DR. OTTO M. RADOSTITS, August 31, 1934 – December 15, 2006.
Senior author 5th to 7th editions. Lead author 8th to 10th editions.

Otto Martin Radostits died after a difficult but courageous battle with renal carcinoma and it is sad that he died a few days before the release of the first printing of this 10th edition. His passing marked the end of his remarkable career as an educator in large animal veterinary medicine. Through his writings, not the least this text, Otto had a profound influence on students and practicing veterinarians throughout the world.

Otto was raised on a small mixed farm in Alberta, Canada; the eldest son of Austrian immigrants. His early farm experiences and those obtained from working with a local veterinarian while attending high school sparked an interest in pursuing a career in veterinary science and were the beginning of his lifelong passion with large animal veterinary medicine. He was admitted to the Ontario Veterinary College in 1954, at that time the only English-speaking veterinary school in Canada. During his undergraduate years his clinical interests and potential were recognized such that following graduation he was invited to join the faculty as a member of the ambulatory clinic practice of the College – at that time a vigorous practice in a rural area. Otto spent the next five years teaching in this position, with the exception of a year spent at the veterinary school at Purdue University in West Lafayette, Indiana.

The Western College of Veterinary Medicine in Saskatchewan, Canada, was established in the mid 1960s and Otto was one of the founding faculty. He established the ambulatory practice and helped design the college clinical buildings and finalize the curriculum. He remained a faculty member at the Western College of Veterinary Medicine until he retired in June 2002 and was awarded the title Emeritus Professor. Here he matured as a clinical teacher to influence students and veterinarians locally and internationally through his writings and presentations at veterinary meetings.

Otto's international recognition in large animal veterinary medicine rests mainly in the strength of his writing and authorship of veterinary texts. These span the spectrum of large animal veterinary medicine from the clinical examination of the individual animal, the epidemiology, diagnosis, treatment and control of livestock diseases, to herd health and preventive medicine.

The most notable are his contributions to this textbook, which has been used by veterinary students and practicing veterinarians around the world for the past 45 years. Otto joined the original authors, Doug Blood and Jim Henderson, for the 5th edition of this text in 1979 and, in 1994, became the senior author for the 8th and subsequent editions. During his sojourn as senior author the text continued its original design as a student textbook with many student friendly features. It also continued its significance as a reference book including the available information on all the diseases of large animals, a truly formidable task. Otto did a large part of the work and would surely have been very proud of this new edition.

In the writing of these and his other texts Otto read the veterinary literature and was a firm believer in evidenced-based medicine. He insisted that all statements in these texts were supported by references in the literature and he maintained the format of a very large bibliography at the end of each disease description. He believed that other veterinary educators should also be current with the veterinary literature and had little brief for those who were not. He could be a forceful presence in discussions but Otto was also one of the quickest to recognize new information that negated previous theories concerning a disease and was one who was always responsive to reasoned argument.

Otto taught that making a correct diagnosis was the crux to the solution of a disease problem and he had a passion for the art and science of clinical examination. And many of his students affectionately remember his admonition "We make more mistakes by not looking than by not knowing". Otto's insistence on the need for accurate diagnosis did not preclude this realization that what the practicing veterinarian needed as the final message from his books was what was the best current information on what to do to cure or prevent it.

Otto has authored other texts. In the late 1990's he became concerned that traditional skills of physical clinical examination were being supplanted by laboratory and instrumental analysis. As a consequence he consulted with veterinary clinicians around the world and in 2000 was a senior author of the text "Veterinary clinical examination and diagnosis". With his work on farms Otto recognized that disease in farm animals commonly was a population concern and recognized the limitations of "fire brigade" medicine. He authored the first major text in herd health and preventive medicine with its first edition in 1985. Otto has many other publications of significance to global veterinary medical education and presented more than 250 invited lectures and seminars in veterinary medicine in countries around the world.

Dr Radostits' contributions have been recognized in many awards. For him, probably the most important was the award of Master Teacher from his university and, nationally, the Order of Canada. The early requirement for a second printing of this 10th edition attests Dr Radostits excellence as the senior author of this text and also allows us to insert this dedication to him. We thank Elsevier and the Publishing Editor of Veterinary Medicine for the opportunity to include this dedication in this second printing.

