crackling sounds are audible over the ventral aspects of the lungs. Death may occur within a few days after the onset of the dyspnea. Secondary bacterial bronchopneumonia may occur but is uncommon.

CLINICAL PATHOLOGY

It is difficult to obtain a definitive etiological diagnosis of BRSV infection because the virus is highly labile in tissue samples and virus detection in specimens is poor because of inadequate laboratory techniques. The virus replicates slowly, classical virus isolation is laborious and several blind passages are often necessary before any cytopathic effect can be seen. Nasopharyngeal swabs for virus isolation and paired serum samples are necessary to make a definitive etiological diagnosis. Successful laboratory diagnosis of BRSV is generally based on one of four criteria:

- Virus isolation
- Detection of BRSV antigen in suspected tissues

- Indications of BRSV seroconversion
- Histopathology.

The high prevalence of antibody titers to the virus, and the need for skilled personnel to process and interpret the diagnostic tests, have hindered development of a routine diagnostic test. Successful isolation of the virus from typical clinical cases of disease is often unsuccessful and can take 11–21 days because of the late appearance of any noticeable cytopathic effect. Because of these difficulties, isolation of the virus is not commonly recommended as a routine diagnostic approach.

Virus isolation or detection

The ideal sample for **isolation** of the virus is a transtracheal aspirate in the very early stages of the disease. The sample also provides cells for **immunofluorescent antibody** (IFA) **staining**.[1,3] Nasopharyngeal swabs are also useful, but sampling technique must insure good contact with the most caudal part of the pharyngeal cavity and the samples must be placed in viral transport medium and shipped on cold packs and not frozen.

The fluorescent antibody test for virus **detection** is one of the most rapid, reliable, and sensitive tests for the diagnosis of BRSV infection.[1] For tracheal aspirates, an aliquot of the sample is centrifuged onto a microscopic slide to obtain a cell preparation for the IFA test.

The **PCR assay** is rapid and sensitive and can be recommended as the method of choice in the analysis of clinical specimens.[3] The presence of the virus can be determined by using PCR on nasal swabs taken in the acute phase of a suspected outbreak. The virus can be detected and quantified in cell cultures using real-time quantitative RT-PCR and quantitative competitive RT-PCR assays.[32] A sensitive RT-PCR assay for detection of the virus in lung tissues from calves with natural or experimental infection has been developed.[33]

The virus can be detected in tissues with monoclonal or polyclonal antibodies and avidin–biotin complex immunohistochemistry.[3] This is typically done on formalin-fixed, paraffin-embedded tissues.

Serology

The standard serological test for specific BRSV antibodies is the **virus-neutralization** (VN) **test**, usually done with microtiter plates.[1,3] Paired acute and convalescent samples from both affected and normal animals in the herd are desirable. The **indirect ELISA** is a rapid and reliable test for detecting antibodies to BRSV in milk, bulk tank milk, and serum.[34] A **microneutralization ELISA** has been developed which correlates well with other assays and is useful in assessing antibody responses to the virus both in naturally occurring disease and in vaccination studies.[35]

A leukopenia and neutropenia are common and are aids to diagnosis.

NECROPSY FINDINGS

Affected lungs are voluminous and heavy, and fail to collapse when the thoracic cavity is opened. The cranioventral portions of the lung are consolidated and usually dark red or plum-colored. The interlobular septa are edematous, and mucoid exudate can often be expressed from small bronchi. Severe interstitial emphysema and edema are prominent over the dorsal and caudal lobes. Subpleural emphysema is often obvious in the cranial and caudal lobes. The caudodorsal lung regions may be 'meaty' in consistency. The caudal lobes are often markedly distended because of interstitial emphysema, and large bullae are common. The interlobular septa of the caudal lobes are usually distended because of emphysema and edema. Subcutaneous emphysema over the withers, thorax, and neck are common. Secondary bacterial bronchopneumonia with pleuritis may occur.

Histologically, there is bronchiolitis and bronchitis. Large multinucleated syncytia are present, projecting from the bronchiolar walls or lying free in the lumen. Hyperplasia or necrosis of the bronchiolar epithelium are common. Exudates consisting of neutrophils, macrophages, desquamated epithelial cells, and syncytia are present in the bronchiolar lumina. Small airways are often occluded with exudate. Alveolar changes include cellular infiltration and thickening of alveolar septae with multinucleate giant-cell syncytia in the alveoli. Epithelial syncytia containing eosinophilic intracytoplasmic inclusion bodies are often present on alveolar walls. The presence of epithelial syncytia is a useful feature but the numbers and prominence of these structures can vary considerably. Other viruses can also induce these syncytia. In the caudodorsal lung regions, there is severe emphysema, often with rupture of alveolar walls, alveolar edema, sometimes with hyaline membrane formation and swelling of alveolar epithelial cells.[8]

In experimental BRSV pneumonia, the findings include bronchitis, bronchiolitis, proliferative and necrotizing bronchiolitis, interstitial pneumonia with areas of atelectasis and alveolar edema, epithelial syncytium formation on bronchiolar and alveolar walls, and pneumocyte hyperplasia. The virus antigen can be demonstrated by immunoperoxidase or immunofluorescent staining of bronchiolar and alveolar epithelium.

Isolation of the BRSV from natural field cases has always been difficult because of the long duration required for the appearance of characteristic cytopathic effects. Fluorescent microscopy can be used for detection of the antigen in the cranioventral lung areas but PCR is a more sensitive technique. It is advisable to collect and **sample several areas of lung** as viral antigen/nucleic acid will be most abundant in areas of acute infection. The virus can also be demonstrated in formalin-fixed paraffin-embedded bovine lung tissue using immunohistochemical techniques.[32]

Samples for confirmation of diagnosis

- **Histology** –fixed lung (several sites) (LM, IHC)
- **Virology** – chilled lung (several sites) (FAT, PCR); nasal swab (ELISA, PCR).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes those infectious diseases of the respiratory tract of young cattle that commonly affect groups of animals in a short period of time.

It is not usually possible to make a definitive etiological diagnosis based on the clinical findings. However, the combination of the epidemiological and clinical findings are usually suggestive of an acute viral respiratory disease. It is not usually possible to be more specific than making a clinical diagnosis of acute undifferentiated respiratory disease.

- Acute respiratory disease due to BRSV infection in weaned beef calves is characterized by marked dyspnea, anorexia, mouth-breathing, fever, subcutaneous emphysema, loud breath sounds, and death in a small percentage of animals in a few days or less. In some cases there may be a history of respiratory disease in the affected group several days previously[36]
- Infectious bovine rhinotracheitis (IBR) is characterized by outbreak of coughing, profuse nasal discharge, fever, inappetence, the presence of typical nasal lesions; pneumonia is not common. Recovery occurs in several days
- Pneumonic pasteurellosis is characterized by anorexia, toxemia, fever, abnormal lung sounds, coughing, nasal discharge, and response to treatment with antimicrobials. fibrinous pneumonia at necropsy is typical
- Lungworm pneumonia occurs most commonly in groups of young cattle on summer pasture and is characterized by coughing, nasal discharge, tachypnea, abdominal breathing, fever and inappetence, and increased breath sounds with crackles. A necropsy diagnosis is usually necessary
- BRSV infection in mature dairy cattle may be mild and is characterized by a slight drop in milk production, fever for a few days, inappetence, and recovery in a few days. Adult cattle lacking immunity may develop severe fatal pneumonia which must be distinguished from pneumonic pasteurellosis, infectious bovine rhinotracheitis, and other causes of interstitial pneumonia.

TREATMENT

Antimicrobial therapy

Broad-spectrum antimicrobials given daily for 3–5 days for secondary bacterial pneumonia are commonly administered but may not be necessary. Recovery usually occurs gradually over a period of 3–5 days. Severely affected animals will become worse in spite of therapy.

Non-steroidal anti-inflammatory agents

These are used for their anti-inflammatory effect but are unnecessary and there is no evidence that they are efficacious.

CONTROL

Reliable control measures are unavailable. The ubiquitous nature of the virus, the persistency of infection in herds, the movement of cattle between herds, the expansion of herds and the replacement practices used in herds, and recurrent infections make control difficult.

Management

A rationale approach to control would be management of the herd to minimize stressors such as inadequate ventilation. Herd replacements brought into the herd should be quarantined from the rest of the herd for 2–3 weeks before mixing with the remainder of the herd.

Vaccines and immunization

Several modified live virus and inactivated virus vaccines are available for the control of respiratory disease due to BRSV infection, but there are few randomized clinical trials evaluating the efficacy of the vaccine under naturally occurring conditions against BRSV infection or clinical disease. Because calves under 6 months of age are most frequently infected with BRSV despite the presence of colostral antibodies, there is a need for a vaccine which is effective in calves. The presence of passively derived antibodies to BRSV interferes with immunization by vaccination of young calves with commercially available inactivated vaccines. Vaccines must therefore be effective at an early age and be able to overcome the immunosuppressive effects of colostral antibodies.

Protection has been reported in experimental challenge models in cattle for several vaccines. field trials, with live or inactivated BRSV vaccines revealed different levels of protection, while others found that vaccination enhanced disease in calves.[37] The intramuscular administration of the vaccine in calves which had colostral antibodies, was least efficacious, and intranasal inoculation of live virus in colostrum deprived calves proved most effective.[37]

Cattle vaccinated with MLV BRSV vaccines generally develop high concentrations of virus neutralizing antibodies (VN) and fusion inhibiting antibodies, compared with low to moderate concentrations of total BRSV-specific IgG.[38] In contrast, cattle receiving inactivated virus vaccines develop lowered concentrations of VN antibodies and high concentrations of virus-specific (non-neutralizing) IgG.

Formalin-inactivated BRSV vaccines have not been successful when tested by experimental challenge of vaccinated calves.[21,39] This is similar to the enhanced disease which may occur in children vaccinated with a formalin-inactivated alum adjuvanted vaccine.[39] However, one adjuvanted inactivated BRSV vaccine did provide protection in vaccinated calves challenged by experimental infection.[38]

A BRSV vaccine inactivated with beta-propiolactone and adjuvanted provided calves with colostral antibodies to the virus with protection against challenge with the virus.[40] A schedule of three vaccinations in calves with high levels of antibodies or two vaccinations in calves with moderate levels provided protection for nearly 6 months. However, in one study in beef herds, calves vaccinated with an inactivated BRSV vaccine developed clinical, serological, virological and pathological evidence of BRSV pneumonia 2 months after vaccination.[37]

A modified-live BRSV vaccine provided protection in calves against a challenge model that mimics severe naturally occurring disease.[41] Vaccinated calves shed reduced numbers of virus, had less pulmonary disease, and had vaccine-induced cell-mediated immune responses. The cell-mediated immunity was a more consistent measure of protection than prechallenge serum antibody.

A single intranasal dose of MLV BRSV vaccine protected calves from experimental challenge and the vaccine induced cell-mediated immunity characterized by the production of BRSV-specific interferon-gamma (IFN-ê) by mononuclear cells isolated from various tissue specimens.[42]

Subunit vaccines which can overcome maternal antibodies have been examined. The use of immunostimulating complexes (ISCOMs) against BRSV has been evaluated and compared to a commercial inactivated vaccine in calves with BRSV-specific maternal antibodies.[43] Following experimental challenge, vaccinated calves remained healthy, while control calves developed severe clinical disease. Significantly higher BRSV-specific nasal IgG, serum IgG1, and IgG2 titers were detected before and after challenge in calves vaccinated with ISCOMs compared to the results in calves vaccinated with the commercial vaccine. BRSV was isolated from the nasopharynx of control calves none from the calves vaccinated with ISCOMs. The vaccine overcame the suppressive effect of colostral antibodies and induced a strong clinical and virological protection against a BRSV challenge.

Vaccination of dairy heifers with a vaccine containing chemically altered temperature-sensitive infectious bovine rhinotracheitis (IBR), PI-3 viruses, two strains of killed bovine virus diarrhea viruses, and a modified live virus BRSV, compared to a similar vaccine but without the BRSV, twice at a 2-week interval with the second vaccine administered at 2–3 weeks before calving, may increase milk production and first insemination conception rates.[31] Milk production was increased in first-parity cows during the first 21 weeks of lactation. Vaccination did not have any effect on milk production after the first 21 weeks of lactation in cows of any parity.

INFECTIOUS BOVINE RHINOTRACHEITIS (IBR, RED NOSE), BOVINE HERPESVIRUS-1 (BHV-1) INFECTION

Synopsis

Etiology Bovine herpes virus-1 subtypes: BHV-1.1 (respiratory); BHV-1.2a and 1.2b (genital); BHV-1.3 (BHV-5; encephalitic)
Epidemiology Worldwide occurrence in cattle; high prevalence of infection; low incidence of disease; transmitted directly; latent infection characteristic; economic losses due to deaths and abortions, latent infection in breeding animals cause international trade problems and entry into artificial insemination units
Signs Rhinitis with typical nasal lesions, tracheitis, fever, conjunctivitis, coughing, nasal discharge, and recovery in few days; severe systemic disease in newborn calves, abortion outbreaks
Clinical pathology Isolation or detection of virus with tissue culture or PCR; serology with serum-neutralizing titer, ELISA. Bulk tank milk antibodies
Lesions Rhinotracheitis, bronchopneumonia, non-suppurative encephalitis, alimentary tract necrosis in calves with systemic disease, aborted fetuses autolyzed
Differential diagnosis All diseases associated with bovine respiratory tract disease: pneumonic pasteurella, viral interstitial pneumonia, *Haemophilus pleuropneumoniae*, allergic rhinitis
Treatment Antimicrobials for secondary bacterial infections
Control Vaccination of young breeding herd replacements using modified live virus or inactivated virus vaccines. Subunit and marker vaccines becoming available are superior to conventional vaccines. Some countries eradicating infection by identifying and eliminating seropositive animals

ETIOLOGY

The bovine herpesvirus type-1 (BHV-1), or the infectious bovine rhinotracheitis (IBR) virus is an alphaherpesvirus and the cause of the respiratory disease, abortion, conjunctivitis, and other clinical forms of the disease complex.[1] Genetic analyses of various clinical isolates has found at least three distinct **BHV-1 subtypes**: a **respiratory subtype, a genital subtype, and an encephalitic subtype** designated as BHV-1.1, BHV-1.2, and BHV-1.3, respectively. BHV-1.3 has been renamed BHV-5.[1,2] Antigenic differences between isolates of the virus may account for some of the diverse epidemiological and pathological patterns of behavior of this herpesvirus.

The literature on the evolution of the herpesviruses has been reviewed.[3] Four ruminant alphaherpesviruses are related to BHV-1 and have the potential for cross-infection of cattle in Europe: Bovine herpesvirus-5, caprine herpesvirus-1 (CpHV-1), cervine herpesvirus-1 (CvHV-1), and cervine herspesvirus-2 (CvHV-2). Buffalo herpesvirus-1 and elk herpesvirus are also closely related to BHV-1.[4] BHV-5 is the cause of fatal meningoencephalitis in calves.[5] CpHV-1 causes enteritis and generalized infection in neonatal kids. Most CpHV-1 infections in adults are subclinical, the virus can cause vulvovaginitis, balanoposthitis, or abortion. CvHV-1 can cause ocular disease in red deer and is widespread in free-living and farmed red deer. CvHV-2 has been isolated from reindeer in finland and serological evidence of infection with a virus similar to BHV-1 has been reported in caribou in Canada. Although these viruses differ considerably in their virulence, they are closely related both genetically and antigenically, and can establish latent infections similar to that of BHV-1.[4] An immunofluorescence assay using monoclonal antibodies can discriminate between these related herpesviruses.[4] Restriction endonuclease and monoclonal antibody analysis has been used to analyze Brazilian isolates of BHV-1 and BHV-5.[6]

Bovine herpesvirus 4 has been associated with mastitis in cattle.[7,8]

EPIDEMIOLOGY

Prevalence of infection and occurrence of disease

Disease complexes associated with this virus have been recognized in most cattle-raising countries of Europe, Asia, North America, Africa, and in Australia and New Zealand. The respiratory form of clinical disease is most common in feedlot cattle, and cattle on diary and beef farms without a routine vaccination program.

Seroprevalence surveys have found that 10–50%, or even higher, of cattle are serologically positive to the virus depending on vaccination practices in individual herds, and the frequency of contact between infected and non-infected animals.[3] The percentage can also vary between dairy and beef cattle in the same geographical area. The seroprevalence in a country or area also changes over time. A serological survey in Belgium found that infection is endemic in the cattle population.[9] In Great Britain in the 1960s, serological surveys indicated that less than 10% of cattle were positive. In the mid- to late-1970s, the incidence of infection increased markedly, and by 1986 35% of the animals and 48% of the herds were positive. In beef herds in northern Australia, up to 96% of bulls and 52% of cows are seropositive, most of which may be venereal because respiratory disease is uncommon in cattle on extensive range conditions. The genital carrier state is important in the maintenance of venereal IBR virus and in the occurrence of sporadic infectious pustular vulvovaginitis (IPV) and infectious pustular balanoposthitis (IPB) in these herds. Outbreaks of IPV and IBP were not uncommon in Britain in the 1960s and 1970s, and then occurred only rarely after the introduction of stricter control measures in artificial insemination centers.[10] In 1997, an outbreak of IPV and IBP occurred in a dairy herd with 70–80% of the cows manifesting signs of both the respiratory and genital form of BHV infection.[10] Both oculonasal and vaginal isolates were typed as type 2b, which is the same as the Oxford isolate commonly associated with both IPV/IBP and typical low/medium virulence outbreaks of IBR.[10]

The bovine herpesvirus-1 has not been reported in recent years in a number of countries such as Norway, Sweden, finland, Estonia, Iceland, Denmark, Bulgaria, and Moldova.[11] Since 1994, Norway has been free of BHV-1 and certain defined additional guarantees for cattle to be imported are in place to protect the disease status.[12] IBR/IBV is a reportable disease in Norway. Some countries in Europe are in the process of eradicating the virus from the cattle population. In beef herds in Yucutan, Mexico, where vaccination is not practised, seropositivity was associated with large and older herds.[13]

Wildlife

Bovine herpesvirus infections exist in wild ruminants.[14] Infections may be endemic in white-tailed deer in certain parts of Canada, and it is suggested a mild form of the disease occurs in these animals. About 29% of both wild and farmed red deer in Britain are seropositive to the closely related herpesvirus of Cervidae 1. Mule deer are susceptible to infection, the disease has occurred naturally in a goat, and antibodies to the virus have been found in pronghorn antelope in western Canada, and in Tanzania in game animals and cattle. According on serological surveys, the virus is widespread in African wildlife, particularly the buffalo, which may be a reservoir of infection among the wildlife population. The virus has been recovered from the wildebeest in Africa, which suggests further that wildlife may serve as reservoirs. Antibodies to the alpha-herpesviruses were found in reindeer (28.5%), roe deer (3.0%) and in red deer (0.5%) in Norway.[15] In Saskatchewan, Canada, 52% of Woodland

Caribou were seropositive to the bovine herpesvirus-1.[16]

Morbidity and case fatality

The uncomplicated form of the respiratory disease in cattle is not highly fatal, most losses being due mainly to secondary bacterial bronchopneumonia. The morbidity and case fatality rates in dairy cattle are about 8% and 3%, respectively, while in feedlot cattle the morbidity rate is usually 20–30% in unvaccinated cattle and may rarely reach 100%. The case fatality rate in feedlot cattle is invariably associated with secondary bacterial tracheitis and bronchopneumonia and may reach 10%, but is usually no more than 1%. Morbidity and mortality are **higher in feedlot cattle** than in dairy herds because of the frequent introduction of susceptible animals into an enzootic situation. The case fatality rate in the systemic form of the infection in newborn calves is almost 100%.

Methods of transmission

The main sources of infection are the nasal exudate and coughed-up droplets, genital secretions, semen, and fetal fluids and tissues. Aerosol infection is the method of spread of the respiratory disease. Experimentally, the BHV-1 can be shed from calves into the environment and transported by air over a distance of at least 3.85 m to sentinel calves housed in a separate building.

Venereal transmission is the method of spread of the genital diseases. The virus may survive for up to 1 year in semen frozen at –196°C (–321°F).

Introduction of animals into a group often precedes an outbreak of the disease. However, it can arise simultaneously in a number of dairy farms in an area and spread from these to adjacent farms until the entire area is affected. The same pattern of occurrence simultaneously in a number of foci is seen in feedlots, and from these foci infection spreads to other pens in the lot. An outbreak usually reaches its peak in the 2nd or 3rd week and ends by the 4th–6th week.

To determine whether or not an infection in a herd will spread from a small inoculum, the number of secondary cases resulting from one infectious animal must be estimated. The ratio of secondary cases to originally infected animals is called the reproduction ratio and is commonly denoted by R_0. When $R_0 < 1$, the infection will not spread and the animal population is effectively protected from the infection. When the infection is established, but R_0 is reduced to less than one, the infection will disappear provided that some additional, commonly satisfied assumptions are met. When $R_0 > 1$, the infection can spread. Therefore, a strategy for controlling an infectious agent is effective when, and only when, the ratio for that strategy is less than one. The value of R_0 for a given host population is determined by a number of different factors including: the transmissibility of the infection; the period over which an infected host is infectious; the population density of hosts; and where appropriate, the density of vectors and the capacity of the vectors to transmit the infection.

Risk factors

Animal risk factors

Age and breed susceptibility

All ages and breeds of cattle are susceptible but the disease occurs most commonly in animals over 6 months of age, probably because of their greater exposure. There is no seasonal variation in incidence, except possibly a higher occurrence in feedlot cattle in the fall and winter months when large numbers of susceptible animals are assembled. The disease complexes associated with the virus occur most commonly in animals that lack acquired immunity from previous natural infection or vaccination. **An unvaccinated herd of breeding cattle or a group of feedlot animals are highly susceptible to epidemics of respiratory disease and abortion.** Newborn calves are highly susceptible to the systemic form of infection if the level of specific antibody to the virus in the colostrum is inadequate or if there is failure of transfer of passive immunity.[17]

The analysis of the relationship between interferon genotype and severity of clinical disease in cattle experimentally inoculated with BHV-1 revealed that certain alleles of the interferon were significantly associated with the more severe clinical phenotype. A second allele at another locus was associated with the milder disease genotype. Thus, selective breeding programs aimed at altering the frequency of these alleles in cattle populations may potentially improve animal health and lessen the economic impact of BHV-1 infections.[18]

Environmental and management risk factors

Several managemental factors have been associated with BHV-1 infection in a herd. Infected herds purchase cattle and participate in cattle shows more often than negative farms. The positive farms have more visitors and are situated closer to other cattle farms.[19] The failure to vaccinate regularly and keep reliable records of vaccination dates are commonly associated with inadequate disease control.

In countries with BHV-1 eradication programs, the loss of certification is commonly associated with yearly number of cattle purchased, farm density within a 1 km radius, and cattle density within a 1 km radius.[20]

Pathogen risk factors

The **IBR-like viruses** are now designated **BHV-1.1**, and the **IPV-like viruses** are designated **BHV-1.2**, with the latter subtype being further divided into two groups given the letter designations a and b.[2] **Subtype 1.2a isolates cause abortion**, 1.2b isolates are not abortifacient.[2] **Subtype 1.3, or BHV-5**, is the encephalitic strain.[21,22] **Inactivation of the thymidine kinase gene from BHV-1** reduces the abortifacient activity of the virus but does not eliminate the aborifacient activity of BHV-1.[2] Currently available vaccines, which are made with 1.1 subtype vaccines, cannot be given to pregnant cattle because they are abortifacient. The currently available MLV BHV-1 vaccines can cause infertility in cattle infected 14 days after breeding.

The BHV-1 genome is not stable during host animal passage, and variations can occur in the restriction endonuclease patterns of the viruses within individual animals during both acute infections, and after viral reactivation or after viral reactivation followed by superinfection with a different subtype of BHV-1 than was used for the primary inoculation.

The virus of IBR is similar to the virus causing IPV in cows and IPB of bulls. Manifestations occurring suggest that strains with differing tissue affinities may exist in the field, and slight differences can be detected by immunological and biochemical means. Only rarely do the respiratory and genital forms of the disease occur together. However, by routine methodology it is difficult, and usually impossible, to distinguish between isolates obtained from the reproductive tract and the respiratory mucosa. Likewise, with the exception of temperature-sensitive mutants, vaccine strains cannot be distinguished from field isolates.

The virulence of several strains of one genotype can vary widely.[23] The outcome of BHV-1 infection can vary from subclinical to a systemic infection in neonatal calves that is often highly fatal.[24] A subclinical infection of bulls in an artificial insemination unit with BHV-1 can last for several months, even in vaccinated animals.[25] Vaccine strains of BHV-1.1 have been associated with outbreaks of meningoencephalitis in feedlot cattle within 7–10 days after routine vaccination intranasally with a vaccine intended for the intramuscular route.[26] Newborn calves under 3 days of age are susceptible to the highly fatal systemic form of IBR if vaccinated intramuscularly with a

modified live virus BHV-1 and PI-3 vaccine.[27]

Using DNA restriction endonuclease and polyacrylamide gel electrophoresis (PAGE) it is now possible to compare the antigenic differences between isolates obtained from different clinical syndromes, different species, tissues, and countries. Several different genotypes of the virus have now been identified, which may explain the emergence of a more severe form of the respiratory form of the disease in some countries as well as the different forms of the disease.[25] The increasing number of BHV-1 isolates recovered in the United Kingdom, and the sudden increase in the incidence of IBR is probably due to the importation of a BHV-1 isolated within imported North American Holsteins.[28] The Colorado and Strichen strains produced the characteristic clinical signs, whereas the Oxford strain produced a mild clinical response with minimal pathological lesions.[25] Based on the evidence of epidemiology, molecular genotype analysis, and experimental pathogenicity, the more severe form of IBR that occurred in cattle in Britain in the mid-1970s was associated with BHV-1.1, which had a greater propensity for spread and was probably introduced in imported cattle.[25] The herpesviruses isolated from reindeer is a distinct species within the family Herpesviridae.[14]

Restriction endonuclease analysis of Australian BHV-1 isolates recovered between 1989 and 1993 revealed emergence of a new BHV-1 genotype, BHV-1.2b, which appears associated with severe respiratory disease.[29] There is no evidence to date of the BHV-1.1 genotype in Australia.

Outbreaks of IBR have occurred in feedlot cattle vaccinated against the infection.[30] The causative viruses were mutants of BHV-1 which did not react with a monoclonal antibody specific for one of the epitopes on glycoprotein D, one of the most important antigens of the virus.

An outbreak of a subclinical form of IBR has been described in a dairy herd of high health status and managed under high standards of biosecurity, and known to be serologically negative for the virus for the previous 15 years.[31] Although 70% of the cows had seroconverted to the virus no clinical signs were observed with the exception of an ocular discharge in a few cows, and their performance and productivity were unaffected. The causative virus was isolated after reactivation with corticosteroids and had the DNA profile of a BHV-1 strain normally associated with severe respiratory disease.

The virulence of the virus or its host tissue specificity changes due to unknown factors. It has been suggested that the IPV was transmitted to North America from Europe in infected cattle, but continued to cause lesions in only the genital tract until its introduction into dense populations of cattle in feedlots encouraged rapid passage through many hosts and thus encouraged adaptation to the respiratory tract.

Restriction endonuclease DNA fingerprints of herpesviruses isolated from unrelated epidemics of bovine encephalitis have revealed that they are similar to each other, and totally different from BHV-1 and other ruminant herpesviruses.[21] Though antigenically and genetically related to BHV-1, the bovine herpes encephalitis virus is distinctly different.[32] A BHV-5 has been isolated from naturally occurring cases of non-suppurative meningoencephalitis in calves[21] and can be reproduced experimentally.[5]

The glycoprotein E (gE) gene is a virulence factor of BHV-1 is important in the development of gE-negative marker vaccines used in eradication programs.[23] These marker vaccines, either inactivated or live-attenuated, are deleted in the gene coding for the non-essential glycoprotein E (gE) of BHV-1 in order to allow serological differentiation between vaccinated and infected cattle. A glycoprotein E-deleted BHV-1 strain has been isolated from cattle in the field.[33]

Immune mechanisms

Immunity to the virus is complex and consists of relationships between local and systemic antibody, and cell-mediated immunity. Following natural infection or vaccination with the modified live virus (MLV) vaccines, both cell-mediated and humoral components of the immune system are activated. The level of humoral immunity has been used as an indicator of previous infection and an indirect measure of resistance to clinical disease. However, the level of serum neutralizing (SN) antibody is not a reliable indicator of resistance to clinical respiratory disease. Animals with low levels of antibody may be immune because of cell-mediated immunity. The level of cell-mediated immunity can be evaluated using the delayed-type hypersensitivity test. Experimentally, the virus-neutralizing (VN) titers are lower in calves inoculated with both the IBR and parainfluenza-3 (PI-3) viruses than in calves infected with a single virus. This suggests that mixed viral infections may result in greater immunosuppression, although infectious virus synthesis may be suppressed by interference.

Following intranasal infection or the use of a MLV IBR virus vaccine intranasally, local secretory antibody and interferon are produced. The interferon appears in 3 days and persists for 10 days. The presence of the interferon does not protect calves against experimental challenge 3 days after vaccination. However, the presence of even low levels of antibody in the serum or nasal secretion, which appears by day 7 following vaccination, provides varying degrees of resistance to clinical disease for 9 months.

Colostral immunity

Calves acquire colostral antibodies from dams with humoral antibody. The duration of the colostral immunity varies from 1 to 6 months of age dependent on the initial level acquired by the calf. Maternal antibody in the calf may interfere with the successful vaccination of calves before 6 months of age.

Economic importance

BHV-1 infection can cause major economic consequences in a dairy or beef cattle breeding herd, or in a beef feedlot. Losses are incurred due to epidemics of abortion, infertility due to IPV and IPB in bulls, loss of production and deaths from the respiratory form of the disease in all ages of cattle, deaths from the highly fatal systemic form of the disease in newborn calves, and the cost of treatment when secondary bacterial infections of the respiratory tract occur.

PATHOGENESIS

The virus causes disease through several different pathways including a primary infection restricted to the respiratory tract, eyes, and the reproductive tract. Systemic spread to many organs by viremia occurs as well as neuronal spread. In addition, the virus can establish latency in neuronal or lymphoid cells. Upon reactivation, the viruses re-establish the lytic cycle of replication.

Respiratory disease

The BHV-1 virus infects the nasal cavities and upper respiratory tract, resulting in rhinitis, laryngitis, and tracheitis. The pharyngeal tonsil is readily infected by the virus and may be an important lymphoid tissue for early anti-viral responses.[34] There is extensive loss of cilia in the trachea leaving the tracheal epithelium covered by microvilli. Intratracheal administration of the virus results in almost complete denudation of tracheal columnar cells, which presumably has an adverse effect on the defense mechanisms of the respiratory tract. Spread from the nasal cavities to the ocular tissues probably occurs by way of the lacrimal ducts and causes conjunctivitis with edema and swelling of the conjunctiva, multifocal plaque formation on the conjunctivae, peripheral corneal edema, and deep vascularization. The

virus can also enhance the prevalence and severity of IBR in calves. In neonatal calves, potentially fatal infection, associated with the continued presence of viral antigen and active inflammation, contrasts with repair and clearance of viral antigen in weanling calves.[34] Experimentally, the endobronchial inoculation of calves with the BHV-1 causes an interstitial pneumonia.[35] The viral antigen can be detected in the desquamated cells and macrophages of bronchoalveolar fluid.

Encephalitis

The mechanism by which the brain is infected is presumed to be spread of the virus from the nasal mucosa via the trigeminal peripheral nerve to the trigeminal ganglion, resulting in a non-suppurative encephalitis. However, a viremia has been suspected. Severe encephalitis can be produced experimentally in colostrum-deprived calves with neurovirulent type BHV-1.3.[22] Experimental infection with BHV-1.1 produces respiratory disease and a mild encephalitis.[22] Intranasal inoculation of young calves and adult cows with BHV-1 can result in non-fatal trigeminal ganglionitis and encephalitis, which may be an important mechanism for latent infection. A rabbit model has been used to study the neuropathogenesis of BHV-5 infection.[36]

Abortion

Systemic invasion by the virus is followed by localization of the virus in several different tissues. The virus may be transported by peripheral leukocytes to the placenta and transferred to the fetus to cause abortion. The fetus is highly susceptible to the virus, which causes a peracute infection that is usually fatal. Infection in the last trimester of gestation may result in mummification, abortion, stillbirth, or weak calves with the usual lesions of IBR as well as the lesions of the stomachs and intestines that have been produced by experimental administration of the virulent virus to newborn calves.

The systemic form of the infection in newborn calves is characterized by severe inflammation and necrosis of the respiratory and alimentary tracts, including the pharynx, esophagus, lungs, larynx, lymph nodes, liver, and nephritis and encephalitis. There is severe laryngeal edema and respiratory distress which results in difficulty in swallowing and aspiration pneumonia. A severe, highly fatal syndrome characterized by diffuse erosion and ulceration of the upper alimentary tract, including the oral cavity, has occurred in beef feedlot cattle.

Latency

The **BHV-1 virus can become latent** following a primary infection with a field isolate or vaccination with an attenuated strain.[3,37,38] The virus may remain latent indefinitely and recrudescence, reactivation, and shedding of the virus can occur following the use of large doses of corticosteroids which mimic the effects of stress.[39] Transportation of cattle with latent infection can reactivate the virus, resulting in re-excretion of the virus and a rise in neutralizing antibodies. Attenuated vaccine strains can remain in a latent stage and vaccination does not provide protection against the establishment of latent infection with a wild strain.[40] Vaccination also does not inhibit re-excretion of a wild strain that was in the latent form at the time of vaccination. The vaccine virus and the field isolates can be excreted after live virus vaccination and subsequent field isolate challenge. Colostral antibodies in calves do not prevent initial virus replication, and latency can persist after the decline in colostral immunity and the calves are seronegative.[41]

The location of latency of the virus in the body varies; the virus remains localized near the site of its first multiplication and during recrudescence will be re-excreted by the tissue primarily infected. The BHV-1 can be isolated from the **trigeminal ganglion** of clinically normal cattle during the latent period, and trigeminal ganglionitis can be observed during recrudescence.

Latent infection with virulent BHV-1 virus may occur in the trigeminal ganglion of calves previously vaccinated with the MLV vaccine.[3,38] The virulent virus may spread along the trigeminal peripheral nerve despite the presence of humoral antibodies in vaccinated calves. Recrudescence of the virus from the trigeminal ganglion and spread along the peripheral nerves by intra-axonal flow to the nasal mucosa can occur in calves treated with corticosteroids and, presumably, occurs following stress. The virus has been isolated from the trigeminal ganglia of 10% of clinically normal cattle at slaughter, 40% of which had SN antibody to the virus.

The practical aspect of latency is that all cattle from endemic herds must be considered as potential sources of BHV-1 virus and capable of spreading infection to previously unexposed animals. Some latent carriers do not possess detectable antibodies. The only method of identification is by treatment with dexamethasone to initiate recrudescence and detection of the virus from nasal secretions, or the PCR examination of the trigeminal ganglion at necropsy.

A combined serological and clinical surveillance of 20 dairy herds over three consecutive years revealed wide variations in the circulation of the virus. In some herds there was no identification of active infection, while in others one or two cycles of infection occurred in calves and yearlings, often without any clinical evidence of disease. Reactivation and shedding of the virus can occur in known carrier bulls at the time of mating, which may explain the higher incidence of titers in bulls than cows in some beef herds. Breeding bulls in an artificial insemination center which were vaccinated with a MLV vaccine were shedding the vaccine virus in the semen, and the virus could be recovered from preputial washings[42] 2–3 months after the last immunization. However, the frequency of recurrent infections and the amount of virus excreted are reduced after vaccination.

The presence of passively acquired antibodies in calves does not prevent virus replication and establishment of latent infection.[43] It is also possible to experimentally produce BHV-1 seronegative passively immunized calves which do not have antibody response after infection but develop a cell-mediated immune response after infection detected by a specific interferon gamma assay. The failure to easily detect such animals presents an epidemiological threat for the control of BHV-1 infections. Marker glycoprotein E-negative vaccines can also establish latency not only in naïve but also in passively immunized neonatal calves after a single intranasal inoculation.[44] This indicates that gE-negative vaccines, when used in calves with passive antibodies can result in seronegative vaccine virus carriers.[45]

The experimental intrapreputial infection of young bulls with BHV-1.2, caused acute balanoposthitis, latent infection, and detection of viral DNA in regional neural (sacral nerve ganglia, pelvic sympathetic plexus) and non-neural tissues (lymph nodes) 50 days after experimental reactivation.[46] Following experimental infection in calves the BHV-5 also can result in latent infection of surviving animals.[5]

Parturition may also be a stimulus for reactivation and shedding of a thermosensitive vaccine strain of the virus in vaccinated animals.[22] Reactivation and shedding of the virus has also been observed in cattle that recovered from the respiratory form of the disease and 5 months later were experimentally infected with *Dictyocaulus viviparus*. The placenta may harbor the virus in a latent stage for up to 90 days without transmitting the virus to the fetus. Recrudescence may be differentiated from primary infection and re-exposure by the intranasal route based on the distribution of antiviral antibody activity among serum IgM, IgG_1, and IgG_2 isotypes.

Predisposition to pneumonia

The role of the virus in affecting the lung clearance mechanism of cattle in the pathogenesis of pneumonic pasteurellosis has been reviewed and is presented in the section on shipping fever pneumonia in cattle. Experimental aerosol exposure of calves with the BHV-1 virus impairs the function of alveolar macrophages, which allows *Mannheimia haemolytica* to persist and proliferate in the lung and produce the characteristic lesion. In vitro studies indicate that the BHV-1 virus can interfere with the function of effector cells, such as macrophages, neutrophils, and lymphocytes. Aerosol exposure of calves to BHV-1 can affect the composition of alveolar phospholipids, which can alter the function of lung surfactant and compromise pulmonary defense mechanisms.[47] The BHV-1 can cause alteration in the glycoconjugate composition of bovine nasal epithelial surfaces, which may promote *Mann. haemolytica* proliferation in the early stages of pneumonic pasteurellosis.[48] The virus also causes varying degrees of obstructive lung disease, resulting in increased resistance to breathing, retention of carbon dioxide, and increased resting lung volume. Excessive airway constriction and impairment of bronchial relaxation occurs, which may compromise lung defense mechanisms and allow development of secondary bacterial pneumonia. A severe fatal BHV-1 pneumonia can occur.

Experimentally, active BHV-1 infection function affects bovine peripheral blood neutrophils, enhances the binding of *Mannheimia haemolytica* leukotoxin to bronchoalveolar leukocytes, and increases their killing.[47] The virus increases the number of bronchoalveolar leukoctyes, resulting in many more leukotoxin-responsive cells being present in the lung.

Reproductive failure

The **intrauterine inoculation of the BHV-1 into cattle results in an acute necrotizing endometritis** in the uterine body and caudal portions of the uterine horns but minimal lesions in the anterior parts of the horns. Experimental inoculation of the virus into heifers on the day after estrus and insemination can result in lesions of the ovaries consisting of focal necrosis and cellular infiltration. Commercially available vaccinal strains of the BHV-1 virus can produce similar lesions. The ovarian lesions have marked effects on luteal function, and plasma progesterone values in the first estrus after inoculation are markedly lower than those in subsequent normal cycles. Whether the BHV-1 virus causes reproductive failure as a result of necrosis of the corpus luteum or embryonic infection remains to be determined. Recently hatched bovine embryos can be infected with any of several strains of BHV-1 and such infection in vitro is embryocidal. Experimentally induced infection during early pregnancy (7–28 days) will cause oophoritis and, in some cases, embryonic mortality. The effects of the virus on the genital tract and on reproductive performance in cattle have been reviewed.[1]

Bovine mastitis

The BHV-1 and BHV-4 have been associated with mastitis in cattle.[7,8] Both viruses, and including the foot-and-mouth disease virus, and the PI-3 virus have been isolated from milk. The BHV-4 has been isolated from cows with clinical mastitis which also developed antibodies against the virus at the time of the mastitis and no bacteria were isolated from the milk samples.[7] Bovine umbilical cord endothelial cells were used to culture the virus. Experimental inoculation of the ductus papillaris of the teat has resulted in replication of the virus and subclinical mastitis after BHV-4 infection.[8] Simultaneous intramammary and intranasal inoculation of lactating cows with BHV-4 did not induce clinical but subclinical mastitis.[49] It is unlikely that BHV-4 is a major mastitis pathogen.

CLINICAL FINDINGS

Rhinitis, tracheitis and conjunctivitis (red nose)

After experimental infection there is an incubation period of 3–7 days, but in infected feedlots the disease occurs 10–20 days after the introduction of susceptible cattle.

There is considerable variation in the severity of clinical signs following natural infection, dependent on the strain of the virus, the age susceptibility, and environmental factors. In North America, where the disease is endemic, the clinical disease is usually mild in dairy cattle and in range beef cattle. A severe form of the disease can occur in feedlots where crowding and commingling from several sources occur. A severe form of upper respiratory tract disease and encephalitis have been reported in neonatal beef calves.[50]

There is sudden onset of anorexia, loud coughing, fever (up to 42°C, 108°F), severe hyperemia of the nasal mucosa, with numerous clusters of grayish foci of necrosis on the mucous membranes of the nasal septum visible just inside the external nares, a serous discharge from the eyes and nose, increased salivation, and sometimes a slight hyperexcitability. A marked fall in milk yield may be the earliest indication in diary cattle. The respirations are increased in rate and are shallow, but only an increase in the loudness of breath sounds are audible on auscultation of the lungs unless secondary pneumonia is present. A severe primary viral, or secondary bacterial, tracheitis may cause inspiratory dyspnea with abnormal tracheal breath sounds transmitted to the lungs. Respiratory distress is evident on exercise. A short, explosive cough is characteristic of some outbreaks but not in others. Sudden death within 24 hours after first signs appear can result from extensive obstructive bronchiolitis.

In dairy cattle, many animals in a herd become affected within a few days. The disease is usually mild, characterized by inappetence, coughing, profuse bilateral serous nasal discharge, excessive salivation, nasal lesions, moderate fever, moderate drop in milk production, and recovery in a few days. Several animals may have the corneal form of the disease with obvious corneal edema, conjunctivitis, and profuse ocular discharge. The affected animals as a group do not return to full production for 10–14 days. The outbreak of respiratory disease will be followed by abortions in several days up to 90 days after the index case occurred.

In feedlot cattle the illness is often more prolonged, the febrile period is longer, the nasal discharge becomes more profuse and purulent, and the convalescent period is longer. Some deaths may occur in the acute febrile period, but most fatalities are due to a secondary bronchopneumonia and occur after a prolonged illness of up to 4 months in which severe dyspnea, complete anorexia, and final recumbency are obvious signs. Some recovered animals may have a persistent snoring respiration and a grossly thickened, roughened nasal mucosa accompanied by nasal discharge.

Ocular form of IBR

Conjunctivitis is a common finding in typical 'red nose', but outbreaks of conjunctivitis may occur as the major clinical finding. One or both eyes may be affected, which is easily misdiagnosed as infectious keratoconjunctivitis (pinkeye) associated with *Moraxella bovis*. However, the IBR lesions are confined to the conjunctiva and there are no lesions of the cornea except diffuse edema. The conjunctiva is reddened and edematous, and there is a profuse, primarily serous, ocular discharge. Calves less than 6 months of age may develop encephalitis, which is marked by incoordination, excitement alternating with depression, and a high mortality rate. Salivation, bellowing, convulsions and blindness are also recorded.[1]

Systemic disease in newborn calves

In newborn calves under 10 days of age, the systemic form of the disease is severe and highly fatal. Sudden anorexia, fever, excessive salivation, and rhinitis, often accompanied by unilateral or bilateral conjunctivitis, are common. The oral mucous membranes are usually hyperemic, erosions of the soft palate covered by tenacious mucus are common, and an acute pharyngitis covered by tenacious mucopurulent exudate is characteristic. The larynx is usually edematous and respiratory distress is common. Bronchopneumonia is common, and loud breath sounds, crackles and wheezes associated with consolidation are present. Outbreaks of the disease commonly occur in highly susceptible herds where the herd immunity has declined, the dams are not vaccinated, and there is minimal, if any, specific colostral immunity. Diarrhea and dehydration, referred to as the alimentary form of BHV-1 infection, occur in some affected calves. The cause of the diarrhea is uncertain but it may be related to the ruminal lesions.

Abortion

Abortion is a common sequel and occurs some weeks after the clinical illness or parenteral vaccination of non-immune pregnant cows with the MLV vaccine of bovine tissue culture origin. Abortion may occur up to 90 days following vaccination if the virus becomes latent in the placenta and infects the fetus much later than usual. This raises the possibility that vaccination even with safe vaccines may appear to be the cause of abortion if natural infection preceded vaccination. It is most common in cows that are 6–8 months pregnant. Retention of the placenta often follows, but residual infertility is unimportant. However, endometritis, poor conception and short estrus can occur after insemination with infected semen. The infectious bovine rhinotracheitis virus has been isolated from semen 12 months after storage.

Infectious pustular vulvovaginitis is characterized by frequent urination, elevation of the tail, and a mild vaginal discharge. The vulva is swollen, and small papules, then erosions and ulcers, are present on the mucosal surface. Mucosal ulcers may coalesce and sloughing of brown necrotic tissue may occur. Recovery usually occurs in 10–14 days unless there are complications.

Balanoposthitis is characterized by similar lesions of the glans penis and preputial mucosa.

CLINICAL PATHOLOGY

Virus isolation or detection

Isolation of the virus from nasal swabs using tissue culture, combined with a four-fold rise in antibody titers, between acute and convalescent phase sera are desirable for a positive diagnosis of the disease.[1] When using nasal swabs, cotton and polyester swabs are recommended rather than calcium alginate swabs, which are viricidal within 2 hours. The virus can be detected in nasal swabs by the use of an ELISA, direct and indirect immunofluorescence techniques, immunoperoxidase, and by electron microscopic examination which may reveal herpes-like viral particles. The sensitivity of the direct immunofluorescence techniques is comparable to the cell culture technique. The ELISA is highly sensitive. A combination of the indirect immunofluorescence test and virus isolation from both ocular and nasal swabs of several animals will increase the recovery rate.[1]

The PCR assay is as sensitive as virus isolation and is a practical alternative for the rapid detection of the virus.[1] The results are available in 1 day, compared to virus isolation which requires 7 days. Virus could be detected in nasal swabs for up to 14 days after experimental infection of cattle, and the assay can also detect the virus in bovine fetal serum and semen samples. The PCR assay can be used for detection of virus in semen and is considered equivalent to that of standard virus isolation and dot blot hybridization.[51] The PCR assay with Southern blot hybridization is considered to be highly sensitive and can detect the virus in semen before they develop any detectable antibody.[52] The PCR assay can also detect five times as many positive semen samples as the virus isolation on egg yolk-extended semen.[53]

Using restriction endonuclease analysis of viral DNA it is now possible to distinguish field isolates of the virus from vaccine strains, which may be useful in the investigation of vaccine-induced epidemics of the disease.

A PCR assay is used to screen large numbers of milk samples for the presence of BHV-4.[54]

Serology

Several serological tests are available for the detection of antibody and a rise in titer between the acute and convalescent phases of the infection.

The primary immune response to BHV-1 experimental inoculation of cattle is characterized by the formation of IgM and IgG antibodies, primarily IgG_1, by postinoculation day 7. Secondary immune responses are characterized primarily by the formation of IgG_2 antibody. A secondary immune response resulting from abortion induced by intra-amniotic virus inoculation is characterized by a substantial increase in IgM antibody. A secondary BHV-1 exposure by the intranasal route does not result in secondary IgM antibody formation.

The VN test has been widely used and is the standard by which other techniques have been evaluated.[55] The ELISA is a specific, sensitive, and practical test for detection of BHV-1 antibodies and has advantages over the SN test. The IgM–ELISA test is useful for the diagnosis of recent infection with BHV-1 in calves.[56] A micro-ELISA test is being used for the control program of BHV-1 infection in Switzerland. The test is simple, rapid, and convenient compared to the SN test, which requires cell culture facilities and is time-consuming.

The detection of latent BHV-1 infection in cattle is important in control programs and in international trade activities. Therefore, tests to detect specific antibodies in serum must be highly sensitive in order to detect low levels of BHV-1-specific antibodies.[57] This emphasizes the need for international standardization of tests to detect BHV-1-specific antibodies in cattle. In a comparison of European laboratories to evaluate a panel of test sera, including negative, weak and strong positive samples as well as international reference sera, VN tests and ELISAs demonstrate high specificity.[57] The quality of most laboratories was adequate. The VN test and the gB-specific ELISAs were most sensitive for the detection of antibodies in serum; the indirect ELISAs are the tests of choice for assaying milk samples. Most of the ELISAs demonstrate 100% specificity. Discrepancies occur with the low amounts of specific antibody. An indirect ELISA using undiluted test serum demonstrated 100% sensitivity. A commercial anti-BHV-1 blocking ELISA test kit is available to differentiate between cattle immunized with a marker BHV-1 vaccine and naturally infected cattle, but the sensitivity is only 74%.[58]

An immunofluorescence assay using monoclonal antibodies can discriminate between the four ruminant alphaherpesviruses related to the BHV-1.[4]

They include the bovine herpesvirus-5, caprine herpesvirus-1 (CpHV-1), cervine herpesvirus-1 (CvHV-1), and cervine herspesvirus-2 (CvHV-2). Buffalo herpesvirus-1 and elk herpesvirus are also closely related to BHV-1.[4]

Four serological tests have been evaluated to detect serum colostral antibodies to BHV-1 in calves.[59] A blocking ELISA demonstrated superior sensitivity in the detection of antibodies in calves up to 9–11 months of age compared to calves up to 7 months of age.[59]

The serological tests used for the BHV-1 eradication programs in The Netherlands

have been compared.[60] The combination of the gB-ELISA (for screening), and the Danish test – a blocking and an indirect ELISA (for conformation), provides a sensitivity of >99.0 % and a specificity of >99.9%.

Bulk tank milk testing for BHV-1 antibodies may be useful in eradication and monitoring programs because it offers the possibility of rapid and inexpensive screening.[61,62] The correlation between the bulk milk test and the within-herd prevalence of seropositive animals can be as high as 0.86.[61] If BHV-1 is detected in the bulk milk, there is a high probability that more than one animal in a herd is infected and that the infection has spread.[63] The BHV-1 blocking ELISA is in use on bulk milk samples as part of the Danish surveillance system for BHV-1 infection in dairy herds.[64] The test can detect seropositive herds, with prevalence proportions as low as one seropositive cow out of 70 cows.

Specific antibody against BHV-1 may be detectable in fetal fluids and increases the rate of diagnosis of abortion.

NECROPSY FINDINGS

In **adult cattle**, gross lesions are restricted to the muzzle, nasal cavities, pharynx, larynx and trachea, and terminate in the large bronchi. There may be pulmonary emphysema or secondary bronchopneumonia, but for the most part the lungs are normal. In the upper respiratory tract there are variable degrees of inflammation, but the lesions are essentially the same in all anatomical regions. In mild cases there is swelling and congestion of the mucosae. Petechiae may be present and there is a moderate amount of catarrhal exudate. In severe cases the exudate is profuse and fibrinopurulent. When the exudate is removed, the mucosa is intact except for small numbers of necrotic foci in the nasal mucosa but there may be diffuse denudation of epithelium in the upper part of the trachea. Lymph nodes in the throat and neck region are usually swollen and edematous. Histologically, there is acute, catarrhal inflammation of the mucosa. Inclusion bodies are rarely seen in natural cases but do occur transiently in the nuclei of respiratory epithelial cells in experimentally infected animals. Secondary bacterial invasion will cause a more severe necrotizing change, which is usually followed by the development of bronchopneumonia. The virus is usually isolated from affected tissues using cell culture techniques. It can also be demonstrated in paraffin-embedded tissues by utilizing immunohistochemical techniques.

In the systemic form in **neonatal calves** a severe epithelial necrosis has been observed in the esophagus and rumen, the adherent necrotic epithelium having the pultaceous quality of milk curd. The laryngeal mucosa is congested and edematous, with multiple focal lesions in the mucosa. Bronchopneumonia is common with a thick white exudate coating the tracheal lumen and extending into the bronchi. Histologically, there is necrosis of the pharynx, larynx, associated lymph nodes, esophagus, and liver. Inclusion bodies are evident in many surviving epithelial cells.

Aborted fetuses show moderately severe autolysis and focal necrotizing hepatitis. Microscopically, foci of necrosis rimmed by very few leukocytes are visible in the liver and many other organs. Occasionally, intranuclear inclusion bodies can be seen. Viral antigen can be demonstrated in sections of the lung, liver, spleen, kidney, adrenal gland, placenta, and in mummified fetuses using the avidin–biotin complex system. Using this system, the viral antigen can be found in fetal tissues from which virus could not be isolated in cell culture.

The **encephalitic form** lacks gross lesions but is characterized microscopically by non-suppurative inflammation, neuronal degeneration and gliosis, located particularly in the cerebral cortex and the internal capsule. Inclusion bodies are sometimes present. Both immunoperoxidase and PCR tests are capable of detecting BHV-5 antigen in formalin-fixed brain tissues affected with bovine herpesviral encephalitis.[65]

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed samples: *abortion/neonate*: lung, liver, trachea, kidney, adrenal gland, rumen, esophagus, pharynx; *respiratory form*: nasal turbinate, trachea, pharynx, lung; *encephalitic form*: half of midsagittally-sectioned brain (LM, IHC)
- **Virology** – *abortion/neonate*: lung, liver, kidney, rumen; *respiratory form*: lung, trachea, nasal swab; *encephalitic form*: half of midsagittally-sectioned brain (FAT, ISO, PCR).

DIFFERENTIAL DIAGNOSIS

Infectious bovine rhinotracheitis is characterized by acute rhinotracheitis, coughing, profuse nasal discharge, nasal septum lesions, bilateral conjunctivitis, anorexia, fever, and gradual recovery in a few days. Secondary bacterial tracheitis and pneumonia can occur. It must be differentiated from the following:

- Pneumonic pasteurellosis is characterized by marked toxemia and depression, coughing, anorexia, gauntness, fever, abnormal lung sounds, good response to antimicrobials
- Bovine virus diarrhea is characterized by depression, anorexia, salivation, oral erosions and ulcers, persistent diarrhea, dehydration and death in a few days
- Malignant head catarrh is characterized by remarkable mental dejection, prominent lesions of nares, severe erosive lesions in oral cavity, interstitial keratitis, enlarged peripheral lymph nodes, high persistent fever, hematuria, terminal encephalitis and death in several days
- Calf diphtheria occurs usually in a single animal and there is depression, fever, unable to suck or eat, inspiratory dyspnea and stridor, fetid oral and laryngeal lesions and the severe toxemia are typical
- Viral pneumonia of calves occurs in a group of calves and characterized mild depression, inappetence, fever, coughing, dyspnea, abnormal lung sounds, no nasal lesions and recovery in a few days
- Allergic rhinitis occurs in cattle on pasture in summer months and is characterized by sneezing and wheezing with inspiratory dyspnea, mouth breathing, normal temperature, profuse thickened nasal discharge caseous and greenish-orange in color
- Systemic form of IBR in newborn calves must be differentiated from acute pneumonia, septicemia, and toxemias.

TREATMENT

Antimicrobial therapy

Broad-spectrum antimicrobials are indicated if secondary bacterial tracheitis and pneumonia are present. Affected cattle should be identified, isolated, and monitored frequently for evidence of secondary bacterial disease accompanied by anorexia and toxemia, and treated accordingly. The tracheitis is particularly difficult to treat; antimicrobials daily for several days are necessary and often slaughter for salvage is the most economical course.

CONTROL

The diseases associated with the virus may occur unpredictably at any time, and even closed herds with no introductions may remain free of the disease for several years and suddenly experience an outbreak. The current strategies for control are **natural exposure, biosecurity, vaccination**, or **eradication** of the virus from a herd or even the cattle population of a country.

Natural exposure or vaccination

Natural exposure

Cattle that have recovered from a natural infection with the virus are immune to further clinical disease. However, to depend on natural exposure of the herd is risky because not all animals will become infected and become immune. Abortion storms occur in herds that are not

vaccinated and depend on natural exposure. Vaccination is therefore recommended in areas where the prevalence of infection is high and eradication is not feasible because of the extensive nature of the cattle population and movement of animals from one area to another.

Biosecurity

Biosecurity is any practice or system which prevents the spread of infectious agents from infected animals to susceptible animals or which prevents the introduction of infected animals into a herd, region or country in which the infection has not yet occurred. Biosecurity is an integral part of any successful livestock enterprise, and reduces the risks and consequences of introducing an infectious disease.[66] The components of biosecurity, include management and placement programs, farm layout, decontamination, pest control, and immunization. All of these factors directly affect productivity and profitability.

The introduction of new infections into herds can be prevented or minimized by purchasing animals directly from herds known to be free of a particular disease. The adoption of this principle requires awareness of the possibility of purchasing unknown infected animals and testing animals for the infection before entry into the herd. It may also require keeping the introduced animal in quarantine for several weeks after arrival before it is mixed with the other animals.

Veterinarians need to work with their clients to develop a specific disease control and biosecurity protocol for each farm. The benefits of a rigidly enforced biosecurity program need to be stressed. Veterinarians can assist producers in developing methods to handle livestock and to purchase replacement stock by designing protocols which concentrate on general and specific aspects, such as design and construction of isolation rates.

Closed herd. A closed farming system to prevent the introduction of infectious diseases into dairy farms is technically possible and is economical. A closed dairy farming system could prevent the introduction of BHV-1 and can be a good starting point for eradication of infectious diseases from the herd.

In the cattle industry, animals are moved freely from their farms of origin to veterinary clinics, cattle shows and sales, auction markets, 4H club events, and community grazing pastures. Cattle are commonly returned to their farms of origin after being at shows and sales, veterinary clinics and other events where animals from other farms are mixed. Animals may commingle with those from adjacent herds (broken fences or cattle breaching fences from one pasture to another). Breeding bulls may be leased from their farm or origin, used on another farm, and then returned to the farm of origin. The mixing of animals which occurs in all of the above circumstances provides opportunities for the transmission of important infectious agents.

Biosecurity of veterinary practices and veterinary teaching hospitals is now an important aspect of health management of food producing animals.

Vaccination

With currently available diagnostic tests, it is not possible to identify animals which have a latent BHV-1 infection. The next best strategy is to use a well-planned vaccination program.

Rationale for vaccination

The rationale for vaccination is based on the following:

- The virus is ubiquitous and the occurrence of the disease unpredictable
- Economic losses from abortion, neonatal disease, and respiratory disease can be high
- Colostral immunity in calves wanes by 4–6 months of age
- The vaccine will prevent abortions due to the virus and provide protection against respiratory disease if given at least 10 days before natural exposure.

Both the aerosol and IM administration of a virulent strain of the virus to colostrum-deprived seronegative cattle (6–12 months of age) results in comparable levels of serum antibody, but no measurable nasal secretory antibody. When these same cattle are challenged later by aerosol exposure they are protected from clinical disease and nasal secretory antibodies will develop.

Conventional vaccines

Based on the effectiveness of active immunization following natural exposure, both MLV and **inactivated virus** vaccines have been available.

Modified live-virus vaccines. There are two types of MLV vaccines. One is the parenteral Vaccine usually made with bovine fetal kidney tissue culture, and the other is an intranasal vaccine of rabbit tissue culture origin. An intranasal vaccine of bovine tissue culture origin containing a temperature-sensitive mutant is also available.

MLV vaccines offer three advantages over inactivated vaccines:

1. Induction of a rapid immune response
2. Relatively long duration of immunity
3. The induction of local immunity.

Protection from infection and disease has been observed within 40–96 hours following intranasal or IM vaccination with MLV vaccines.[40] This rapid development may be due to interferon induced locally, but intranasal vaccination also induces secretory IgA antibody and cell-mediated immunity. Vaccinational trials have found the traditional MLV vaccines are safe and effective in preventing clinical disease and are more effective than inactivated vaccines.[67]

Both the parenteral and intranasal vaccines stimulate the production of humoral antibody. The **intranasal vaccine** stimulates the production of local interferon and local antibody in the nasal mucosae, is safe for use in pregnant cows, and is highly effective for the prevention of abortion, due to the virus. The **parenteral vaccine** of bovine tissue culture origin is abortigenic, especially in non-immune cows. The intranasal vaccine provides protection against respiratory disease induced by experimental challenge 72 hours after vaccination. In general, the intranasal vaccine provides effective protection against the respiratory form of the disease but occasionally disease occurs in vaccinated animals. The intranasal vaccines do not cause a significant systemic reaction, and have been used in the face of an outbreak where all in-contact animals are vaccinated in an attempt to reduce the number of new cases.

A major requirement of the intranasal vaccine is that the vaccine virus must multiply on the nasal mucous membranes. If the vaccine is not administered into the nasal cavities carefully, or if the animal is difficult to handle or snorts out the vaccine, vaccination will not occur. The careful administration of a temperature-sensitive vaccine in 2 mL of diluent into one nostril is as effective as a two-nostril vaccination method using a total of 5 mL of diluent. The pre-existence of some local antibody from natural exposure or co-infection with a virulent strain of the virus may also restrict the multiplication of the vaccine virus, especially the temperature-sensitive mutants.

Temperature-sensitive BHV-1 MLV – An intranasal BHV-1 vaccine containing a MLV strain whose growth is restricted to the upper respiratory tract has been developed in Europe. The vaccine strain is chemically treated to produce a temperature-sensitive characteristic, so that it cannot replicate at the body temperature of the animal. Prebreeding vaccination of replacement heifers with the vaccine provides fetal protection.[68] The vaccine is efficacious and safe for use in pregnant cattle. Intranasal vaccination

stimulates both systemic and local cell-mediated immunity and antibody. Dairy cows develop antibodies within 2 months after the vaccination, and 30 months later 91% of the vaccinated animals that responded still had detectable antibodies.[69] A percentage of unvaccinated animals may also seroconvert suggesting, but not proving that vaccine virus has been transmitted to them. Thus vaccine-induced antibodies may persist for years and interfere with control programs that are based on serological monitoring.

Disadvantages of MLV vaccines – The extensive use of MLV vaccines has reduced the incidence of clinical disease but there are some potential disadvantages. MLV vaccines must be stored and handled properly to avoid loss of potency. The parenteral MLV vaccine is potentially abortigenic and cannot be used on non-immune pregnant cattle. The virus in MLV vaccines can also become latent following vaccination. Fatal, generalized BHV-1 infection has been associated with vaccination of beef calves under 3 days of age with MLV containing BHV-1 and PI-3.[27] An outbreak of meningoencephalitis occurred in purchased Holstein–Friesian male calves vaccinated intranasally at 1 and 3 weeks of age with a commercial MLV vaccine containing BHV-1, bovine virus diarrhea virus (BVDV), PI-3, bovine adenovirus infection type-7 and bovine respiratory syncytical virus (BRSV).[26] Parenteral vaccination was recommended as the proper vaccination protocol. The isolated virus was classified as BHV-1.1.[26]

Shedding of virus by vaccinated animals – There is some concern that vaccinated calves may shed the vaccine virus, which could then spread to pregnant cattle resulting in abortion. In calves vaccinated with the intranasal vaccines, the virus replicates in the respiratory tract and is shed for 7–14 days. In non-immune calves, replicating virus can be detected 9 hours after vaccination, with peak shedding occurring at 4 days. However, the intranasal vaccination of feeder calves at 7 months of age does not result in transmission of the vaccine virus to non-vaccinated animals co-mingled with the vaccinates. Calves vaccinated with a live temperature-sensitive mutant of BHV-1 vaccine were protected against clinical illness from experimental challenge, but excreted the virus 2 months later following treatment with corticosteroids. This emphasizes the general principle that the use of a MLV vaccine implies a continuing commitment to vaccination which may reduce the incidence of disease but is unlikely to eradicate the infection.

Inactivated vaccines. Inactivated virus vaccines were developed because of some of the disadvantages of MLV vaccines. They do not cause abortion, immunosuppression or latency, although they do not prevent the establishment of latency by field strains. They do not cause shedding and are safe for use in and around pregnant animals. They are also relatively stable in storage.

Inactivated vaccines, however, may not be as efficacious as MLV vaccines because of the potential for destruction of some of the protective antigens during the inactivation process. They require two doses of the vaccine and protection is not observed until 7–10 days following the second dose of the vaccine which is usually given 10–14 days after the primary vaccination.

A major disadvantage of both the MLV and inactivated vaccines is that neither allows for differentiation between vaccinated and naturally infected animals. These factors render conventional vaccines ineffective for a concurrent vaccination and eradication strategy, as well as inappropriate for use in breeding bulls for export market or artificial insemination units which demand BHV-1-free animals. These limitations, along with major advances in molecular biology and protein purification techniques, have encouraged the development of genetically engineered attenuated vaccines as well as nucleic acid-free subunit vaccines.

Subunit vaccines. A subunit vaccine contains only one or more of the antigens of the pathogen necessary to evoke protective immunity, and lacks the components that might cause unwanted side-effects.[38] The major surface glycoproteins of the BHV-1 are the antigens responsible for stimulating protective immunity. To produce a subunit vaccine containing only surface glycoproteins, the proteins are isolated from the virus of virus-infected cells, or the peptides can be synthesized. The major glycoproteins of BHV-1 originally designated gI, gIII and gIV are now named gB, gC, and gD,[38] and they induce high levels of antibody in cattle that are fully protected from experimental disease. The level of immunity based on serum antibody titers and protection against experimental challenge is much greater with the individual glycoproteins than are those immunized with commercially available inactivated vaccines.

BHV-1 subunit vaccines provide a number of advantages:

- They do not contain live virus and therefore cannot be shed to other animals, cause abortion or establish latent infections
- They prevent infection and disease
- They are not immunosuppressive
- Serological assays, based on one or more antigens not present in the vaccine provide a potential to differentiate vaccinates from naturally infected animals.

Prevention of infection by the use of a BHV-1 subunit vaccine combined with the use of a diagnostic test to identify infected cattle, offers the potential for vaccination of breeding bulls for artificial insemination units and export, as well as for eradication of the virus.

The potential disadvantages of subunit vaccines include:

- Because of the amount of glycoprotein needed, two immunizations may be necessary for protection
- Subunit vaccines will have to be compatible with the commonly available multivalent vaccines
- The efficiency of subunit vaccines is highly dependent upon the use of an effective adjuvant.

An experimental subunit vaccine containing truncated BHV-1 glycoprotein protected beef calves vaccinated at 3 and 7, or at 6 and 7, months of age from experimental aerosol infection with BHV-1, 12 days after the second vaccination. Vaccinated calves had higher levels of SN antibodies and nasal antibodies than control.[70] Low levels of maternal antibodies did not interfere with the antibody response of calves to two-dose vaccination at 4 and 5 months of age. The level of protection was similar in calves vaccinated at 3 and 7, or at 6 and 7 months of age, which suggests that calves can be primed with the first vaccination at an early age and respond well to revaccination at weaning. This provides a management strategy of the first vaccination at spring branding, and the second vaccination at weaning. The nasal and serum antibody levels in calves vaccinated at 3 and 4 months of age declined to negligible levels 3 months later which may be a disadvantage.

A subunit BHV-1 vaccine containing only the virus glycoprotein IV along with a recombinant *Mann. haemolytica* vaccine was compared with a MLV BHV-1 vaccine for the prevention of respiratory disease in feedlot calves.[71] The subunit vaccine was considered superior to the MLV BHV-1 vaccine in reducing mortality due to respiratory disease.

Marker vaccines. A marker vaccine is based on deletion mutants of one or more microbial proteins, which allows the distinction between vaccinated and infected animals based on respective antibody responses.[72] A marker vaccine must be accompanied by a diagnostic test,

which enables distinction of infected from vaccinated animals. These tests detect antibodies against a **glycoprotein that is lacking in the vaccine.** The desirable characteristics of the companion diagnostic test include:

- Antibodies detectable in 2–3 weeks after infection, both in vaccinated and unvaccinated cattle
- Antibodies must persist for at least 2 years, preferably lifelong
- A low level of virus replication gives rise to detectable antibody formation
- Cattle repeatedly given the matching marker vaccine remain negative in the test
- The test should be suitable to detect antibodies in milk
- A high sensitivity and specificity in comparison with conventional antibody tests.[72]

Mutants of BHV-1 have been developed by deleting one or more of the non-essential glycoproteins. Marker vaccines offer the advantage of evaluating the effect of vaccination on the circulation of the field virus under naturally occurring conditions. In a randomized clinical field trial the incidence of infection can be determined by measuring the number of cattle that develop antibodies against gE during the experimental period.[72] Vaccination of calves with a glycoprotein E-negative vaccine for BHV-1 was effective in reducing both the clinical signs and the excretion of challenge virus as early as 7 days after IM vaccination, or 3 days after intranasal vaccination.[73]

Experimental results demonstrate the efficacy of the potential marker vaccines. A thymidine kinase-deficient gC deletion mutant protected calves against disease and reduced shedding of virus following challenge.[74] A double vaccination with a killed gE-negative vaccine prevented clinical disease after challenge infection, and the duration peak of virus shedding was significantly reduced.[75] An intranasal vaccination with a live gE-negative vaccine reduced the challenge virus replication following contact challenge 2 days after vaccination.[76] A double vaccination with an experimental subunit gD BHV-1 vaccine was highly efficacious in preventing clinical signs after challenge, but also prevented replication and subsequent excretion of the challenge virus.[77] In some cases, the inactivated BHV-1 marker vaccine is more efficacious in reducing virus excretion after reactivation than a live marker vaccine.[78]

Using a gE-deleted BHV-1 strain, both a killed virus and MLV marker vaccine have been developed.[79] These vaccines induce all the relevant immune responses against BHV-1-specific immune reactions, including antibodies against gE. Both vaccines have the capacity to reduce, and even to stop, the spread of BHV-1. A serological test that detects gE-specific antibodies in serum and milk is also available.[79] These vaccines have been tested according to the current European requirements for the development of bovine vaccines. The live vaccine is safe in pregnant cattle and is considered safe for all kind of breeding cattle, including bulls. The live virus marker vaccine is also efficacious in the presence of maternal antibody, and vaccination of very young calves, irrespective of their BHV-1 status, can be recommended. An inactivated BHV-1 gE-negative vaccine resulted in only a slight decrease of about 1.4 liters per cow in milk production after a double vaccination.[80]

Combination or multivalent vaccines. The vaccines available for the control of diseases associated with BHV-1 infection are mostly multivalent antigen vaccines containing other respiratory pathogens such as PI-3, BRSV, and BVDV. Some also contain the antigens for the control of leptospirosis and campylobacteriosis. Vaccines containing only the BHV-1 are not in common use. A Canadian field trial to compare the serological responses in calves to eight commercial vaccines against BHV-1, PI-3, BRSV, and BVDV[81] found some differences. Antibody responses to BHV-1 were higher in calves vaccinated with MLV vaccines than in those vaccinated with the inactivated vaccines.[81] There were no differences in seroconversion rates and titers to BHV-1 between intranasal and MLV IM vaccines following a single vaccination. However, after double vaccination with MLV BHV-1 vaccines, both seroconversion rates and changes in titers to the virus were higher in calves vaccinated IM than in those vaccinated intranasally. Whether or not these differences in antibody titers reflect differences in vaccine efficacy against naturally occurring disease in the field situation is unknown.

The vaccination of calves with multivalent vaccines containing MLV or MLV and inactivated BHV-1 is associated with virus-specific interferon gamma production and protection from clinical disease due to challenge 5 days after a single vaccination.[82]

Immunization and latency

Immunization with vaccines, as with natural infection, does not prevent subsequent infection and the possibility of latency.

Vaccination programs in herds

Beef breeding herds. Beef calves should be vaccinated 2–3 weeks before weaning as part of a preweaning preconditioning program. Calves vaccinated with the parenteral MLV BHV-1 vaccine before colostral BHV-1 antibody titers reach low levels do not develop an immediate, active serological response, as indicated by serological titers, but are sensitized to the virus. Revaccination at a later date, when maternal antibodies have decreased to undetectable levels, results in a marked serological response. **Heifer and bull replacements are vaccinated at least 2 weeks before breeding.** When outbreaks of the respiratory disease occur in unvaccinated beef herds, all cattle in the herd may be vaccinated with the intranasal vaccine. Whether or nor beef herds should be vaccinated annually following the initial vaccination is uncertain. There are field reports of outbreaks of abortion due to the virus in beef cattle that were vaccinated 3 years previously, which suggests that revaccination of breeding females every 2 years may be indicated. Since both natural infection and vaccination results in latent infection it may be that the persistence of the virus, combined with natural exposure, may result in persistence of antibody. The duration of protective immunity following vaccination is uncertain, but usually lasts 1 year. Antibodies last for at least 5.5 years in heifers following experimental infection and complete isolation during that time.

The MLV BHV-1 vaccine given intranasally or parenterally can enhance the prevalence of infectious bovine keratoconjunctivitis in beef calves vaccinated between 4 and 10 months of age, when the risk for the ocular disease is highest. The explanation for the pathogenetic mechanism is uncertain.

Feedlot cattle. Feedlot cattle should be vaccinated at least 10 days before being placed in the lot, especially one in which the disease may be enzootic. If this is not done a high incidence of the respiratory form of the disease may occur in recent arrivals. If vaccination before arrival is not possible, the next best procedure is to vaccinate the cattle on arrival and place them in an isolation starting pen for 7–10 days during which time immunity will develop.

Prevention of pneumonia. A field trial of pre-shipment vaccination of cattle with a combination BHV-1 and PI-3 vaccine administered intranasally 3 weeks before shipment from western Canada to Ontario did not have a significant effect on treatment rates of the animals for pneumonia after their arrival in the feedlot. The vaccination trial was designed to examine the hypothesis that vaccination with a BHV-1 virus vaccine prior to the stress of shipment would decrease the incidence of bovine respiratory disease, most of which is pneumonic pasteurellosis.

Experimentally, vaccination of cattle with the BHV-1 virus vaccine prior to inoculation with an aerosol of BHV-1 virus, followed later by an aerosol of *Mann. haemolytica*, provides protection against the bacterial pneumonia. There was no significant difference between vaccinated and non-vaccinated animals in terms of liveweight gains and incidence rate of subclinical disease. A commercially available MLV BHV-1 intranasal vaccine has been used in veal calves for this purpose but the lack of controls makes it difficult to interpret the results.

Dairy cattle. The necessity of vaccinating dairy cattle will depend on the prevalence of the disease in the area and in the herd, and the movement of cattle in and out of the herd. A closed herd may remain free of BHV-1 infection indefinitely and vaccination may not be indicated. But to avoid unpredictable abortion storms due to the virus in dairy herds, **heifer replacements should be vaccinated for the disease 2–3 weeks before breeding.** Vaccination of a large dairy herd with a persistent BHV-1 infection has been successful in controlling the respiratory form of the disease. The intranasal vaccine has been used extensively in newborn calves in problem herds, but its efficacy at such an age is unknown. **The parenteral vaccination of beef calves under 3 days of age with a MLV BHV-1 and PI-3 vaccine caused high mortality.**[26] If the systemic form of the disease poses a threat to a potential calf crop, the pregnant cows could be vaccinated with the intranasal vaccine in late pregnancy; this will increase the level of colostral antibody available to the newborn calf and will provide newborn calves with protection against the highly fatal systemic form of the disease.[17]

Bulls intended for use in artificial insemination centers present a special problem of disease control because the virus in semen can have severe consequences on reproductive performance. Bulls that are seropositive to the virus must be considered as carriers and potential shedders of the virus, and should not be allowed entry to these centers. Not all bulls that are seronegative can necessarily be considered free of the virus, and regular attempts at the isolation of the virus must be made from preputial washing and semen. Bulls that become infected while at the centers should be kept isolated, and culled and replaced with clean bulls. Bulls from herds that routinely vaccinate against BHV-1 should not be vaccinated with conventional vaccines if destined for an artificial insemination center. Cattle destined for export should not be vaccinated in case importing countries prohibit the introduction of seropositive cattle. This will not guarantee that such animals will not become positive from natural infection. The use of marker vaccines has some potential in breeding bulls intended for artificial insemination units and for export.

Eradication

Eradication of the BHV-1 virus from a single herd or the cattle population in a country can be considered as an alternative to vaccination. One of the prerequisites for the exportation of pedigree cattle is that the animals are serologically negative, which requires that the herd be free of infection with BHV-1. With careful planning and health management, it is possible to establish a seronegative herd. In a preliminary study in one closed beef herd in which there was latent BHV-1 infection, the calves were raised in isolation separate from the cows, following weaning. All of the maternally derived BHV-1 titers in the calves decayed to zero at weaning time and remained seronegative while raised in isolation. Serologically positive animals are removed or culled, and only seronegative animals introduced into the herd.

In 1983, Switzerland began a national program for the eradication of IBR.[83] The disease was made notifiable and the use of vaccination was prohibited. The program is based on:

- Annual serological testing of the national herd
- Restrictions on the trade with seropositive animals
- First priority of eradication was given to farms with breeding animals
- Stepwise elimination of seropositive animals.

By 1987, the breeding stock was virtually free of IBR.[84] The virus was also eradicated from a beef feedlot farm in Switzerland that raised 750 calves over a period of 12–13 months for market at 500 kg BW. Seropositive animals were identified serologically, kept separate from seronegative animals, and monitored serologically every 3 months. Eradication was complete within 9 months.[84]

In other countries, control is being attempted by segregation and elimination of seropositive animals and reduction of animal movement to prevent spread. This approach is not feasible in countries with extensive cattle populations and where management practices result in movement of cattle from one region to another.

Eradication using marker vaccines. Some countries are beginning an immunization program with the marker vaccines, which will protect the cattle against disease but still allow differentiation between vaccinated animals and those that have been naturally infected and are potential carriers of the latent virus. These infected animals could be eliminated over a period of time. Successful eradication depends not only on the efficacy of the vaccine but also on the quality of the tests. False-positive test results can lead to unnecessary culling of cattle, an increase of costs, and reduced co-operation of farmers in the eradication program.

In The Netherlands, a compulsory eradication program for BHV-1 began in 1998. The program required that farms either vaccinate all cattle twice yearly or be approved for a certified BHV-1 free status – or SPF (specific pathogen free). To become a certified BHV-1 free herd, cattle have to be sampled individually and all seropositive animals culled as soon as their status is known. The BHV-1 free herd status is monitored by monthly bulk milk samples.[85] The spread of BHV-1 between herds can be prevented using a surveillance system of sampling herds annually, both individual milk samples and blood samples.[86]

Herds with BHV-2 infected (seropositive) animals are required to vaccinate with a glycoprotein E (gE)-negative BHV-1 vaccine.[87] The vaccine may be either an inactivated or live vaccine both based on a spontaneous BHV-1 mutant without the complete gE gene.[78] These so-called marker vaccines or 'diva' (differentiating infected from vaccinated animals) vaccines allow the identification of cattle infected with the wild-type BHV-1 within a vaccinated population using a gE-ELISA or a commercially available gE-blocking ELISA (Idexx) which both specifically detect gE antibodies. The eradication program is based on the presumption that all BHV-1 wild-type strains express gE and induce antibodies which can be measured with a gE-blocking ELISA.

The success of the marker vaccines depends on their capability to reduce transmission of the virus in the field. To prevent major outbreaks on a farm, the transmission ratio R_0 between animals must be below 1. If the Ro between animals is below 1 on all farms eradication of BHV-1 would be certain. However, even when Ro between animals is not below 1, eradication can still occur when the Ro between herds is below 1, because the reduced transmission within a farm, makes farms less susceptible and less infectious. For BHV-1 it is possible that vaccination with a live gE-negative vaccine would reduce Ro in a herd below 1.

The efficacy of a live E-negative BHV-1 vaccine to reduce the transmission of BHV-1 in cattle was evaluated in a randomized, double blind, placebo-

controlled field trial in 84 dairy herds in the Netherlands.[88] The incidence of BHV-1 infections during 17 months was monitored by detecting antibodies against glycoprotein E. The transmission ratio R_0 in the placebo-treated herds was estimated at 2.5 and 1.2 in the vaccinated herds. Thus the use of the live gE-negative BHV-1 vaccine reduces the incidence and transmission of infection in the field.[88]

Before the eradication program began, a large field trial to evaluate the efficacy of the live gE-negative BHV-1 vaccine found that some placebo herds, which were not vaccinated. were seronegative for gE-negative BHV-1, but seropositive for BHV-1 by glycoprotein B (gB) blocking ELISA.[87] The source of the gB seropositive occurrence was undetermined. Antibodies against BHV-5 may be differentiated from those of BHV-1 in a BHV-1 glycoprotein E blocking ELISA.[89] The gE-negative BHV-1 vaccine strain is not re-excreted after corticosteroid treatments, and not transmitted to susceptible cattle.[90]

An epidemiological and economic simulation model to evaluate the spread and control of BHV-1 in the Netherlands indicates that compulsory vaccination would be necessary to reach a BHV-1 free status.[91] Simulation modeling of BHV-1 control programs at the national level with special attention to sensitivity analysis has been described.[92]

Side effects of BHV-1 marker vaccine in the Netherlands

Between May 1, 1998 and February 22, 1999 it was compulsory for Dutch cattle farmers to take measures to control BHV-1. Cattle on farms not already certified as BHV-1 free had to be vaccinated twice yearly with a gE-negative BHV-1 marker vaccine. In February 1999, the Dutch Animal Service advised all veterinary practices to postpone vaccination against BHV-1 using the marker vaccine.[93] Severe disease had occurred in herds vaccinated with the marker vaccine. Using monoclonal antibodies, bovine virus diarrhea virus (BVDV) type 2 was found in the vaccine batch. Batches of vaccine which contained the BVDV type induced clinical signs of BVDV when inoculated into susceptible animals.[94] The first clinical signs of illness occurred 6 days after vaccination. Morbidity was up to 70%; on some farms none. During the first week feed intake and milk production decreased. In the second week, some animals become severely ill with fever, nasal discharge, and diarrhea. By the third week the number of affected animals increased rapidly and some died. Necropsy findings included erosions and ulcers of the digestive tract. Contamination of the marker vaccine with the BVDV was a consequence of infection of fetal calf serum used in vaccine manufacture. Vaccination of calves with a BHV-1 marker vaccine containing BVDV type 1 did not induce clinical disease.[95]

By the end of 1999, 6997 cattle farmers had lodged complaints related to the vaccine.[96] During the compulsory vaccination period, 13% of the herd vaccinations resulted in clinical disease and complaints.