The Tenth Edition of this text, *Veterinary Medicine*, marks the passing of an era. For the first time Professor D. C. Blood, the originator of this text, is not a contributor and author. Doug Blood has had a passion for veterinary science and over the past 60 years he has made a remarkable contribution to the science of clinical veterinary medicine and to the profession of veterinary medicine. Not the least of these contributions is this text, in print for the past 45 years. He has taught clinical veterinary medicine to 40 years of veterinary students. The undergraduate education of all four of the senior authors of this edition has been profoundly impacted by Doug Blood's teaching and philosophy and the period of time of this influence ranges from the late 1950s to the early 1980s. Our postgraduate education and experience has also had significant influence from Doug Blood and we reflect on his influence on the profession and dedicate this edition to him.

As a background, Doug received his veterinary degree from the University of Sydney in 1942 and served in the Australian Army Veterinary Corps until the end of the Second World War. He then returned to teach and practice clinical veterinary medicine in the Clinical Department of the Faculty of Veterinary Science in the University of Sydney for 12 years, during which he spent a year on a Fulbright stipend at the veterinary school at Cornell University. In 1957 he joined the Department of Clinical Medicine at the Ontario Veterinary College in Guelph, then part of the University of Toronto, Canada.

In these early years Doug Blood revolutionized the teaching of clinical veterinary medicine. For those of us privileged to have been taught by him at this time he was a superlative teacher. Doug was one of the first teachers in veterinary clinical medicine to recognize that pathophysiology was the basis for teaching the disease processes in large animals. He also concentrated on its principles for the explanation of disease syndromes and in teaching clinical examination and diagnosis. This was an approach that he developed from the teaching of his mentor, the Oxford veterinary scientist, H. B. Parry, to whom this text was dedicated in the first edition. This approach to clinical teaching was in marked contrast to the rote learning that was common in many of the disciplines taught at that time and in stark contrast to the teaching in clinical examination and diagnosis, which then primarily relied on pattern recognition.

Doug Blood also taught that the method of clinical examination should be system-based, that it should be conducted in a systematic manner and that it should be conducted using all available senses and techniques. He further taught that the intellectual diagnostic rule-out process should also incorporate a consideration of the presenting epidemiology of the disease problem, the probability of disease occurrence and an examination of the environment. Although these approaches might seem obvious to recent graduates, in the 1950s and early 1960s they were revolutionary. In fact, they set the foundation for current teaching principles in large-animal clinical veterinary medicine. Students of that older vintage recall with great appreciation the understanding of clinical veterinary medicine imparted by Doug Blood and his particular contribution to their education. Throughout subsequent years in his teaching career Doug has shown the ability to inspire students and is held in respect, admiration and even veneration by the generations of students that he has taught.

The first edition of this text was published in 1960 and authored by D. C. Blood and J. A. Henderson. It was entitled *Veterinary Medicine: A Textbook of the Diseases of Cattle, Horses, Sheep, Pigs and Goats* and was based on Doug Blood's and Jim

Henderson's lectures and Doug's teaching and philosophical approach. At that time there were few textbooks in the disciplines of veterinary science and none that were either current, or published in English, that were primarily concerned with clinical veterinary medicine and diseases in agricultural animal species. The text was divided into two major sections: one, entitled General Medicine, covered system dysfunction and the other, Special Medicine, covered the specific diseases of the large animal species. This format has been followed in subsequent editions. The second edition was published in 1963 and had an additional two chapters covering parasitic diseases. Subsequently, new editions have been published approximately every 5 years with major or minor changes in format in most editions, such as the addition of new chapters dealing with new subjects or the addition of material in specific subheadings to highlight, for example, the epidemiology or zoonotic implications of disease. However, always, with each edition there was an extensive revision of disease descriptions based on current literature. Professor Henderson's involvement with the text ceased with the Fifth Edition and that edition recruited Professor O. M. Radostits as a senior author and others as contributing authors. The list of senior and contributing authors has expanded since the Fifth Edition but, until this present edition, Doug Blood has always been a major author.

In the preface to the First Edition it was stated that the book was directed primarily at students of veterinary medicine, although it was expected that the book would be of value to practicing veterinarians and field workers. The latter expectation has certainly proved true and the book has come to be

extensively used as a reference by veterinarians in large- and mixed-animal practice around the English-speaking world. Editions of the text have also been translated into French, Italian, Spanish, Portuguese, Japanese and Chinese.