Following recognition of the outbreaks associated with the marker Vaccine some dairy farmers identified a 'chronic wasting' syndrome in their cows which they attributed to the vaccine. field investigations of these cases could not associate them with the vaccine.[97,98] A review of the research into the chronic wasting syndrome of dairy cows found no evidence to associate the syndrome with the vaccine.[99] Vaccination of pregnant heifers in their third trimester experimentally with a high dose of the marker vaccine did not have any adverse effects.[100] Comparison of performance of dairy herds which were or were not vaccinated with the marker vaccine in 1998 could not discern any differences due the vaccine.[98]

Loss of certification. The probability of and risk factors for the introduction of BHV-1 into SPF Dutch dairy farms has been examined.[85] A total of 95 SPF dairy farms were monitored for 2 years during which time 14 introductions of infectious diseases occurred on 13 of the 95 farms for a total incidence rate per herd-year at risk was 0.09. Outbreaks were usually associated with allowing cattle to return to their farm, more often grazed cattle at other farms, and less often provided protective clothing to the veterinarian. For a successful eradication program, farms should remain BHV-1 free which can be achieved by a more-closed farming system.[101] A more-closed farming system is one which rules out the possibility of direct contact with other cattle from other farms. Also, the farmer requests that professional visitors like veterinarians and AI technicians to wear protective farm clothing when handling cattle. Protective farm clothing are coveralls or overcoats and boots which can be worn over 'off-farm' clothing and which the farmer provides to the visitors before handling cattle. A sanitary barrier is a covered area outside the barn in which visitors put on protective farm clothing over their 'off-farm' clothes. A sanitary barrier has a 'dirty' side, where visitors leave, their 'off-farm' boots and a 'clean' side, where visitors wear protective clothing and can enter the barn. All of these measures would be economical.[85]

CHRONIC ENZOOTIC PNEUMONIA OF SHEEP (CHRONIC NON-PROGRESSIVE PNEUMONIA, SUMMER PNEUMONIA, PROLIFERATIVE EXUDATIVE PNEUMONIA)

Synopsis

Etiology Unknown, multifactorial
Epidemiology Affects sheep under 12 months of age. Seasonal occurrence, summer and autumn in southern hemisphere. Common disease affecting most flocks but severity varies between farms
Clinical findings Insidious onset. Coughing, nasal discharge and uneven weight gain
Lesions Consolidation of anterioventral lobes of lung. Pleuritis
Diagnostic confirmation Postmortem lesions
Treatment Antimicrobials for severely affected individual sheep
Control No effective control procedure established

Enzootic pneumonia is defined here as the common, lowly pathogenic disease of sheep, particularly lambs, which is common in all sheep populations. The disease is recognized by different names in different areas of the world. It can be differentiated from the acute fibrinous pneumonia and pleurisy associated with *Mannheimia (Pasteurella) haemolytica*, which is often called enzootic pneumonia in the British literature, and from the chronic progressive pneumonias, maedi and jaagsiekte.

ETIOLOGY

Although the disease is well-known, its cause is not well defined. This is partly due to its **non-fatal** character, which leads to incomplete examination of early cases; most of those submitted for examination or necropsy are distorted by the addition of secondary bacterial invaders. It has a multi-factorial etiology. *Mycoplasma ovipneumoniae*, *Bordatella parapertussis*, chlamydia, parainfluenza-3 (PI-3) virus, adenovirus, a respiratory syncytial virus, and reovirus have been nominated as causes. *Mann. haemolytica* is a common secondary infection and may lead to more acute respiratory disease. The disease, which might be most accurately identified as **chronic undifferentiated enzootic pneumonia of sheep**, is probably a collection of etiologically specific diseases.

M. ovipneumoniae

M. ovipneumoniae is considered to be important in the disease complex and may be the initiating cause.[1–4] It is commonly isolated in large numbers from the lungs of affected sheep, but can also be isolated from the nasal cavity of some normal sheep and less occasionally from normal lung. Experimental challenge with pure cultures of the organism produces minimal lesions, but aerosol or intrabronchial challenge with homogenates of affected lung that contain the organism produces proliferative interstitial and lymphoid pneumonic lesions indistinguishable from the natural disease.[3,5] *M. ovipneumoniae* is a facultative pathogen that requires compromised lung defense mechanisms in order to initiate lesions; infection with this organism subsequently predisposes the lung to secondary infection with organisms such as *Past. haemolytica*.[1,3] There is considerable heterogeneity in *M. ovipneumoniae* and several different strains may be isolated from a pneumonic lung.[5] Differences between strains in pathogenicity are not determined. Other mycoplasma, including *M. mycoides* subsp. *mycoides*, *M. mycoides* subsp. *capri*, *M. putrifasciens*, and *M. arginini* may be associated with chronic enzootic pneumonia in tropical zones.[6]

B. parapertussis

B. parapertussis is a common isolate from the nasal cavities and lungs of sheep with chronic enzootic pneumonia and is also believed to have an initiating role in the disease.[7] It produces a cytotoxin that damages ciliated epithelium in the trachea and experimental challenge of colostrum-deprived lambs produces mild pulmonary lesions similar to those seen early in the natural disease. *B. parapertussis* also can predispose pneumonic pasteurellosis.[8]

Parainfluenza-3 (PI-3) virus

PI-3 is a cause of a mild undifferentiated pneumonia in sheep, and surveys around the world have shown that it is a widespread infection.[2–4] The disease is clinically mild and marked by the presence of interstitial pneumonia. Antibodies to PI-3 are present in lambs soon after birth, but the half-life is short and lambs are susceptible by the time they are weaned and mixed with other lambs, which is when clinical disease often occurs. In the experimentally produced disease in lambs[9] there is a slight seromucosal nasal discharge, coughing, increased sensitivity to tracheal compression, and fever of 40–41°C (104–106°F). At necropsy there is obvious hyperemia of the upper respiratory mucosa, including the trachea, the bronchial lymph nodes are enlarged, and there are small foci of catarrhal inflammation of pulmonary parenchyma of the apical and cardiac lobes.[9] However, challenge of lambs at 2 weeks of age with this

virus and *Mann. haemolytica*, while producing disease, did not result in prolonged disease lasting to slaughter, and it was concluded that these agents, without other factors, were not the cause of enzootic pneumonia.[10] This conclusion is supported by the results of vaccine trials with PI-3 against enzootic pneumonia.[11]

Bovine respiratory syncytial virus (BRSV)

BRSV has resulted in pneumonia following experimental challenge of sheep and is evidenced clinically by fever and hyperpnea, and pathologically by multifocal pulmonary consolidation and necrosis of epithelial cells. There is little evidence for BRSV as a cause of significant respiratory disease in sheep.[3,4,12]

Other agents

Adenovirus[13] and a type-3 *reovirus*[14] have been used experimentally to produce pneumonic lesions, and a vaccine has been produced to protect lambs against the adenovirus infection.[15] Similarly, sheep herpesvirus, *caprine herpesvirus-1*, will produce an interstitial pneumonia in experimentally challenged SPF lambs, but there is no evidence of a causal association with chronic enzootic pneumonia.

Autoantibodies to upper respiratory cilia have been detected in sheep colonized with *M. ovipneumoniae* and it is suggested that they contribute to the pathogenesis of coughing in this disease.[16]

EPIDEMIOLOGY

Occurrence

Enzootic pneumonia affects animals up to 12 months but may commence as early as 6 weeks of age. The disease can occur in both lambs at pasture and housed lambs. In many affected flocks, 80% of 4–5-month-old lambs have clinical signs and lesions, and the disease is credited with causing a significant **depression in growth rate** after weaning in lamb flocks with a high prevalence. This has been confirmed in controlled studies on the effect of the experimentally produced disease on weight gain in housed and pasture-fed lambs.[2–4]

Enzootic pneumonia has a **seasonal pattern** which differs according to locality and management. In Australia and New Zealand, the period of peak prevalence is in the late summer and autumn. In a longitudinal slaughter study of lambs in New Zealand the prevalence of pneumonic lesions was found to increase from early summer to early autumn with an overall prevalence of pneumonia of 42%. There were significant differences in prevalence between different regions of the country.[17] Factors such as **comingling** sheep from different sources and environmental stress can precipitate clinical disease.

Environmental risk factors

In Australia and New Zealand, clinical outbreaks of enzootic pneumonia in lambs aged 5–8 months are often associated with heat stress, frequent yarding after weaning, use of plunge or shower dips, and transport or mustering of sheep in hot dry conditions. Cases commence within 1–3 weeks after transport. In contrast in the United Kingdom and Europe this disease occurs primarily in the late winter and early spring and in the Northern hemisphere the disease is commonly associated with problems in the housing environment. In Ireland, an association has been made between the occurrence of lesions at slaughter and the extent of rain and windchill experienced by the sheep in the 2 months prior to slaughter.[18]

Economic importance

Death loss from this disease is minor but economic loss is considerable and includes reduced growth rate, prolonged periods on the farm before reaching slaughter weight, the drug and labor costs associated with treatment, slaughterhouse wastage, and downgrading of carcasses with pleural adhesions and an effect on carcass quality. The situation is similar to that with enzootic pneumonia of pigs.

CLINICAL FINDINGS

The disease is insidious in onset and persists in a group of lambs for 4–7 months. The **disease is mild** in its clinical manifestations, and the primary signs are poor and uneven weight gains, an increased nasal discharge, coughing, an increased respiratory rate, and respiratory distress with exercise. Increased intensity and a higher pitch of breath sounds are heard on auscultation over the region of the bronchial hilus, and sounds of fluid in the airways are heard in some cases at rest but can usually be elicited by inducing the lamb to cough. There may be periods of fever.

There is a relationship between the proportion of the lung affected with pneumonia and average daily gain and in one study weight gain was reduced by 50% when greater than 20% of the lung was affected.[17] The weight loss is most apparent clinically soon after the disease commences.

NECROPSY FINDINGS

At postmortem there are clearly demarcated areas of consolidation in the anterioventral lobes and there may be pleuritis with pleural adhesions. The diagnosis is on gross lesions and the presence of typical lesions on histological examination.[3,4]

TREATMENT AND CONTROL

Treatment is not usually undertaken unless there is secondary infection to produce acute respiratory disease. Control is based on the avoidance of stress factors that can exacerbate existing infection.

OVINE PROGRESSIVE PNEUMONIA (MAEDI, MAEDI-VISNA)

Ovine progressive pneumonia and **maedi** are North American and European terms for slow virus diseases of sheep in which a **chronic progressive pneumonia** is a major manifestation. The name maedi is derived from the Icelandic term for dyspnea. Maedi-visna virus can also produce visna which is a disease of the nervous system and is discussed elsewhere under that heading. Additional manifestations of infection are arthritis, indurative mastitis, and ill-thrift. These diseases have a close relationship with caprine arthritis encephalitis. La bouhite and Graff–Reinert disease are local names for maedi in France and South Africa, respectively. In the United States it was originally described as **Montana progressive pneumonia**, and in Holland as zwoergersiekte.

Synopsis

Etiology Ovine retroviruses
Epidemiology Most sheep infected as lambs. Persistent infection. High prevalence of infection in many countries but low prevalence of clinical disease. Transmission is via infected colostrum and milk but lateral transmission also occurs
Clinical findings Clinical disease of mature sheep, long incubation, long clinical course. Dyspnea and respiratory distress, initially with exercise but eventually also at rest. Some sheep also manifest chronic wasting and/or indurative mastitis
Necropsy findings Lungs uniformly increased in bulk with enlargement of bronchial and mediastinal lymph nodes. Lymphocytic interstitial pneumonia. Discrete or diffuse hardening of mammary glands with lymphoid infiltration
Diagnostic confirmation Clinical signs, pathology and serology. Serology provides confirmation of infection. PCR
Treatment None
Control Segregated rearing. Test and cull

ETIOLOGY

Maedi-visna virus and ovine progressive pneumonia virus are ovine lentiviruses; **non-oncogenic ovine retroviruses** which constitute a species of the lentivirus genus. They induce a **persistent infection** in sheep that may cause lymphoproliferative changes in the lung, mammary tissues, brain, and joints. There is a high degree of **relatedness** with the lentivirus associated with caprine arthritis encephalitis, and the ovine and caprine lentiviruses share nucleotide homology and serological properties.[1,2]

Although they belong to a single virus species, isolates obtained from naturally infected sheep are genetically heterogeneous, **antigenic drift** is common, and antigenic variation of the surface protein facilitates the persistence of the virus in the host. There is evidence for variation in pathogenic potential between isolates.

There is some evidence that the North American strains of ovine lentivirus may have originated from cross-species transmission of caprine arthritis–encephalitis virus rather than from maedi lentivirus,[3] but the similarity in clinical manifestation of maedi and ovine progressive pneumonia permits the discussion of these diseases as a single entity.

EPIDEMIOLOGY

Occurrence

The earliest reports of the disease were from South Africa and the United States, but it now occurs in **all major sheep-producing countries** with the **exception** of Australia, New Zealand, Iceland, and Finland. The disease was present in Iceland but was eradicated in 1965. Maedi virus was introduced into Iceland in 1933 by the importation of infected sheep, and because of breed susceptibility of the local sheep and management practices it developed to a problem of major national significance. In individual flocks the annual mortality was often 15–30% and in these circumstances sheep farming was not economically feasible. Approximately 105 000 sheep are believed to have died of the disease and 650 000 sheep had to be slaughtered in order to eradicate it from the country.[4]

The **international movement** of sheep has facilitated the spread of the disease and it is believed to have been introduced into Denmark, Norway, Sweden, and Great Britain since the 1970s through the importation of infected sheep. No other country has experienced the severity of disease that occurred in Iceland.

Host range

Sheep and goats are the only species known to be susceptible and infection cannot be established by experimental challenge in cattle, deer, pigs, dogs, horses, chickens, mice, and rats.[6] Rabbits are susceptible, but infection is limited to the acute stage prior to the production of antibody, and chronic infection does not occur as it does in sheep and goats.[5] A serological survey of **wildlife** in the United States has shown no evidence of infection in bighorn sheep, elk, white tail deer, or antelope.[5] All breeds of sheep appear to be susceptible to infection, but there may be differences in **breed susceptibility** based on breed differences in seroprevalence in flocks with more than one breed of sheep.[6,7] Differences in breed susceptibility are not consistent and it is possible that in any one flock they reflect differences in the susceptibility of family lines within the breed.[7] Apparent differences in breed susceptibility in surveys could also be a reflection of management differences between flocks and regions.[7,8]

Prevalence

The prevalence of infection varies between farms, breeds and countries. In the United States, true prevalence is not known, but a seroprevalence of 26% is recorded in samples voluntarily submitted from sheep in 29 States, and 48% of flocks had one or more seropositive sheep. An earlier study found 1–68% reactors in culled ewes from different States. Infection appears more common in western States.[9] A random nationwide survey in Canada[10] found 19% of sheep over 1 year of age with antibodies; 63% of flocks were infected, and the mean flock prevalence was 12%; similar prevalence rates are recorded for the province of Ontario.[11] The disease does not have significant national occurrence in countries such as the United Kingdom where infection has been introduced relatively recently, but there is concern that the prevalence may be increasing.[12,13] Prevalence rates vary markedly between countries and between flocks in the same country.[4,8,11,14]

There is considerable variation in the prevalence of seropositive sheep between flocks. Rates of seropositivity increase with age, and flock seroprevalence is influenced by the average age of the flock. **Flock seroprevalence** also has been positively associated with the use of foster ewes, allowing lambs older than 1 day to have contact with other lambing ewes, flock size, close contact during confinement for lambing, stocking density on pasture, and the length of time that the flock has been in existence.[10,11] Rates of seropositivity are much higher in flocks that also are infected with pulmonary adenomatosis than in those which are not.[15]

Transmission

The disease is spread by the respiratory route, by ingestion of infected milk and by in utero infection. The relative importance of these routes appears to vary with the flock and its management, but lateral transmission is important in all.

Lambs may contract the infection at birth, or shortly following, from contact with infected ewes or from ingestion of infected colostrum and milk. Mononuclear cells in the colostrum and milk of infected ewes are infected with virus and virus from these cells may pass through the intestinal wall to infect the lamb.[16] Lambs born to seropositive ewes have a significantly greater risk for infection than those from seronegative ewes, and lambs born to ewes that have been infected for a long time are at greater risk for infection. The chance of transmission to lambs from infected ewes increases with the period of contact but can occur within the first 10 hours of life.[7,11]

Lateral transmission can also occur in **older sheep**. Lateral transmission appeared an important method of transmission of the disease in Iceland and the Basque area and has been a significant component of the spread of infection of the virus in flocks in the United Kingdom since its initial introduction.[12,13,17] In some flocks, the spread of infection can be rapid and the majority of the flock can seroconvert within a few years of the introduction of infected sheep.[12,18]

Infection can be transmitted in utero but the relative importance of this route in the spread of the disease in flocks is debated.[13,19] Virus is also shed in the semen of infected rams that have leukospermia.[8]

The spread of infection is frequently very rapid in flocks that are concurrently infected with the retrovirus causing pulmonary adenomatosis.[12,20] Macrophages are numerous in the lungs of sheep affected with pulmonary adenomatosis, and these cells will be infected with ovine progressive pneumonia virus where there is a dual infection. The copious lung fluid produced by sheep with pulmonary adenomatosis contains maedi–visna virus in dual-infected sheep and is believed to increase the risk for lateral transmission.

Economic importance

The economic importance of the disease rests with losses associated with decreased longevity, mortality with clinical disease, decreased value of cull animals and possible effects of subclinical infection on productivity.

Clinical disease occurs in sheep 2 years old or older, usually in sheep 3 to 4 years of age and is more likely to appear when the infection prevalence exceeds 50%.[4] The **case fatality rate** is 100%. Whereas infection is common in many flocks, the occurrence of clinical disease is commonly rare as most infections are subclinical. High mortality rates occurred in infected flocks in Iceland and have been recorded in Texel flocks in The Netherlands and in some flocks in the USA, but this is the exception and in most infected flocks clinical disease is rare. Despite the high serological prevalence in areas of Canada, ovine progressive pneumonia is not a common diagnosis in the region's diagnostic laboratories.[21]

It is possible that the major economic loss associated with infection with these viruses rests with the effects of subclinical infection on **productivity** of infected flocks. Subclinical infection of breeding ewes in some flocks has been associated with a reduction in conception rate, as well as lowered birth weights in some flocks and/or reduced growth rates in their lambs.[14,18,21] The reduction in growth rate of the lamb has a significant association with changes in the udder of the ewe and probably results from lowered milk intake.[18] This may be reflected in depression of growth rate only in lambs from older parity ewes.[14] In other flocks there has been no evidence of effect on the birth weight or growth rate of lambs born of infected ewes.[6] Subclinical infection has no effect on mature ewe body weight or greasy fleece weight.[6]

PATHOGENESIS

The virus infects cells of the monocyte–macrophage lineage and attaches to cells by the binding of its envelope glycoprotein to specific receptors on the cell surface. The virus replicates its RNA genome via a DNA intermediate provirus which is integrated into the chromosomal DNA of infected cells. With initial infection there is virus replication; this is followed by an immune response that restricts viral replication but fails to eliminate the virus completely.[1] The immune response occurs between 2 and 8 weeks after infection, with antibody to different viral antigens emerging at different times during this period. Serological latency, with some sheep not developing an antibody response until several months after infection, is recorded.[8]

Replication is restricted and does not proceed beyond the synthesis of provirus in most infected cells. The principal virus replication is in the macrophage, and pulmonary secretions and milk containing infected macrophages are the main source of virus for natural transmission. Diseases such as **pulmonary adenomatosis**, which increases the number of macrophages in lung secretions, will facilitate transmission of ovine progressive pneumonia virus.

There is **persistence and replication** of virus in the presence of viral-specific immune responses, with the development of immune-mediated lesions in various organ systems. Persistent production of viral antigen results in lymphocytic hyperplasia. The infected macrophages in the various tissues are surrounded by an inflammatory response creating a focus of mononuclear cell aggregation. The lungs, mammary gland, brain, joints, lymph nodes, and blood vessels are affected by the maedi–visna/ovine progressive pneumonia viruses and, whereas any or all of these organs can be affected in a single sheep, breed and virus differences often lead to a predominance of a single syndrome in a flock.

In the **lung** there is a gradual development of an interstitial pneumonia without any evidence of healing or shrinkage of tissue, so that the lungs continue to increase in size and weight. The alveolar spaces are gradually filled so that anoxia develops. The pathological lesions develop very slowly during the preclinical and clinical stages of the disease, so that they are very widespread and uncompensatable when clinical signs appear. In the **central nervous system** there is infiltration of the meninges and white matter with lymphocytes. The demyelination that occurs in visna is believed to result from the direct effect of the virus on oligodendrocytes and astrocytes as well as being the result of an inflammatory response provoked by the presence of viral antigen in these cells.[22] Similar infiltrations occur in the **udder**. Lymphoid follicles are found in the alveolar parenchyma, often with atrophy of the alveolar tissue. Numerous lymphocytic follicles also occur around the lactiferous ducts, some of which may be occluded by lymphocytic aggregates protruding into their lumens.[22,23]

CLINICAL FINDINGS

There is a long incubation period and clinical disease, if it occurs, does not develop before 2 years of age. Most clinical sheep are older than 3 years. The clinical signs develop insidiously, progress slowly, and there is a **long clinical course**. The earliest signs are usually listlessness and loss of body condition which progresses to **emaciation**. The presenting syndrome can be one of an increased cull rate of ewes in poor condition. Signs of respiratory involvement are not evident in the initial stages of the disease, but there is exercise intolerance and affected sheep will fall back behind the flock when the flock is moved. **Dyspnea** with an increase in respiratory rate and flaring of the nostrils, or open mouth breathing, develops later. There is no evidence of excess fluid in the lungs. The respiratory rate is increased to 80–120/min at rest. There may be coughing and some nasal discharge but in most instances this occurs in sheep with secondary bacterial pneumonia. There may be inflammation of the third eyelid. The body temperature is in the high normal range. Clinical illness lasts for 3–10 months and the disease is always fatal. Clinically affected sheep are more prone to diseases such as pregnancy toxemia. In some sheep, clinical respiratory disease is minimal and the major manifestation is wasting and the **thin ewe syndrome**.

The involvement and induration of the **mammary glands** is also insidious in onset, and ewes are usually in their third or later lactation by the time the disease fully manifests, although histological change is evident earlier.[18,24] In early stages it is more easily detected at the time of drying off. In advanced cases the udder is enlarged and uniformly very firm, but the teats are limp and there is very little milk in the teat cistern. The milk is normal in appearance. Mammary involvement may occur, along with signs of respiratory infection, or affected ewes may show no other clinical abnormality. It is called colloquially **hard bag** or hard udder. The lambs of ewes with less severe involvement may show growth retardation.

Arthritis is occasionally seen in naturally infected sheep but this manifestation appears restricted to the United States. It occurs in sheep from 1 to 6 years of age. The carpal joints are most commonly involved and show obvious

swelling.[25] Affected sheep become lame and emaciated.

CLINICAL PATHOLOGY

There is a progressive, moderate hypochromic anemia, with hemoglobin levels falling from 12–14 g/dL down to 7–8 g/dL and some depression of the red cell count. There is a tendency to leukocytosis, and in experimental cases this is observed to be quite marked in the period between exposure and the onset of clinical disease, but the count returns to normal when signs appear. There is also hypergammaglobulinemia. Lymphocytes and neutrophils in bronchoalveolar lavage fluid are increased in number, with an increase in CD^+8 cells and decrease in CD^+4 cells and an inversion of the CD^+4/CD^+8 ratio.[26]

In clinical cases diagnosis is by the presence of the appropriate clinical syndrome, supported by the presence of a positive serological test for the virus. A positive serological test, by itself, has limited value as an aid to diagnosis of disease in the individual sheep, as there is a high prevalence of seropositivity in many flocks, especially in the older animals. A positive test does indicate that the animal is infected but does not indicate that signs or lesions are attributable to infection with the virus. Thus, for example, a positive serological test in a wasting ewe could only be considered as supportive for a diagnosis of this disease as the cause of the chronic wasting.

Flock status with respect to the presence or absence of infection and the determination of the infection status of an individual sheep currently relies on serological testing.

Antigen detection. Antigen can be detected by PCR but this detection method for this disease is not commonly available. PCR is a sensitive method for detection of small amounts of viral nucleic acid[27] but its expense is likely to preclude its use in routine diagnosis. It has been used to detect antigen in the third eyelid of infected sheep.[28]

Serological tests. Flock status with respect to the presence or absence of infection and the determination of the infection status of an individual sheep currently relies on serological testing. Agar gel immunodiffusion (AGID) tests, and ELISA tests are used in most countries. The AGID test is easy to perform and is inexpensive, and for these reasons is probably the most common test in use for routine diagnostic testing. The AGID test with the appropriate antigen is considered to have high specificity, but may lack in sensitivity.[8,27] Indirect ELISA and competitive ELISA tests may have better sensitivity, depending on the antigen used.[8,27] The slow development of antibody following infection must be considered in the interpretation of a negative test. An analysis of currently available teat systems showed high specificity but sensitivities that were inadequate for diagnosis of infection in individual animals – varying from 64% to 97%.[29] A competitive-inhibition ELISA for the detection of antibodies to the surface envelope antigens has a reported high sensitivity and specificity.[30]

The value of serological testing with current methodologies rests primarily with the establishment of the infection status of the flock. A negative test in an individual sheep could mean that the sheep is free of infection, but can also occur in an infected animal that has not yet responded to infection.

NECROPSY FINDINGS

Lesions may be present in the lungs and associated lymph nodes, brain, joints, mammary gland and blood vessels, but gross lesions in most sheep are confined to the lungs and, in some cases, the mammary glands. In advanced cases, the lungs are larger and two to four times as heavy as normal lungs. They collapse much less than normal when the chest is opened, and are gray-blue to gray-yellow in color. There is a diffuse thickening of the entire bulk of both lungs, and the abnormal color and consistency are generalized and unvarying in all lobes. Enlargement of the bronchial and mediastinal lymph nodes is constant. Histopathological changes are characteristic of a chronic interstitial pneumonia, with proliferation of lymphoid tissue and the presence of numerous lymphoid follicles. There is infiltration of lymphocytes and macrophages in the interalveolar septa, which are thickened, and the bulk of the alveolar space is replaced by the thickened alveolar walls. Larger airways are unaffected. There is a complete absence of healing, suggesting that the disease is a progressive one and never reaches a healing stage. A vasculitis is often a significant lesion.

There are frequently associated lesions of arthritis, encephalitis, and mastitis. The mastitic lesion comprises an interstitial accumulation of lymphocytes and the presence of periductal lymphoid nodules with atrophy of alveolar tissue.[18] Culture of the virus is difficult, and confirmation of the diagnosis is often limited to the presence of characteristic microscopic lesions, preferably supported by a positive serologic titer to the virus. Nucleic acid probe techniques discussed above are not yet widely available.

Samples for confirmation of diagnosis

- **Virology** – lung, mammary gland, synovial membrane, brain (ISO)
- **Serology** – heart blood serum (AGID, ELISA)
- **Histology** – formalin-fixed lung, bronchial lymph node, mammary gland, synovial membrane, half of midsagittally-sectioned brain (LM).

DIFFERENTIAL DIAGNOSIS

There are several chronic pneumonias requiring differentiation from maedi:

- Jaagsiekte
- Parasitic pneumonia
- Chronic suppurative pneumonia
- Caseous lymphadeniti
- Post-dipping pneumonia
- Enzootic pneumonia (pp. 1336–1343)
- Melioidosis (pp. 1082–1083).

Chronic wasting conditions:

- Johne's disease (pp. 1017–1044)
- Caseous lymphadenitis.

TREATMENT

No treatment has been successful.

CONTROL

In the past, the only control attempted has been eradication of the disease by complete destruction of all sheep in the area and subsequently restocking. However, it is possible to greatly reduce the prevalence by either of two methods.

Segregated rearing

This requires a management system of separating the lambs from the ewes at birth, giving them no colostrum, or bovine colostrum, and rearing them on milk replacer quite separately from other sheep. This method is effective in establishing an infection-free flock[31,32] and is of particular value where there is a requirement to retain genetic lines in the eradication procedure. However, it is very labor-intensive and expensive, and there is no cash flow unless the infected sheep are maintained in production pending the establishment of a mature infection-free flock. This can create a considerable potential for reinfection of the artificially reared flock.

Test and cull

This involves the detection and culling of scropositive animals and is the preferred method where lateral transmission is the dominant mode of transmission in the flock.[17] All sheep (and goats) on the farm are serologically tested annually or twice a year, and seropositive animals and their progeny of less than 1 year of age are culled. Ideally they should be slaughtered

but this may not be economically feasible, in which case they must be kept separate from the seronegative sheep. The seronegative flock must subsequently be kept isolated from infected sheep, as well as people and equipment in contact with the seropositive animals. Testing is continued semiannually or annually until there are at least two consecutive negative tests. The offspring of older seronegative ewes are kept for replacements.

Future flock introductions with both methods should be from a seronegative flock.

Other control procedures

Control procedures that attempt to limit or delay the spread of infection, and consequently the occurrence of clinical disease within an infected flock, have limited success. Shed lambing and close lambing is thought to be very conducive to spread of the disease and its discontinuance is recommended in infected flocks. In flocks that have a high incidence of clinical disease, the determination of the age of onset of clinical disease and the establishment of a culling policy based on this information can reduce the economic impact of the disease.

In countries where the disease is enzootic, there is often a great deal of movement of animals between farms, especially of rams, and in some management systems of replacement ewes. Flock introductions should be from seronegative flocks where possible. In several countries, breed societies, or other bodies, have established certification programs for flocks free of this infection. In the absence of such programs, severe restriction of inter-farm movement and outdoor housing may limit the spread of the disease.

The fact that some sheep in infected flocks retain freedom from infection in the face of continual exposure to infection suggests that there is a genetic resistance to infection. The identification of these determinants may prove to be the future method for the control of this disease. There is currently no effective vaccine.[8]

Flock biosecurity

Once infection is introduced to a flock it is difficult and expensive to eradicate and all efforts should be directed to prevent its introduction. The specificity and sensitivity of most currently available serological tests are inadequate to determine the infection status of an individual and the results of flock tests of a potential source of replacement sheep should be used coupled with an examination of postmortem records in the potential source flock, if available. Rams and replacement ewes should be acquired from accredited free flocks in countries where these are registered. The sheep should be transported directly from the source farm rather than through a market.

OVINE PULMONARY ADENOCARCINOMA (JAAGSIEKTE, PULMONARY ADENOMATOSIS)

Synopsis

Etiology Jaagsiete sheep retrovirus
Epidemiology Disease of mature sheep with geographic clustering but low prevalence. Spread probably mainly by respiratory route
Key signs Dyspnea, profuse watery pulmonary discharge, loud fluid sounds on auscultation, long clinical course with progressive emaciation
Pathology Tumors in lung
Diagnostic confirmation Histological changes are diagnostic and histopathological confirmation is the only method currently available
Treatment None
Control Culling

Jaagsiekte is Afrikaans for 'driving disease' because of the tendency for affected sheep to show clinical signs when driven. The disease manifests clinically as a chronic progressive pneumonia and is a contagious disease of sheep resulting from the development of a **bronchioalveolar adenocarcinoma** in the lungs.

ETIOLOGY

The disease is associated with an infectious betaretrovirus, jaagsiekte sheep retrovirus (JSRV) of the family Retroviridae. JSRV has two forms, an exogenous infectious form that alone can produce the disease and an endogenous RSRV-related provirus that is present in all sheep genomes.[1] The disease has been transmitted experimentally with partially purified retrovirus from infected lungs, by infection with cloned JSRV,[2,3] and supportive evidence for retrovirus as the causative agent includes an inverse dose relationship between reverse transcriptase activity in the infectious inoculum and the incubation period of the experimental disease.[2–4]

The presence of retrovirus has been demonstrated in the lungs of sheep with jaagsiekte in **different countries,** there is serological cross-reactivity and strains from different countries have been sequenced.[4]

A herpesvirus has also been isolated in several countries from the lungs of sheep with jaagsiekte but epidemiological studies show that it is not the causative agent.[3]

EPIDEMIOLOGY

Occurrence

The disease has worldwide distribution and is recorded in most countries that have significant sheep populations, with

the exception of Australia and New Zealand.[3] Until recently there has been no practical method to detect infected sheep and estimates of the prevalence of jaagsiekte are largely based on clinical or postmortem observations. The prevalence of the disease appears to vary depending upon the breed of sheep and the type of flock management. In most endemically infected flocks annual losses attributable to jaagsiekte are between 2% and 10%, although the tumor is present in a much higher proportion of the flock and infection without lesions is also common.[3-6] Annual mortality can be higher in flocks where the infection has recently been introduced and before the disease becomes endemic. PCR analysis of peripheral blood leukocytes of sheep in infected flocks show significantly higher rates of non-clinical infection.

Prevalence varies between countries and there can be **areas of high prevalence** within countries; in Britain, the Borders and the east coast of Scotland, and East Anglia in England, appear to be foci of infection from which other outbreaks arise.[3,6] The prevalence may be higher than generally recognized and, in a biased sample, histological evidence of jaagsiekte was detected in 25% of cases of pneumonia in sheep submitted to a diagnostic laboratory in Scotland over a 6-year period.[7] The disease is also a significant cause of mortality in adult sheep in South Africa and Peru, but is a minor disease in the United States and Canada.

The disease occurred in epizootic proportions in Iceland during the same period of time as the maedi-visna epizootic but has been eradicated by a rigorous slaughter policy.

Animal and environmental risk factors

Mature sheep, 2 to 4 years of age are most commonly affected but the disease can occur in younger animals. There are reports of the occurrence of jaagsiekte in goats at very low prevalence rates in India and Greece, and the disease has been experimentally transmitted to goat kids.[8,9] The lesions produced were small and circumscribed, and **goats have low susceptibility** to infection.[9]

Jaagsiekte has a prolonged clinical course and is **uniformly fatal**. In some reports there is a greater prevalence of onset of clinical disease in the winter months but in others there is no seasonal variation in clinical onset. Ewes may show a sudden onset of clinical disease in late pregnancy.

The **incubation period** in natural cases is 1–3 years, but may be as short as 5–12 months after experimental transmission. Clinical disease is rare in sheep younger than 2 years and is most common at 3–4 years of age. Very rarely, cases occur in lambs 3–6 months old and disease can be reproduced in lambs of this age by challenge of very young lambs.[3] A genetic or familial susceptibility to the disease is suspected.[3,6]

Because of the method of spread, the disease is likely to assume more importance in systems of sheep husbandry where there are significant periods of **close contact** as, for example, occurs with intensified lamb-rearing systems. Close housing during the winter is a potent predisposing cause and probably accounted for the occurrence of the disease in epizootic form in Iceland. However, the disease occurs commonly in range sheep in other countries. Sheep that have a **combined infection** with jaagsiekte and the maedi-visna lentivirus have an increased ability to transmit maedi-visna infection,[10] and flocks with the combined infection can suffer high losses from pneumonic disease.[11]

Transmission

Experimental transmission has been effected by pulmonary or IV injection, or by intratracheal inoculation of infected lung material.[3] The incubation period of the experimental disease in young lambs is much shorter than that in mature sheep. The disease has also transmitted by inhalation of infected droplets when sheep are kept in close contact, and it is assumed that the natural mode of transmission is by droplet infection from respiratory secretions, which are copious in sheep with clinical disease. A longitudinal study of the natural transmission showed that infection established readily and rapidly in young lambs and also horizontally in adult sheep, but that the majority of infected sheep did not show clinical disease during their commercial life span.[5]

PATHOGENESIS

The virus replicates in the **type II pneumocytes** in the alveolus. Type II pneumocytes and Clara cells in the terminal brochioles are transformed, and their growth produces intra-alveolar and intrabronchiolar polypoid ingrowths. These cells are surfactant-producing secretory cells and there is also copious production of fluid. The excessive surfactant-like protein produced in the tumor provides a stimulus for the accumulation of macrophages seen in association with this disease. The adenomatous ingrowths of alveolar epitheliums encroach gradually upon alveolar air space so that anoxic anoxia occurs. The lesions produced by experimental inoculation are identical with those of the naturally occurring disease.[3]

CLINICAL FINDINGS

Affected sheep are afebrile and show progressive respiratory distress with loss of weight. Clinical signs are not evident until a significant proportion of the lung is compromised by the tumor. Occasional coughing and some panting after exercise are the earliest signs but coughing is not a prominent sign in this disease unless there is concurrent parasitic pneumonia. Emaciation, **dyspnea,** lacrimation and a **profuse watery discharge from the nose** follow. Death occurs 6 weeks to 4 months later. A diagnostic test, colloquially known as the **wheelbarrow test**, in this disease is to hold the sheep up by the hind legs: in affected animals a quantity of watery mucus (up to about 200 mL) runs from the nostrils. **Moist crackles** are audible over the affected lung areas and may be heard at a distance, so that a group of affected animals are said to produce a sound like slowly boiling porridge. There is no elevation of body temperature unless there is secondary infection, and the appetite is normal. Advanced cases may have cor pulmonale. Pasteurellosis (*Mannheimia haemolytica*) is a common complication and often the cause of death.

CLINICAL PATHOLOGY

No immune reaction can be detected in affected animals and there is no serological test. Sheep in advanced stages of the disease may show neutrophilia and lymphocytopenia. The pulmonary fluid contains round or spherical clusters of epithelial cells, which have the hyperplasic adenomatous epithelium typical of pulmonary lesions and increased numbers of macrophages. Earlier reports of a consistent elevation in circulating immunoglobulin concentrations have not been substantiated. JSRV can be detected by exogenous JSVR specific PCR in peripheral blood leukocytes.[12,13]

NECROPSY FINDINGS

Lesions are usually restricted to the thoracic cavity. As in maedi, the lungs are grossly increased in size and in weight (up to three times normal). There are extensive areas of **neoplastic tissue**, particularly of the anterioventral regions of one or both lungs, with smaller lesions in the diaphragmatic lobes. The affected areas are solid and slightly raised above the adjacent normal lung. This, with the excess frothy fluid in the bronchi, is characteristic. The bronchial and mediastinal lymph nodes are enlarged and hyperplastic, and occasionally contain small metastases. Pneumonic pasteurellosis is a frequent complication, and secondary pulmonary abscesses and pleurisy may develop. Histologically, the alveolus is lined by cuboidal and columnar epithelial

cells that form characteristic **adenomatous ingrowths** of alveolar epithelium into the alveolar spaces.

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed lung, bronchial lymph node (LM).

DIFFERENTIAL DIAGNOSIS

Chronic pneumonias requiring differentiation from jaagsiekte:

- Maedi
- Parasitic pneumonia
- Chronic suppurative pneumonia
- Caseous lymphadenitis
- Post-dipping pneumonia
- Enzootic pneumonia
- Melioidosis.

TREATMENT

No treatment is available.

CONTROL

In Iceland, where the disease assumed epizootic proportions, eradication was effected by complete slaughter of all sheep in the affected areas. In areas where the prevalence is lower, the disease can be satisfactorily controlled, but not eradicated, by slaughter of the clinically affected sheep. There is evidence that the disease is spreading in sheep populations in some countries, and flocks that are free of disease should attempt to obtain replacement sheep from flocks that are free of jaagsiekte. Infected flocks can reduce the prevalence of disease by culling sheep at the onset of clinical signs, and also culling the progeny of affected ewes. PCR can detect infection in the preclinical stages but there has been no trial to establish if eradication from a flock can be achieved with this technology.

ENZOOTIC NASAL ADENOCARCINOMA OF SHEEP AND GOATS (ENZOOTIC INTRANASAL TUMOR)

Intranasal adenocarcinoma has been recorded as a sporadic disease of sheep and goats for many years but it is now recognized that it is a contagious neoplasm in these species. The disease in sheep and goats is associated with related but different retroviruses, the ovine nasal adenocarcinoma virus (ENT-1) and the caprine adenocarcinoma virus respectively. These retroviruses are highly homologous with the retrovirus that causes jaagsiekte (JSVR) but can be distinguished by unique sequences of the genome.[1] Nasal adenocarcinoma is not a component of the disease jaagsiekte, nor are pulmonary tumors present in sheep and goats with nasal adenocarcinoma. Infections with the viruses of enzootic nasal adenocarcinoma and jaagsiekte can occur in the same sheep and this can potentiate the proliferation of jaagsiekte virus in the infected sheep.[2]

Enzootic nasal adenocarcinoma is recorded in the United States, Canada, Europe, Japan, India, and Africa[3] and is believed to occur on all continents except Australia and New Zealand and is not present in the UK.[1] The disease occurs sporadically but is often clustered in certain flocks and herds, and is assumed to transmit by the respiratory route. The prevalence in affected flocks varies in different countries. It is generally less than 2% but can be as high as 10–15%.[1]

There is no seasonal occurrence and no apparent breed or genetic predisposition.

There is no apparent influence of nasal myiasis on the prevalence of nasal adenocarcinoma in infected flocks.[4]

Clinical disease is recorded occurring as early as 7 months of age but most occurs in mature sheep between 2 and 4 years-of-age. Affected animals are afebrile, have a profuse seromucous or seropurulent nasal discharge, and sneeze and shake their head frequently. There is depilation around the nostrils. The tumor may be unilateral or bilateral.

As the disease progresses, there is dyspnea, stertorous breathing with flaring of the nostrils at rest, and open-mouthed breathing following exercise. Some animals develop facial deformity and protrusion of one or both eyes from tumor growth, and the tumor may protrude from the nostril. There is progressive loss of weight, emaciation, and death after a clinical course of 3–6 months. There is no detectable immune response in affected animals.

At **postmortem**, the tumor masses are in the ethmoid turbinates, with metastasis to regional lymph nodes in some cases. The tumors may be unilateral or bilateral and are gray or pink in color with a granular surface. The tumors originate in the serous glands of the turbinates and have the histological features of adenocarcinoma.[1]

The disease has been transmitted experimentally in both goats and sheep with challenge of young kids resulting in disease at 12–16 months of age.[5,6]

Viral diseases characterized by nervous signs

EASTERN AND WESTERN VIRAL ENCEPHALOMYELITIS OF HORSES

Synopsis

Etiology Eastern encephalitis and Western encephalitis viruses
Epidemiology Disease limited to the Americas. Arthropod, usually mosquito, borne virus. Mammals, including horses, are accidental hosts. Horse is dead-end host for EEE and WEE. Case fatality rate 5–70%. WEE and EEE occur as sporadic cases and as outbreaks
Clinical signs Fever, muscle fasciculation, severe depression, head pressing, incoordination, recumbency, opisthotonos and paddling, and death
Clinical pathology Leukopenia
Lesions Non-suppurative encephalomyelitis
Diagnostic confirmation Virus isolation and identification. Identification of viral antigen by indirect immunofluorescence. Serological confirmation of exposure, preferably demonstrating an increase in hemagglutination inhibition, virus neutralization, or complement fixation titer
Treatment No specific treatment. Supportive care
Control Vaccination with formalin-inactivated vaccines (EEE, WEE). Insect control

ETIOLOGY

Equine encephalomyelitis is associated with one of the two immunologically distinct arthropod borne alphaviruses (family Togaviridae): **Eastern equine encephalomyelitis** virus (EEE), **Western equine encephalomyelitis** virus (WEE).

- There is one EEE virus strain, but two antigenic variants of it: North American and South American[1]
- WEE likely arose as a recombinant of EEE and Sindbis virus.[2] There are strains of WEE from Argentian, Brazil, and South Dakota that differ antigenically[2] and there are 4 major lineages of WEE in California whose geographical distributions overlap.[1,2]

All the viruses are extremely fragile and disappear from infected tissues within a few hours of death. **WEE** is the least virulent of these viruses in horses and humans.

EPIDEMIOLOGY

These encephalitis viruses cause disease in horses, humans, pigs, and various birds including ratites and domestic pheasants.[3]

Distribution

Equine Eastern and Western encephalomyelitis viruses are restricted to the Americas. The two viruses have distinct geographical ranges that may overlap: **EEE** is restricted to South America and North America generally east of the Mississippi river whereas **WEE** is found west of the Mississippi river and predominantly in the western United States and Canada, although it also occurs in Florida and South America.

Viral ecology

Humans, horses, cattle, pigs, dogs, and ratites are accidental hosts of the virus. The EEE and WEE viruses are normally maintained in a host–vector relationship by cycling between mosquitoes, and some other hematophagous insects, and the definitive host. However, there are some important differences in the ecology of the different viruses.

Western equine encephalomyelitis

The definitive hosts of endemic WEE are wild birds, which are not clinically affected, and the vectors are the mosquitoes *Culex tarsalis* (in the western United States) and *Culiseta melanura* (in the eastern and southern United States).[4] Infected mosquitoes bite susceptible birds, usually nestlings or fledglings, that then develop viremia. Mosquitoes are infected by feeding on viremic birds or by vertical transmission.[5] Vertical transmission is likely an important over-wintering mechanism in WEE, and possibly EEE.

Epidemics of WEE are uncommon, but sporadic individual cases are not. Epidemics of WEE are associated with factors that increase the number of infected mosquitoes or their feeding on susceptible (unvaccinated) horses. The disease in horses occurs in mid-summer and fall, and is associated with a change in the feeding habits of *Culex tarsalis*.[6] Horses, and humans, are dead-end hosts, as the viremia in these species is not sufficiently severe to allow infection of feeding mosquitoes.

Eastern equine encephalomyelitis

The primary **maintenance cycle of EEE virus** is transmission between passerine birds by the mosquito *Culiseta melanura*, an inhabitant of drainage ditches and swamps.[4] However, other mosquitoes, including *Aedes solicitans* and *A. vexans*, can propagate the virus through infection of large shore birds. The Carolina chickadee and yellow-crowned night-heron are the most common avian hosts in the southeastern United States.[7] Horses are usually dead-end hosts, although viremia may be sufficiently severe in some horses to permit infection of mosquitoes.[4] The reservoir of the virus during winter is not known, but may involve the vertical transmission of infection to larvae that survive the winter.

Epidemics of EEE have occurred in the provinces of Ontario and Quebec, in virtually all the states of the United States east of the Mississippi River, and in Arkansas, Minnesota, South Dakota, and Texas, in many of the Caribbean Islands, in Guatemala, Mexico, and Panama, and in Argentina, Brazil, Columbia, Ecuador, Guyana, Peru, Suriname, and Venezuela.[1] Eastern equine encephalomyelitis continues to cause significant death losses annually in horses in Florida, primarily in unvaccinated horses.[8] It is suggested that the incidence of clinical disease due to EEE in Florida is much higher than reported, and there is a need to increase public awareness about the importance of vaccination, particularly in foals.[8] **Unexpected epizootics** occur in inland States of the United States, and frequently the source of the infection is undetermined, although **meteorological factors** that allow rapid movement of infected mosquitoes may be important. For instance, in 1972, outbreaks of EEE occurred in Quebec, Canada and in Connecticut, USA that originated with mosquitoes carried on surface winds from Connecticut to Quebec, a distance of 400 km, in 14–16 hours at a speed of 25–30 km/h and a temperature of 15°C.[9] There may be a continual cycle of EEE virus in mosquitoes and birds in the southeastern US, from where the virus could be distributed by infected mosquitoes on the wind along the Gulf and Atlantic Coasts and up the Mississippi Valley.[10]

Animal risk factors

Recovered horses are resistant to infection for at least 2 years, and vaccination confers immunity of variable duration (see under 'Control'). **Unvaccinated horses** are at increased risk of disease – the risk of a vaccinated horse contracting EEE is only 0.14 that of an unvaccinated horse.[8,11] The disease is more severe, and mortality is higher, in unvaccinated horses than in vaccinated horses.[12] The mortality in young foals from non-immune mares, that are infected with WEE, is always high, often as high as 100%.

Housing and **exposure to mosquitoes** are important risk factors for EEE, and presumably WEE. During an outbreak in 1831, only horses kept at pasture were affected.[13] The use of **insect repellants** reduces the odds of a horse being infected with EEE to 0.04 that of an unprotected horse.[11] Similarly, keeping horses at pasture near woods increases the risk of disease by almost four times, and the presence of **swamp land** increases the risk by over two times.[11] Horses kept in areas with **high precipitation** have an increased risk of the disease, presumably because of the density of mosquitoes in these areas.[14]

Morbidity and case fatality

Morbidity varies widely depending upon seasonal conditions and the prevalence of insect vectors; cases may occur sporadically or in the form of severe outbreaks affecting 20% or more of a group. The prevalence of infections, as judged by serological examination, is much higher than the clinical morbidity. The **case fatality rate** differs with the strain of the virus; in infection with the WEE virus it is usually 20–30% and with the EEE it is usually between 40 and 80% and may be as high as 90%.

Zoonotic implications

The **susceptibility of humans** to the causative virus gives the disease great public health importance. Humans can become infected with the EEE virus and the WEE virus.[1]

PATHOGENESIS

Inapparent infection is the mildest form of the disease and may be characterized by only a transient fever. A more severe form of the disease is manifested by tachycardia, depression, anorexia, occasional diarrhea, and fever.

A transitory **viremia** occurs at the height of the fever. Penetration of the virus into the **brain** does not occur in all cases and the infection does not produce signs, other than fever, unless involvement of the central nervous system occurs. The lesions produced in nervous tissue are typical of a viral infection and

are localized particularly in the **gray matter of the cerebral cortex, thalamus and hypothalamus**, with minor involvement of the medulla and spinal cord. It is this distribution of lesions that is responsible for the characteristic signs of mental derangement, followed at a later stage by paralysis. The early apparent blindness and failure to eat or drink appear to be cortical in origin. True blindness and pharyngeal paralysis occur only in the late stages.

CLINICAL FINDINGS

The diseases associated with EEE and WEE viruses are **clinically indistinguishable**. The **incubation period** for EEE is 1–3 days and 2–9 days for WEE. Uncomplicated disease usually lasts about 1 week. In the initial viremic stage there is fever, which may be accompanied by anorexia and depression, but the reaction is usually so mild that it goes unobserved. In the experimental disease, the temperature may reach 41°C (106°F) persisting for only 24–48 hours, with signs of neurologic dysfunction appearing at the peak of the fever. Animals that have signs of neurologic disease for more than 24 hours are often not pyrexic.

Initial signs of neurologic disease include hypersensitivity to sound and touch, and in some cases transient periods of excitement and restlessness, with apparent blindness. Horses can have a period of anorexia and colic before onset of signs of neurologic disease. Affected horses may walk blindly into objects or walk in circles and in severe cases can mimic signs of horses with catastrophic intestinal disease. Involuntary muscle movements occur, especially tremor of shoulder and facial muscles and erection of the penis. A stage of severely depressed mentation follows. Affected horses stand with the head hung low; they appear to be asleep and may have a half-chewed mouthful of feed hanging from the lips. At this stage the horse may eat and drink if food is placed in its mouth. The pupillary light reflex is still present. The animal can be aroused, but soon relapses into a state of somnolence.

A stage of **paralysis** follows. There is inability to hold up the head, and it is often rested on a solid support. The lower lip is pendulous and the tongue protrude from the mouth. Unnatural postures are adopted, the horse often standing with the weight balanced on the forelegs or with the legs crossed. Head-pressing or leaning back on a halter are often seen. On walking, there is obvious incoordination, particularly in the hindlegs, and circling is common. Defecation and urination are suppressed and the horse is unable to swallow. Complete paralysis is the terminal stage. The horse goes down, is unable to rise and usually dies within 2–4 days from the first signs of illness. A proportion of affected horses do not develop paralysis and survive, but have persistent neurological deficits.

Pigs

EEE causes an encephalitis and myocarditis of piglets less than 2 weeks of age.[3] The disease is characterized by incoordination, seizures, vomition, weight loss, and paddling. Recovered piglets can have retarded growth.[3]

CLINICAL PATHOLOGY

There are no characteristic hematological or biochemical abnormalities. The absence of biochemical indication of liver disease (hyperbilirubinemia, increased activity in serum of liver-specific enzymes such as sorbitol dehydrogenase or gamma glutamyl transferase, absence of hyperammonemia) rules out hepatic encephalopathy.

Diagnostic confirmation is achieved by one or more of several means:[6]

- Isolation of virus from an affected animal
- Detection of viral antigen or nucleic acid in an animal with appropriate clinical signs
- Seroconversion or an increase in serum titer of sick or recovered animal.

Virus isolation provides definitive proof of infection. However, viremia may have resolved by the time nervous signs have developed, and it may be advantageous to sample febrile animals instead of animals showing more advanced signs of the disease. Virus can be cultured in intracranially inoculated suckling mice, weanling mice, guinea pigs, cell culture, newly hatched chicks, or embryonated eggs.[1] Virus isolates can be identified by complement fixation, hemagglutination inhibition, virus neutralization, PCR, IFA, and antigen capture ELISA.[1,6] Acute and convalescent sera taken 10–14 days apart for the presence of neutralizing, hemagglutination-inhibiting, or complement-fixing antibodies in the serum of affected or in-contact horses, is of value in detecting the presence of the virus in the group or in the area. A four-fold increase in complement-fixing antibodies is considered positive.

Demonstration of viral nucleic acid in tissue, blood or insects by PCR test may be a useful indicator of the presence of the virus.[15] There may be sufficient viral antigen to be detected by ELISA in clinical material, and this may provide a useful test in the early stages of an epidemic.[6]

The presence of a high her agglutination-inhibition, compleme fixation and neutralizing antibody in **single serum sample** obtained from horse during the acute phase of illne associated with the WEE virus can be us as presumptive evidence of infection, wi this virus.[16] However, antibodies agair the WEE virus can persist for years, a produced after vaccination with WEE WEE/EEE bivalent vaccines, and in foa might be due to colostral immunity. Ther fore, a single serum sample cannot be us to make a confirmed diagnosis of WI using the hemagglutination-inhibitio complement fixation or neutralization tes Horses infected experimentally or natura with either the WEE or the EEE virus not produce detectable hemagglutinatio inhibition or neutralizing antibody f 5–10 days after infection.

Circulating antibody appears on near the day of onset of clinical illnes Infection with the WEE virus results in t production of serum IgM specific to WE and the ELISA test is a rapid, sensitiv and specific test for IgM against WI and EEE viruses.[3] Additionally, the rat of titers of EEE and WEE can be usef in detecting infection by EEE – rati of >8:1 are highly suggestive of EI infection.[17]

NECROPSY FINDINGS

The brain meninges may appear co gested, but there are generally no gro changes. Histological examination of t brain reveals perivascular accumulatio of leukocytes and damage to neurons The gray matter of the forebrain a midbrain are the most severely affect areas. Lesions associated with EEE antig are also present in myocardium, stomac intestine, urinary bladder, and spleen.[19]

Cell culture and transmission expe iments utilizing brain tissue as inoculum are the traditional means confirming a diagnosis, and require th the brain be removed within an hour death. Transmission is by intracereb inoculation of brain tissue into sucki mice or duck embryo tissue cultu Fluorescent antibody tests have be developed to detect EEE virus in bra tissue.[20] A PCR-based diagnostic test available for EEE virus.[21] Lesio generally similar to those seen in hors have also been described in a beef c infected with EEE.[22] **The disease piglets** is characterized by disseminat perivascular cuffing, gliosis, focal necro of the cerebral cortex, and multifo myocardial necrosis.[3]

Samples for postmortem confirmation of diagnosis

- One half of midsagittally-sectioned brain and liver and spleen should be

submitted for fluorescent antibody and PCR testing, virus isolation and bioassay
- One half of midsagittally-sectioned brain, fixed in formalin, should be submitted for light microscopic examination.

Note the zoonotic potential of these organisms when handling the carcass and submitting specimens.

DIFFERENTIAL DIAGNOSIS

Clinically, the disease has very great similarity to the other viral encephalomyelitides, from which it can often be discriminated by the geographical location of the horse, and to the hepatic encephalopathies and a number of other diseases (see below and in Table 22.1).

West Nile encephalitis – predominantly a myelitis with later development of signs of neurologic disease whereas EEE and WEE have predominant signs of encephalopathy.

- Rabies
- Borna disease – occurs in Europe
- Japanese encephalitis – occurs in Asia
- Various other viral infections that are geographically restricted
- Hepatic encephalopathy, such as that associated with poisoning by *Crotalaria*, *Senecio*, and *Amsinckia* spp.; acute serum hepatitis or hepatopathy
- Botulism causes weakness evident as muscle fasciculation, recumbency and dysphagia, but does not cause cerebral signs (irritation, behavioral abnormalities)
- Yellow star thistle poisoning (*Centauria solstitialis*, and poisoning by fumonisins (*Fusarium moniliforme*) can produce similar clinical signs to that of the encephalitides, with the exception of fever.

TREATMENT

There is no definitive or specific treatment. Supportive treatment may be given with the intention to prevent self-inflicted injury, and maintain hydration and nutritional status.

CONTROL

Control of viral encephalomyelitis of horses is based on:[16,23,24]

- Accurate clinical and laboratory diagnosis of the disease in horses
- Use of sentinel animals to monitor the presence of the virus in the region
- Quarantine of infected horses to stop movement of virus donors
- Insect abatement when deemed necessary
- Vaccination of all horses.

Vaccination

Vaccination of horses is important not only because it minimizes the risk of disease in vaccinated horses but also because of the possibility that for EEE it prevents viremia, subsequent infection of feeding mosquitoes, and propagation of the epidemic.

Formalin-inactivated EEE and WEE virus vaccines are available and are effective although over 50% of horses with EEE had been vaccinated within the previous year.[17,25] This apparent poor protection can be explained by many horses not developing a detectable change in antibody titer after vaccination with a bivalent vaccine and rapid decreases in antibody titer from a peak value achieved 2–4 weeks after vaccination.[17] Vaccines are available as univalent or bivalent preparations and in combination with other antigens (for instance, tetanus toxoid). Horses should be vaccinated well in advance of the anticipated encephalomyelitis season in a given area. Vaccination against both strains of the virus is advisable in areas where the strain has not been identified or where both strains exist. The currently recommended vaccination schedule consists of two doses of the vaccine initially, 10 days apart, followed by annual revaccination using two doses. **Annual revaccination** is currently recommended because the duration of effective immunity beyond 1 year is not known. It is probable that the initial two-dose vaccination lasts for up to 3–4 years. The emphasis in a vaccination program should be on the young horses.

Colostral antibody can be detected in the blood of foals from vaccinated dams for up to 6–7 months, after which time it declines rapidly. Foals from vaccinated dams should be vaccinated at 6–8 months of age and revaccinated at 1 year of age. Foals from unvaccinated dams may be vaccinated at 2–3 months of age and again at 1 year of age. Colostral antibodies in the foal will prevent the development of autogenous antibodies, and foals vaccinated when less than 6 months should be revaccinated when they are 1-year-old or, in high-risk areas, foals from vaccinated mares should be vaccinated at 3, 4, and 6 months of age.

Experimental DNA vaccines hold promise for the prevention of WEE.[26]

Protection from insects

Housing of horses indoors at night, especially in flyproofed stables, and the use of insect repellents may restrain the spread of the virus. Use of insect repellents decreases the risk of EEE in horses to 0.04 that of unprotected horses.

Widespread spraying of insecticides to reduce the population of the vector insects has been used in the control of VEE, however, such measures are not practical for preventing sporadic cases of EEE or WEE, and the environmental impact of widespread insecticide use should be considered.

Complete eradication of the virus appears to be impossible because of the enzootic nature of the ecology of the virus. The horse being an accidental host for EEE and WEE virus make elimination of the virus impossible with methods currently available.

Zoonotic aspects of control

Control of the disease in humans in areas where the disease may occur is dependent on insect control, and a monitoring and surveillance early warning system is necessary to decide whether or not to take control measures. In areas where WEE occurs, clinical cases of the disease in unvaccinated horses usually precede the occurrence of the disease in human.[27] The establishment of a reporting system whereby practicing veterinarians report all clinical cases of the disease in horses will also assist in predicting potential epidemics of WEE virus infection in the human population. Serological surveys of wildlife may also serve as good indicators of the geographical distribution and seasonality of circulation of these viruses and provide an early warning system prior to the detection of human cases.

EQUINE ENCEPHALOSIS

Seven serotypes[1–7] of equine encephalosis virus (EEV) infect equids of southern Africa including Kenya, Botswana and South Africa.[1] The virus is an insect-borne orbivirus that is transmitted by a variety of *Culicoides* spp.[2] and is closely related to bluetongue and epizootic hemorrhagic disease viruses. It has characteristics in cell culture similar to African Horse Sickness.[5] The virus replicates in midges although the rate differs depending on species of midge and strain of the virus. The genetic and phenotypic stability of strains of the virus are unknown and there exists the potential for emergence, or recognition, of new strains. Variations in pathogenicity are not recognized, perhaps because of incomplete knowledge of this importance of this virus, but might exist. There is independent persistence of virus serotypes in a maintenance cycle based on observation of increased rates of seasonal seroconversion to a specific serotype with ongoing low level of infection by other serotypes.[1] Horses, donkeys, and zebra in southern Africa frequently have antibodies to a group epitope of the virus indicating widespread infection of these Equidae. Seventy seven percent of 1144 horses, 57% of 518 horses, 49 % of 4875 donkeys and up to 88% of zebra in South Africa have antibody to EEV.[1–4] Elephant seldom have antibodies to EEV.[4]

The virus was originally isolated from a horse with signs of neurologic disease, hence the name. However, the disease associated with infection by EEV is poorly documented and, given the high prevalence of infection, EEV might be falsely incriminated in some situations. Most infections are subclinical based on the high seroprevalence rate and lack of reports of outbreaks of the disease. Clinical signs commonly attributed to EEV infection include fever, lassitude, edema of the lips, acute neurologic disease and enteritis. Abortion has been associated with infection by EEV. Disease associated with EEV has not been recorded in donkeys or zebra.[2] Characteristic abnormalities in serum biochemistry or hematology are not reported. Antibodies to the virus are detected by serum neutralization assays (which are serotype specific) and ELISA, which is not serotype specific. A group specific, indirect sandwich ELISA detects EEV antigen and does not cross react with African Horse Sickness virus, Bluetongue virus, or epizootic hemorrhagic disease virus.[6] Necropsy examination reveals cerebral edema, localized enteritis, degeneration of cardiac myofibers and myocardial fibrosis but whether all these abnormalities are attributable to EEV is unclear.[5] Definitive diagnosis is difficult, if not impossible, at the current time because of the high prevalence of seropositive animals and the ill-defined clinical and necropsy characteristics of the disease. There are no recognized treatment, control or preventive measures. There is no vaccine.

VENEZUELAN VIRAL ENCEPHALOMYELITIS OF HORSES

Synopsis

Etiology Venezuelan encephalitis virus (types 1AB, 1C, and, to a lesser extent, 1E)
Epidemiology Disease limited to the Americas. Arthropod, usually mosquito, borne virus. Mammals, including horses, are accidental hosts. Horse are amplifying hosts and can spread VEE. Care fatality rate 5–70%. VEE occurs as epidemics
Clinical findings Fever, muscle fasciculation, severe depression, head pressing, incoordination, recumbency, opisthotonos and paddling, and death
Clinical pathology Leukopenia
Lesions Non-supparative encephalomyelitis
Diagnostic confirmation Virus isolation and identification. Identification of viral antigen by indirect immunofluorescence. Serological confirmation of exposure, preferably demonstrating an increase in hemagglutination inhibition, virus neutralization, or complement fixation titer
Treatment No specific treatment. Supportive care
Control Vaccination with formalin-inactivated or modified live virus. Insect control

ETIOLOGY

Venezuelan equine encephalomyelitis is associated with an arthropod borne alphavirus (family Togaviridae) Venezuelan equine encephalomyelitis virus (VEE). The VEE complex has one virus, VEE, with six antigenically related subtypes: I, VEE; II, Everglades; III, Mucambo; IV, Pixuna; V, Cabassou; and VI, AG80–663. Within subtype I are at least five variants. Epidemic (pathogenic) VEE in horses is associated with variants IAB (originally identified as distinct variants, A and B are now considered the same variant) and IC; all other subtypes of I (D–F), and other variants of VEE virus, are usually non-pathogenic for horses and are found in sylvatic or enzootic, non-equine cycles. The epidemic variants are exotic to the United States. **Outbreaks** occurred in Mexico in 1993 and 1996, and in Venezuela and Columbia in autumn 1995.[1,2] The Columbian outbreak affected 90 000 people and killed an estimated 4000 horses.[1] The strain involved in the Columbian outbreak was IC, while that involved in the Mexican outbreaks was a variant of the usually non-pathogenic IE.[2] The outbreak in Mexico was associated with a variant of VEE that did not cause viremia in horses, although it was capable of causing neurologic disease in this species, and it might have been this attribute that abbreviated the course of the epidemic.[3] There is evidence of continuing enzootic circulation of VEE IE in southern Mexico.[4]

The viruses is extremely fragile and disappear from infected tissues within a few hours of death.

EPIDEMIOLOGY

The encephalitis viruses cause disease in horses, humans, pigs, and various birds including ratites and domestic pheasants.[5]

Distribution

Pathogenic or epidemic VEE is found in northern South America, Central America, Mexico and, rarely, in the southern United States.[5] Non-pathogenic, or endemic, strains of VEE are found in South and Central America and in parts of the southern United States.

Viral ecology

VEE exists as both non-pathogenic and pathogenic strains. **Non-pathogenic VEE viruses** persist in sylvatic cycles in northern South America, Central America and parts of the southern United States, and are important because they are the source of the epizootic strains of the virus that emerge at infrequent intervals.[2,6–8] The enzootic strains also confound the diagnosis of VEE because of the extensive

serological cross-reactivity among endemic and epidemic VEE viruses. However, recent advances in diagnostic techniques may have solved this diagnostic problem. The non-pathogenic viruses are maintained in rodents associated with swamps, and transmitted by mosquitoes of the genus *Culex*, and perhaps other hematophagous insects. Humans, horses, cattle, pigs, dogs, and ratites are accidental hosts of the virus. **Epidemics of VEE** occur irregularly, the latest being in northern Columbia in 1995, and Mexico in 1993 and 1996.[1,2] The source of virus during outbreaks is infected horses. **Horses** develop a profound viremia and are **amplifying hosts** that aid in the spread of the epizootic; other domestic species, including cattle, pigs, and goats are not considered to be amplifiers of the virus. During epizootics, all species of mosquitoes that feed on horses, including *Aedes*, *Psorophora* and *Deinocerites* species, are thought to be capable of spreading the infection. Epizootics end as the population of susceptible horses decreases below a critical level, either by death or vaccination. The **reservoir of the virus between outbreaks**, which may be up to 19 years, was unknown until it was demonstrated that epidemic VEE type IAB virus arises by **mutation of endemic strains** (types ID–F and II–vi), or that type IE (enzootic) mutates into an epizootic form serologically very similar to IE. This mutation of the endemic virus into the epidemic form has occurred on at least three occasions associated with epidemics of VEE.[2,6–8] It is likely that pathogenic strains of VEE will continue to emerge in areas where the non-pathogenic strains of the virus are endemic.[8]

Animal risk factors

Recovered horses are resistant to infection for at least 2 years, and vaccination confers immunity of variable duration (see under 'Control'). **Housing** and **exposure to mosquitoes** are important risk factors for EEE, and presumably VEE.

Morbidity varies widely depending upon seasonal conditions and the prevalence of insect vectors; cases may occur sporadically or in the form of severe outbreaks affecting 20% or more of a group. The prevalence of infections, as judged by serological examination, is much higher than the clinical morbidity. The **case fatality rate** is usually 40–80% and may be as high as 90% with VEE.

Zoonotic implications

The **susceptibility of humans** to the causative virus gives the disease great public health importance. Humans can become infected with sylvatic and epizootic VEE subtypes.[1] A recent outbreak of VEE in Columbia caused 75 000 human cases, 300 fatalities and killed approximately 4000 horses.[1] **Human infections** generally follow equine infections by approximately 2 weeks. The infection in humans is usually a mild, influenza-like illness in which recovery occurs spontaneously. When clinical encephalitis does occur it is usually in very young, or older, people. Occurrence of the disease in humans can be limited by the use of a vaccine in horses, thus limiting the occurrence of the disease in horses in the area. There is a strong relationship between the **mosquito population** and the incidence of the disease in horses and in humans.[10] The occurrence of the disease in humans may be predicted by an unusually high activity of virus in mosquitoes. There are usually, but not always, widespread mortalities in horses before the disease occurs in humans.[10] VEE infections have occurred among **laboratory workers** as a result of aerosol infections from laboratory accidents and from handling of infected laboratory animals. The TC83 live attenuated VEE virus vaccine may be **teratogenic** in humans.[11]

PATHOGENESIS

Inapparent infection is the mildest form of the disease and may be characterized by only a transient fever. A more severe form of the disease is manifested by tachycardia, depression, anorexia, occasional diarrhea, and fever.

Viremia persists throughout the course of the disease in VEE and the blood provides a source of infection for biting insects. Transplacental transmission of the VEE virus can occur in pregnant mares infected near term.[12] The virus is present in saliva and nasal discharge, and this material can be used to transmit the disease experimentally by intranasal instillation.

Penetration of the virus into the **brain** does not occur in all cases and the infection does not produce signs, other than fever, unless involvement of the central nervous system occurs. The lesions produced in nervous tissue are typical of a viral infection and are localized particularly in the **gray matter of the cerebral cortex, thalamus and hypothalamus**, with minor involvement of the medulla and spinal cord. It is this distribution of lesions that is responsible for the characteristic signs of mental derangement, followed at a later stage by paralysis. The early apparent blindness and failure to eat or drink appear to be cortical in origin. True blindness and pharyngeal paralysis occur only in the late stages.

CLINICAL FINDINGS

The diseases associated with the different viruses are **clinically indistinguishable**. The **incubation period** for VEE is 1–6 days. Uncomplicated disease usually lasts about 1 week. In the initial viremic stage there is fever, which may be accompanied by anorexia and depression, but the reaction is usually so mild that it goes unobserved. In the experimental disease, the temperature may reach 41°C (106°F) persisting for only 24–48 hours, with nervous signs appearing at the peak of the fever. Animals that have shown nervous signs for more than 24 hours may then have a temperature within the normal range.

Early nervous signs include hypersensitivity to sound and touch, and in some cases transient periods of excitement and restlessness, with apparent blindness. Affected horses may walk blindly into objects or walk in circles. **Involuntary muscle movements** occur, especially tremor of shoulder and facial muscles and erection of the penis. A stage of **severe mental depression** follows. Affected horses stand with the head hung low; they appear to be asleep and may have a half-chewed mouthful of feed hanging from the lips. At this stage the horse may eat and drink if food is placed in its mouth. The pupillary light reflex is still present. The animal can be aroused, but soon relapses into a state of somnolence.

A stage of **paralysis** follows. There is inability to hold up the head, and it is often rested on a solid support. The lower lip is pendulous and the tongue may hand out. Unnatural postures are adopted, the horse often standing with the weight balanced on the forelegs or with the legs crossed. **Head-pressing** or leaning back on a halter are often seen. On walking, there is obvious incoordination, particularly in the hindlegs, and circling is common. Defecation and urination are suppressed and the horse is unable to swallow. Complete paralysis is the terminal stage. The horse goes down, is unable to rise and usually dies within 2–4 days from the first signs of illness. A proportion of affected horses do not develop paralysis and survive, but have persistent neurological deficits.

In the experimental infection of horses with the endemic strain of the **VEE virus**, a fever and mild leukopenia occurs.[13] Following infection with the epidemic strain of the virus, a high fever and severe leukopenia are common, and a high level of neutralizing antibodies develop about 5–6 days after infection. Clinical findings include profound depression, accompanied by flaccidity of lips, partially closed eyelids, and drooped ears; some horses

chew continuously and froth at the mouth. In the terminal stages, there is recumbency and nystagmus.

CLINICAL PATHOLOGY

There are no characteristic **hematological or biochemical abnormalities**. The **absence of biochemical indication of liver disease** (hyperbilirubinemia, increased activity in serum of liver-specific enzymes such as sorbitol dehydrogenase and gamma glutamyl transferase, absence of hyperammonemia) rules out hepatic encephalopathy.

Diagnostic confirmation is achieved by one or more of several means:[14]

- Isolation of virus from an affected animal
- Detection of viral antigen or nucleic acid in an animal with appropriate clinical signs
- Seroconversion or an increase in serum titer of sick or recovered animal.

Virus isolation provides definitive proof of infection. However, viremia may have resolved by the time nervous signs have developed, and it may be advantageous to sample febrile animals instead of animals showing more advanced signs of the disease. Virus can be cultured in intracranially inoculated suckling mice, weanling mice, guinea pigs, cell culture, newly hatched chicks, or embryonated eggs.[9] Virus isolates can be identified by complement fixation, hemagglutination inhibition, virus neutralization, PCR, IFA, and antigen capture ELISA.[9,14] A recently developed indirect fluorescent test using monoclonal antibodies enables the differentiation of endemic from epidemic strains of VEE.[15] Interpretation of the results of serological tests of horses in an area where endemic, non-pathogenic VEE virus exists is difficult because of the cross-reaction between endemic and epidemic strains of the virus. Therefore, in areas where there is endemic, non-pathogenic VEE, demonstration of the presence of antibodies should not be considered persuasive evidence of the presence of the disease.

Acute and convalescent sera taken 10–14 days apart for the presence of neutralizing, hemagglutination-inhibiting, or complement-fixing antibodies in the serum of affected or in-contact horses, is of value in detecting the presence of the virus in the group or in the area. A four-fold increase in complement-fixing antibodies is considered positive.

Demonstration of viral nucleic acid in tissue, blood or insects by PCR test may be a useful indicator of the presence of the virus. There may be sufficient viral antigen to be detected by ELISA in clinical material, and this may provide a useful test in the early stages of an epidemic.[14]

NECROPSY FINDINGS

The brain meninges may appear congested, but there are generally no gross changes. Histological examination of the brain reveals perivascular accumulations of leukocytes and damage to neurons.[16] The gray matter of the forebrain and midbrain are the most severely affected areas. In some cases of VEE, liquefactive necrosis and hemorrhage are visible in the cerebral cortex.[17] Cell culture and transmission experiments utilizing brain tissue as an inoculum are the traditional means of confirming a diagnosis, and require that the brain be removed within an hour of death. Transmission is by intracerebral inoculation of brain tissue into sucking mice or duck embryo tissue culture. Fluorescent antibody tests have been developed to detect VEE virus[6] and EEE virus in brain tissue.[6]

Samples for postmortem confirmation of diagnosis

- One half of midsagittally-sectioned brain and liver and spleen should be submitted for fluorescent antibody and PCR testing, virus isolation and bioassay
- One half of midsagittally-sectioned brain, fixed in formalin, should be submitted for light microscopic examination.

Note the zoonotic potential of these organisms when handling the carcass and submitting specimens.

DIFFERENTIAL DIAGNOSIS

Clinically, the disease has very great similarity to the other viral encephalomyelitides, from which it can often be discriminated by the geographical location of the horse, and to the hepatic encephalopathies and a number of other diseases (see below and in Table 22.1).

- Rabies
- West Nile virus encephalomyelitis
- Borna disease – occurs in Europe
- Japanese encephalitis – occurs in Asia
- Various other viral infections that are geographically restricted
- Hepatic encephalopathy, such as that associated with poisoning by *Crotalaria*, *Senecio*, and *Amsinckia* spp.; acute serum hepatitis or hepatopathy
- Botulism causes weakness evident as muscle fasciculation, recumbency and dysphagia, but does not cause cerebral signs (irritation, behavioral abnormalities)
- Yellow star thistle poisoning (*Centauria solstitialis*) and poisoning by fumonisins can produce similar clinical signs to that of the encephalitides, with the exception of fever.

TREATMENT

There is no definitive or specific treatment. Supportive treatment may be given with the intention to prevent self-inflicted injury, and maintain hydration and nutritional status.

CONTROL

Control of VEE of horses is based on:[18–20]

- Accurate clinical and laboratory diagnosis of the disease in horses
- Use of sentinel animals to monitor the presence of the virus in the region
- Quarantine of infected horses to stop movement of virus donors
- Insect abatement when deemed necessary
- Vaccination of all horses.

Vaccination

Vaccination of horses is important not only because it minimizes the risk of disease in vaccinated horses but also because it prevents viremia, subsequent infection of feeding mosquitoes, and propagation spread of VEE.

One of the most important aspects of the control of VEE is the vaccination of the horse population to minimize the number of horses that are viremic and serve as amplifying hosts. **A tissue culture-attenuated virus vaccine TC83**, is available for immunization of horses against VEE. The vaccine is considered to be safe and efficacious[21]; concerns about reversion of the virus to virulence appear unfounded,[9] but should be reconsidered in light of the observation that the source of epidemic VEE virus is mutation of endemic strains.[2,6,8]

A **highly effective immunity** is produced within a few days following vaccination, and serum neutralizing antibodies persist for 20–30 months.[1] The vaccine causes a mild fever, leukopenia and a viremia and, because of conflicting reports about its capacity to cause abortion, should not be used in pregnant mares.[1] Antibodies to the heterologous alphaviruses, WEE and EEE, existing at the time of TC83 vaccination, may suppress the VEE antibody response to the vaccine.