In addition to his passion for the method and accuracy of diagnosis of disease in individual animals and herds, Doug Blood also has had a passion for preventive medicine and has been a firm proponent of the thesis that subclinical disease is economically more important than clinical disease in agricultural animal populations. With other colleagues at the University of Melbourne he developed, and trialed practically in private herds and flocks, health programs for dairy cattle, beef cattle and sheep. These programs were based on a whole-farm approach and centered on the concept that performance targets could be monitored by computer-based productivity monitoring to detect deviation from target performance. Doug Blood was a very early proponent of the use of computers to manage and analyze data in clinical diagnosis and herd health management. These herd health programs have been successfully commercially adopted in several countries.

Doug has stated on many formal occasions that he is immensely proud to be a member of the veterinary profession and in addition to his teaching and writing in clinical veterinary medicine he has attested this by his other outstanding contributions to the profession. In 1962 he returned to Australia to establish a Faculty of Veterinary Science within the University of Melbourne. He was appointed Professor of Veterinary Clinical Medicine and was also the Founding Dean of the current veterinary school in the university. The successful formation and funding of a new Faculty (College) within the University was a remarkable political achievement requiring cooperation with agricultural commodities, veterinarians, politicians and the public.

Doug has always been active in promoting the profession of veterinary medicine and active in organized veterinary medicine. He has actively encouraged his colleagues to have equivalent involvement and commonly would invite, pick up and transport new graduates or new faculty to the local veterinary association meetings in Melbourne.

In the 1970s Doug was instrumental in establishing the Australian College of Veterinary Science, which continues to provide continuing education and specialty certification for practicing veterinarians in Australia and New Zealand. He has served on a large number of state and national veterinary association committees including service as President of the Victorian Veterinary Association. In recognition of his service to the veterinary profession he was awarded the Gilruth prize by the Australian Veterinary Association. This is the highest honor that the Australian Veterinary Association can bestow. Other honors include prestigious international honors such as the award of the Order of the British Empire (OBE) for outstanding service in veterinary science, the award of an Honorary Associate in the Royal College of Veterinary Surgeons in the UK and the bestowment of Honorary Doctor of Laws awarded by both the University of Guelph and the University of Saskatchewan.

With all of his activities, Doug acknowledged the strong support of his wife Marion, recently deceased, and his family of five daughters. His house was always open to students and graduate students to discuss anything from subjects in veterinary medicine to a discussion of the current book of the month, for the enjoyment of a tasting of Australian wines or to meet with an overseas veterinarian, who so often had come to meet with Doug on the visit to Australia and had ended up staying as a guest in the Blood household during the period of this visit.

Doug is currently retired in Werribee, Victoria with a continuing interest in his many past students and a major interest in ornithology and photography.

Preface to the Tenth Edition

We are pleased to present the Tenth Edition of *Veterinary Medicine*, 45 years since the first 'Blood and Henderson' *Veterinary Medicine* was published in 1960. Because the demand for this book continues undiminished, we assume that we have a philosophy, a format and a price that is attractive and meets the demands of undergraduate veterinary students and graduate veterinarians working in the field of large-animal medicine. For this edition, significant changes were needed to keep up to date with the increasingly rapid expansion of knowledge about the diseases of large animals. The entire book was reviewed and revised as necessary, and new diseases added, based on literature published worldwide since 2000. We have attempted to ensure the book continues to have an **international scope** by including most of the diseases occurring in large animals **worldwide**.

Professor D. C. Blood continues to be an important inspiration and guiding light but retired from this edition of the book. We dedicate this edition to him.

Dr Clive Gay revised the chapters on diseases of the newborn, practical antimicrobial therapy, diseases caused by physical agents, the infectious diseases of sheep and goats, a new chapter on diseases associated with prions, and some of the metabolic and protozoan diseases and diseases of unknown etiology.

Dr Kenneth Hinchcliff, Ohio State University, completely revised the sections on specific equine diseases and added many newly described diseases of the horse. The section on equine colic, which had been expanded in the Ninth Edition, was completely revised for this edition. A section on care and management of the recumbent horse is a new addition. Dr Hinchcliff also revised the chapter on diseases of the respiratory system and diseases of the hemolymphatic and immune system. Dr Hinchcliff's section on the **formulary of drugs** used in large animal practice has been highly successful and useful to students, clinicians, and practitioners. It serves as a quick reference for the busy practitioner who needs to know the dosage schedule of a certain drug.

Dr Peter Constable has joined us a co-author. He reviewed major parts of Chapter 2, on systemic states, and revised the chapters on diseases of the cardiovascular system, the urinary system, the nervous system, and the mammary gland.

Dr Otto Radostits continued his role as senior author with major responsibilities for chapters in general medicine including systemic states, alimentary tract, ruminant stomachs, respiratory system, and musculoskeletal system. He also revised the chapters on metabolic diseases, nutritional diseases and most of the infectious diseases of cattle and some of the diseases of uncertain etiology.

Professor Dennis Jacobs, University of London, revised the chapter on diseases caused by helminths and completely reorganized the material into more distinct groups according to effects of the various helminths on body systems.

Dr Ross A. McKenzie revised the chapter on diseases caused by toxins in plants, fungi, cyanophytes, clavibacteria, and venoms in ticks and vertebrate animals.

Professor Basil O. Ikede, revised the major exotic viral and protozoan diseases and introduced some new tabular information that may be useful to the reader.

Dr Doug Colwell joined our book by revising the chapter on diseases caused by arthropod parasites.

Professor Stanley Done also joined our book as a major contributor and revised all the diseases of pigs. It was a major task given the very large literature base on infectious diseases of pigs on a worldwide basis.

Dr Rob Bildfell, reviewed and revised the necropsy findings for most of the specific diseases. His contribution in the Ninth Edition, **Samples for confirmation of diagnosis**, has been a successful section to serve as a guideline for the collection of samples at necropsy. The details of the guidelines are described in the section dealing with '**How to use this book**'.

Computerized word processing greatly facilitates the achievement of our long-term objective to produce an up-to-date review of the field of large-animal veterinary medicine as it is practiced, and the parallel stream of research work into the **etiology, epidemiology, pathogenesis, treatment** and **control** of diseases of large animals. We continue to emphasize a good understanding of **pathogenesis** of each disease, which is important in understanding the rationale for the diagnosis, treatment and control. This means that we strive to maintain an optimum balance between published research and what field veterinarians find useful in their daily work, which necessitates that our authors and contributors maintain a strong contact with clinical work, especially with the clinical techniques and treatment and control measures.

The knowledge base in **veterinary epidemiology**, particularly risk factors for disease, continues to increase and become more complex. A system of subheadings has been introduced and the material has been rearranged under them in order to simplify the reader's task in locating material in these presentations. A major change for this edition is giving special emphasis to the risk factors for disease, which are so important to the veterinarian in the clinical management and control of disease, particularly on a herd basis. We also continue to include the **zoonotic implications** of many diseases and how the large-animal veterinarian is becoming more involved in the control of diseases transmissible to humans. We also indicate those diseases of concern as agents of bioterrorism.

The use of **individual diagnostic tests**, described under clinical pathology of each disease, continues to be a challenge for all of us. A very large number of publications deal with the development of laboratory diagnostic tests but most of them have little information on their sensitivity and specificity for diagnostic purposes and will likely never be employed in routine diagnosis. There is also regional and national variation in tests that are used and it is not possible nor desirable to detail these in the book. We have chosen to concentrate on those tests that are accepted through common use, to discuss their limitations if they are known, and to provide a reference to newer tests that have future promise in diagnosis.

Restraining the size of the book has been a constant preoccupation and a difficult task with the ever increasing volume of published information and the constantly growing list of diseases. Our intention has always been to provide information on all recorded diseases. In spite of reductions in reference lists, word paring editing made possible by word processing, and overall editing to minimize repetition, the book is still quite large. The references have been culled and those included are considered to be current. **Synopses** have been included for each disease topic for which the material exceeded approximately 1000 words. To make it easier for the reader to find particular pieces of information, long passages of prose have been divided into smaller sections using more **headings** and **subheadings. Key words, terms** and **phrases** have been emboldened for emphasis and to make it easier for the reader to identify important points.

Other reference books to which the readers are referred, include the 3rd edition of *Herd Health* (2001), the companion

reference to animal health management of farm animals, and the 3rd edition of *Saunders Comprehensive Veterinary Dictionary* (2006) with its complete coverage of definitions and spellings of all words used by undergraduate and graduate veterinarians.

We are satisfied that we have completed another authoritative, responsible and comprehensive review of the literature of large animal medicine, at a standard at least equal to that of the previous nine editions, and we hope that it will provide the information necessary for the needs of students and practitioners for the next 5 years.