Table 22.1 Diseases of horses characterized by signs of intracranial or disseminated lesions of the central nervous system

Disease	Etiology and epidemiology	Clinical and laboratory findings	Treatment and control
Infection causes			
Viral encephalomyelitis (Western, Eastern, Venezualan: WEE, EEE, VEE)	Summer season. Insect vector, usually mosquitoes Young non-vaccinated horses at greatest risk, outbreaks may occur	Stage of slight hyperexcitability and mild fever initially, impaired eyesight, circling and walking. Stage of mental depression, somnolence, leaning, feed hanging from mouth, unsteady. Stage of paralysis, unable to swallow, weakness, recumbency; dies 2–4 days after onset. Serology for diagnosis	Supportive therapy, thick bedding. Recovery rate 60–75% Vaccinate foals at 6 months of age and other horses for the first time, twice 2 weeks apart and once or twice annually thereafter
Rabies	All age groups, knowledge of disease in area, wildlife. Usually single animal affected. Not common	Ascending paralysis, hyper-salivation, will bite. Ataxia and paresis of hindlimbs, lameness, recumbency, pharyngeal paralysis, colic, loss of tail and sphincter tone, fever. Dies in 1 week. Immunofluorescent antibody testing on brain for positive diagnosis	No treatment. All die. Vaccinate horses if anticipate outbreak
Herpesvirus myeloencephalopathy (EHV-1)	Can occur as outbreaks. Neurologic disease usually preceded by fever. Mature horses	Symmetrical ataxia and paresis, bladder paralysis, recumbency may occur, spontaneous recovery possible, CSF (hemorrhage or xanthochromia). Vasculitis with subsequent focal malacia in gray and white matter of brain and spinal cord	No specific therapy. Anti-inflammatory drugs may be useful. Use of corticosteroids is controversial.Recovery may occur spontaneously
West Nile encephalomyelitis (WNE)	West Nile virus. Late summer in temperate regions. Can occur as . epizootics. Now enzootic in most of North America	Fever, muscle fasciculations, weakness, ataxia, depression, cranial nerve disease, recumbency. Prominent signs of spinal cord precede sign of intracranial disease in most cases	Supportive. Antiserum. Interferon. Anti-inflammatory. drugs including corticosteroids. Prevention by vaccination
Borna	Virus. Direct transmission. Germany and other European countries. Disease is recorded in Japan. Low morbidity, high case fatality rate	Pharyngeal paralysis, muscle tremor, flaccid paralysis, course 1–3 weeks. Viral encephalomyelitis with inclusion bodies	No treatment
Japanese encephalitis	Japanese encephalitis virus. Sporadic. Asia including Japan and China, parts of Oceania including New Guinea and Torres Strait. Pig is mammalian amplifying host. Vector mosquitoes, birds infected	Fever, lethargy, jaundice, dysphagia, incoordination, staggering, recovery in 1 week. Serology	Spontaneous recovery. Vaccination in endemic areas
Protozoal myeloencephalitis	*Sarcocystis neurona*. Single animal affected. Infectious but not contagious	Any central nervous system disorder. Usually causes ataxia but can cause cerebral and cranial nerve disease	Antiprotozoal medications (pyrimethamine + sulphonamide, ponazuril, or nitazoxanide). Vaccine available in USA but not recommended
Cerebrospinal nematodiasis (verminous encephalitis)	Migration of larval stages of *Strongylus vulgaris, Habronema* sp., and Filaroides. *Micronema deletrix (Helicephalobolus) deletrix*. Not common	Clinical signs referable to gray matter lesions are common. Hypalgesia, hyporeflexia, hypotonia, muscle atrophy and cerebral, cerebellar and cranial nerve involvement. Progressive encephalitis, incoordination, sensory deficits, blindness in one or both eyes, course of several days. Pleocytosis of CSF. Hemorrhage and malacia of thalamus, brain stem, cerebellum	Ivermectin or moxidectin at usual doses. High dose benzimidazole. Anti-inflammatory drugs. Parasite control
Brain abscess	Sporadic. Often a complication of strangles	Obtunded mentation, variable signs of intracranial disease. Leukocytosis. Variable pleocytosis and increased protein concentration in CSF. CT scan	Antimicrobials. Surgical drainage Prognosis is poor
Physical			
Traumatic injury to the brain	History of traumatic injury (falling, rearing-up and falling backwards)	Coma, depression, hemorrhage from nose and ears, blindness, cranial nerve deficits. Often rupture of longus capitus muscle	Anti-inflammatory drugs, mannitol. Fair to poor prognosis
Facial nerve paralysis	Associated with prolonged surgical recumbency and compression of facial nerve	Facial nerve paralysis lasting several days. Paralysis of ear, eyelid, lip, nostril on one side. No alteration in sensation or vestibular function	Supportive

Table 22.1 (*Cont'd*) Diseases of horses characterized by signs of intracranial or disseminated lesions of the central nervous system

Disease	Etiology and epidemiology	Clinical and laboratory findings	Treatment and control
Lightning strike	Observed lightning strike or history of recent thunderstorm activity	Death is most common. Horses that survive strike often have prominent signs of vestibular disease	Supportive. Recovery is possible
Fracture or arthritis of the temporal-stylohyoid articulation, otitis media	Sporadic in older horses	Acute onset circling, head tilt, nystagmus, unilateral facial paralysis, dysphagia	Antibiotics, anti-inflammatory drugs, supportive care
Intoxications			
Horsetail poisoning (*Equisetum arvense*)	Ingestion of plants mixed with hay. Not common	Incoordination, swaying from side to side, muscle tremor recumbency, bradycardia, cardiac arrhythmia	Thiamine parenterally. Good response
Equine leukoencephalomalacia (fumonisin toxicosis)	Horses eating moldy corn grain contaminated with *Fusarium moniliforme* fungus	Muscle tremor, weakness, staggering gait, dysphagia, depression	Nil
Hepatoencephalopathy associated with hepatotoxic plants (*Crotalaria, Senecio* and *Amsinckia*)	Horses on inadequate pasture forced to eat poisonous plants. More than one animal may be affected. Geographical distribution	Develops slowly, commonly ill for 2–3 weeks previously, depression, pushing, ataxia, hypertonic face and lips, yawning, compulsive walking, loss of weight, icterus, photosensitization occasionally. Serum liver enzymes elevated and liver function tests abnormal. Hyperammonemia. Gross and histopathological liver lesions	No treatment. Prevent access to poisonous plants
Lead poisoning	Grazing on pastures contaminated by atmospheric lead from nearby factories, not common now	Usually a chronic disease. Inspiratory dyspnea due to paralysis of recurrent laryngeal nerve. Pharyngeal paralysis, dysphagia, aspiration pneumonia, paralysis of lips, weakness and recumbency. Ingestion of large amounts causes subacute form similar to that seen in cattle	Calcium versenate
Yellow-star thistle poisoning (*Centaure* sp., anigropallidal encephalomalacia of horses)	Ingestion of yellow-star thistle in California and Australia. Summer months on weedy pasture	Difficult prehension, fixed facial expression with mouth held half open, hypertonic face and lips, persistent chewing movements and rhythmic protrusion of tongue, yawning and somnolence but easily aroused, aimless walking, slight stiffness of gait, high mortality Malacia of globus plants pallidus and substantia nigra	No treatment. Prevent access to poisonous plants
Botulism	Ingestion of preformed toxin of *Cl. botulinum* in decaying grass or spoiled silage, hay or grain. Sporadic in horses. Endemic in foals in some areas of North America	Flaccid paralysis of skeletal muscles leading to weakness, stumbling and recumbency. Mentation normal. Skin sensation normal. Paralysis of tongue and thoracic muscles. Die in 2–4 days. Some recover. Filtrates of intestinal tract into laboratory animals	Supportive therapy, antitoxins. Vaccination in enzootic areas. Prevent contamination of feed by animal carcasses
Tetanus	Wounds infected with *Cl. tetani*. Sporadic	Generalized tetany of all skeletal muscles. Fever, hyperesthesia, protrusion of third eyelid, trismus, recumbency followed by tetanic convulsions, die in 5–10 days	Prognosis unfavorable. Dark stall, penicillin, muscle relaxants, supportive therapy and antitoxin parenterally or into subarachnoid space Toxoid vaccination
Metabolic and idiopathic			
Lactation tetany	Lactating mares, suckling foals Hypocalcemia	Acute onset of generalized stiffness, trismus, no hyperesthesia, no prolapse of third eyelid, diaphragmatic flutter, soft heart sounds. Serum hypocalcemia	Rapid response to calcium borogluconate intravenously
Idiopathic epilepsy of Arabians	Single horse. first noticed from shortly after birth up to 6 months of age. Etiology unknown	Recurrent episodes of typical clonic tonic convulsions lasting 10–15 minutes, loss of consciousness, sweating, tachycardia, spontaneous defecation. No lesions	Control seizures with phenobartibal or potassium bromide. Spontaneous recovery as foals mature
Idiopathic epilepsy of adult horses	Sporadic disease. Unknown cause. Can be associated with brain lesions detectable on EEG or CT	Tonic-clonic convulsions. Variable periodicity and intensity	Control seizures acutely with diazepam and in long term with phenobarbital and/or potassium bromide. Spontaneous recovery unlikely

Table 22.1 (*Cont'd*) Diseases of horses characterized by signs of intracranial or disseminated lesions of the central nervous system

Disease	Etiology and epidemiology	Clinical and laboratory findings	Treatment and control
Cerebellar hypoplasia of Arabian and Swedish Gotland foals	Inherited. Signs noticeable from 2 to 6 months of age	Defective eye blinks, ataxia, headnodding, slight tremor of head and neck, intention tremor of the head, high-stepping gait, difficulty in rising, legs wide apart, difficulty in jumping over obstacles, fall backwards if dorsiflex head and neck. Cerebellar hypoplasia grossly or histologically	Eliminate carrier animals
Lower motor neuron disease	Associated with stabling and no access to pasture. Sporadic. North America and Europe. Low serum vitamin E concentrations	Weight loss, weakness, muscle fasciculations, maintained appetite. Normal mentation. Low serum vitamin E concentration. Diagnosis by muscle biopsy	No definitive cure. Some cases stabilized with administration of oral vitamin E. Poor prognosis for return to function

Note: *Other less common diseases affecting the nervous system of horses include: space-occupying lesions (cholesteatomas of old horses, tumors), intracranial myiasis due to migration of* Hypoderma bovis, *hydrocephalus in young horses, the accidental injection of an ataractic drug into the carotid artery and bacterial meningitis in young horses as a sequel to streptococcal infection.*

However, the response to the vaccine is adequate to provide protection against VEE, and the interference is not considered significant.[22] There is inconclusive evidence that WEE and EEE antibodies protect horses against infection with virulent VEE virus, or conversely that VEE antibodies protect against infection with WEE and EEE viruses.[23] Simultaneous vaccination using formalin-inactivated EEE, WEE, and VEE (the TC83 strain of VEE) is effective and recommended in areas where all three viruses may be present.

Protection from insects

Housing of horses indoors at night, especially in flyproofed stables, and the use of **insect repellents** might restrain the spread of the virus.

Widespread spraying of insecticides to reduce the population of the vector insects has been used in the control of VEE in humans, along with vaccination of horses.[24] **Complete eradication** of the virus appears to be impossible because of the enzootic nature of the ecology of the virus: epidemic VEE arising by chance mutation of endemic strains of VEE, make elimination of the virus impossible with methods currently available.

JAPANESE ENCEPHALITIS

Japanese encephalitis is associated with the **Japanese encephalitis flavivirus** (JEV), a member of the Flaviviridae family.[1] Antigenically related viruses include Murray valley encephalitis virus, Kunjin virus, and West Nile virus. There appear to be a number of variants of JEV, with there being genetic and antigenic differences between endemic and non-endemic strains, and isolates of different years.[1,2] The virus cycles between avian and mammalian amplifying hosts and the mosquitoes.[1] The pig is the principal mammalian amplifying host among domestic animals. Horses and humans become infected but likely play only a minor role in the spread of the virus. The disease is listed by the OIE.

The disease occurs **throughout the Orient and South-East Asia** and has extended into Papua New Guinea, the Torres strait, and northern Australia. Outbreaks of disease occurred in the Torres strait in 1995 and disease in humans has occurred rarely in northern Australia.[3] Outbreaks of disease have not occurred in Australia, despite large populations of wild pigs, wading birds, and mosquitoes probably because the mosquitoes prefer to feed on marsupials, which are poor hosts for JEV.[3]

Horse deaths are now uncommon in Japan, due to vaccination of most horses, but 15–70% of race horses have antibodies to JEV that are not induced by vaccination.[4] Seroepidemiological surveys of cattle in Japan reveal that about 68% of animals are positive.[5] Disease in horses and humans occurs in China.[1] The prevalence of the disease is related to the population of pigs, the main amplifying host, the mosquito vector, and susceptible human and equine hosts.[1] Factors affecting the number of mosquitoes include availability of suitable habitat, such as rice field in which survival of mosquito larvae is enhanced by application of nitrogenous fertilizers and the presence of phytoplankton which provide food and shelter for the larvae.[6,7]

The **clinical manifestations** of the disease in horses vary widely in severity.

Mild cases show fever up to 39.5°C (103°F), anorexia, sluggish movements, and sometimes jaundice for 2–3 days only. More severe cases show pronounced lethargy, mild fever, and somnolence. Jaundice and petechiation of the nasal mucosa are usual. There is dysphagia, incoordination, staggering, and falling. Transient signs include neck rigidity, radial and labial paralysis, and blindness. In the most severe cases there is high fever (40.5–41.5°C, 105–107°F), hyperexcitability, profuse sweating, and muscular tremor. Violent, uncontrollable activity may occur for a short period. This severe type of the disease is uncommon, representing only about 5% of the total cases, but is more likely to terminate fatally. In most cases complete recovery follows an illness lasting from 4 to 9 days. A variety of tests are available to detect antibodies to JEV.[8] A latex agglutination test provides accurate detection of antibodies in the field.[9] However, definitive diagnosis of Japanese viral encephalitis should not be based exclusively on serology because infection with antigenically related viruses including Murray Valley encephalitis virus, Kunjin virus, and West Nile virus can cause false-positive (from the perspective of JEV) results.[8]

The disease in **cattle, sheep and goats** is usually clinically inapparent and of little overall significance. Widespread losses, however, have been reported in **swine**, particularly in Japan. The disease occurs as a non-suppurative encephalitis in pigs under 6 months of age. Sows abort or produce dead pigs at term.[10] There are no characteristic gross changes. As is typical of most viral encephalitides, microscopic changes include a nonsuppurative encephalomyelitis, focal gliosis, neuronal necrosis, and neuronophagia. Isolation of this flavivirus is difficult and bioassay techniques are comparatively slow. As a result, detection via PCR is likely to be increasingly utilized. Immunohistochemistry can be used to demonstrate this virus in formalin-fixed, paraffin-embedded sections

Samples for confirmation of diagnosis

- **Virology –** 5 mL chilled CSF fluid, chilled brain (split along midline) (ISO, BIOASSAY, PCR)
- **Histology –** fixed samples of other half of brain, lung, spleen, liver, heart (LM, IHC).

Note the zoonotic potential of this organism when handling carcass and submitting specimens.

There is no specific treatment for the disease. **Control** is by vaccination. Formalinized **vaccines** afford excellent protection in pigs and horses.[4]

WEST NILE ENCEPHALITIS

Etiology West Nile virus, a flavivirus
Epidemiology Maintained in a bird–mosquito cycle. Mammals are incidentally infected. Enzootic in Africa and, recently, North America. Epizootics in the Mediterranean littoral and southern Europe. Affects a wide variety of species including horses, humans, sheep, camelids, and dogs
Clinical signs Weakness, incoordination, altered mentation, muscle fasciculations, recumbency
Clinical pathology MAC-ELISA for diagnosis
Lesions Polioencephalomyelitis
Diagnostic confirmation MAC-ELISA, clinical signs, lesions
Treatment None specific. Supportive care
Control Vaccination. Mosquito control

ETIOLOGY

Encephalitis in horses, humans, and other species is associated with West Nile virus, an arthropod borne flavivirus in the Japanese encephalitis virus group. Other viruses in the group include Japanese encephalitis virus (Japan and South-East Asia), St Louis encephalitis virus (United States), Kunjin virus (now considered a subtype of West Nile virus, Australia), Murray Valley encephalitis virus (Australia), and Rocio virus (Brazil).[1] The virus was first isolated in 1937 from a human with fever in Uganda. There are at least two lineages of the virus, with one lineage (lineage 1) isolated from animals in central and North Africa, Europe, Israel, and North America whereas the other (lineage 2) is enzootic in central and southern Africa.[2] The recent outbreak in North America was associated with a virus identical to that isolated from diseased geese in Israel.[3] Viruses of both lineages can circulate at the same time in the same geographic region.[1] Virus of either lineage can cause disease, although that of lineage 1 appears to be associated with more severe disease in horses and other species. There are anecdotal reports of Kunjin virus being associated with isolated cases of encephalomyelitis in horses in Australia.

The West Nile virus causes disease in humans, horses, birds (including geese, raptors, and corvids), sheep, alpacas, and dogs.[2,4–6]

EPIDEMIOLOGY

Distribution

West Nile encephalitis virus is enzootic to Africa and sporadic outbreaks of the disease occurred in the 1960s in Africa, the middle East and southern Europe.[7] Recently, outbreaks affecting horses and other animals have occurred in southern France, Tuscany, Israel and other parts of southern Europe.[8–11] The virus was introduced into New York city in North America in 1999 and subsequently spread widely across the continent, including Canada, Mexico and the Caribbean, in the next several years, and reaching the west coast by 2004.[12] The virus caused widespread deaths of wild birds and disease and death in humans, horses and other species in North America during this period.[13]

Introduction of the infection to North America was associated with an epizootic of disease that over several years moved across the continent. During the initial years of the epizootic there were large numbers of cases in horses (15 000) and humans (4000) and death of at least 16 500 birds.[14] As the front of the epizootic moved across the country, the infection became enzootic and the number of cases in horses in these regions decreased markedly over those in the first year.

Viral ecology

The virus is maintained by a cycling between amplifying hosts, usually birds, and insect vectors. Large mammals, including horses and humans, are incidentally infected and are not important in propagation of the virus. Amplifying hosts are those in which the viremia is of a sufficient magnitude and duration (1–5 days) to provide the opportunity to infect feeding mosquitoes. Mammals, and in particular horses, are in general not amplifying hosts because of the low level of viremia.[15] The virus is spread by the feeding of ornithophilic mosquitoes, usually of the genus *Culex*. Infected mosquitoes carry the virus in salivary glands and infect avian hosts during feeding. The virus then multiplies in the avian host causing a viremia that may last for up to 5 days. Mosquitoes feeding on the avian host during the viremic phase are then infected by the virus. This pattern of infec-

tion of amplifying hosts and mosquitoes is repeated such that the infection cycles in these populations. Increases in mosquito number, such as occur at the end of the summer, and enhanced viral replication in mosquitoes at higher ambient temperatures, increase the likelihood that avian hosts, or incidental hosts, will become infected. This results in an increase in the incidence of disease in late summer and early autumn.[16–19]

The principal avian host and vector species vary markedly between geographic regions. In North America the house sparrow (*Passer domesticus*) is the principal amplifying host and *Culex pipens* is the principal vector. *Culex pipens*, and other mosquito vectors, feed almost exclusively on passerine and columbiform birds early in the season, but later in the summer in temperate regions switch to feeding on mammalian hosts.[20] This change in feeding behavior is associated with increased frequency of infection and disease in mammals, including horses and humans, in the late summer.

The virus cycles between the avian host and insect vectors year round in tropical regions. However, in temperate regions in which mosquitoes do not survive during the winter the mechanism by which the virus survives over winter is unknown.[13]

Transmission

Transmission is only by the bite of infected insect vectors. There is no evidence of horizontal spread of infection among horses. The disease can be spread in humans by transfusion of blood or transplantation of organs obtained from an infected person.[21]

Animal risk factors

The disease occurs in parts of the world as epidemics apparently associated with sporadic introduction of the virus into non-endemic regions, such as the Mediterranean littoral. Introduction of the virus to these regions occurs infrequently enough that horses have no active immunity and are susceptible to infection and disease. Horses immune through either natural infection or vaccination are resistant to the disease. The effect of immunity was evidenced in North America by the marked decrease in morbidity and mortality among horses after the epizootic waned and the disease became enzootic. The decrease in morbidity was attributed to both natural and vaccinal immunity. Interestingly, although the number of cases in horses decreased rapidly there was not a similar decrease in the number of human cases, perhaps because of the lack of a vaccine for use in humans.[13]

Horses of all ages appear to be equally susceptible to infection. Disease is report in horses aged from 5 months to >20 years. There does not appear to be any predilection based on breed or sex.[16]

Morbidity and case fatality

The incidence of the disease during an epizootic can be as high as 74 cases per 1000 horses at risk.[17] The case fatality rate among horses treated in the field is 22–38%[16,17,22] whereas it is 30–43% of horses in referral centers.[19,23]

Zoonotic implications

Infection of humans by West Nile virus can result in fatal encephalitis, although less severe disease or inapparent infection is more common. The virus has zoonotic potential and tissues from potentially infected animals and virus cultures should be handled in containment level 3 facilities, particularly material from potentially infected birds.[24]

PATHOGENESIS

Horses are infected by the bite of infected mosquitoes. Feeding by as few as 7 infected mosquitoes is sufficient to cause infection in seronegative horses.[15] Viremia, which persists for less than 2 days, occurs 2 to 5 days after feeding by infected mosquitoes.[15] West Nile encephalitis occurs in only a small proportion of infected horses. The virus localizes in cells in the central nervous system where it induces a severe polioencephalomyelitis with the most severe lesions being in the spinal cord.[25] Lesions are often evident in the ventral horn of the spinal cord, which is consistent with clinical signs of weakness.

CLINICAL FINDINGS

The incubation period after natural infection is estimated to be 8–15 days. Fever occurs early in the disease but is uncommon at the time that signs of neurologic disease become evident.[16,17] Affected horses are often somnolent, listless, or depressed although hyperexcitability has been reported. The signs of neurologic disease, including muscle fasciculation, weakness, and incoordination, develop within a period of hours and may progress over several days. Muscle fasciculations are common in the head and neck, but can occur in any muscle group. Weakness is most pronounced in limb and neck muscles and severely affected horses are recumbent with flaccid paralysis. Signs of neurologic disease are usually, but not reliably, bilaterally symmetrical. Altered mentation, blindness, and cranial nerve abnormalities, if they occur, usually become evident after signs of spinal cord disease are apparent.

Weakness with or without ataxia is present in almost all affected horses, whereas altered mentation is detected in approximately 66% of horses.[19] Cranial nerve abnormalities are evident in approximately 40% of horses, whereas apparent blindness or lack of menace reflex occurs in 3–7% of horses.[17,19]

Median recovery time for horses treated in the field is 7 days, with a range of 1–21 days.[17]

The prognosis depends on the severity of clinical signs. Horses that become recumbent and unable to rise are approximately 50 times more likely to die than are horses that remain able to stand while affected by the disease.[22] Most horses that survive the initial disease do not have signs of neurologic dysfunction 6 months later.[19]

Other species

Disease associated with West Nile virus is documented in small numbers of other species, including squirrels, chipmunks, bats, dogs, cats, reindeer, sheep, alpacas, alligator and a harbor seal during intense periods of local viral activity.[24] The disease in camelids is characterized by acute recumbency and altered mentation.[2,5]

CLINICAL PATHOLOGY

Affected horses are often mildly lymphopenic, and hyperbilirubinemic (likely due to anorexia), and occasionally azotemic.[19] These changes are not diagnostic of West Nile encephalitis.

Cerebrospinal fluid is abnormal in approximately 70% of horses with signs of neurologic disease. Abnormalities include mononuclear pleocytosis and elevated total protein concentration.[26]

Serological tests

Antibody can be identified in equine serum by IgM capture enzyme-linked immunosorbent assay (IgM capture ELISA, MAC-ELISA), hemagglutination inhibition (HI), IgG ELISA or plaque reduction neutralization (PRN).[23] Equine WN-specific IgM antibodies are usually first detectable 7–10 days after infection and persist for 1–2 months.[15] Because the incubation period of the disease after infection by bite of infected mosquitoes is at least 8 days, West Nile-specific IgM is usually present at the time of development of clinical signs of the disease. The MAC-ELISA is therefore a useful test in the diagnosis of the disease.[19]

WNV neutralizing antibodies are detectable in equine serum by 2 weeks post-infection and can persist for more than 1 year. In some serological assays, antibody cross-reactions with related flaviviruses (St Louis encephalitis virus or Japanese encephalitis virus), can be encountered.[23] The PRN test is the most specific among WN serological tests and all affected horses have titers ≥1:100 4–6 weeks after recovering from the

disease, and 90% of horses maintain this titer 5–7 months after recovery.[27]

Detection by MAC-ELISA of West Nile specific IgM in serum at dilutions greater than 1:400, in the presence of appropriate clinical signs, is considered diagnostic of WNV.[28] Similarly, a four-fold increase in PRN titer in serum collected during the acute and convalescent stages of the disease, in the absence of vaccination and in the presence of appropriate clinical signs is considered diagnostic.

Identification of WNV

The virus can be grown in cell culture and viral nucleic acid can be demonstrated in tissues of infected animals by RT-PCR.[29] Note that infected horses have much lower concentrations of virus than do infected birds, and failure to demonstrate viral antigen in infected horses is not uncommon, especially if less sensitive techniques, such as immunohistochemistry, are used.[24,25]

NECROPSY FINDINGS

Gross lesions are infrequently seen. When present they consist of multifocal areas of congestion and hemorrhage within the medulla oblongata, midbrain, and spinal cord. Histopathologic changes include a nonsuppurative poliomeningoencephalomyelitis with multifocal glial nodules and neuronophagia. The inflammatory changes and viral distribution are concentrated in the rhombencephalon and spinal cord, with comparatively little damage to the cerebrum. One immuohistochemical study of naturally infected horses concluded that examination of the spinal cord is required to accurately identify WNV infection.[25] Another report, in which RT-PCR was employed, concluded that high quality samples of medulla were sufficient to detect the presence of the virus.[30] Postmortem confirmation of the diagnosis through virus isolation is possible but the sensitivity is generally inferior to molecular biology-based techniques. RT-PCR is generally superior to IHC. The processing of tissue from multiple CNS sites is recommended in order to increase the chances of finding a virus-rich focus. High concentrations of WNV are not found in non-CNS tissues of infected equids, in contrast to the distribution of the virus in many other species.

Samples for confirmation of diagnosis

- **Virology** – minimum sample is one half of sagittally sectioned hindbrain (*must include medulla*). Ideally a segment of thoracolumbar spinal cord as well. Submit samples chilled (VI, RT-PCR)
- **Histology** – same samples, fixed in formalin (LM, IHC, RT-PCR).

Note the zoonotic potential of this disease when collecting and submitting specimens. Some authorities recommend using containment level 3 precautions when handling potentially infected tissues, such as that from birds.[24]

DIFFERENTIAL DIAGNOSIS

Differential diagnoses for West Nile encephalitis include (Table 22.1):

- Eastern and Western encephalitis
- Venezuelan equine encephalitis
- Equine herpesvirus 1 myeloencephalopathy
- Rabies
- Botulism
- Hepatic encephalopathy
- Borna disease
- Equine protozoal myeloencephalitis
- Leucoenephalomalacia
- Lower motor neurone disease

TREATMENT

There is no specific treatment for West Nile encephalitis although administration of interferon or hyperimmune globulin has been advocated. Affected horses are often administered non-steroidal anti-inflammatory drugs such as flunixin meglumine, dimethyl sulfoxide, or corticosteroids in an attempt to reduce inflammation in neural tissue.[19] Administration of corticosteroids minimally but statistically significantly increases the likelihood of survival[22] but this practice is controversial. Treatment is based on supportive care and prevention of complications of neurologic disease and includes assistance to stand, including use of a sling support, administration of antimicrobials, and maintenance of hydration and nutrition.

CONTROL

Control of disease associated with West Nile virus is achieved by vaccination and minimization of exposure. Elimination of the virus is not practical given that it cycles through avian and insect vectors and that the horse is incidentally infected.

Vaccination is believed to be effective in preventing development of disease, and has been demonstrated to reduce the likelihood of death in horses with West Nile encephalitis by approximately 2–3 times.[17,22] Efficacy of vaccination in preventing disease in horses has not been formally demonstrated although there is general agreement that vaccination is an important aspect to control of the disease.[13] There is no evidence that administration of the inactivated virus vaccine increases the risk of fetal loss in mares.[31] Vaccination prevents viremia in most horses following exposure to WNV-infected mosquitoes.[32]

Both inactivated virus vaccine and a live canarypox-vectored recombinant vaccine are available in North America. The inactivated virus vaccine should be administered in two doses at an interval of 3–6 weeks in early summer in the first instance, and then again once to twice yearly before the season of peak disease incidence. Foals from unvaccinated mares should be administered the vaccine beginning at 2–3 months of age, and foals of vaccinated mares should be administered the vaccine beginning at 7–8 months of age.

Administration of the recommended two doses of inactivated virus vaccine fails to induce an adequate plaque reduction titer in approximately 14% of horses 4–6 weeks after vaccination, and in 30% of horses 5–7 months after vaccination.[27] This effect was especially evident in horses >10 years of age.[27] These results indicate that some horses will not develop protective immunity against WNV despite administration of vaccine in the recommended dose and interval.

Minimization of exposure of horses to the virus includes reducing the population density of mosquitoes and protecting horses from being bitten. Reducing the population of mosquitoes includes widespread spraying with insecticides and elimination of mosquito breeding sites. Widespread spraying in cities is employed when the disease is a risk for humans but is not practical for controlling mosquitoes in rural areas. Environmental concerns make this approach to control unacceptable in many regions.

Removal of larval habitat by draining standing water is recommended for control of WNV, although the efficacy of this approach has not been demonstrated. Standing water includes not just dams and ponds but also poorly maintained outdoor swimming pools, bird baths, discarded vehicle tires, and other receptacles that could hold water. Use of larvicidal compounds in standing water is recommended by some authorities.

Minimizing the frequency with which horses are bitten by mosquitoes has the potential to reduce the risk of contracting the disease. However specific recommendations are not available. Housing during periods of peak mosquito activity, especially at dawn and dusk, might reduce the risk of disease.

Table 22.2 Differential diagnosis of diseases characterized by lesions of the teat skin only

Disease	Epidemiology: Method of spread	Epidemiology: Course of disease	Lesions	Clinical pathology
Cowpox (usually vaccinia) virus	Very rare. More commonly vaccinia from recently vaccinated people. Contact spread via teat injuries	2–4 weeks. In immune herd heifers only. Mastitis sequel	Vesicle, pustule, ulcers to 1–2 cm, thick red brown scabs on teats and udder. Rarely to perineum, vulva month of calves. Scrotum of bull	Electron microscopy of swab from lesion. Tissue culture
Pseudocowpox	Very common. Morbidity 5–10% affects whole herd. Little immunity and recurs quickly. Spread by contact, hand, cloth, teat cup. On milker's hands as nodule	Slow spread, long healing time, and cyclical recurrence in individual cows, disease lasts up to 18 months in herd	Erythema, vesicle, pustule scab in ring or horseshoe pattern. Elevated due to granulation tissue. 0.5–2.5 cm. Heal in 7–10 days. Rare lesions in mouth	Electron microscopy of vesicle fluid. Tissue culture
Bovine ulcerative mammalilitis	Affects 20–100% (average 50%). Insect transmission into herd. Seasonal autumn. Milking machine spread *plus* teat injury. Recurs in herd after 13 months	Self-limiting. Persists 6–14 weeks. Many cows culled because of bad ulcers and mastitis; subsequently heifers only affected	Test swollen, painful, exudes serum, skin sloughs, leaving raw ulcer covering most of teat. Mild cases have 0.5–2 cm ring-like erythema around nodule or ulcer. Lesions heal 10 days to 2 months. Fresh cows have extensive sloughing of teat and udder. Rarely lesions in mouth of calves sucking cows	Tissue culture of herpesvirus from *early* lesion. High antibody titer. Tissue culture of herpesvirus DN599
Udder impetigo	Spread during milking by contact. Pustules on milker's hands	Disappears quickly from each cow but recurs within 6 months and may persist in herd	Small 2–4 mm diameter pustules (may be large boils) at teat base, spread to teat and udder skin	Microbiological culture of swab of pus: *Staphylococcus aureus*
Black pox	Sporadic only. Due to poor milking machine technique	Intractable to treatment. Mastitis common sequel	Deep crater-shaped ulcer with black spot in center. At teat tip, involve sphincter	Culture of *Staphylococcus aureus*
Teat fibropapilloma	Contact at milking time via teat cups, hands etc. to abrasions of teat skin. May be 20% of herd affected	Disappear spontaneously 2–3 up to 5 months. Cause annoyance	Small white slightly elevated nodules 0.3 cm dia or elongated tags 1 cm long removable by traction

BORNA DISEASE

Borna disease is an **infectious encephalomyelitis** of horses and sheep first recorded in Germany. It is associated with a negative sense, single-stranded RNA virus classified as *Bornavirus* within the order Mononegavirales.[1] The disease and the virus are indistinguishable from near Eastern equine encephalomyelitis. Borna disease is now recognized as a subacute meningoencephalitis in horses, cattle, sheep, rabbits, and cats in Germany, Sweden and Switzerland.[2–4] There are reports of encephalitis with Borna disease virus genome detected in lesions by PCR in a horse and a cow in Japan.[5,6] Encephalitis associated with BDV was detected in young ostriches in Israel.[8]

Borna disease virus (BDV) is suspected of causing disease in humans, including lymphocytic meningoencephalitis, but BDV infection is not associated with an increased prevalence of psychiatric disorders.[8,9] Others suggest that the presence of circulating BDV immune complexes (BDV antigen and specific antibodies) is associated with severe mood disorders in humans.[10] The role, if any, of BDV in human neurologic or psychiatric disease has not been established with any certainty.

Detection of **BDV genome** by PCR analysis suggests that, while the spontaneous disease in horses and sheep occurs predominantly if not exclusively in Europe, clinically unapparent BDV infection is widespread in a number of species including horses, cattle, sheep, cats, and foxes.[11,12] However, concern has been raised that some of these reports might be based on flawed laboratory results as a consequence of contamination of PCR assays.[11] **Antibodies** to BDV in serum or cerebrospinal fluid have been detected in horses in the eastern United States, Japan, Iran, Turkey, France, and China,[11,13–17] and in healthy sheep and dairy cattle in Japan.[18,19] In areas in which the disease is not endemic between 3% (US) and 42% (Iran) of horses have either antibodies or BDV nucleic acid, detected by PCR, in blood or serum. Similarly, approximately 12–20% of horses have serological evidence of exposure to BDV in areas of Europe where the disease is endemic. Antibodies to BDV and nucleic acid have been detected in humans in North America, Europe, and Japan.[20,21] Closed flocks of sheep and herds of horses have evidence of persistent infection of some animals, based on serological testing.[22,23] It is worth noting that animals infected

with the virus and clinically ill may have undetectable to very low antibody titers.[22]

The method of transmission of infection between animals is unknown, but it is thought to be horizontal by inhalation or ingestion. Seropositive, clinically normal horses and sheep can excrete virus in conjunctival fluid, nasal secretions and saliva,[22,24] suggesting that they might be important in the transmission of infection. Removal of all seropositive and BDV RNA positive sheep from a closed flock did not prevent seroconversion of other animals in the flock the following year.[22] The possibility of vertical transmission is raised by the finding of BDV RNA in the brain of a fetal foal of a mare that died of Borna disease.[25]

There is a seasonal distribution to the prevalence of the disease, with most cases in horses occurring in spring and early summer.[21] The virus has not been isolated from arthropods, including hematophagous insects.

The **morbidity** in Borna disease is not high, approximately 0.006–0.23% of horses affected per year in endemic areas of Germany,[21] but most affected animals die.

The **pathogenesis** of the disease involves infection of cells of the central nervous system. It is assumed that the virus gains entry to the central nervous system through trigeminal and olfactory nerves, with subsequent dissemination of infection throughout the brain.[27,28] Viral transcription and replication occurs within the cell nucleus.[28] Viral replication does not appear to result in damage to the infected neuron. However, infected cells express viral antigens on their surface which then initiate a cell-mediated immune response by the host that then destroys infected cells – immunosuppression prevents development of the disease.[29] The inflammatory response is largely composed of $CD3^+$ lymphocytes.[30] The disease is subacute; infection and the development of lesions may take weeks to months. Clinically inapparent infection appears to be common in a number of species, including horses.

In **field outbreaks** the incubation period is about 4 weeks, and possibly up to 6 months.[28]

Clinical signs of the disease in horses include:

- Moderate fever
- Pharyngeal paralysis
- Lack of food intake
- Muscle tremor
- Defects in proprioception
- Hyperesthesia.[27]

Lethargy, somnolence and flaccid paralysis are seen in the terminal stages, and death occurs 1–3 weeks after the first appearance of clinical signs. Infection without detectable clinical signs is thought to be common on infected premises. The frequency with which BDV is detected in horses with gait deficits is greater than in clinically normal horses, suggesting a role for the virus in inducing subtle disease.[31,32]

The disease in cattle has a similar presentation as that in horses, with affected animals having reduced appetite, ataxia, paresis, and compulsive circling.[2,3] The disease ends in the death of the animal after a 1–6-week course.[2]

Hematology and routine serum biochemistry are typically normal, with the exception of fasting induced hyperbilirubinemia in anorexic horses. Clinicopathological identification of exposed animals is achieved with the complement fixation, ELISA, western blot, or indirect immunofluorescent tests.[33]

At **necropsy** there are no gross findings, but histologically there is a lymphocytic and plasmacytic meningoencephalitis, affecting chiefly the brain-stem, and a lesser degree of myelitis. The highest concentration of virus is in the hippocampus and thalamus.[27] The diagnostic microscopic finding is the presence of intranuclear inclusion bodies within neurons, especially in the hippocampus and olfactory bulbs. The virus can be grown on tissue culture and demonstrated within tissues by immunofluorescence and immunoperoxidase techniques.[28] BDV can also be detected in formalin-fixed, paraffin-embedded brain tissues using a nested PCR.[34]

Specific **control measures** cannot be recommended because of the lack of knowledge of means of transmission of the virus. The role of inapparently infected horses in transmission of the disease is unknown, and there is no widespread program for testing for such horses. An attenuated virus vaccine was produced by continued passage of the virus through rabbits and used in the former East Germany until 1992.[21] However, its use was discontinued because of questionable efficacy.

BUNYAVIRIDAE (CALIFORNIA GROUP, SNOW SHOE HARE)

There are a number of Bunyaviridae that cause disease in horses in the western hemisphere.[1] The viruses are maintained in a mosquito-vertebrate host-mosquito or midge-vertebrate host-midge cycles with horses being infected and developing signs of neurologic disease occasionally.

The **California serogroup** of viruses are mosquito-transmitted viruses of the family Bunyaviridae which can cause acute encephalitis in horses.[1,2] There are 12 serotypes isolated in Africa, Europe, Asia, and North and South America. Snowshoe hare and Jamestown Canyon are two of these serotypes that have been isolated in Canada and California, and that have the potential to cause disease in humans. The **snowshoe hare virus** is the most widely occurring arbovirus in Canada and is maintained in an amplification cycle involving small mammals, such as snowshoe hares, and mosquitoes, primarily of the genus *Aedes*.[2] In one reported case, the horse recovered completely within 1 week and there was seroconversion to the snowshoe hare serotype of the California serogroup of viruses.[3] Approximately 15% of horses in California have antibodies to **Jamestown Canyon virus** in horses in southern California.[4] The virus has been isolated from vesicular lesions in a horse.[5]

The **Cache Valley virus** has been isolated from a clinically normal horse and the high seroprevalence of specific antibody suggests enzootic transmission.[6]

The **Main Drain virus** has been isolated from a horse with severe

encephalitis in California.[1] Clinical findings included incoordination, ataxia, stiffness of the neck, head-pressing, inability to swallow, fever, and tachycardia. The virus is transmitted by rabbits and rodents and by its natural vector, *Culicoides varipennis*.

OTHER VIRUSES

The **Powassan virus**, a flavivirus, occurs in Ontario and eastern United States, and produces a non-suppurative, focal necrotizing meningoencephalitis in horses.[7] Approximately 13% of horses sampled in Ontario in 1983 were serologically positive to the virus. Experimental intracerebral inoculation of the Powassan virus into horses resulted in a neurological syndrome within 8 days.[8] Clinical findings include a 'tucked-up' abdomen, tremors of the head and neck, slobbering and chewing movements resulting in foamy saliva, stiff gait, staggering, and recumbency. Pathologically, there is a non-suppurative encephalomyelitis, neuronal necrosis, and focal parenchymal necrosis. The virus has not been isolated from the brain.

Nigerian equine encephalitis, a disease with low morbidity but high mortality, is characterized by fever, generalized muscle spasms, ataxia, and lateral recumbency of 3–5 days duration. The virus has not been identified.[9]

Nipah virus is a cause of encephalitis in humans and pigs in south-east Asia.[10] The virus is a member of the henipavirus family, which includes Hendra virus, which is transmitted from frugiverous bats (*Pteropus* sp.) to pigs, among which it spreads horizontally to other pigs and humans. Horses can be exposed and develop antibodies to the virus, and there is one anecdotal report of dilated meningeal vessels in a horse from which Nipah virus was isolated.[11]

Salem virus has been isolated from horses, but does not appear to cause disease in this species.[12]

GETAH AND ROSS RIVER VIRUS

Getah virus and Ross river virus are both alphaviruses within the Semliki Forest complex of togaviruses. These are small enveloped viruses with a single-stranded, positive sense RNA genome. Getah virus causes disease in horses and pigs, whereas Ross River virus causes disease in humans and, arguably, horses.

The geographic range of the viruses is distinctive, with Getah virus reported from Japan, Hong Kong, south-east Asia, Korea, and India, and Ross River virus found in most areas of continental Australia, Tasmania, West Papua and Papua New Guinea, New Caledonia, Fiji, Samoa, and the Cook Islands.[1] Reports from the 1960s document antibodies to Getah virus in animals in Australia, but the presence of this virus in Australia has not been confirmed using modern techniques that are able to differentiate antibodies to Getah virus from those of the related Ross River virus and other viruses in this complex. There are no reports of disease caused by Getah virus in Australia. There is considerable sequence homology between Getah and Ross River virus genomes.[2] There is geographic genetic variability among isolates of Ross River virus, and temporal, but not geographic, variability among isolates of Getah virus from South-east Asia and Japan.[3,4]

Both viruses are arthropod-borne, and infection is through the bite of an infected mosquito. The virus is maintained in the mosquito-vertebrate-mosquito host cycle typical of arboviruses. The definitive, amplifying vertebrate host for Getah virus is unknown although a number of vertebrates including horses, cattle and pigs can be infected by the virus. Horses and pigs become viremic and presumably can infect mosquitoes, although this does not appear to have been confirmed experimentally. The life cycle of Getah virus has not been explicated. The virus is assumed to be maintained in a mosquito–pig–mosquito cycle in those areas in which there is mosquito activity year round.[5] Persistence of the virus in areas in which mosquito activity is seasonal has not been explained, and whether transovarial or transtadial transmission occurs within the mosquito population is not reported.[5] The vertebrate hosts of Ross River virus include a large number of eutherian, marsupial, and monotreme mammals and birds.[1] Macropod species, including kangaroos and wallabies, are assumed to be the most important amplifying hosts, although this is debated.[1]

There is suspicion that during outbreaks of disease Getah virus is spread by horse-to-horse contact, based on the rapidity of spread among horses, the short duration of the outbreak, and the lack of mosquito activity at the time that some horses developed the disease.[6,7] However, experimental evidence suggests that this route of spread is likely of limited importance in propagation of epidemics because of the low concentration of virus in nasal and oral secretions of infected horses, and the large inoculum required to cause disease in horses by the intranasal route.[8]

The prevalence of serological evidence of infection of horses by Getah virus in Japan ranges from 8 to 93%, depending on the region of the country in which the samples were collected and the disease history of the band or stable of horses.[6,9] Seroprevalance was 17% in India and 25% in Hong Kong.[8,10] These results confirm the widespread incidence of subclinical infection of horses by Getah virus in endemic areas.

There is a similar high incidence of Ross River virus infection of horses in endemic regions of Australia. Prevalence of seropositive horses in Queensland, an area in which year-round mosquito activity was likely, is approximately 80%, whereas that of horses around the Gippsland lakes in southern Australia, a region with seasonal mosquito activity, is 50%.[11] These high rates of infection, in the absence of similarly high rates of clinical disease, suggest that the virus is minimally pathogenic in horses, and increases the likelihood that seroconversion or virus isolation from horses with clinical abnormalities is a chance event and not causally related.

The **disease syndrome** caused by infection by **Getah virus** is better defined than that of Ross River virus, but infection by either virus appears to cause disease in horses that has a number of clinical features in common.[6,7,11,12] Disease associated with Getah virus infection is characterized by pyrexia, edema of the limbs, and an abnormal gait, often described as 'stiffness'.[6,7] Eruptions of the skin, urticaria, and submandibular lymphadenopathy are reported in some horses with the disease in Japan, but not in India.[6,7] The clinical disease persists for 7–10 days. Abortion is not a feature of the disease and foals born of mares that have had the disease during gestation are normal.[13] Subclinical infection is very common.

Hematological abnormalities induced by Getah virus infection in horses include lymphopenia.[6] Increases in serum activity of muscle derived enzymes, such as creatine kinase, are not characteristic of the disease. Affected horses can have mild to moderate hyperbilirubinemia secondary to inappetance.[6]

The disease associated with **Ross River virus infection of horses** is typified by pyrexia, lameness including 'stiffness', swollen joints, inappetance, reluctance to move, and mild colic.[11,12] The duration of disease caused by Ross River virus in horses is uncertain, and some veterinarians consider that the

disease can persist for weeks to months, or recur in horses. There is some skepticism regarding the pathogenicity of Ross River virus in horses because, at least in part, the disease syndrome associated with Ross River virus infection of horses is not well characterized. Descriptions of the disease are based on a very small number of horses in which there was demonstrated viremia concurrent with development of clinical signs of disease, or larger number of horses with serum antibodies to the virus. Horses infected experimentally with Ross River virus have minimal clinical signs of disease.[14] There are insufficient reports of disease to determine if characteristic or diagnostic abnormalities in serum biochemistry or hematology occur in affected horses.

Diagnosis of infection by Ross River virus is achieved by virus isolation from serum or heparinized blood samples collected during the acute phase of the disease, or detection in serum of antibodies to the virus.[12] Detection of IgM antibodies to Ross River virus is indicative of recent infection whereas detection of IgG antibodies is indicative of more distant infection.[12] Seroconversion confirms exposure, and presumably infection, by the virus. Isolation of Ross River virus has been achieved from horses with IgM antibody to the virus, but not with IgG antibody, likely because of the temporal pattern of antibody appearance in blood of infected horses.[12] In addition to culture of the virus in mice or tissue culture, Ross River virus can be detected in blood and synovial fluid using an RT-PCR.[14] It is important to remember that subclinical infection of horses in endemic regions is very common and that this high rate of subclinical infection increases the risk of incorrect attribution of clinical abnormalities to infection by the virus – it is possible that clinical abnormalities in a horse with Ross River viremia or serum antibodies to the virus are not attributable to infection by Ross River virus.

There are not reports of postmortem examination of horses with disease confirmed to be caused by Ross River Virus.

Diagnosis of disease caused by **Getah virus** is achieved by detection of clinical signs consistent with the disease, isolation of the virus from blood of affected horses, and seroconversion to the virus.[4] Interpretation of serological data from horses in Japan is hindered by the widespread use of a vaccine against Getah disease that induces detectable antibodies to Getah virus in serum.[9]

Reports of postmortem examination of horses with disease caused by Getah virus are limited to experimental studies because the disease is typically not fatal. Horses with disease induced by inoculation with pathogenic Getah virus typically have mild changes including atrophy of splenic and lymphoid tissue with destruction of lymphocytes, and perivascular and diffuse infiltration of focal skin lesions by lymphocytes, histiocytes, and eosinophils. Lesions in the central nervous system are equivocal and limited to mild perivascular cuffing in the cerebrum and small hemorrhagic foci in the spinal cord.[13]

Treatment of affected horse is supportive. Affected horses might benefit from administration of analgesics and antipyretics such as phenylbutazone. Administration of antimicrobials is not indicated in uncomplicated cases.

An inactivated virus vaccine is available in Japan for immunization of horses against disease caused by Getah virus.[9] The vaccine, which is combined with that for Japanese encephalitis, is considered effective. For both Getah virus and Ross River virus minimizing the exposure of horses to infected mosquitoes is prudent although the efficacy of this technique in preventing infection is unknown. During outbreaks of disease caused by Getah virus it is prudent to isolate affected horses, given the potential for horse-to-horse spread of the virus.

There is no vaccine to prevent infection or disease of horses by Ross River virus.

Zoonotic implications

Disease of humans caused by Getah virus has not been documented.

Disease associated with Ross River virus infection is common in humans in Australia with an estimated 4800 cases per year, and much larger numbers during epidemics of the disease.[15] The horse is believed to be an amplifying host of the virus because experimentally infected horses can infect mosquitoes.[16] The disease in humans is characterized by mild pyrexia and constitutional signs initially, with subsequent development of a rash on the skin and oral lesions. Arthritis or arthralgia is common and affects primarily the wrists, knees, ankles and small joints of the extremities. These signs and symptoms can persist for 2–3 months, and the disease can relapse.

RABIES

Synopsis

Etiology *Lyssavirus* of family Rhabdoviridae

Epidemiology Occurs in all farm animals worldwide except Australia and New Zealand. Major zoonoses. Transmitted by bites of infected animal. Many different wildlife are vectors depending on geographic location; vampire-bats in South America, foxes in Europe and North America, skunks in North America, mongoose in Africa, raccoon in the United States recently

Signs Incubation period varies from 2 weeks to several months. *Cattle* – Paralytic form: bizarre mental behavior (yawning, bellowing), incoordination, decreased sensation of hindquarters, drooling saliva, recumbency, and death in 4–7 days. Furious form: hypersensitive, belligerent, then paralysis and death as in paralytic form. *Sheep* – Outbreaks common; sexual excitement, wool pulling, attacking, incoordination, and then paralysis. *Horses* – Abnormal postures, lameness or weakness, depression, ataxia, pharyngeal paralysis, recumbency, hyperesthesia, biting, loss of anal sphincter tone, death in 4–6 days. *Pigs* – Excitement, attack, twitching of nose, clonic convulsions, paralysis

Clinical pathology No antemortem test

Lesions Non-suppurative encephalomyelitis

Differential diagnosis list:

- *Cattle*: Lead poisoning, lactation tetany, hypovitaminosis-A, listerial meningoencephalitis, polioencephalomalacia, nervous acetonemia
- *Horse*: Viral encephalomyelitis, herpes viral paralysis, cerebrospinal nematodiasis, equine degenerative myeloencephalopathy, protozoal encephalomyelitis, neuritis of cauda equina, horsetail poisoning, Borna, Japanese encephalitis, botulism
- *Sheep*: Enterotoxemia, pregnancy toxemia, louping-ill, scrapie
- *Pig*: Pseudorabies, Teschen's disease, Glasser's disease, and other meningitides (*E. coli* and *Streptococcus suis*).

Diagnostic confirmation Fluorescent antibody test of brain. Negri bodies histologically

Treatment None. All rabies cases are fatal

Control Prevention of exposure. Vaccination of domestic animals and wildlife. Quarantine and biosecurity to prevent entry of virus into country

ETIOLOGY

Rabies is associated with the rabies virus of the genus *Lyssavirus* of the family Rhabdoviridae.[1] The genus is composed of at least six genotypes.

It was recognized long ago that the strain of virus known as the 'street' rabies virus differed in some way from 'fixed' strains which had been cultivated for vaccine production (grown in cell culture or passaged through serial generations of laboratory animals). It is now known that t there are several strains of rabies virus, which are adapted to particular host species but remain infective for any warm-blooded mammal.[2]

EPIDEMIOLOGY

Occurrence

Rabies occurs in all warm-blooded animals.[1,3] The disease occurs in cattle, sheep, pigs, and horses in most countries, except the insular countries that exclude it by rigid quarantine measures or prohibition of the entry of dogs. However, the genus Lyssavirus can still cause surprises. In 1996 and 1998, two women died in Queensland, Australia, from infections with a newly discovered rabies-related virus (Australian bat lyssavirus).[4] In 2002, a man died in Scotland after contracting European bat lyssavirus rabies indicating that after a century of apparent freedom from rabies, the disease is now enzootic in the UK.[4]

South America, Latin America and the Caribbean

Rabies in cattle is a major economic and public health problem in South America, where vampire bat-transmitted rabies results in cyclic outbreaks. Bovine paralytic rabies is endemic in the tropical regions extending from northern Mexico, to northern Argentina, and on the island of Trinidad.[1] An outbreak in cattle in Guyana was associated with a large number of bats that had inhabited a culvert that was not cleaned regularly because of excessive rainfall.

Europe

In Europe, sylvatic rabies is a major problem where the **red fox** is the principal vector. The disease is still spreading from a focal point that developed in Poland in the mid-1930s. It is endemic in Yugoslavia and Turkey, and has spread westward to Germany, Denmark, Belgium, Czechoslovakia, Austria, Switzerland, and France. Spread continues at the rate of about 30–60 km (18–37 miles) per year and the threat to the United Kingdom increases each year. finland had been free of rabies since 1959, but in 1988 sylvatic rabies occurred with the raccoon dog as the vector. Monoclonal antibody indicated the virus was an Arctic-type strain possibly related to the red fox. France reported more than 2000 cases of rabid cattle between 1968 and 1982, and had more cases in sheep than in either dogs or cats during the same time period. In former East Germany, sheep were the second most frequent animal diagnosed with rabies after foxes.

Epidemiological studies of rabies in Lithuania from 1990 to 2000 found that rabies among wildlife comprised 54% with the majority of cases in foxes (27%), followed by raccoon dogs (21%).[5] The incidence of rabies in foxes and raccoon dogs increased over the period of study. Also, the number of humans attacked by domestic animals and wild animals has increased.

Africa

Rabies occurs in most countries in the African continent, but the reported incidence is surprisingly low for an area with such a high population of wild carnivores. The incidence of rabies, and the range of species involved, is increasing in Africa, and a number of wildlife hosts has been identified, including wild dogs, jackals and mongoose. Because of dislocation of civilian life, rabies in Zimbabwe has increased in prevalence and geographical distribution in recent years.

Rabies is now a very serious zoonotic disease in South Darfur, Sudan.[16]

South Africa

Over a 4-year period, of all the domestic animal rabies cases reported, cattle accounted for one-half of the rabies cases in South African domestic animals. The **mongoose** accounted for 70% of the wild animal cases reported.[7] Widespread distribution of the rabies virus occurs when the young mongooses are evicted from their parents' territory during the winter months, forcing them to scatter over a wide area. This increases the probability of domestic animals coming in contact with rabid animals.

Canada

The arctic fox variant of rabies invaded most of Canada south of 60°N and east of the Rocky Mountains in the early 1950s largely by the migration of **arctic foxes** into the populated areas.[8] It died out in most of that range, but persisted for over 40 years in southern Ontario with sporadic incursions into narrow adjacent strips in western Quebec and northern New York. The principal vectors were red foxes (*Vulpes vulpes*) and, to a lesser extent, striped skunks (*Mephitis mephitis*). During the period 1957 to 1989, Ontario experienced more animal rabies cases than any almost every North American jurisdiction almost every year, and over 95% of those cases were limited to the southernmost 10% of the province's land area.

A second major outbreak, involving **striped skunks**, progressed from North Dakota into the prairie provinces during the late 1950s and 1960s. In the 1990s, the endemic areas in Canada are southern Ontario, which accounts for 85% of the Canadian diagnoses, and the prairie provinces where rabies is endemic in skunks. In western Canada, the main reservoirs of the rabies virus are skunks, bats, and foxes.

In southern Ontario, Canada, the ecogeographic patterns of rabies indicate that townships could be aggregated into 12 rabies units or clusters.[9] The units had different behaviors in terms of species composition, persistence, and periodicity. The ratio of rabid skunks to rabid foxes varied between areas which may be due to seasonal factors and urban development. This information is useful for planning rabies control programs.

United States

Information on rabies surveillance in the United States is published annually by the Centers for Disease Control and Prevention.[10–14] From 1999 to 2003, more than 90% of cases occurred in wild animals, 6 to 9% in domestic animal species. The disease occurred in humans, raccoons, skunks, bats, foxes, cats, dogs, cattle, sheep and goats, horses and mules, mongoose, rodents and lagomorphs.

Most cases of rabies reported annually in the United States occur among three groups of carnivores: raccoons, skunks, foxes, and among bats.[15] However, between 1960 and 2000, a total of 2851 cases of rabies in 17 other carnivore taxa were reported to the Centers for Disease Control and Prevention, Atlanta, Georgia.[15] Three species of other carnivores (mongooses, coyotes, and bobcats accounted for 92% of the cases reported among other carnivorous mammals.

The most frequently reported rabid wildlife cases occurred in raccoons, skunks, bats, and foxes.[10] The relative contributions of those species continue to change in recent decades because of fluctuations in enzootics of rabies among animals infected with several distinct variants of the rabies virus.

During the past 30 years, rabies in domestic animals has steadily decreased in the United States, whereas annual occurrence in wild animals has increased. Wild animals accounted for 92% of all reported cases of rabies in 1995, a decrease from 1994. Raccoons were the most frequently reported rabid animal (50.3% of all animal cases), followed by skunks (22.5%), bats (10.0%), foxes (6.5%) and other wild animals, including rodents and lagomorphs (2.7%). Domestic animals accounted for nearly 8% of all rabid animals in the United States in

1995. In recent years, the number of rabid cattle was equal to, or greater than, the number of rabid dogs. The incidence of rabies in horses is low compared to wildlife or domestic small animals but some yearly fluctuations occur.

In 1990, for the first time since surveillance began in 1950, the number of cases in raccoons exceeded that in skunks. Raccoon rabies spread from Florida to raccoons in Georgia, Alabama, South Carolina, and North Carolina by natural spread.[2] A separate focus in the northeastern States was caused by a translocation of raccoons from Florida, with legal permits to Virginia for restocking of hunting preserves.[2] From the index case in a raccoon in 1977, near the Virginia–West Virginia border, over the next 17 years, 20 000 cases of rabies were recorded in raccoons, and several thousand associated cases in domestic dogs and other animals. In Canada, the rabies virus isolates from rabies-positive raccoons from 1982 to 1994 were the same strains found in foxes and skunks in eastern Canada,[8] and is different from the 'Mid-Atlantic' strain found in raccoons in the eastern United States. Local dynamics of epidemics of rabies in raccoons in the United States can be predicted.[16]

Historically, in North America, the number of cases of rabies in skunks exceeded that in either raccoons or foxes. Endemic skunk rabies occurs mainly in four geographical regions: southern Ontario and Quebec and upper New York State; the north central United States and the Canadian provinces of Manitoba, Saskatchewan, and Alberta; California; and south central United States. Within these broad areas, the disease persists in enzootic foci and erupts every 6–8 years. Experimental studies suggest that the species specificity of endemic rabies is due to differences in the pathogenicity of variants of rabies virus. Skunk rabies peaks in the spring and early winter, which is probably a reflection of certain life history events within the skunk population.

The prevalence of rabies in bats in the United States is about 6%, and transmission to humans is rare even though sensational journalism has caused many people to consider bats as a serious threat to health. All of the confirmed cases of rabies in bats in Michigan in 1993 were associated with the big brown bat; in New York the prevalence in 1993 was 4.6% and nearly 90% of rabid bats were the common big brown bat. However, the silver-haired bat was associated with two human cases of rabies.

Trends in national surveillance for rabies among bats in the United States from 1993 to 2000 have consistently found a diffuse geographic pattern of rabies in bats throughout the continental United States.[17] Although spillover infection of bat variants of rabies among terrestrial animals such as dogs and cats are rare, these variants of rabies virus have been associated with 92% of the indigenously acquired human rabies infections in the United States since 1990.[11] Data from 37 states from 1993 to 2000 indicate an increased risk of rabies among certain groups of bat species was consistently found across season and most geographic regions of the US.[17] The Brazilian free-tailed, eastern pipistrelle, and the silver-haired bats, when considered as a single group, were more rabid more frequently than were other bat groups.

All warm-blooded animals, with the possible exception of opossums, are susceptible, and there is no variation in susceptibility with age; 1-day-old pigs have been affected. Variation in susceptibility between species is noticeable. Foxes, cotton rats, and coyotes are extremely susceptible; cattle, rabbits, and cats are highly susceptible; dogs, sheep, and goats are moderately susceptible; and opossums little if at all.

Distribution of virus variants

The *Lyssavirus* genus belongs to the Rhadoviridae family of the Mononegavirales order and includes unsegmented RNA viruses causing rabies encephalomyelitis. They are well fitted to vectors belonging to the orders Carnivora (flesh-eating mammals including skunks), and Chiroptera (the order which comprises all of the 178 genera in 16 families of bats). Seven genotypes have so far been delineated within the genus. These genotypes are divided into two immunopathologically and genetically distinct phylogroups. Phylogroup I includes two African genotypes: *Mokola virus*, which has been isolated from shrews and cats, although its reservoir remains unknown, and *Lagos bat virus*, which has been found mainly in frugivorous bats but also in an insectivorous bat. Phylogroup II has five genotypes: *Duvenhage virus* (Africa), *European bat lyssavirus I* (EBLV-1; Europe), EBLV-2 (Europe), *Australian bat lyssavirus* (Australia), and the classical *Rabies virus* (RABV, worldwide). Members of the genotypes *Duvenhage virus*, EBLV-1, and EBLV-2 are exclusively found in insectivorous bats, members of the genotype *Australian bat lyssavirus* are found in both insectivorous and frugivrorous bats, and member of the genotype RABV are found in carnivorous and American bats (insectivorous, frugivorous, and hematophagus). The fact that lyssaviruses are well established in two ecologically distinct mammal orders may very likely be the consequence of successful host switching.

Analysis of 36 carnivoran and 17 chiropteran lyssavirus representing the main genotypes and variants strongly supports the hypothesis that host switching occurred in the history of the lyssaviruses. In fact, lyssaviruses evolved in chiroptera long before the emergence of carnivoran rabies, very likely following spillovers from bats.[18] Using dated isolates, the emergence of carnivoran rabies from chiropteran lyssaviruses is estimated to have occurred 888 to 1459 years ago.

In Europe, bat rabies is associated with two specific virus strains: European bat lyssavirus type 1 and European bat lyssavirus type 2. European bat lyssavirus type 1 isolates have been found in serotine bats in France.[19] European bat lyssavirus type 2 virus have now been found in Daubenton's bats in England and Scotland.[20]

In North America, variants of rabies virus are maintained in the wild by several terrestrial carnivore species, including raccoons, skunks, and a number of bat species.[21] Each antigenically and genetically distinct variant of the virus in mammalian species occurs in geographically discrete areas and is strongly associated with its reservoir species.[11] Within each area, a spillover of rabies into other species occurs, especially during epidemics. Temporal and spatial analysis of skunk and raccoon rabies in the eastern United States, indicated that epidemics in raccoons and skunks moved in a similar direction from 1990 to 2000. However, to date there is no evidence that the raccoon rabies virus variant is cycling independently in the skunk population of the eastern United States or that the variant has undergone any genetic adaptations among skunks.[21]

Within broad geographic regions, rabies infections in terrestrial mammals can be linked to distinct virus variants, identified by panels of monoclonal antibodies or by genetic analysis.[2] These analyses have demonstrated substantial differences between isolates from various parts of the world. Most outbreaks of rabies tend to be host species-specific. Each variant is maintained primarily by **intraspecific transmission** within a dominant reservoir, although spillover infection of other species may occur within the region. Geographic boundaries of the currently recognized reservoirs for rabies in terrestrial mammals have been established. Reservoirs for rabies virus are found worldwide. The virus is maintained at endemic and epidemic levels in a wide variety of Carnivora and Microchiroptera

(bats) species. There are also antigenically similar rabies-like viruses, including the Makola virus, the Lagos bat virus, Duvenhage virus, European bat lyssavirus 1 and European bat lyssavirus 2 rabies, which are found principally in small mammals (rodents, insectivores, insectivorous or frugivorous bats). These strains appear to be limited in their geographical distribution to regions in Africa, unlike rabies virus which is distributed worldwide. The rabies-related viruses represent potential public and veterinary threats because of the lack of effective vaccines and the difficulties with diagnosis.

The geographic boundaries of the currently recognized reservoirs for rabies in terrestrial species in North America are as follows:

- Raccoons in the southeastern United States
- Red and arctic foxes in Alaska, resulting in spread across Canada as far east as Ontario, Quebec, and the New England states
- Striped skunks in California, the north central States, and the south central States
- Gray foxes in small reservoirs in Arizona
- Coyotes in south Texas as a result of spread from domestic dogs in a long-standing reservoir at the Texas–Mexico border.

The first reported occurrence of rabies in a human being infected with the raccoon rabies virus was from Virginia in 2002.[14]

In Ontario, wildlife rabies persists in two predominant species: the red fox and the striped skunk. Molecular epidemiology studies indicate that there is no host specificity, but rather there are very clear and consistent differences in the virus from distinct geographical regions. Such analyses will allow further epidemiological study of the behavior of the virus in different regions.

Overlying the disease in terrestrial mammals are multiple, independent reservoirs for rabies in several species of insectivorous bats. Distinct viral variants can be identified for different bat species, but geographical boundaries cannot be defined for rabies outbreaks in the highly mobile bat species.

Certain antigenic variants exist in nature against which conventional vaccines do not fully protect. In Canadian studies, two major antigenic groups can be distinguished among the rabies virus isolates examined. One group is found in Ontario, Quebec and the Northwest Territories and is represented in the wild by endemic red fox and striped skunk rabies that originated in northern Canada. The second group is found in Manitoba where striped skunk rabies is endemic.

The epidemiology of rabies in Chile and the animal species which serve as rabies reservoirs have been examined.[22] None of Chilean isolates segregated with viruses from the terrestrial reservoirs. No non-rabies lyssaviruses were found, and the Chilean samples were not related to viruses of the sylvatic cycle maintained by the common vampire bat. The Brazilian free-tailed bat was identified as the reservoir for the rabies genetic variant most frequently isolated in Chile from 1977 to 1998. The close association of a group of rabies viruses obtained from a domestic dog, Brazilian free-tailed bats, and a red bat with viruses maintained by red bat species in North America implicated species of this genus as the possible reservoirs of this particular genetic variant in Chile.

In Trinidad, bovine rabies is common and is due to the bat type.[23]

Methods of transmission

The source of infection is always an infected animal, and the method of spread is almost always by the **bite** of an infected animal, although contamination of skin wounds by fresh saliva may result in infection. Not all bites from rabid animals result in infection because the virus is not always present in the saliva and may not gain entrance to the wound if the saliva is wiped from the teeth by clothing or the coat of the animal. The virus may appear in the milk of affected animals, but spread by this means is unlikely as infection. The rabies virus is relatively fragile, susceptible to most standard disinfectants, and dies in dried saliva in a few hours.

One of the most important parameters in rabies models is the transmission rate, or the number of susceptible animals infected by a diseased animal per unit of time. In a population of 19 raccoons feeding at a concentrated, common food source available during the summer in rural eastern Ontario, raccoons bite and are bitten an average of 0.99 to 1.28 times per hour, respectively.[24]

Because of the natural occurrence of rabies in animals in caves inhabited by infected insectivorous bats, inhalation as a route of infection came under suspicion. It is now accepted that interbat spread, and spread from bats to other species is principally by bites, but that infection by inhalation also occurs. That infection can occur by ingestion has been put to use in devising systems of vaccinating wildlife by baiting them with virus-laden baits. This also has implications for epidemiological study generally. For example, attenuated viruses used in baits could be taken by other than the target species, thus creating an unexpected seropositive segment of the animal population. It is also considered likely that outbreaks occurring naturally amongst carnivores may originate by them eating bats that have died of rabies.

Animal vectors

Traditionally, the dog, and to a minor extent the cat, have been the main source animals. However, native fauna, including foxes, skunks, wolves, coyotes, vampire, insectivorous and fruit-eating bats, raccoons, mongoose, and squirrels provide the major source of infection in countries where domestic carnivora are well-controlled. In general, foxes are less dangerous than dogs, foxes tending to bite only one or two animals in a group, while dogs will often bite a large proportion of a herd or flock. Raccoons and skunks are major reservoir of rabies in North America.

Bats are the important species in which subclinical carriers occur. Multiplication of the virus without invasion of the nervous system is known to occur in fatty tissues in bats, and may be the basis of the 'reservoiring' mechanism in this species. Violent behavior is rare in rabid animals of this species, but has been observed. Bats represent a serious threat of spread of rabies because of their migratory habits. Most spread is within the species, but the threat to humans and animal species by bats cannot be completely disregarded. Although rodents can be infected with the rabies virus they are not thought to play any part in the epidemiology of rabies, either as multipliers or simply as physical carriers of the virus. Many of the viruses they carry are rabies-like rather than classical rabies.

Rabies has occurred in swine herds where the skunk population is high, where farms were settled from rough terrain resulting in considerable interface between wildlife and domestic animals, and in which the management system allows the pigs to run free on the premises. The disease has occurred in pigs reared in a closed feeder barn where access by wildlife was very unlikely.

There is a difference in role between vectors. For example, in Europe it is thought that foxes carry the infection into a new area, but other species disseminate it within an area.[25] Foxes are the principal vectors and, as in Canada, cattle are the principal receptors. In western Canada, the main reservoirs of infection are skunks, bats, and foxes. This would have important consequences for control programs based on wildlife surveillance.

Domestic livestock like cattle are rarely a source of infection, although chance

transmission to humans may occur if the mouth of a rabid animal is manipulated during treatment or examination. The virus may be present in the saliva for periods up to 5 days before signs are evident.

Seasonal spread

Spread of the disease is often seasonal, with the highest incidence in the late summer and autumn because of large-scale movements of wild animals at mating time and in pursuit of food. In Canada, the frequency of rabies infection in livestock populations increases in the fall when adolescent foxes mature, begin mating behavior, and travel over large areas.

Latent infection

Because of rapid developments in virological techniques, especially serological screening of animal populations to obtain presumptive diagnoses of the presence of a virus in the population, the question of latent infection and inapparent carriers of rabies has assumed some importance. The presence of rabies antibodies in animals in a supposed rabies-free area is likely to arouse concern. Inapparent carriers do occur in bats and there is some evidence that latent infections can occur in other species.

Zoonotic implications

The prime importance of rabies is its transmissibility to humans, with veterinarians being at special risk. European data indicate that by far the greatest proportion of humans requiring pre-treatment for rabies have been exposed to a rabid domestic animal, not a wild one.[1,3]

Human rabies is extremely rare in countries where canine rabies is controlled by regular vaccination. In the United States, a total of 28 cases of human rabies occurred from 1980 to 1995. Most were due to viral variants associated with bats. Rates of post-exposure prophylaxis in developing countries are about 10 times higher than those in the United States, and rates of human rabies are approximately 100 times higher. According to the WHO, over 30 000 people die each year from rabies and more than 10 million undergo post-exposure treatment, having been bitten by a rapid animal.[3] In 1987, according to surveillance conducted by the World Health Organization, dogs were responsible for 91% of all human rabies cases; cats, 2%; other domestic animals, 3%; bats, 2%; foxes, 1%; and all other wild animals, fewer than 1%. The disease is a major occupational hazard for veterinarians who should receive pre-exposure prophylaxis. Because horses will bite each other and their handlers, rabid horses that are aggressive pose a serious threat to humans.

There is a lack of general rabies knowledge among the public.[26] The laissez-faire attitude toward rabies by Americans causes instances of rabies exposure to be commonplace. A survey of middle school children in Texas found a lack of basic knowledge about rabies. Only 0.3% of children achieved a minimum score of 75% on a survey of knowledge about rabies.[26] Respondents lacked knowledge about the disease is transmitted, and less than one-third were even aware of rabies epidemic in southern Texas despite the fact that a rabies epidemic had been occurring in southern Texas for the previous 13 years. Even more astonishing was the finding that 80% knew of the risk of acquiring rabies from an unvaccinated pet buy 57% claimed to own unvaccinated pets.

Rabies is not of major economic importance in farm animals, although individual herds and flocks may suffer many fatalities. The disease in human has always been considered **fatal**. Since 1970, there have been reports of five patients said to have survived rabies encephalitis.[4] All patients had received some rabies vaccine before the onset of clinical signs but none had had rabies immunoglobulin.

A 15-year-old girl who developed rabies one month after being bitten by a bat survived following intensive medical therapy including induced coma while a native immune response matured, and treatment with ketamine, midazolam, ribarvirin, and amantadine.[27] Probable drug-related toxic effects included hemolysis, pancreatitis, acidosis, and hepatotoxicity. The patient was discharged to her home after 76 days, and at nearly 5 months after her initial hospitalization she was alert and communicative, but with choreoathetosis, dysarthria, and an unsteady gait.

Rabies in the Americas. Between 1993 and 2002, the number of human and canine rabies cases in the Americas Region fell by approximately 80%.[28] There were 39 human cases in 2002, 63% of them transmitted by dogs. Human rabies transmitted by wildlife, mostly by bats is a risk to inhabitants in many countries in the Region. This sharp reduction is attributable mainly to the control measures implemented by the countries in the Region, such as mass vaccination of dogs and prophylactic treatment of people who have been exposed.

Economic importance

The economic costs of rabies in a country are associated with pet animal vaccinations, animal bite investigations, confinement and quarantine of domestic animals which bite humans or which are suspected of exposure to rabid animals, salaries of animal control officers, laboratory diagnosis, the costs of pre-exposure and post-exposure prophylaxis and treatment and consultation, public education, staff training and clerical costs.

The cost of the '**point infection control**' program as a response to raccoon rabies introduction in Ontario in 1999 was $363 000 (Cdn) or $500 Cdn/km^2. The costs were justified as by containing the spread of raccoon rabies, annual savings to Ontario are estimated at $8 to 12 million.[29] The reported associated costs in Ontario before raccoon rabies occurred were estimated at about $6 million annually, excluding pet vaccination costs.

PATHOGENESIS

Following the deep introduction of rabies virus by the bite of a rabid animal, initial virus multiplication occurs in striated muscle cells at the site. The neuromuscular spindles then provide an important site of virus entry into the nervous system. Entry into the nervous system may also occur at motor end plates. In the olfactory end organ in the nares, neuroepithelial cells are in direct contact with the body surface and these cells extend without interruption into the olfactory bulb of the brain. Following entry of the virus into nerve findings, there is invasion of the brain by passive movement of the virus within axons, first into the spinal cord then into the brain[1,4] The immune response during this phase of the infection is minimal and explains why neutralizing antibody and inflammatory infiltration are usually absent at the time of onset of encephalitic signs. Antibody titers reach substantial levels only in the terminal stages of the disease. Following entry of rabies virus to the central nervous system (CNS), usually in the spinal cord, an ascending wave of neuronal infection and neuronal dysfunction occurs.

The primary lesions produced are in the CNS, and spread from the site of infection occurs only by way of the peripheral nerves. This method of spread accounts for the extremely variable incubation period, which varies to a large extent with the site of the bite. Bites on the head usually result in a shorter incubation period than bites on the extremities. The severity and the site of the lesions will govern to a large extent whether the clinical picture is primarily one of irritative or paralytic phenomena. The two extremes of the paralytic or dumb form and the furious form are accompanied by many cases that lie somewhere between the two. Gradually ascending paralysis of the hindquarters may be followed by

severe signs of mania, which persist almost until death. Destruction of spinal neurons results in paralysis, but when the virus invades the brain, irritation of higher centers produces manias, excitement, and convulsions. Death is usually due to respiratory paralysis. The clinical signs of salivation, indigestion and pica, paralysis of bladder and anus, and increased libido all suggest involvement of the autonomic nervous system, including endocrine glands. At death, there are viral inclusions and particles in almost all neurons in the brain, spinal cord and ganglia, but none in the supportive cells of the CNS. Electron microscopic examination also shows the presence of the virus in the cornea, which it reaches centrifugally along the peripheral nerves.

Virus reaches the salivary glands and many other organs in the same way, but the highly infective nature of saliva arises from passage of the virus along the olfactory nerve to taste buds and other sensory end organs in the oropharynx, rather than from the salivary glands. Experimentally, infection of non-nervous tissues in skunks and foxes has been reproduced in the adrenal medulla, cornea, and nasal glands.[19] The virus may be found in milk, in some organs and in fetuses, but the virus cannot be demonstrated in the blood at any time.

Variations in the major manifestations as mania or paralysis may depend upon the source of the virus. Virus from vampire bats almost always causes the paralytic form. 'fixed' virus that has been modified by serial intracerebral passage causes ascending paralysis in contrast to 'street' virus, which more commonly causes the furious form. The site of infection and the size of the inoculum may also influence the clinical course. There is also geographical difference in the proportion of animals affected by the furious or paralytic form of the disease. In the Americas most cases are paralytic. In Africa and India most cases in farm animals are the furious form.

The disease is always fatal, but infrequently an experimentally infected animal shows clinical signs of the disease but recovers. There are two recent records of spontaneous recovery in man, and the occurrence of non-fatal rabies in all species has been reviewed. There appears to be no field occurrence in domestic animals of the finding in experimentally infected mice that some strains of virus invade only peripheral nerves and spinal ganglia leaving a number of survivors with permanent nervous disability. The pathogenesis of recovery from rabies is important relative to vaccination and serological testing to determine the incidence and prevalence of the disease. The literature on the animal models used for the study of the pathogenesis and treatment of rabies has been reviewed.[1]

CLINICAL FINDINGS

Cattle and sheep

Cattle

Among farm animals, cattle are most commonly affected. The incubation period in naturally occurring cases is about 3 weeks, but varies from 2 weeks to several months in most species, although incubation periods of 5 and 6 months have been observed in cattle and dogs. In one large-scale outbreak in sheep, deaths occurred 17–111 days after exposure.

Experimentally, in cattle the average incubation period was 15 days and the average course of the disease was 3.7 days. Unvaccinated cattle had shorter incubation and clinical duration of disease than vaccinated cattle. Major clinical findings included excessive salivation (100%), behavioral change (100%), muzzle tremors (80%), vocalization (bellowing 70%), aggression, hyperesthesia and/or hyperexcitability (70%), and pharyngeal paralysis (60%). The furious form occurred in 70%.

In sheep, experimentally, the average incubation period was 10 days, and the average course of the disease was 3.25 days. Major clinical findings included muzzle and head tremors (80%), aggressiveness, hyperexcitability and hyperesthesia (80%), trismus (60%), salivation (60%), vocalization (60%), and recumbency (40%). The furious form occurred in 80% of sheep.

In the **paralytic form**, knuckling of the hind fetlocks, sagging and swaying of the hindquarters while walking, often deviation or flaccidity of the tail to one side, are common early signs. Decreased sensation usually accompanies this weakness and is one of the best diagnostic criteria in the detection of rabies. It is most evident over the hindquarters. Tenesmus, with paralysis of the anus, resulting in the sucking in and blowing out of air, usually occurs late in the incoordination stages just before the animal becomes recumbent. This is a characteristic finding but it may be transient or absent. Drooling of saliva is one of the most constant findings. The **yawning movements** are more accurately described as voiceless attempts to bellow. When paralysis occurs, the animal becomes recumbent and unable to rise. Bulls in this stage often have paralysis of the penis. Death usually occurs 48 hours after recumbency develops and after a total course of 6–7 days. The paralytic form of rabies has been reproduced experimentally by the IM injection of brain tissue from naturally occurring cases of paralytic rabies ('derriengue') in cattle in Mexico.

In **furious rabies** the animal has a tense, alert appearance, is hypersensitive to sounds and movement, and is attracted to noise so that it may look intently or approach as though about to attack. In some cases, it will violently attack other animals or inanimate objects. These attacks are often badly directed and are impeded by the incoordination of gait. Frequently, loud bellowing is usual at this stage. The sound is characteristically hoarse and the actions are exaggerated. Sexual excitement is also common, bulls often attempting to mount inanimate objects. Multiple collections of semen for artificial insemination have been made during very short periods from bulls that later proved to be rabid. With this violent form of the disease the termination is characteristically sudden. Severe signs may be evident for 24–48 hours and the animal then collapses suddenly in a paralyzed state, dying usually within a few hours.

There is no consistent pattern in either the development or the range of signs. Body temperatures are usually normal but may be elevated to 39.5–40.5°C (103–105°F) in the early stages by muscular activity. Appetite varies also. Some animals do not eat or drink, although they may take food into the mouth. There is apparent inability to swallow. Others eat normally until the terminal stages. The course may vary from 1 to 6 days. So wide is the variation in clinical findings that any animal known to be exposed and showing signs of spinal cord or brain involvement should be considered rabid until proved otherwise.

Sheep

In **sheep**, rabies often occurs in a number of animals at one time due to the ease with which a number of sheep can be bitten by a dog or fox. Clinically, the picture is similar to that seen in cattle. The minority show sexual excitement, attacking humans or each other, and vigorous wool pulling; sudden falling after violent exertion, muscle tremor, and salivation are characteristic. Excessive bleating does not occur. Most sheep are quiet and anorectic. Goats are commonly aggressive, and continuous bleating is common.

Horses

Most recorded cases in horses are lacking in distinctive nervous signs initially, but incline to the paralytic form of the disease. Experimentally, the average incubation period was 12 days and the average duration of disease was 5.5 days.[30] Unvaccinated animals had shorter incubation periods and duration of clinical disease. Muzzle tremors were the most frequently observed and most common initial signs. Other clinical findings

included pharyngeal paresis (71%), ataxia or paresis (71%), and lethargy or somnolence (71%). The furious form occurred in 43% of cases, some of which began as the dumb form. The paralytic form was not observed.

In naturally occurring cases, the initial clinical findings may include abnormal postures, frequent whinnying, unexplained aggressiveness and kicking, biting, colic, sudden onset of lameness in one limb followed by recumbency the next day, high-stepping gait, ataxia, apparent blindness, and violent head-tossing. Lameness or weakness in one leg may be the first sign observed, but the usual pattern of development starts with lassitude, then passes to sternal recumbency and lateral recumbency, followed by paddling convulsions and terminal paralysis.

In a series of 21 confirmed cases in horses, the clinical findings at the time of initial examination included ataxia and paresis of the hindquarters (43%), lameness (24%), recumbency (14%), pharyngeal paralysis (10%), and colic (10%).[31] The major clinical findings observed over the course of hospitalization included recumbency (100%), hyperesthesia (81%), loss of tail and anal sphincter tone (57%), fever ~38.5°C (52%), and ataxia and paresis of the hindquarters (52%). Mean survival time after the onset of clinical signs was 4.47 days (range, 1–7 days). Clinical findings of the furious form of rabies, such as aggressiveness (biting), compulsive circling, and abnormal vocalization, were evident in only two horses. Supportive therapy, given to nine horses, had no effect on survival time and did not correlate with the detection of Negri bodies at necropsy. Horses developing the furious form show excitement, become vicious, and bite and kick. Their uncontrolled actions are often violent and dangerous and include blind changes, sudden falling and rolling and chewing of foreign material or their own skin. Hyperesthesia and muscular twitching of the hindlimbs followed by crouching and weakness are also recorded in the horse.

Pigs

Pigs manifest excitement and a tendency to attack, or dullness and incoordination. Affected sows show twitching of the nose, rapid chewing movements, excessive salivation, and clonic convulsions. They may walk backward. Terminally, there is paralysis and death occurs 12–48 hours after the onset of signs. The clinical findings in pigs are extremely variable, and individual cases may present in a variety of ways and only one or two of the classical findings may occur.

CLINICAL PATHOLOGY

No antemortem laboratory examination is of diagnostic value, but tests for lead on blood, urine, and feces may help to eliminate lead poisoning as a possible diagnosis. Virus neutralization tests are available, but the presence of antibodies is not diagnostic. Other available tests are passive hemagglutination, complement fixation, radioimmunoassay, and indirect fluorescent antibody staining. These are used to determine immune status rather than as a diagnostic aid. An ELISA is available for measurement of rabies-specific antibody in the sera of major domestic and wildlife reservoirs in North America.

NECROPSY FINDINGS

Confirmation of a diagnosis of rabies depends on careful laboratory examination of fresh brain. The recommended laboratory procedure includes the following three tests and it is recommended that at least two of them be used on all specimens.

- A fluorescent antibody test (**FAT**) on impression smears from the brain – current recommendations include sampling of the hippocampus, **medulla oblongata**, cerebellum or gasserian ganglion. However, a recent publication stipulates that the hippocampus and cerebellum are less desirable samples than the thalamus, pons, or medulla for the detection of viral antigen, and that the current sampling recommendations stem from the visibility of Negri bodies, rather than the true distribution of viral antigen.[32] An FAT can be completed in approximately 2 hours and is highly accurate when done routinely by experienced personnel. The reliability of FAT confirmed by the mouse inoculation test is over 99%.[14] Those specimens that are negative on FAT, and have contact with humans, are inoculated into experimental mice. The incubation period in mice before clinical signs are seen averages 11–12 days (range of 4–18 days), and death occurs in 7–21 days. The mouse brain is harvested as soon as signs appear and is submitted to the same tests described above. Thus a positive result can be obtained as soon as 4–7 days after inoculation. Some mice must be left for the full 21 days because only a negative result at that time can give a complete negative to the test. A tissue culture infection test is now available, which allows demonstration of the virus in stained tissue culture cells within 4 days. This may replace the mouse inoculation test
- A dot **ELISA** is available for the detection of rabies antigen in animals.[33] It is rapid, simple, economical and, in comparison with the FAT, the agreement is 95%.

A **histological search** for Negri bodies in tissue sections with results available in 48 hours. Because of false-positive diagnoses the technique is in some disrepute. An **immunoperoxidase** test for rabies can be used on formalin-fixed, paraffin-embedded brain tissues of domestic animals and wild animals when fresh tissues are not available.[16,23] In some cases, the brain tissue may be negative for the rabies virus using standard diagnostic techniques but immunohistochemical tests may detect the presence of antigen.[20] A reverse transcriptase polymerase chain reaction test has been found of value in detecting rabies infection in decomposed brain samples that were negative by the direct fluorescent antibody test.[34]

The histopathologic changes of rabies infection include a non-suppurative encephalomyelitis and ganglioneuritis, with neuronal necrosis and the formation of glial nodules. Negri bodies are most commonly found in the Purkinje cells of the cerebellum in ruminants. Spongiform change has also been reported in the brain of a heifer infected with rabies virus.[35]

Samples for confirmation of diagnosis

- **Histology** – one half of midsagittally-sectioned brain, cervical spinal cord (including root ganglia), gasserian ganglion, parotid salivary gland (LM, IHC)
- **Virology** – one half of midsagittally-sectioned brain, cervical spinal cord (FAT, ISO, BIOASSAY).