November 2006

Introduction

Objectives and principles of farm animal practice

The primary objective of this book is to provide the veterinary student and the practitioner with the knowledge and information necessary to provide animal health management for farm animals. This is a commentary on the objectives and principles of veterinary practice related to the animal health and production of cattle, sheep, goats, pigs and horses.

FOOD-PRODUCING ANIMALS

Food-producing-animal veterinary practice provides service primarily to the owners of the meat-, milk- and fiber-producing animals such as dairy and beef cattle, pigs, sheep and goats. Veterinarians also provide service to owners of captive ungulates, such as red deer, elk and bison, that are being raised under farm conditions for the production of meat and byproducts such as hides. While some commercially processed horsemeat is consumed by humans, the market is small compared to beef and pork, and horses are not usually included in discussions about food-producing animal veterinary practice. Poultry, fish and rabbits are also important sources of human food but are not the subject of this book.

For the past several decades, the major activity in food-producing-animal practice, and a major source of income for veterinarians, was the provision of **emergency veterinary service** to the owners of herds or flocks in which a single animal was affected with one of the common diseases. Occasionally, outbreaks of disease affecting several animals occurred. In addition, routine elective veterinary services such as castration, vaccination, dehorning, deworming, the testing for diseases such as brucellosis and tuberculosis and the dispensing of veterinary drugs, pharmaceuticals and biologicals accounted for a significant source of revenue for the veterinarian. Since about the early 1970s, there has been a shift from emphasis and dependence on emergency veterinary medicine and routine procedures to more attention being paid by the veterinarian and the producer to **planned animal health and production management** using the whole-farm approach. Livestock producers are now much more knowledgeable about animal agriculture and are concerned about the cost-effectiveness and the scientific basis of the recommendations made by veterinarians and agricultural advisors. More and more producers are doing the routine elective procedures themselves. From firsthand experience and extension courses provided for them they have also learned how to diagnose and treat many of the common diseases of farm livestock. Many veterinary pharmaceuticals antimicrobials and biologicals can now be purchased by producers from either veterinary or nonveterinary sources.

INDUSTRIALIZED ANIMAL AGRICULTURE

The intensification of animal agriculture has created complex animal health and production problems for which there are no simple and reliable therapeutic and preventive procedures, and this has made the task of the veterinarian much more challenging. For example, acute undifferentiated respiratory disease is a common disease of feedlot cattle that is difficult to treat and control effectively because the etiology and epidemiology are complex. Acute diarrhea of calves under 30 days of age may be caused by several different enteropathogens but a knowledge of the risk factors or epidemiological determinants such as colostral immunity and population density is probably more important for effective clinical management and control of the disease. The rearing of pigs intensively and in complete confinement has exaggerated a number of disease problems, many exacerbated by inadequacies of the environment.

Suboptimal reproductive performance due to a variety of management and environmental factors is common, and pneumonia in growing and finishing pigs may be almost impossible to eradicate unless the herd is depopulated and repopulated with minimal-disease breeding stock. Infectious diseases such as porcine reproductive and respiratory syndrome are difficult to control. The solutions to these complex problems are not always readily apparent, in part because of insufficient research on etiology and epidemiology and different control strategies in the herds where the problems are occurring. The veterinarian must be knowledgeable and skillful in the principles of epidemiology, applied nutrition and animal housing, the education and training of animal attendants and the analysis of production indices, including profit and loss, which includes the use of computers, in addition to being skilled in the traditional veterinary disciplines of medicine, reproduction, pharmacology and pathology. Thus, the food-producing-animal practitioner must become more skilled in the simultaneous management of animal health and production; the modern livestock producer is cost-conscious and anything veterinarians do or recommend must be cost-effective.

COMPANION ANIMAL PRACTICE

In contrast, developments in companion animal medicine (small animals) have followed in the footsteps of human medicine with an ever-increasing emphasis and reliance on extensive use of clinical pathology for the in-depth evaluation of the hematology, clinical chemistry, enzymology, immune status and many other body functions of the individual animal.