Note the zoonotic potential of this organism when handling carcass and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The diagnosis of rabies is one of the most difficult and important duties that a veterinarian is called upon to perform. Since in most cases there is a probability of human exposure, failure to recognize the disease may place human life in jeopardy. It is not even sufficient to say that if rabies occurs in the area one will classify every animal showing nervous signs as rabid, because nervous signs may not be evident for some days after the illness commences. In addition, many animals suffering from other diseases will be left untreated. The best policy is to handle all suspect animals with extreme care but continue to treat them for other diseases if such treatment appears to be indicated. If the animal is rabid, it will die and the diagnosis can then be confirmed by laboratory examination.

Several diseases are characterized by signs of abnormal mental state or paralysis, or a combination of both (see Table 22.1 for the horse; Table 32.3 for cattle). Rabies must be differentiated from the following common diseases affecting the nervous system, according to species:

Cattle and sheep

- Lead poisoning. In acute and subacute lead poisoning in cattle the clinical findings are similar to those of furious and dumb rabies. In acute lead poisoning, the common clinical findings are blindness, convulsions, champing of the jaws with the production of frothy saliva, and twitching of the eyelids and ears. In subacute lead poisoning in cattle there is blindness, stupor, head-pressing, grinding of the teeth, and almost no response to treatment. Rabid cattle are usually not blind, and signs of motor irritation such as convulsions and twitching of the facial muscles usually do not occur. However, there are signs of bizarre mental behavior, such as wild gazing, bellowing, yawning, attacking, and compulsive walking
- Lactation tetany occurs in lactating cattle on lush pasture in the spring during cold wet and windy weather, and is characterized by hyperesthesia, tremors, convulsions, recumbency, and rapid death
- Vitamin A deficiency occurs in groups of young cattle from 6 months to 18 months of age not receiving adequate carotene intake or vitamin A supplementation and is characterized by blindness in the ocular form and episodes of tremors and convulsions
- Polioencephalomalacia in cattle and sheep is characterized by blindness, nystagmus, opisthotonos, and convulsions; bellowing, loss of sensation, and tenesmus do not occur
- Listeriosis in cattle and sheep is manifested by localizing signs of circling and facial nerve paralysis
- Enterotoxemia in sheep is usually confined to lambs on heavy carbohydrate diets
- Pregnancy toxemia is a disease of pregnant ewes and is readily differentiated by the presence of ketonuria
- Louping-ill in sheep is transmitted by insects, has a seasonal occurrence, and a localized geographical distribution.

Pigs

In pigs, rabies must be differentiated from pseudorabies, Teschen's disease, and involvement of the brain in several other diseases of the pigs, such as hog and African swine fever, meningitis associated with *Streptococcus suis* type II, *Haemophilus* spp., Glasser's disease, *Escherichia coli*, septicemia, and erysipelas.

Horses

In horses, rabies must be differentiated from several diseases of the nervous system (summarized in Table 22).

The most common include: viral encephalomyelitis, herpes virus myeloencephalopathy, cerebrospinal nematodiasis, equine degenerative myeloencephalopathy, equine protozoal myeloencephalitis, neuritis of the cauda equina, horsetail poisoning, Borna, Japanese encephalitis, botulism.

TREATMENT

No treatment should be attempted after clinical signs are evident. If the bite is seen, immediately after exposure, irrigation of the wound with 20% soft soap solution or a solution of Zephiran may prevent the establishment of the infection. Immediate and thorough washing of all bite wounds and scratches with soap and water is perhaps the most effective measure for preventing rabies in veterinarians bitten by rabid animals. In experimental animals, simple local wound cleansing has been shown to markedly reduce the likelihood of rabies. Post-exposure vaccination is unlikely to be of value in animals, as death usually occurs before appreciable immunity has had time to develop. Euthanasia of suspect animals must be avoided, particularly if human exposure has occurred, since the development of the disease in the animals is necessary to establish a diagnosis. Antirabies serum may become available for animal treatment at some future date. **In some countries, cases of rabies in farm animals are notifiable to the animal health and disease regulatory bodies.**

CONTROL

The major goal of rabies control in domestic and wild animals is the reduction or elimination of human rabies. The most rational approach to reducing human rabies is to reduce the prevalence and incidence of disease in animals. In developed countries, this has been accomplished by vaccination of dogs and cats, leaving much rabies in wildlife to be controlled. In countries without wildlife reservoirs, such as the Philippines, it would be economically advantageous to eliminate dog rabies. In Africa, where the incidence of rabies as well as the range of species involved is increasing, there is a need to develop new and economical methods of vaccinating domestic animals.

Pre-exposure immunization for individuals, like veterinarians, who are at high risk to rabies, has been recommended by the World Health Organization, since it reduces risk and provides a more rapid anamnestic response, eliminating the need for human globulin should exposure occur. Rabies pre-exposure vaccination is now mandatory in many veterinary colleges. Despite some mild adverse reactions, immunization against rabies is an important prophylaxis measure well-accepted by veterinary students.

For farm animals, there are two useful control techniques: the **prevention of exposure** and **pre-exposure vaccination**.

Prevention of exposure to the virus

This can be achieved by controlling access of wildlife species which are likely to come into contact with the farm livestock in particular areas or through vaccination of the wildlife. Foxes accounted for a very large proportion (85% in Europe) of wildlife rabies, and a control program aimed at reducing their population using poison or traps was attempted until the 1970s.[36] This method of population reduction failed to control outbreaks or reduce enzootic rabies.

Point infection control. To control the introduction of raccoon rabies in Ontario in 1999, 'point infection control' was used to control the epidemic.[29] This involves the use of three tactics: population reduction, trap-vaccinate-release, and oral vaccination with baits to control the spread of raccoon rabies. Some raccoons were captured and euthanized which resulted in an 83 to 91% reduction in the raccoon population in an area of 225 km^2 around the location of the three original cases of raccoon rabies. Raccoon density in the population reduction zones declined from 5.1 to 7.1 km^2 to 0.6 to 1.1 km^2 following control. Cats were also captured, vaccinated and released. Raboral V-RG oral rabies vaccine was distributed aerially to vaccinate free ranging raccoons. The point infection control program is considered to be highly successful and will continue to be used to contain isolated cases of raccoon rabies.[29]

Pre-exposure vaccination of humans

The most successful form of rabies prevention is pre-exposure vaccination. In human medicine, there are no reported cases of rabies deaths in anyone who has had pre-exposure vaccination followed by a booster vaccination if exposed.[4]

The Centers for Disease Control (CDC) and Prevention has published the recommendations of the Advisory Committee on Immunization Practices (ACIP) for human rabies prevention, which indicate that rabies pre-exposure vaccination should be offered to persons more likely to be exposed to rabies virus than the population of the United States at large.[37] The recommendations of the ACIP for pre-exposure prophylaxis and maintenance of a detectable antibody titer differ depending on the estimated degree of risk of exposure to the virus. Four risk categories have established: continuous; frequent; infrequent; and rare. The classification depends on factors such as the occupation of the individual and geography.[38]

With directed continuing education, common sense, first aid, and the availability of modern biological agents, human rabies is nearly always preventable.[1] Rabies pre-exposure vaccination is recommended for anyone at increased risk of exposure to rabies, including veterinarians, veterinary students who

work in university veterinary teaching hospitals, laboratory staff working with rabies, vaccine producers, animal and wildlife control personnel, and zoologists.

The standard pre-exposure regimen is three doses of vaccine IM or ID on days 0, 7, and 28 (or 21). A booster dose after 1 year increases and prolongs the antibody response.[4] This pre-exposure vaccination permits post-exposure vaccination to consist of two doses of vaccine on days 0, and 3 instead of 5 on days 0, 3, 7, 14, and 28 and avoids the need for postexposure of administration of human rabies immunoglobulin.

A large proportion of at-risk staff members working in veterinary clinics, animal shelters, and wildlife rehabilitation centers in a study area did not receive rabies pre-exposure vaccination according to the recommendations of the ACIP of the CDC.[37,38] Cost may be factor because many of these employees are commonly short-term, part-time, or volunteer workers.

Post-exposure vaccination of humans

Modern post-exposure treatment is highly successful if done adequately. Wound care with passive and active rabies immunization are essential especially after severe exposure. Post-exposure treatment is assumed to neutralize or inactivate virus while it is still in the wounds, before it gains access to the nervous system where it is protected from the immune system. Therefore, treatment after exposure to rabies virus is very urgent, even if the patient was bitten months before. Thorough washing of rabies-infected wounds with soap and water can increase survival by 50%.[3] However, this inexpensive, readily available treatment is omitted in most cases.

The World Health organization recommends a multi-site intradermal regimen of 0.1 mL of vaccine at eight sites on day 0, at four sites on day 7, and at one site each on days 28 and 90.[39]

Passive immunization with human rabies immunoglobulin lowers mortality after severe exposure.

Post-exposure vaccination of domestic animals

An effective post-exposure protocol for unvaccinated domestic animals exposed to rabies includes immediate vaccination against rabies, a strict isolation period of 90 days, and administration of booster vaccinations during the third and eighth weeks of the isolation period.[40] The protocol has been effective in dogs, cats, cattle, and horses.[40]

Vaccination of domestic animals

A *Compendium of Animal Rabies Control* is published annually by the National Association of State Public Health Veterinarians, Inc. in the United States and Canada.[25] It provides recommendations for immunization procedures in domestic animals, the vaccines licensed and marketed in the United States. Detailed information is provided on pre-exposure vaccination, management of dogs and cats and livestock, post-exposure management, and control methods in wild animals. Such publications should be consulted when necessary. In general, for cattle, sheep, and horses the primary vaccination is given at 3 months of age and boosters given annually. Farm livestock in endemic areas where clinical cases of rabies occur commonly should be vaccinated.

In countries where vampire bats are a major vector for rabies in farm livestock, vaccination of livestock is necessary but in countries such as Argentina, vaccination does not support a cost benefit analysis.[41]

Vaccines

Almost all rabies vaccines for domestic animals are inactivated.[25] Inactivated tissue culture cell vaccines given to cattle result in neutralizing antibodies in 1 month after the primary vaccination. A booster given 1 year later increases the titers, which are detectable 1 year after the booster. A vaccine inactivated with binary-ethylenimine, and containing aluminum hydroxide adjuvant, provides excellent protection for up to 3 years and is very useful for the control of rabies in cattle in Latin America where the vampire bat is the main vector.

Vaccinal antibodies are present in the colostrum of vaccinated cows and it is recommended that, where cattle are vaccinated annually, calves be vaccinated at 4 months of age and again when 10 months of age. Calves from unvaccinated dams can be protected by vaccinating them at 17 days of age. Postvaccinal paralysis does not occur after its use.

A post-exposure vaccination protocol including immediate rabies vaccination, with a minimum of one booster vaccination prior to release from quarantine, and 90 days strict isolation, was 99.7% successful in unvaccinated cattle, horses, sheep, goats, and pigs.

Vaccination of wildlife

The literature on oral rabies vaccination of wild carnivores in the United States has been reviewed.[42] Mass oral vaccination of terrestrial wild animals is a rabies control method that is feasible, effective, and internationally accepted.[36,42,43] It is based on the concept of applied herd immunity. The vaccines are efficacious when fed as vaccine-baits. The factors affecting acceptance of baits for delivery of oral rabies vaccine to raccoons have been examined.[44]

The oral immunization of foxes has resulted in a substantial decrease in the number of rabies cases in Europe. As a result of oral vaccination of the red fox (*Vulpes vulpes*) against rabies, using hand and aerial distribution of vaccine-laden baits, the rabies virus has almost been completely eradicated from Western and Central Europe.[45] The same dramatic decrease occurred in southern Ontario, Canada. In most countries, vaccine baits were distributed twice yearly; during the spring (March to May) and autumn (September to October). Several European countries have become rabies-free: Belgium, Luxembourg, France, Italy, Switzerland, finland and the Netherlands.[43] With the European Union consisting of 25 countries from May 2004, all the scientific knowledge is available for establishing efficient and adapted oral vaccination programs aimed at eliminating terrestrial rabies from this area.

Progress has been made in applying oral rabies vaccination to contain and eliminate some strains of terrestrial rabies in North America.[42] Notable examples include near elimination of rabies from red foxes in southern Ontario. Containment and elimination of canine rabies coyotes from south Texas, containment and near elimination of raccoon rabies from Ohio, prevention of raccoon rabies spread through the Lake Champlain Valley in New York and across northern Vermont and New Hampshire, and reduced incidence of rabies where other oral rabies vaccination projects targeting raccoons have occurred. As of 2005, both Ontario and New Brunswick were free of raccoon rabies for greater than 10 months and 2 years, respectively, after implementation of 'point infection control' strategies[29] but continued surveillance is critical to monitor effectiveness.

Raboral V-RG is the only rabies vaccine licensed for use in the United States. It has not produced sufficient levels of population immunity in skunks in the wild at the current dose and V-RG may be less effective in skunks than other species. Skunks are a major contributor to rabies in North America with 38% of cases associated with the raccoon variant of rabies virus involved skunks in 2001.[12] This has raised concerns about an independent maintenance cycle for raccoon rabies in skunks. The national rabies management goals of virus containment and elimination of will likely remain elusive until an oral vaccine is licensed that is immunogenic in all terrestrial rabies reservoir species. Skunk rabies virus, which has the broadest geographic distribution of all terrestrial rabies variants in the USA can currently be addressed only through local trap-

vaccinate-release or population suppression programs.[42]

A satisfactory vaccine for oral mass vaccination of skunks has not yet been developed. Many experimental and commercial-produced live-modified or recombinant-based oral rabies virus vaccines have been tested in skunks with contradictory results. An oral modified live rabies virus Vaccine SAD B19, used in striped skunks was innocuous and may be safer and more effective in skunks after oral vaccination than previously considered.[46] An attenuated SAG-2 vaccine was efficacious in challenge studies in skunks and raccoons and may satisfy both safety and efficacy concerns for oral rabies vaccination of major North American rabies reservoirs.[47]

During the 1990s in the United States, oral vaccination programs concentrated upon raccoons, gray foxes, and coyote, with similar success. As a result, raccoon rabies has not spread west of its initial concentration in the eastern states, and grey fox rabies in contained in the west central Texas, and no recent cases of rabies have been reported in coyotes away from the Mexican border for several years. However, vaccination is not a panacea and should be considered as an important adjunct to traditional prevention and control techniques in human and veterinary medicine.

It is notable that no practical vaccination methods have been developed for bats.[36] Phylogenetic analyses of viruses from bats and carnivores suggest a historical basis for still existing viral origins due to interactions between these taxa. Thus the possibility for pathogen emergence resulting from transmission by rabid bats with subsequent perpetuation among other animals cannot be discounted easily on any continent. Vampire bats have been vaccinated IM, scarification, oral, or aerosol routes using a vaccina-rabies glycoprotein recombinant vaccine.[48] The highest antibody titers occurred in animals vaccinated by the IM and scarification routes. All animals vaccinated by the IM, scarification, and oral routes survived experimental challenge, except 1 of 8 receiving the aeosol vaccination died.

Most consistent progress was achieved and maintained where:

- Large coherent territories covering certain sized areas were treated simultaneously
- All areas of fox habitat were included by using both manual and aerial distribution
- Vaccination zones were progressively expanded towards the infected area
- At least two vaccinations were done
- The bait density was a certain minimum.

The vaccination will succeed in reducing or eradicating rabies only if a sufficient proportion of the target population can be immunized. Mathematical modeling techniques are now being tested to examine the population biology of rabies in wildlife species such as raccoons and skunks.[49] Mass immunization of foxes by aerial distribution of vaccine-baits containing liquid rabies vaccine was highly successful in controlling rabies in both urban and rural areas of Ontario.[36,42]

In 1989, the Ontario began a 5-year experiment to eliminate terrestrial rabies from a study area in the eastern end of southern Ontario.[50] Baits containing oral rabies vaccine were dropped annually in the area at a density of 20 baits/km^2 from 1989 to 1995. The experiment was successful in eliminating the arctic fox variant of rabies from the entire area. In the 1980s, an average of 235 rabid foxes per year were reported in the study area. Between 1993 and 2001, no cases were reported. Cases of fox rabies in other species also disappeared. In 1995, the last bovine and companion animal cases were reported and in 1996 the last rabid skunk occurred. Only bat variants of rabies were present until 1999, when the raccoon variant entered from New York.

Quarantine and biosecurity

The most effective method of preventing the entry of rabies into a country free of the disease is the imposition of a quarantine period of 4–6 months on all imported dogs. This system has successfully prevented the entry of the disease into island countries, but has obvious limitation in countries that have land borders. The occurrence of the disease in two dogs in the United Kingdom in 1969–1970 in which the incubation period appeared to last 7–9 months suggests that the more usual period of 6 months may give incomplete protection. Therefore, vaccination on two occasions with an inactivated vaccine while the animal is still in quarantine for 6 months is the current recommendation. To require a longer period of quarantine would encourage evasion of the law by smuggling. The situation in the United Kingdom, and in any country where the disease does not occur, is a vexed one. It is possible to rely chiefly on quarantine and act swiftly to stamp the disease out if it occurs. The shock eradication program would include quarantine of, and vaccination in, a risk area, ring vaccination around it, and destruction of all wildlife. This procedure is likely to be adopted in countries where the risk is small, such as Australia. Where the risk is great, consideration must be given to mass vaccination of wildlife by baits, because wildlife are the cracks in the defense armor. The use of combined vaccines containing rabies vaccine in other vaccines used in dogs would be an effective and panic-free way of increasing the immune status of the pet population.

PSEUDORABIES (AUJESZKY'S DISEASE)

Etiology Aujeszky's disease virus (suid herpesvirus 1) (SHV-1)
Epidemiology In pigs worldwide and major economic importance in swine-raising areas. High prevalence of infection; lower incidence of disease. Infected pig source of infection; latent infection is characteristic; spread occurs within herds, between herds, and due to infected carriers; long-distance aerosol transmission occurs from area to area; immunity follows infection or vaccination
Signs Fever, incoordination, recumbency, convulsion and death in piglets. Coughing, nasal discharge, sneezing, and dyspnea in older growing pigs. In cattle and sheep, intense pruritus at site of bite, excitement, circling, convulsions, fever, recumbency, paralysis, and death in 48 hours or less
Clinical pathology Serology for virus neutralizing antibodies. Detection of virus in tissues
Lesions Viral encephalitis
Diagnostic confirmation Detection of virus in tissues; serology; inclusion bodies in nervous tissue and respiratory tract
Differential diagnosis
Swine:
- Viral encephalomyelitis (Teschen disease)
- Rabies
- Streptococcal meningitis
- Hog cholera
- African swine fever
- Glasser's disease
- Septicemias (*Escherichia coli*, erysipelas, salmonella)
- Bowel edema
- Salt poisoning
- Reproductive insufficiency (parvovirus).

Cattle and sheep:
- Nervous form acetonemia
- Rabies C
- Acute lead poisoning.

Treatment None
Control Depopulation and repopulation, test and removal, segregation of progeny, and vaccination with subunit vaccines which distinguish between infected and vaccinated pigs

ETIOLOGY

Pseudorabies is associated with porcine herpesvirus-1, Aujeszky's disease virus, or pseudorabies virus, a member of the family of Herpesviridae, subfamily Alphaherpesvirinae. The biological functions of the virus in the pathogenicity, immunogenicity, and transmission of vaccine strains of the virus in pigs have been described and reviewed.[1]

EPIDEMIOLOGY

Occurrence

Pseudorabies primarily affects pigs and occurs incidentally in other species. Pseudorabies had a wide geographical distribution including the United States, Britain, Europe, North Africa, Asia, South America, New Zealand, and Ireland. Recently, many countries have achieved freedom from the disease and those that have not have started some form of control and eradication scheme.

Epidemiologic modeling of the herd-to-herd transmission of pseudorabies over a 20-year period in the United States concluded that, if there is no eradication program in place, the projected prevalence would be 43% in high-risk States, 22% in moderate-risk States, and 5% in low-risk States by 2012.[2] The current program of eradication projected 23% prevalence rate in high-risk States, 10% in moderate-risk States, and 1% in low-risk States. With an increase in expenditure for eradication programs of 25%, the respective prevalence rates by 2012 would be 14%, 3% and <0.3%. In Belgium the overall herd prevalence was deemed to be 35%.[3] Many countries including Australia, Canada, and Norway are free of the infection.

Pseudorabies is primarily a disease of pigs, and naturally occurring cases in cattle and horses are rare and usually fatal. Cases in cattle occur only sporadically but a number of animals may be affected when cattle and pigs are commingled. An outbreak of clinical disease occurred in sheep in Northern Ireland after the sheep had been shorn and housed adjacent to pigs excreting the virus[4]; cats on the same farm were also affected. The disease has occurred in goats that have been housed with swine, and the virus has been isolated from horses with neurological disease.[5] Pseudorabies infection has been recorded in feral swine in Florida, and may undermine eradication efforts in domestic swine.[6]

Morbidity and case fatality

Typically, the disease spreads rapidly in infected herds over a period of 1–2 weeks and the acute stage of the outbreak lasts 1–2 months. In sucking pigs, the morbidity and mortality rates approach 100%, but in mature swine there may be no clinical signs, and affected animals usually recover. The highest morbidity occurs initially in unweaned piglets, but as the outbreak continues and piglets become passively immunized through the sow's colostrum, the major incidence may occur in weanlings.

In recent years there has also been an increase in the morbidity and case fatality rates in older pigs associated with the intensification of pig rearing and the dominance of more virulent strains.

Risk factors

Animal risk factors

The seroprevalence of infection varies widely between herds, and between breeding and finishing pigs within herds.[7] The most important animal risk factors of virus persistence are **herd size** and the **population density** of the sows in the herd.[8] Endemic infection is more likely in herds of breeding sows with more than 66 sows. In Belgium, when testing 720 herds, 40% of the herds with young sows were highly positive.[3] Herds over 70 sows were also more likely to be infected.[3] In breeding herds, spread of infection is positively associated with increasing size of the herd, having the gilts in the same barn as the sows (gestation barn), and serological evidence of infection in the finishing pigs.[9] The seroprevalence of infection is low in quarantined breeding herds, which makes them prime candidates for elimination of the disease by test and removal.[10]

In the early period of a compulsory vaccination program with gI-deleted vaccines, in an area endemically infected with the disease, the seroprevalence of infected breeding females is higher in farrow–finish than farrow–feeder herds.[11] Mandatory vaccination is beneficial in both herds but the pattern is linear in farrow–feeder herds and curvilinear in farrow–finish herds, being more rapid in the early period of the program. In the farrow–finish herds, the odds of infected breeding females were associated positively with seropositivity in the finishing pigs of the herd and with the density of the pigs in the county in which the herd is located.[11]

In Belgium the presence of finishing pigs in the same herd increased the chances of being infected.[3] The spread and transmission of the virus between herds can be reduced by a reduction in the contact rate between the herds and their size and by a reduction of the transmission within the herd.[12]

The factors associated with circulation of the virus within herds include:

- Confinement of finishing pigs
- Concurrent infection with *Actinobacillus pleuropneumoniae*
- The length of time since the herd has been under quarantine
- The presence of clinical disease.

In general, pseudorabies does not increase the susceptibility of animals to infection with other pathogens.[7] In an experimental situation it has been shown that the virus is transmitted between vaccinated conventional pigs but not amongst vaccinated SPF pigs.[13]

The primary risk factors associated with seroprevalence of the virus in 500 swine herds in Illinois included **total confinement** and **density of infected herds** in the geographical area.[14] For counties with a high regional density of pseudorabies infection, the prevalence of infection within a county increased with increasing average herd size and increasing geographical density of swine herds in the county.[15] In Minnesota, there was a high geographical density of pseudorabies infected herds within 5 km.[16] Similarly it was calculated than in Belgium if there were over 455 pigs/km^2 then there was a 10-fold increase in the risk of PRV.[3] Total confinement is associated with higher seroprevalence, presumably because of increased density of population and increased risk of transmission. In Pennsylvania, decreased density of pseudorabies-quarantined herds was associated with reduced risk of a herd becoming quarantined, whereas increased density of non-quarantined, uninfected herds was associated with a decreased probability of a herd becoming quarantined.[17] A farrow–finish herd was associated with increased probability of becoming quarantined, compared with being a feeder pig herd. Seroprevalence is higher in vaccinated herds, increases over the course of the eradication program, and decreases with an increased time between quarantine and the development of a herd plan.

In The Netherlands, the risk factors contributing to seroprevalence of infection in breeding herds included:

- Presence of finishing pigs
- Production type (producers of finishing pigs had a higher prevalence than producers of breeding stock)
- Vaccination of sows during nursing (in comparison to vaccinating all sows simultaneously at 5-month intervals, or vaccination during the second half of gestation)
- Pig density in the municipality where the herd was located (seroprevalence increased with higher pig density)
- Herd size of fewer than 100 sows
- Average within-herd parity (seroprevalence increased with higher within-herd parity)
- Replacement pigs raised on the premises
- Vaccine strain administered to the sows.[18]

Environmental risk factors

The survival capabilities of the virus under various environmental conditions influences the methods of transmission and control procedures.[19] The virus may survive for 2–7 weeks in an infected environment, dependent on temperature fluctuations and pH level, and for up to 5 weeks in meat. The stability of the virus suspended in aerosol under different conditions of temperature and relative humidity has been examined.[20] The infectivity of the virus in an aerosol decreases by 50% in 1 hour. Environments at 4°C supported the survival of the virus in aerosol better than at 22°C. The virus is lipophilic and sensitive to several commonly used disinfectants. Sodium hypochlorite (5.25%) is the most desirable and practical disinfectant. Suspensions of the virus in saline G solution and on the solid fomites, whole corn, and steel remained infectious for at least 7 days. Loam soil, straw, and concrete supported survival of the virus at 25°C for up to 1 week.[19] During shipment of pigs, bedding material and surfaces in contact with pigs may become contaminated. Rinsing a needle between sampling may reduce the probability of mechanically transmitting the disease.[21]

Pathogen factors

Field strains of the virus differ in virulence. Numerous genomically different strains of the virus exist, and restriction endonuclease (RE) analysis can distinguish between virus isolates, which is useful for identifying new isolates of the virus as they appear in pig populations.[22] A retrospective analysis of virus isolates from England and Wales over a 22-year period revealed considerable homogeneity of certain RE sites (*Bam*HI), both in number and size. The appearance of an isolate with a new DNA fragment in 1981 coincided with a marked increase in the number of outbreaks of disease.[22] A PCR assay was able to discriminate between the established strains and the new type. By relating this type to pig movement records it was possible to trace the spread of the new type virus which was isolated in 65% of the new outbreaks of pseudorabies in England and Wales in 1982.[22] In Denmark, restriction fragment analyses of older clinical isolates, and of isolates from all the virologically confirmed outbreaks since 1985, indicated the introduction of foreign strains. Strain variation in virulence has been observed in field isolates and produced by laboratory attenuation. The viral proteins that determine virulence of the virus have been described.[1] Some field strains of the virus from Poland and Hungary have been identified by restriction fragment pattern analysis as derivatives of conventionally attenuated vaccine strains.[23] This is considered a rare event but must be considered in relation to trade in semen from vaccinated boars or trade in live animals between disease-free areas and areas where vaccination with live attenuated strains is practiced.

Methods of transmission

Pigs, and possibly rodents, appear to be the primary host for the virus. The virus is present in the nasal discharge and in the mouth of affected pigs on the first day of illness and for up to 17 days after infection.

Within herds

Transmission within herds occurs by direct oral–nasal contact between infected and susceptible pigs, and aerosols from projection of discharges during sneezing, but may also occur via contaminated drinking water and feed. Transmission within herds is independent of the size of the population.[24]

The spread of virus from infected animals to contact-exposed animals can be predicted using a reproduction ratio. The ratio of secondary cases to originally infected animals is called the basic reproduction ratio denoted as R_0. In the model, R_0 has a threshold property. When $R_0 > 1$, the infection can spread; when $R_0 < 1$, the infection will not spread and will disappear, and the animal population is effectively protected.[25] Experimentally, the quantification of vaccine-induced reduction in virus transmission indicates that vaccinating twice with a marker vaccine significantly reduced virus transmission. In unvaccinated groups, the R_0 was 10.0; in the vaccinated group the R_0 was 0.5.[26] Thus, it is possible to measure transmission experimentally.

The transmission of virus decreases rapidly following the start of a vaccination program[27] but extensive spread can still occur even among finishing pigs vaccinated twice.[28] Vaccinated pigs may shed more virulent virus than mildly virulent virus

but there are no significant differences in magnitude of transmission.[29] Mixing of chronically infected pigs with seronegative pigs may not result in seroconversion in the seronegative pigs until a clinical outbreak of disease occurs.[30]

Between herds

Transmission between herds is due to introduction of infected animals, and the virus may still be introduced into vaccinated breeding herds.[31] Other methods of transmission of the virus into uninfected herds have been suggested, including farm laborers, vehicles, feedstuffs, rodents, and wild or domestic animals.

Within an area

Transmission within an area is a major problem and not well-understood. Spread is occurring across the United States despite an intensive eradication program.[16] Some evidence indicates that area spread may be associated with which swine market is used and the frequency of delivery of pigs to market per year.[32] In France it has been suggested that the presence of an infected herd within 1 km is an important factor in the spread of PRV.[33] The concurrent occurrence of an outbreak of disease on many farms in the same area in Denmark suggested long-distance airborne transmission of the virus.[32]

Infection is spread by **airborne transmission**.[34] Exposing pigs to aerosols of the virus results in respiratory and other clinical signs similar to field cases.[35] Sneezing probably generates the airborne virus. In a series of outbreaks in Britain between 1981–1982, seven of 11 were found to be likely to have been transmitted by aerosol on meteorological grounds.[36] Airborne spread occurred between herds 2–9 km apart. An epidemic in Denmark in 1987–1988, associated with foreign strains of the virus, suggests that airborne transmission occurred across the German–Danish border[34] especially as a southerly wind was blowing during the period of transmission. An epidemic occurred in 10 herds located within close proximity of each other in Indiana, and the clinical and meteorological data supported aerosol transmission of the virus.[37] An epidemic during the winter of 1987/88 was associated with an unusual predominance of southerly winds, supporting the hypothesis of airborne transmission of the disease.[32]

Computer modeling based on the mean dose of virus received by an animal at a farm downwind can be used to predict the airborne spread of the virus.[38] To test the hypothesis that the virus can be spread by aerosol, the application of a Gaussian diffusion model has been applied to an epidemic of pseudorabies in 10 herds located in Indiana.[39] The epidemic spread through 10 farms across an area of 150 km. The county was free of infected herds for 2 years prior to the epidemic, which was well-documented. The transport of the virus was assumed to occur during the prepatent period from 3 to 7 days prior to the onset of clinical signs. Estimates of the virus dose received at a given barn indicate that transport of the virus was more efficient during the night than during the day. The low temperatures during the night resulted in decreased ventilation of the barn and greater cycling of air contaminated with the virus over the pigs.

The infection is transmitted in **feral swine** through the venereal route.[40] Following commingling of uninfected gilts with virus infected boars, the virus could be recovered from the reproductive tracts of the gilts and could not be recovered from the upper respiratory tract.

Virus is excreted in the milk of infected sows and in utero infection occurs. The virus is inactivated in meat after 35 days of storage at –18°C (0.5°F). Meat from infected pigs may cause infection when fed to dogs. Venereal transmission of latent infection in sows and boars has been suspected, but there is no direct evidence. The effects of pseudorabies infection in adult boars are related to the effects of the clinical disease rather than any direct effect on semen quality. The virus cannot usually be isolated from the urine or semen from infected boars, and therefore the preputial secretions and the ejaculate are unlikely vehicles for shedding of the virus.

Latency

Pigs that recover from infection are latent carriers of the virus for life. Reactivation, followed by shedding and spreading the virus, may occur following stress such as transport or farrowing, or by the administration of corticosteroids.[41,42] Serological testing of latent carriers detects the antibody response to the whole virus or to a pseudorabies virus glycoprotein.[43] During natural infection, the virus replicates at the site of infection, usually in the oronasal areas. The virus gains entry into the nerve endings and ascends by retrograde axonal transport, to the cell body in the trigeminal ganglion. Viral components can be found in both the trigeminal ganglion and the tonsils.[41] The tonsil is a primary site of virus replication and serves as an area for monitoring virus shedding during acute infection and reactivation. The virus can be isolated from tissue fragments of pigs clinically recovered from disease for up to 13 months and followed by a challenge with the live virus, which may be shed by sows for up to 19 months after initial infection. Virus gene products can be found in the trigeminal ganglia and tonsils for many weeks following acute infection.[44] Latent infection can also occur in vaccinated pigs.

Other species

The rarity of spread to other species is due to the scanty nasal discharge and the improbability of the discharge coming into contact with abraded skin or nasal mucosa of animals other than pigs. The disease has occurred in sheep and cattle following the use of a multiple-dose syringe previously used in infected swine. The disease may spread from normal or clinically affected pigs to animals of other species, but does not usually spread between animals of the other species. For example, sheep and calves can be infected experimentally, but there is no evidence that they excrete the virus. The disease may occur in pigs, sheep, and cattle on the same farm. Brown rats may be a minor source of infection but are unlikely to be an important reservoir; they are capable of spreading the disease to dogs. The wild Norway rat is thought to have only a minor role in the transmission of the disease to farm animals. The virus causes fatal disease in dogs, which are usually infected from close association with infected pigs. The raccoon can be infected experimentally, but is not considered to be a long-term subclinical carrier of the virus. The possible role of wild animals in transmission of pseudorabies in swine has been examined with inconclusive results. It has been seen in Kodiak, Polar and Himalayan bears fed on a diet of raw pig's heads.[45] five viral isolates were recovered from latently infected wild boar originating from two regions of East Germany[46] but in the Netherlands the wild boar were said to be rarely affected.[47] The PRV infections in the wild boar in Germany are said to exist in the country as an endemic infection and persist completely separately to the domestic population and also do not appear to affect it.[48] The sacral ganglia and trigeminal ganglia of wild pigs were said to be a source of infection.[49] The latency was shown in 9/16 sacral ganglia, 7/16 trigeminal ganglia and 5/13 tonsils[49] from feral swine in the USA, but even so most of the transmission in feral swine is expected to be venereal. There seems to be little evidence of a high infection rate in the wild boar of the Netherlands but they are in contact with the wild boar of Germany.[50] It seems quite common in Spanish wild boar with 36% of a study of 78 being serologically positive. The wild

boar strain is adapted to the wild boar pig.[51] A group 1 virus was isolated from a wild boar in 1993 and it was suggested that the virus persisted for several years in the wild boar population in Italy[52] and that the species should be considered a reservoir.[52] In Croatia approximately 55% of tested wild boars were found to be seropositive.[53] The experimental infection of wild boars and domestic pigs with different strains has been carried out[51] and the clinical signs depended on the strain but the wild boar could infect the domestic strains and vice versa. The low virulence strains were highly adapted to the wild boar.

Immune mechanisms

When infected with a virulent strain of the virus, pigs develop an immune response that can completely, or almost completely, prevent the virus from replicating after the pig becomes reinfected.[1] Following natural infection, sows acquire immunity, which is transferred to their piglets in the colostrum and persists in the piglets until 5–7 weeks of age. Following intranasal challenge, piglets with colostral immunity from naturally infected sows are protected from clinical disease, but not against subclinical infection.

Vaccination of pigs with attenuated pseudorabies virus prevents clinical disease and death that may otherwise follow exposure to the virulent virus. Vaccination does not, however, prevent either acute or latent infection with virulent virus. As a consequence, vaccinated pigs, as well as non-vaccinated pigs that survive infection with the virulent virus, can become virus carriers and a source of the virus following reactivation of a latent infection. This is of vital importance in eradication programs wherein it is necessary to identify infected pigs regardless of their vaccination status. Maternal immunity interferes with inactivated virus vaccination much more than with live virus vaccination.[54]

Vaccination of pregnant sows induces a maternal immunity, which protects piglets from experimental disease. However, latent infection of young pigs with highly virulent virus can develop in the absence of clinical signs. The virus can reach the uterine and fetal tissues, via infected mononuclear cells, the presence of circulating antibodies induced on vaccination.[55] Vaccination of piglets before challenge exposure has little or no effect on the rate of establishment of virus latency, but vaccination does reduce shedding after subsequent experimental reactivation of the virus with dexamethasone. Attenuated thyrosine kinase-negative vaccine strains of the virus can also establish a reactivatable, latent infection.[56]

In growing and finishing pigs in quarantined herds, the serological status is unpredictable because the infection may continue to spread, may cease temporarily, or may cease altogether. Evaluation of the serological status of the boars in a breeding herd does not accurately reflect the serostatus of the herd.

It has been suggested that the T cells are more important than the B cells in the clearance of PRV from the host[57] and it has been shown that strong T-cell mediated responses after challenge produce the best protection.[58]

Economic importance

The economic losses associated with pseudorabies in swine are due to clinical disease, and the costs of serological analysis and vaccination programs.[32] Because of the variability of expression of the infection in different herds, a description of a single farm's experience with pseudorabies is difficult to put into a larger perspective regarding the impact of disease at a state or national level.[59] Economic loss estimates must include the measurement of losses during and immediately after clinical outbreaks of disease, and the indirect losses incurred until after eradication of the disease. Losses have been estimated at US$25–50/sow per year; these include only losses during the period of the outbreak and the direct losses attributable to death and abortions. When expanding the observations of economic losses to 3 months after the termination of the outbreak, estimated losses may be as high as US$145/sow per year.[32] Economic analyses of the losses in a commercial farrow–finish herd of 240 breeding age sows in the United States revealed that the major part of the loss was caused by death of suckling pigs at 76% of total loss, nursery pig mortality accounted for 12.6% of total net loss, sow culling and deaths accounted for 9.4% of net loss, and market pig deaths accounted for 1.2% of net losses.[32]

The costs of eradicating pseudorabies vary depending on the methods employed.

Depopulation–repopulation is the most expensive method because it requires culling of animals, clean-up costs, and downtime which represents the largest proportion of expense. In addition, the probability of reinfection following repopulation is a risk.

Test and removal is the most inexpensive, and segregation of offspring is intermediate in costs. The cost of eradicating the virus from a swine herd can be in excess of US$220/inventoried sow; some estimates are much higher.[60] In large breeding herds or finishing herds with the continual influx of susceptible pigs, the disease may become endemic. Pseudorabies may also be a significant cause of reproductive inefficiency in pig herds, and infection within the herd may be initially manifest by abortions in the sow herd, followed later by the more typical occurrence of neurological disease in suckling and growing pigs. The economic losses due to the disease can be very high because of mortality in young pigs, decreased reproductive performance, and the necessity to depopulate to eradicate the disease from a herd. An economic assessment of an epidemic of pseudorabies in a 150-sow farrow–finish operation on selected production and economic variables has been made. The mean litter size remained the same throughout the period of observation, but there was a two-fold increase in suckling pig mortality and 3.5-fold increase in stillbirths during the months of the epidemic compared with the period before the epidemic. Following the epidemic, suckling pig mortality was 14% greater and stillbirth rate was 71% greater than during the months preceding the outbreak. The major economic losses (88% of the total loss) were related to breeding herd removal/depopulation and production downtime.

PATHOGENESIS

The portal of entry is through abraded skin or via the intact nasal mucosa. The virus is pantropic and affects tissues derived from all embryonic layers. Receptor and receptor-binding virion proteins which can mediate the virus entry into the cell and cell to cell spread have been described.[61] The various glycoproteins of the virus are required for various stages of virion morphogenesis. For example deletion of glycoproteins gE, gI, and gM inhibits the virion maturation.[62] Pseudorabies glycoprotein gK is a virion structural component involved in virus release from the cell but not viral entry and its presence is important to prevent immediate reinfection.[63] Viremia occurs with localization of the virus in many viscera, but with multiplication occurring primarily in the upper respiratory tract. Spread to the brain occurs by way of the olfactory, glossopharyngeal, or trigeminal nerves i.e. via the autonomic nerves.[64] Cells with the common leukocyte antigen $CD45^+$ populate the CNS infected areas from the local capillaries and the number of cells is increased in proportion to the number of infected neurons.[65] Virus disappears from the brain by the 8th day, coinciding with the appearance of neutralizing antibody in the blood. When

the virus gains entry through a skin abrasion, it quickly invades the local peripheral nerves, passing along them centripetally and causing damage to nerve cells. It is this form of progression that causes local pruritus in the early stages of the disease, and encephalomyelitis at a later stage when the virus has invaded the central nervous system. In pigs, pruritus does not develop after IM injection, but a local paralysis indicative of damage to low motor neurons occurs prior to invasion of the central nervous system in some pigs. In cattle, pruritus of the head and neck is usually associated with respiratory tract infection, while perianal pruritus is usually due to vaginal infection.

Inoculation of the virus into the nasal cavities or brain results in signs of encephalitis rather than local pruritus. With oral inoculation there is an initial stage of viral proliferation in the tonsillar mucosa, followed by systemic invasion, localization, and invasion of the central nervous system along peripheral and autonomic nerve trunks and fibers. Lesions of Auerbach's myenteric plexus and the skin may also occur.[66] The peripheral blood mononuclear cells, tonsil, lymph nodes and bone marrow are a poor source of virus after experimental infection.[67] The trigeminal ganglia and olfactory bulb are good sources of virus.[67] The virus may be present in the trigeminal ganglion of a naturally infected sow without any history of clinical disease. Experimental inoculation of the virus into young pigs can result in a mild pneumonia which may progress to a severe suppurative bronchopneumonia.[68]

The virus can invade the uterus and infect pre-implantation embryos, which can lead to degeneration of the embryo and reproductive failure.[69] Virulent pseudorabies virus can cause lesions in the uterine endothelium and ovarian corpora lutea of pigs in early pregnancy, and gene-deleted mutant virus vaccine given IV during estrus can cause ovarian lesions, which may affect fertility.[69] Through the use of embryo transfer procedures, infected embryos may disseminate the virus from donors to recipients.

CLINICAL FINDINGS

The incubation period in natural outbreaks is about one day.

Pigs

The major signs are referable to infection of the respiratory, nervous and reproductive systems. There is considerable variation in the clinical manifestation, depending on the virulence and tropism of the infecting strain. Nervous system disease is the major manifestation, but with some strains, respiratory disease may be the initial and prime presenting feature. There is also strain variation in the pattern of age susceptibility.

Young pigs a few days to a month old are most susceptible. Very young sucklings develop an indistinct syndrome, but prominent nervous signs occur in older piglets. A febrile reaction, with temperatures up to 41.5°C (107°F), occurs prior to the onset of nervous signs. Incoordination of the hindlimbs causing sideways progression is followed by recumbency, fine and coarse muscle tremors, and paddling movements. Lateral deviation of the head, frothing at the mouth, nystagmus, slight ocular discharge, and convulsive episodes appear in a few animals. A snoring respiration with marked abdominal movement occurs in many, and vomiting and diarrhea in some affected pigs. Deaths occur about 12 hours after the first signs appear. In California, a consistent sign has been blindness due to extensive retinal degeneration.

In growing and adult pigs, the disease is much less severe but there is considerable variation depending upon the virulence of the infecting strain. In growing pigs, mortality falls with increasing age and is generally less than 5% in pigs at 4–6 months of age. With some strains, fever is a prominent sign, while depression, vomiting, and sometimes marked respiratory signs, including sneezing, nasal discharge, coughing, and severe dyspnea are common. Trembling, incoordination, and paralysis and convulsions follow, and precede death. With others, the disease may be manifest at this age by mild signs of posterior incoordination and leg weakness. Concurrent infection has been described with both PCV2 and ADV.[70] In adults, fever may not be present and the infection may cause only a mild syndrome of anorexia, dullness, agalactia, and constipation. However, virulent strains may produce acute disease in adults, characterized by fever, sneezing, nasal pruritus, vomition, incoordination and convulsions, and death. Infection in early pregnancy may result in embryonic death, or abortion, and early return to heat. An abundant vaginal discharge may occur. Infection in late pregnancy may result in abortion, or in the subsequent birth of mummified fetuses, which may involve all or only part of the litter. Abortion may result from the effects of fever or from viral infection of the fetus.

Cattle, sheep, and goats

There may be sudden death without obvious signs of illness. More commonly, there is intense, local pruritus with violent licking, chewing, and rubbing of the part. Itching may be localized to any part of the body surface, but is most common about the head, the flanks, or the feet, the sites most likely to be contaminated by virus. There is intense excitement during this stage, and convulsions and constant bellowing may occur. Maniacal behavior, circling, spasm of the diaphragm, and opisthotonos are often evident. A stage of paralysis follows in which salivation, respiratory distress, and ataxia occur. The temperature is usually increased, sometimes to as high as 41–41°C (106–107°F). final paralysis is followed by death in 6–48 hours after the first appearance of illness. A case of non-fatal pseudorabies in a cow is recorded. There is also a report of pseudorabies occurring in feedlot cattle in which there were nervous signs, bloat, and acute death, but no pruritus. In young calves, it is characterized clinically by encephalitis, no pruritus, erosion in the oral cavity and esophagus, and a high case fatality rate. An outbreak in sheep was associated with skin abrasions acquired at shearing. Affected ewes were dull, inappetent, and had a fever of 41.1°C. About 23 of 29 affected sheep developed the 'mad itch', with nibbling of their fleece and frenzied attempts to bite one area of the skin and rub it against the wall and bars of their pen. Terminally, recumbency, tremors, and opisthotonos were common, and death occurred within 12–24 hours after onset.[4] five farm cats also became ill and died; the virus was isolated from the brain of one cat. In goats, rapid deaths, unrest, lying down and rising frequently, crying plaintively, profuse sweating, and spasms and paralysis terminally are characteristic. There may be no pruritus.

The clinical findings in dogs and cats are similar to those in cattle, with death occurring in about 24 hours.[9] In France, cases in dogs have been linked to strains of virus from wild boars.[71]

CLINICAL PATHOLOGY

Serology

The commonly used serological tests for pseudorabies-specific antibodies are the serum-neutralization (SN) and ELISA.

Serum neutralization test

The SN test using the Shope strain has been the 'gold standard' against which other serological tests are compared and has been most widely used because of its sensitivity and specificity. Specific virus-neutralizing antibodies are detectable in the serum of recovered pigs, and this test is in routine use for herd diagnosis and survey purposes. Antibody is detectable on the 7th day after infection, reaches a peak about the 35th day, and persists for many months. Paired serum samples taken as early as possible, and about 3 weeks later, show a marked antibody

rise. However, the SN test lacks the sensitivity necessary for detection of pigs with low levels of humoral titers of specific SN antibodies which can be enhanced by using the Bartha gIII strain.[72]

Some herds may have no serological evidence of previous infection or current spread of the virus, but have single reactors in the herd which may be infected with the virus.[73] Such singleton reactors may be found in herds being monitored serologically for presence of infection. These singleton reactors may be infected with strains of the virus that are relatively avirulent.

Enzyme-linked immunosorbent assay

The ELISA is more sensitive than the SN test, especially early in the immune response to pseudorabies antigens. However, because of its high sensitivity, screening ELISAs yield some false-positives which must be confirmed by another test, such as another ELISA, SN test or latex agglutination test.[74] False-positives are unlikely to be due to infection with other herpesviruses. ELISA has also been used as a meat juice test[75,76] with high sensitivity (93%) and specificity (98%). The indirect ELISA is a more rapid and convenient procedure, offering many advantages over the SN test for routine serodiagnostic work. An indirect ELISA, using whole blood collected onto paper discs, is a rapid and convenient test and eliminates the costs of using vacutainer tubes and separating the blood. An indirect ELISA based on recombinant and affinity-purified glycoprotein E of PRV to differentiate vaccinated from naturally infected animals has been developed.[77] An indirect ELISA has been developed in the Czech Republic[78] that can be used because of its high sensitivity and specificity for blood serum or frozen pork samples. It has allowed the demonstration of ADV in meat juice with only marginal titers in the blood. Commercial ELISA kits are available and some are more specific than others.[74] A highly sensitive and specific competitive ELISA based on baculovirus expressed pseudorabies virus glycoprotein gE and gI complex has been described.[79] This allows detection as early as 2 weeks post-infection and can handle large numbers of tests without the need to handle live virus.

In countries where vaccination is regularly used for control of the disease, an assay to serologically distinguish infected from vaccinated pigs is critical. While a vaccination program will reduce the circulation of virus in the field, it will not eliminate the virus from the pig population. To eradicate the virus, the ability to differentiate infected from vaccinated pigs is crucial. Several commercial ELISA kits can differentiate between vaccinated and naturally infected pigs.[80] Differentiation is possible when vaccine virus strains have either a natural, or a genetically engineered, deletion that encodes for either glycoprotein-I (gI), gIII, or gX genes. Commercial ELISA kits that specifically detect antibody responses to gI of the virus offer considerable advantages as diagnostic tests for the virus, with a sensitivity of 99.2% and specificity of 100%.[80] The gI ELISA is able to distinguish infected pigs from those vaccinated with gI-negative vaccines[81,82] The field strains of the virus produce antibodies to gI when inoculated into pigs. Unvaccinated pigs, or pigs vaccinated with gI-negative vaccines, that become subclinically infected with field strains of the virus may be detected with the gI–ELISA for a long time after infection. Thus, pigs that are seropositive in the gI–ELISA have either been infected with the pseudorabies virus or have been vaccinated with gI-positive vaccines; gI-seronegative pigs can be considered to be uninfected. Eradication of the virus from swine herds is possible by gI–ELISA testing, and culling gI-seropositive pigs in herds using gI-negative vaccines.

Detection of pigs in the latent phase of infection can be done serologically.[43] Pigs of any age that survive the acute infection phase become latent carriers for life, and serologic testing consistently detects animals in the latent phase of infection if the test detects the antibody response to the whole virus or to a reliable pseudorabies-virus glycoprotein.[43] Of several serological tests examined, the glycoprotein-I and glycoprotein-III marker systems, which performed with similar sensitivity as the screening tests, were superior to the glycoprotein-X marker system in detecting antibodies in infected pigs.

Detection of virus

In infected pigs the virus is usually present in nasal secretions for up to 10 days. A common method for the diagnosis of pseudorabies in sows is to take swabs from the nasal mucosa and vagina. Polyester and wire swabs shipped in 199 tissue culture medium supplemented with 2% fetal bovine serum (FBS) buffered with 0.1% sodium bicarbonate and HEPES will yield optimum recovery of the virus. Wooden applicator sticks with cottonwool have antiviral activity and recovery of the virus may not be possible after 2 days, which is of practical importance if the samples are shipped by mail. The virus can be demonstrated in nasal cells by immunofluorescence and immunoperoxidase techniques.[83] The virus can be detected by direct filter hybridization of nasal and tonsillar specimens from live pigs.[44] The virus survives on tonsil swabs taken with Dacron-tipped applicators for up to 72 hours in cell culture medium under transport.[84]

New PCR techniques have been used[67] and have been used to differentiate between true and false serological positives when single reactor pigs have been found.[85]

NECROPSY FINDINGS

There are no gross lesions typical and constant for the disease, and diagnosis must rely on laboratory examination. When pruritus has occurred there is considerable damage to local areas of skin, and extensive subcutaneous edema. The lungs show congestion, edema, and some hemorrhages. Hemorrhages may be present under the endocardium and excess fluid is often present in the pericardial sac. In pigs, there are additional lesions of visceral involvement. Slight splenomegaly, meningitis, and excess pericardial fluid are observed, and there may be small necrotic foci in the spleen and liver. Foci of hepatic necrosis may also be seen in aborted fetuses. Histologically, in all species, there is severe and extensive neuronal damage in the spinal cord, paravertebral ganglia, and brain. Perivascular cuffing and focal necrosis are present in the gray matter, particularly in the cerebellar cortex. Intranuclear inclusion bodies occur infrequently in the degenerating neurons and astroglial cells, particularly in cerebral cortex in the pig. These inclusions are of considerable importance in differential diagnosis. Necrotizing lesions with inclusion-body formation in the upper respiratory tract and lungs is strongly suggestive of porcine pseudorabies. Ultrastructural observations have been made which included syncytia, cellular debris and macrophages and lymphocytes with vacuoles in their cytoplasm.[86] Virus may be detected by direct fluorescent antibody examination or by growth in tissue culture. The tissues of the head and neck regions of non-immune pigs yield virus most consistently and in the highest concentration after challenge. The immunoperoxidase test can be used to study the distribution of the virus in different tissues. Latent virus can be detected using a DNA hybridization dot blot assay. Where possible, whole carcasses and fetuses should be submitted for laboratory examination. The location of the optimal neural samples, including the paravertebral ganglia, has been described for sheep.[87] The placental lesions in pregnant sows that have aborted from

natural infection with pseudorabies consist of necrotizing placentitis and the presence of intranuclear inclusions. In an experimental infection of loops of intestine it was shown[88] that there was necrosis of the follicles in the Peyer's patches and degeneration of the epithelial cells in the crypts and villi and degeneration of the cells in the myenteric plexuses. Intranuclear inclusion bodies were found 2–4 days after inoculation. The primary target of the wild ADV was the macrophages of the sub-epithelial area of the dome of the Peyer's patch.

Samples for confirmation of diagnosis

- **Histology** – one half of midsagittally-sectioned brain, spinal cord with paravertebral ganglia, Gasserian ganglion, placenta, liver, lung, spleen, tonsil, retropharyngeal lymph node (LM). Immunohistochemistry has been used to confirm rare cases in countries where the disease is rare[89] and other corroborating evidence is lacking.[90] Can also collect muscle samples for meat juice ELISAs[91]
- **Virology** – brain, spinal cord, liver, spleen, tonsil, retropharyngeal lymph node (FAT, ISO). CSF is not good for virus isolation.[67]

DIFFERENTIAL DIAGNOSIS

The different clinical forms of pseudorabies in pigs and ruminants resemble several diseases.

Teschen disease occurs in similar forms in certain areas; the diagnosis is dependent on serology and pathology.

Rabies is rare in pigs and is usually accompanied by pruritus at the site of the bite.

Streptococcal meningitis is restricted to sucking pigs of 2–6 weeks of age, the lesions are usually obvious at necropsy, and the causative organism is readily cultured from the meninges. The response to treatment with penicillin is good and is of value as a diagnostic test.

Encephalopathy associated with hog cholera, African swine fever, salmonellosis, Glasser's disease, *Escherichia coli* septicemia and erysipelas are considerations, and are usually obvious at necropsy.

Bowel edema causes typical edema of the head and eyelids, undo typical circumstances in weaner pigs and rapid death.

Salt poisoning causes typical intermittent nervous signs, with a typical history of water deprivation.

Respiratory form of pseudorabies should be considered in any outbreak of respiratory disease that is poorly responsive to usually effective therapeutic measures.

Reproductive inefficiency associated with enterovirus (SMEDI) and parvovirus infections closely resembles that associated with pseudorabies, and requires laboratory differentiation by virus isolation and serological testing.

In **cattle** the local pruritus is distinctive, but the disease may be confused with the nervous form of acetonemia in which paresthesia may lead to excitement. The rapid recovery that ordinarily occurs in this form of acetonemia is an important diagnostic point. The furious form of rabies and acute lead poisoning cause signs of mania, but pruritus does not occur.

TREATMENT

There is no treatment.

CONTROL

The control of pseudorabies is difficult and currently unreliable because normal healthy pigs may be infected and shed the virus for up to several months.

An important principle in control and eradication of the disease is the reproduction ratio, R_0, which is defined as the average number of new infections caused by one typical infectious animal. When R_0 >1, the infection can spread; when R_0 <1, the infection will disappear. In eradication programs it is essential that R be less than 1 and the infection will die out in the herd.

Strategies available

The methods of control or eradication include depopulation and repopulation, test and removal, segregation of progeny, and vaccination. The selection of a strategy for the control or elimination of the disease depends on the following:

1. Source of the herd infection
2. Method of transmission of the virus
3. Survival of the virus in the environment
4. Sensitivity and specificity of the diagnostic test
5. Risk factors in the herd,[92] which include:
   - type of operation
   - degree of herd isolation
   - prevalence of infection
   - value of the genetic material
   - level of management expertise
   - availability of suitable virus-free replacement swine if depopulation and repopulation is chosen as a strategy.

The eradication of the disease from small herds was described in Hungary.[93] In this country the shared use of boars, the pig density and the infection in the surrounding area were the most significant influences on the spread and control of the disease.

Breeding stock producers favor eradication, farrow–finish producers that do not sell breeding stock or feeder pigs are generally more concerned with the reduction of losses from clinical pseudorabies infection than with eradication. In the USA offsite all in/all out finishing was more frequent amongst the successful farms than the unsuccessful.[94] The unsuccessful also had other infected herds within 3.2 km (2 miles) and often no cleaning or disinfection.[94]

Economics of control and eradication

Depopulation–repopulation is the most expensive, segregation of progeny method is next, and the test and removal the most inexpensive per sow.[60] A computerized decision-tree analysis and simulation modeling can evaluate the economics of control and eradication strategies. The optimal alternative is to test and remove seropositive animals if the initial prevalence is ~57%; otherwise vaccination of sows only is preferred. Vaccination may be recommended at lower prevalence rates as a conservative approach. Eradication by test and removal combined with the use of gene-deleted vaccines is advantageous at any prevalence rate of infection.[95] Depopulation and repopulation is not the best option under any circumstances. Once formulated, a decision-tree analysis can be adapted to the prevailing economic or epidemiological conditions.

An epidemiological model projected future herd–herd disease transmission under alternative eradication or control programs over 20 years, from 1993 to 2012.[60] With current eradication program funding in the United States, the prevalence of infection would be 23% in high-risk states, 10% in moderate-risk states, and 1% in low-risk states. Increased funding for the eradication program would substantially reduce the prevalence of infection. Profitability for the average size farrow–finish herd was estimated to be US$6 per cwt of swine produced for virus-infected herds than for uninfected herds. Estimates of the value of economic welfare indicated that consumers would be the major beneficiaries of eradication because of reduced prices and increased consumption of pork.

In Sweden, it was estimated that an eradication program is economically viable.[96] The maximum benefits are derived where the Swedish agricultural sector is deregulated and consumers obtain about 50% of the benefits excluding program costs. In the current case where Sweden is a member of the European Union, the benefits are reduced mainly due to lower prices of inputs and pork.

An economic analysis of alternative control programs found that, for regions of high pig density, the most economical strategy is to lower herd prevalence by

intensive vaccination before completing eradication by test-and-removal of remaining positive animals.[97]

Eradication and control programs used in France have been reviewed.[97] The eradication of PRV in a 170 sow herd was described[98] in which the affected animals were killed and the rest were then vaccinated and the total cost to the farm was about $50 000.

Determination of prevalence of infection

In large herds, the virus must be eliminated from the growing–finishing pigs and the breeding herd. Large herds that are virus-positive are infected in both groups; smaller herds are frequently infected in only the breeding herd.[99] An initial step in eradication is to determine the prevalence of infection. Representative samples of finishing pigs older than 4 months, and of breeding sows, gilts, and boars are tested. On the basis of the test results and the risk factors in the herd, a cost-effective plan can be devised for the individual herd.

Depopulation and repopulation

When the prevalence of infection in the herd is over 50%, eradication can be achieved by depopulation and repopulation with virus-free breeding stock. However, depopulation is the most expensive method and is not compatible with the retention of valuable pedigree stock. The entire herd is depopulated over a period of months as the animals reach market weight. After removal of the animals the entire premises are cleaned and disinfected. Repopulation should be delayed at least 30 days after the final disinfection, and swine should originate from a pseudorabies-free qualified herd and be isolated on the premises and retested 30 days after introduction. All herd additions should be isolated and tested 3 0 days after introduction.

Test and removal

The test and removal program is recommended when the prevalence of infection in the herd is below 50%. This method requires testing of the entire breeding herd and immediate removal of all seropositive animals; 30 days after removal of seropositive animals, the herd is retested, and if necessary at 30-day intervals, until the entire herd tests are negative. Following a second negative test, the testing regimen may be changed to test only 25% of the herd every 4 months. Seropositive animals are identified and culled. The test and removal method is superior to the vaccination system as a method of control. Valuable genetic material from breeding stock that are seropositive may be salvaged using embryo transfer techniques. Embryos may be transferred safely to susceptible recipient gilts from sows that have recovered from infection, but not from sows that are in the active stages of infection. The virus does not penetrate the outer covering of the embryo, but it can become attached to it so that it may physically transfer to the uterus of the recipient. This transfer of infection may occur if the donor sow is in the active phase of infection.

Offspring segregation

The objective of this strategy is to raise a pseudorabies-negative breeding herd to replace the infected herd. Once the herd is diagnosed as pseudorabies-infected, a regular schedule of vaccination is instituted. Gilts are vaccinated at first breeding, and both sows and gilts are vaccinated 2–4 weeks before farrowing to provide a high level of colostral immunity to their piglets. Offspring are removed at weaning and raised apart from the infected herd. At 4 months of age, and then again before breeding, the segregated replacements are tested for antibody. Since colostral immunity is no longer detectable by 4 months of age, any animals over 4 months of age that are seropositive are considered pseudorabies infected. As the gilts reach reproductive maturity, the old sow herd is replaced. Segregation between the infected sow herd and the clean gilt herd is maintained until all positive sows have been removed and the facilities disinfected. Groups of seronegative pigs are identified and combined into larger groups to establish a new herd. The original herd is gradually depopulated, and the premises cleaned and disinfected. The new herd is then monitored on a regular basis.

Control programs in effect

Pseudorabies was first diagnosed in the North Island of New Zealand in 1976, an eradication program started in 1989 and the virus was cleared from the North island in 1997.[100]

A pseudorabies control program was introduced in England in 1983 when the infection was spreading rapidly. New legislation imposed restrictions on the movement of pigs where clinical signs of the disease were present in the herd. The first part of the eradication scheme involved testing all of those herds previously known to have pseudorabies. Within several months after the beginning of the eradication campaign, 417 herds had been slaughtered, involving 342 275 pigs, of which 72.5% were salvaged. Only 121 herds had been known to be previously infected, while the remaining 296 herds had been identified through tracebacks and reports of new cases. By 1985 it was concluded that the disease was well-controlled in England with only 10–14 infected herds remaining. Farmers were compensated for all animals slaughtered and also for consequential loss associated with the loss of stock. The cost of the eradication program was financed by a levy on all pigs normally marketed for slaughter in England. In 1995, England was free of Aujeszky's disease. Following the successful use of the gene deletion vaccination and eradication program the Netherlands is now free[101] and also Germany.[102] There were originally 70% seropositive sows in 1993, 1% in 1998 and now none (as above). In Sweden the herds were declared free from 12–53 months after the start of the programme.[103] Now In Northern Ireland, pseudorabies is more widespread than it ever was in Britain before the eradication program. Because the infection rate is over 50%, an eradication program based on slaughter of infected herds would destroy the swine industry. Thus the control program in Northern Ireland is based on the use of vaccination, the culling of seropositive animals, and the gradual introduction of seronegative animals.

In the United States, the national pseudorabies eradication program was implemented in 1989 as a joint State–Federal–Industry-sponsored program.[104] Pilot projects were conducted in Iowa, Illinois, Pennsylvania, Wisconsin, and North Carolina from 1984 to 1987. In the pilot projects, 97.5% of 116 herds that were initially pseudorabies-positive were successfully cleared of infection. This indicated that eradication of pseudorabies virus from herds of swine can be efficiently achieved, and is most effective applied on an area basis. The introduction of the gene-deleted pseudorabies vaccines in the program was the technical breakthrough needed to be able to offer the national eradication program, since it was now possible to distinguish between naturally infected and vaccinated animals.[104] The program consisted of:

Stage I, preparation
Stage II, control
Stage III, mandatory herd clean-up
Stage IV, surveillance
Stage V, free.

In Ohio, the eradication has made progress and eradication is expected in 1996 at a minimum cost to the public and the process in Illinois has also been described.[105] In practice what it meant was that all were at stage I by 1991, stage II was in states with over 1% affected and stage III in the states with less than 1% affected, there were still 10 states in stage IV on 1/1/2000 but on the 1/1/2000 33

states were free and all were cleared by 2002. When an outbreak of the disease occurs in a susceptible herd the mortality may be very high, and the first consideration is to prevent spread to uninfected sows and litters and pregnant sows from infected pigs. They should be attended by separate personnel, or adequate barriers to mechanical transmission of infection should be arranged. On affected premises, cattle should be separated from pigs, and dogs and cats should be kept from the area. The affected herd should be quarantined, and all pigs sold off the farm should be for slaughter only.

Vaccines and vaccination

Vaccination is used to reduce clinical disease when outbreaks occur or when the disease is endemic in the herd. An effective immunity develops after natural infection or vaccination, and piglets from immune sows are protected from clinical disease during the nursing period by colostral immunity. **However, the presence of circulating antibody does not prevent infection, the development of latency and subsequent activation and excretion of the virus**. However, vaccination reduces viral shedding after natural infection. On farms in which the disease is endemic or outbreaks have occurred, vaccination of the sows, and management procedures to reduce the spread of infection, have markedly reduced preweaning mortality and reproductive failures. field studies in large numbers of herds where the sows were vaccinated three times annually show that the reproduction ratio was below 0.66, which is significantly below 1,[106] and massive spread of the virus does not occur.

It is often virtually impossible to prevent the spread of infection in a susceptible herd and vaccination of all pigs at risk, especially pregnant sows, is recommended. The vaccine reduces losses in infected herds, limits the spread of infection, and decreases the incidence in endemic areas. With a properly controlled and monitored vaccination and culling program in a breeding herd it is possible to control clinical disease and reduce the infection pressure. All breeding stock present during an outbreak are subsequently vaccinated regularly until they are all culled, which removes the major sources of virulent virus. Following this phase, newly introduced gilts and boars are tested, and monitored regularly. This is considered to be less costly than the test and slaughter policy.

However, in vaccinated herds, the virus continues to circulate and an accurate epidemiological analysis is not possible because titers caused by vaccination cannot be distinguished from those caused by natural infections.

Control of the diseases in many countries has always been based on compulsory intensive vaccination of the entire population.[102,107]

Vaccines

Conventional modified live virus and inactivated virus vaccines have been available. Both vaccines will reduce the incidence rate and severity of clinical disease in an infected herd. They also reduce the field virus shedding and latency in the trigeminal ganglion after exposure to field virus.[108] The vaccine efficiency is however markedly influenced by the modified live virus vaccine strain and the route of administration. The vaccine genotype plays a very important role in the effectiveness of the vaccine program. Recently needle-free transdermal vaccination using a modified live PRV vaccine has been described thereby preventing the loss of any needles in the carcase.[109] Cell mediated immunity in the form of cytotoxic T-cells may play an important part in the effectiveness of the vaccine.[110] The deficiencies of inactivated vaccines in producing virus specific interferon gamma (IFN) can be enhanced by the use of simultaneous administration of IL-12 which appears to upregulate Th1/Th2 expression.[111]

Pregnant sows

Vaccination of pregnant sows induces SN antibodies, which are transferred to the newborn piglets and provide protection against infection. Vaccination during pregnancy produces more protection against PRV for piglets than sow vaccination before mating.[112] A better protection was observed in sows vaccinated with an attenuated virus than in sows vaccinated with inactivated virus.[113] Piglets rely on colostral and milk antibodies for protection, and the vaccination of piglets born from vaccinated sows does not produce a significant serological response until the piglets are about 12 weeks of age. Earlier vaccination of piglets from infected or vaccinated sows is ineffective because high levels of maternal antibodies interfere with a serological response stimulated by the vaccine.[114] Maternal immunity interferes with the development of active immunity from vaccination until at least 15 weeks of age, even when the colostral titers are low. Thus, in a situation in which the majority of sows have been infected or vaccinated, vaccination of weaned pigs may not yield desirable results. Both inactivated virus and attenuated live virus vaccines provide similar results when piglets born from vaccinated sows are vaccinated before colostral immunity has waned.

Growing and finishing pigs

The optimal vaccination strategy for growing and finishing pigs in an eradication program is controversial. In eight persistently infected herds vaccinations, both I/N and I/M[115] were made at 4 and 10 weeks of age.[116] Only one vaccination is given to finishing pigs in endemic areas in Europe. However, this does not reduce the prevalence of infection in finishing pigs in herds with a high prevalence. Double vaccination of finishing pigs will reduce the spread of the virus, but extensive spread can still occur.[28] The presence of maternal antibodies may interfere with the induction of antibodies, and double vaccination 4 weeks later may boost immunity. Mean daily weight gain was also improved by a second vaccination with a direct economic benefit.

Marker or subunit vaccines

A major development in vaccination against pseudorabies has been the introduction of genetically engineered live vaccine strains used to make marker or subunit vaccines. Vaccination with modified live gene-deleted vaccines is now an integral part of pseudorabies eradication programs worldwide.[117] The most common gene deletions are for **glycoproteins E (gE)** or **gI** and **G (gG)** or **gX**, and **gIII**.[118] A gD/gE negative vaccine was described.[119] In Europe, use of **gE**-vaccines has become the standard. In the United States, a gG–gE– pseudorabies vaccine has been introduced.[63] These vaccines in conjunction with a **companion diagnostic test**, can **distinguish between naturally infected and vaccinated animals**. Colostrum can also be used to monitor antibodies against gI protein of the virus.[120]

A study comparing I/N and I/M vaccination showed that pigs given both vaccines (I/N and I/M) had a significantly better clinical and virological protection after challenge than the single I/N vaccination.[121] The recombinant vaccines are able to circumvent the inhibition of active immunity that occurs when maternally derived antibody is still present.[117,122] Animals vaccinated with a deleted vaccine are not able to mount an immune response against the protein whose gene has been deleted in the vaccine virus genome. In contrast, wild-type virus-infected animals produce antibodies against all the viral glycoproteins. Differentiating ELISAs, specific for the deleted marker protein, then allow discrimination between infected animals, which can be culled from the herd, and vaccinated animals. These vaccines reduce the severity of clinical disease and viral shedding. However, the presence of colostral antibodies in growing pigs may

interfere with an immune response, which may result in increased virus excretion on challenge exposure. Repeated vaccination is needed to provide some protective immunity against challenge exposure to virulent virus.

These mutants have also been rendered thymidine kinase-deficient (TK–) mutants, and are avirulent and immunogenic. Pigs inoculated with these mutants are resistant to experimental challenge with the virulent virus, and the virulent virus cannot be recovered from the ganglia, which suggests that vaccination reduced colonization of the ganglia. The ideal vaccine strain should prevent clinical disease and mortality, should not be transmitted to non-immunized animals, should prevent colonization of the ganglia by a potential superinfecting virulent virus and thereby reduce the natural reservoir of the virus. The TK– mutant virus possesses these desirable characteristics. The high efficacy of recently constructed gI-negative deletion mutant vaccines of pseudorabies virus provide a sound basis for implementing the 'gI' approach to the future control of the disease.

Piglets born from sows vaccinated with deleted (gIII-, TK) strains at 3 days and 9 and 11 weeks of age developed detectable antibodies that lasted up to 100 days of age when vaccinated.[123] Maternal antibodies in piglets from sows vaccinated with gIII-deleted vaccine decay to undetectable levels at 7 weeks of age. Vaccination of these piglets at 3 days of age with the same vaccine results in a priming effect, which protects the piglets against virulent virus challenge at 7 weeks of age.[124,125] Thus, effective protection could be provided by active immunization from birth through weaning, in the nursery and into the growing and finishing stages of production.

Although genetically engineered live virus vaccines have been shown to be efficacious and safe, there is a possibility of spread between vaccinated and unvaccinated animals, of persistence in the field and of recombination between different vaccine strains, which can lead to enhanced virulence. New viral mutants lacking glycoproteins gD, gE, gG, and gI may form the basis for the development of new vaccines that do not recombine.[126] A gB deletion vaccine has been described for I/N use and has been shown to produce both local and serum antibodies.[127] Recently, a DNA vaccine was shown to give as good a response as gD plasmid vaccine but the DNA vaccine had to be given intradermally.[128] It can overcome maternally derived antibody[129] and the vaccine described in this case still gave protection against infectious PRV challenge at the end of the finishing period.

Even more radical is a vaccine with a granulocyte-macrophage colony stimulating factor (GM-CSF) which has also been given in a DNWA formulation.[130]

Experimentally, immunized pigs can be latently infected with the wild-type virus without being detected by the gE-specific ELISA routinely used to discriminate between infected and vaccinated pigs.[124] Thus, gE seronegative pigs may still be infected and be a source of infection.

Remarkable progress has been made with the use of gI-deleted vaccines. Intensive regional vaccination of finishing pigs with a gI-deleted vaccine along with companion diagnostic tests, reduced the seroprevalence in infected finishing herds from 81% to 19% in 2 years.[131] Vaccination increases the virus dose needed for establishment of infection, and decreases the level and duration of virus excretion after infection. In the control group, with routine disease control, no significant change in seroprevalence occurred. The consistent application of intensive vaccination of all breeding herds in a region, including those herds participating in a production chain, can also decrease the prevalence of infection in heavily infected areas.[132] The intensive regional vaccination did not completely eliminate virus infections within these herds; the source of infection was not determined.[31] It is suggested that the virus either circulated at a low level within herds, or its introduction or reactivation did not lead to an extensive spread of the virus. A voluntary vaccination program on individual farms was unsuccessful in reducing the prevalence of virus-infected breeding pigs. The importation of breeding stock from outside the area is associated with a higher prevalence of virus-infected pigs because of lack of vaccination. The introduction of infections can be reduced by purchasing virus-free animals and by increasing farm biosecurity procedures.

Vaccination of breeding herds three times annually to insure a high level of immunization can lead to elimination of the disease when the reproduction ratio is less than 1.[133]

The method used for vaccination may influence the effect of the vaccine.[134] Using glycoprotein vaccines, IM vaccination in the neck, and six-point ID vaccination in the back provided the best protection; six-point ID injections resulted in a better vaccination than two-point injections. Body weight changes and viral excretion after challenge were compared with virus-neutralizing titers, antigen-specific IgG and IgA responses in serum, and virus-specific lymphoproliferative responses in peripheral blood during the immunization period.

An intensive eradication program in farrow–finish herds using a gI-deleted vaccine in breeding and growing–finishing pigs, and decreases of movement, and mixing of growing–finishing pigs was successful in 3 years.[135] The initial goal was to decrease viral spread in the growing–finishing pigs, which enabled production of seronegative replacement gilts. Increases in the number of sows culled, combined with an increase in the number of seronegative replacement gilts, resulted in a decrease in seroprevalence of sows. Bimonthly serological monitoring indicated minimal spread of the virus in the growing–finishing pigs after 1 year. Beginning at 18 months after initiation of the program, test and removal of seropositive sows commenced in all herds. All herds were released from quarantine within 3 years, indicating that eradication can be achieved by vaccination and management changes designed to minimize the spread of virus combined with test-and-removal procedures.

An attenuated gI-deleted–TK-deleted vaccine was used to eradicate the virus from a large farrow–finish herd in Sweden.[136] At the start of the program, 86% of the breeding animals were seropositive. The breeding stock was vaccinated every 4 months and monitored serologically. Seropositive sows and boars were culled at an economic rate. The herd was declared gI-negative 39 months after the start of the program. Monitoring the herd for another 4 years, until all vaccinated animals had been culled, revealed the herd free of the virus.

In New Zealand, progress towards eradication using a subunit vaccine is reported.[137] Those farms that combined vaccination with good management techniques, intensive testing and culling eradicated the wild virus infection within 2 years; those that made little or no progress has less than satisfactory standards of hygiene and did not practise an intensive testing and culling program.

Vaccination of both breeding stock and growing pigs is recommended. A combined vaccination–eradication program for the disease would generally comprise four phases:

1. A systematic and intensive vaccination campaign
2. Screening of pigs for gI-antibodies
3. Economic culling of infected breeding pigs
4. Final ending of vaccination.

Piglets at 3 days of age can be vaccinated with one of these genetically engineered vaccines and be protected

from experimental challenge at 5 weeks of age.

A recent study has shown that infection with PRRSv does not inhibit the development of a vaccine-induced protection against PRV.[138]

- **Vaccination of cattle** with an inactivated vaccine is recommended where they are in close contact with swine and where a low level of exposure is likely.

VIRAL ENCEPHALOMYELITIS OF PIGS (TESCHEN DISEASE, TALFAN DISEASE IN THE UK, BENIGN ENZOOTIC PARESIS IN DENMARK, POLIOMYELITIS SUUM, PORCINE ENTEROVIRAL ENCEPHALOMYELITIS)

Synopsis

Etiology Porcine enteroviruses capable of causing encephalomyelitis. Teschen virus, Talfan virus, and others

Epidemiology Certain European countries, Scandinavia, and North America. Morbidity 50%; case fatality 70–90%. Teschen in Europe. Talfan in UK. Viral encephalomyelitis in North America. Transmitted by direct contact

Signs Acute: Teschen. Fever, stiffness, unable to stand, tremors, convulsions, and death in few days

Subacute: Talfan. Milder than acute form. Most common in pigs under 2 weeks of age. Morbidity and case fatality rate 100%. Outbreaks. Hyperesthesia, tremors, knuckling of fetlocks, dog-sitting, convulsions, blindness, and death in a few days. Milder in older growing pigs and adults

Clinical pathology Virus-neutralization tests

Lesions Non-suppurative encephalomyelitis

Diagnostic confirmation Demonstrate lesion and identify virus

Differential diagnosis list:

- Pseudorabies
- Hemagglutinating encephalomyelitis virus.

Treatment None

Control Outbreaks will cease and herd immunity develops

ETIOLOGY

A number of closely related, but antigenically different, enteroviruses, capable of growth in tissue culture, are causes of encephalomyelitis in pigs.[1] Porcine enteroviruses comprising at least 13 serotypes are grouped into three groups.[2,3] They can cause neurological disturbances, infertility and dermal lesions in pigs. **Teschen virus**, initially isolated in Czechoslovakia, is the most virulent and there have been a number of independent isolates, such as the Konratice and Reporyje strains.[4] **Talfan virus**, isolated from England, and other unnamed isolates appear less virulent. Teschen and Talfan virus occur in subgroup 1, which is now called porcine enterovirus group 1 (PEV-1) but isolates from encephalomyelitis are also associated with other subgroups. In 2001 it was proposed that the teschoviruses be regrouped into three[5] with group 1 being the teschoviruses, group 2 the old PEV8 (V13 virus) and group 3 the old PEV9. In the system proposed[6] these are PEV-A and PEV-B. It is now proposed that the PEV-1 Talfan group be regarded as a new genus for the family Picornaviridae.[7] A recent study of group 2 suggests that it may have unique features and may be better called a new picornavirus genus.[8] Within subgroups, strains may be further differentiated using a complement fixation test and monospecific sera. There is variation in virulence between strains, and with many strains, clinical encephalitis following infection appears to be the exception rather than the rule.

EPIDEMIOLOGY

Occurrence and prevalence of infection

Prior to the early 1940s, the incidence of porcine viral encephalomyelitis was restricted to certain districts in Czechoslovakia. Since then, reports of the disease have come from many countries and there is serological evidence that the disease occurs throughout the world. The most severe form of the disease – Teschen disease – appears to be limited to Europe and Madagascar, but the milder forms – Talfan disease, poliomyelitis suum, and viral encephalomyelitis – occur extensively in Europe,[9] Scandinavia, and North America and recently in Japan.[10] A recent outbreak in Indiana has been described[8] and it was ascribed to porcine enterovirus serogroup 5 or 6 with the only characteristic feature being the histological lesions of polioencephalomyelitis. Losses due to the disease result primarily from deaths.

Serological surveys in areas where the disease occurs indicate that a high proportion of the pig population is infected without any clinical evidence of the disease. In the majority of field occurrences, porcine encephalomyelitis is a sporadic disease affecting either one or a few litters, or a small number of weaned pigs.

Morbidity and case fatality

The morbidity rate is usually about 50% and the case fatality rate 70–90% in Teschen disease as it is described in eastern Europe. The disease in Denmark and the United Kingdom is much milder, and the morbidity rate about 6%.

Methods of transmission

Infection is transmitted by ingestion and the aerosol routes. The virus replicates primarily in the intestinal tract but also in the respiratory tract. When infection first gains access to a herd the spread is rapid and all ages of pigs may excrete virus in feces.

Risk factors

Animal risk factors

Depending upon the virulence of the infecting strain, clinical disease primarily affects young pigs but may occur in older pigs at the same stage. As infection becomes endemic and herd immunity develops, excretion of the virus is largely restricted to weaned and early grower pigs. Adults generally have high levels of serum antibody, and suckling piglets are generally protected from infection by colostral and milk antibody. Sporadic disease in suckling pigs may occur in these circumstances in the litters of non-immune or low antibody sows, and may also occur in weaned pigs as they become susceptible to infection. In the recent outbreak in the USA the major factor was the rapid decline of the maternal antibody in the piglets (<21 days). Seroconversion then coincided with the increased mortality in the herd.

Pathogen risk factors

The causative viruses will infect only pigs and are not related to any of the viruses that cause encephalomyelitis in other species. They are resistant to environmental conditions, including drying, and are present principally in the central nervous system and intestine of affected pigs.

PATHOGENESIS

The virus multiplies in the intestinal and respiratory tracts and may invade to produce viremia. Invasion of the CNS may follow, depending upon the virulence of the strains and the age of the pig at the time of infection.[1] There is some strain difference in the areas of the CNS primarily affected, which accounts for variations in the clinical syndrome, and it is possible for histopathological evidence of encephalitis to be present in pigs that have shown no clinical signs of the disease. This may also occur with adenovirus infection.

CLINICAL FINDINGS

Acute viral encephalomyelitis (Teschen disease)

An incubation period of 10–12 days is followed by several days of fever (40–41°C, 104–106°F). Signs of encephalitis follow, although these are more extensive and acute after intracerebral inoculation. They include stiffness of the extremities, and inability to stand, with falling to one side followed by tremor, nystagmus, and violent clonic convulsions. Anorexia is usually complete, and vomiting has been observed. There may be partial or complete loss of voice due to laryngeal paralysis. Facial paralysis may also occur. Stiffness and opisthotonos are often persistent between convulsions, which are easily stimulated by noise and often accompanied by loud squealing. The convulsive period lasts for 24–36 hours. A sharp temperature fall may be followed by coma and death on the 3rd–4th day, but in cases of longer duration the convulsive stage may be followed by flaccid paralysis affecting particularly the hind limbs. In milder cases, early stiffness and weakness are followed by flaccid paralysis without the irritation phenomena of convulsions and tremor. In a recent case in the UK the pigs were off-color, showed anterior limb paralysis and were reluctant to rise and were therefore euthanased. Pigs were bright and keen to eat and drink.

Subacute viral encephalomyelitis (Talfan disease)