Diagnostic techniques such as ultrasonography, endoscopy, nuclear imaging and computed tomography are being used both in veterinary teaching hospitals and in referral veterinary practices. These in-depth 'diagnostic workups' presumably lead to a greater understanding of the etiology and pathophysiology of disease, with the ultimate aim of a more accurate and early diagnosis that allows much more effective medical and surgical therapy than is economically possible or necessary in food-producing animals. There is not the same emphasis on the efficiency of production, epidemiology and cost-effectiveness that constantly faces the food-producing-animal practitioner. More and more companion animal owners, because of the sentimental value of their animals and the growing importance of the human–companion-animal bond, are willing to pay for the costs associated with extensive laboratory and sophisticated diagnostic tests and intensive and prolonged veterinary hospital care. Palliative care for dogs and cats affected with diseases that may not be curable over the long term is now a recognized fact in small-animal practice.

EQUINE PRACTICE

Equine practice has evolved along similar lines to small-animal practice. Some aspects of it, such as reproduction, intensive clinical care of the newborn foal and the treatment of medical and surgical diseases of valuable athletic and competitive horses, have advanced a great deal. The great strides that have been made in our understanding of the diagnosis, prognosis and medical and surgical therapy of colic in the horse are due to the in-depth diagnostic laboratory work and the medical and surgical

expertise that have been used. Our improved understanding of the prognosis of equine colic has in part been due to prospective studies of the clinical and laboratory findings in horses with colic. However, the large advances in improvement in survival made in the early years of surgical and intensive medical treatment of colic have not continued, and there is an urgent need for appropriately designed prospective clinical trials to determine optimal treatment regimes in these horses. The same is true for intensive treatment of sick foals. In addition to the advanced diagnostic and therapeutic procedures being done on valuable horses at veterinary teaching hospitals, there are now many privately owned equine veterinary centers that provide the same service. Undoubtedly the high financial value of some horses has provided the impetus for the development of these services.

While the increasingly sophisticated diagnostic and therapeutic techniques used in equine practice are readily noted, advances in the understanding of infectious and contagious diseases of horses has also increased markedly. This is particularly true for economically important diseases that have the potential to affect large numbers of horses, consequently causing disruption to important athletic events, sales and shipment of horses. These diseases are typically the infectious respiratory diseases and those diseases, such as African horse sickness, that are exotic to most of the horse population worldwide. The economic incentive to control these diseases has resulted in considerable increases in knowledge of their etiology (and consequently vaccinology), epidemiology, immunology, diagnosis and prevention. Few advances have been made in treatment of what are for the most part self-limiting diseases with low case fatality rates.

CONTRASTING OBJECTIVES

It is clear that there are major differences between the objectives and principles of companion-animal practice and those of food-producing-animal practice. In companion-animal practice, the objective is the restoration of the clinically ill animal to a normal state, if possible, or in some cases a less than normal state is acceptable providing it is a quality life, using all the readily available diagnostic and therapeutic techniques that can be afforded by the client. In sharp contrast, in food-producing-animal practice, the objective is to improve the efficiency of animal production using the most economical methods of diagnosis, treatment and control, including the disposal by culling or slaughter of animals that are difficult to treat and are economic losses.

This growing dichotomy in the delivery of veterinary services to the food-producing-animal owner and to the companion-animal owner prompted us to present a short introductory commentary on the objectives and principles of food-producing animal practice.

The objectives of food-producing animal practice

EFFICIENCY OF LIVESTOCK PRODUCTION

The most important objective in food-producing-animal practice is the continuous improvement of the efficiency of livestock production by the management of animal health. This involves several different but related activities and responsibilities, which include the following:

- **Providing the most economical method of diagnosis and treatment** of sick and injured animals and returning them to an economically productive status, or to a point where slaughter for salvage is possible in the shortest possible time. The financially conscious producer wants to know the probability of success following treatment of a disease in an animal and to minimize the costs of prolonged convalescence and repetitive surgery
- **Monitoring animal health and production** of the herd on a regular basis so that actual performance can be compared with targets and the reasons for the shortfalls in production or increases in the incidence of disease can be identified as soon as possible, so that appropriate and cost-effective action can be taken. The routine monitoring of production records and the regular monitoring of bulk tank milk somatic cell counts in dairy herds are examples
- **Recommending specific disease control and prevention programs** such as herd biosecurity, vaccination of cattle against several important infectious diseases that occur under a variety of conditions, and the strategic use of anthelmintics in cattle and sheep
- **Organizing planned herd and flock health programs** for the individual farms with the objective of maintaining optimum productivity through animal health management. This subject is presented in the companion volume to this book, Radostits OM *Herd Health: Food Animal Production Medicine*, 3rd edn. WB Saunders, 2001
- **Advising on nutrition, breeding and general management practices**. Food-producing-animal practitioners must be interested in these matters when they affect animal health. It is a large part of production-oriented health management, and it is now common for veterinarians to expand their health-oriented animal husbandry advisory service to include an animal production advisory service. To do so is a matter of individual preference, an option that some veterinarians take up and others do not. Some veterinarians will rely on consultation with agricultural scientists. However, veterinarians still require a working knowledge of the relevant subjects, at least enough to know when to call in the collaborating advisor for advice. Members of both groups should be aware of the extensive list of subjects and species-oriented textbooks on these subjects, which should be used to support this kind of service.

ANIMAL WELFARE

Encouraging livestock producers to maintain standards of animal welfare that comply with the views of the community is emerging as a major responsibility of the veterinarian. The production of food-producing animals under intensified conditions has now become an animal welfare concern that practitioners must face and in which they must become proactive.

ZOONOSES AND FOOD SAFETY

Promoting management practices that ensure that meat and milk are free of biological and chemical agents capable of causing disease in humans must also become a preoccupation for food-producing-animal veterinarians. This is because the general public is concerned about the safety of the meat and milk products it consumes and the most effective way to minimize hazards presented by certain infectious agents and chemical residues in meat and milk is to control these agents at their point of entry into the food-chains, namely, during the production phase on the farm. Veterinarians will undoubtedly become involved in the surveillance of the use of antimicrobial compounds and other chemicals that are added to feed supplies to promote growth or prevent infections, and will be expected to minimize the risk of the occurrence of zoonotic disease agents in farm animal populations.

Principles of food-producing animal practice

REGULAR FARM VISITS

A unique feature of a food-producing animal veterinary practice is that most of the service is provided by the veterinarian who makes emergency or planned visits to the farm. In some areas of the world, where veterinarians had to travel long distances to farms, large-animal clinics were established and producers brought animals that needed veterinary attention to the clinic. For the past 25 years these clinics have provided excellent facilities in which, for example, surgical procedures such as cesarean sections could be done and intensive fluid therapy for dehydrated diarrheic calves could be administered much more effectively and at a higher standard than on the farm. However, much less veterinary service is being provided in these clinics now because of the high operating costs of providing hospital care and the limited economic returns that are possible for the treatment of food-producing animals, which have a fixed economic value. Producers have also become less enthusiastic about transporting animals to and from a veterinary clinic because of the time and expertise involved.

CLINICAL EXAMINATION AND DIAGNOSIS

The diagnosis, treatment and control of diseases of food-producing animals are heavily dependent on the results of the clinical examination of animals on the farm and the careful examination of the environment and management techniques. This means that the veterinarian must become highly skilled in obtaining an accurate and useful history on the first visit to an animal or group of animals and in conducting an adequate clinical examination in order to make the best diagnosis possible, and economically so that the treatment and control measures can be instituted as soon as possible. On the farm, during the day or in the middle of the night, the veterinarian will not have ready access to a diagnostic laboratory for the rapid determination of a cow's serum calcium level if milk fever is suspected. The practitioner must become an **astute diagnostician** and a skillful user of the physical diagnostic skills of visual observation, auscultation, palpation, percussion, succussion, ballottement and olfactory perception. On the farm, the clinical findings, including the events of the recent disease history of an animal, are often much more powerful, diagnostically, than laboratory data. It therefore becomes increasingly important that the clinical examination should be carefully and thoughtfully carried out so that all clinically significant abnormalities have been detected.

An outline of the clinical examinations of an animal and the different methods for making a diagnosis are presented in Chapter 1. Becoming efficient in clinical examination requires the diligent application of a systematic approach to the task and, most importantly, evaluation of the outcome. A most rewarding method of becoming a skillful diagnostician is to retrospectively correlate the clinical findings with the pathology of those cases that die and are submitted for necropsy. The correlation of the clinical findings with the clinical pathology date, if available, is also an excellent method of evaluation but is not routinely available in most private practices. The food-producing-animal practitioner must also be a **competent field pathologist** and be able to do a useful necropsy in the field, usually under less than desirable conditions, and to make a tentative etiological diagnosis so that additional cases in the herd can be properly handled or prevented. Doing necropsies on the farm or having them done by a local diagnostic laboratory can be a major activity in a specialty pig or beef feedlot practice, where clinical examination of individual animals is done only occasionally, compared with dairy practice.

EXAMINATION OF THE HERD

The clinical examination of the herd in which many animals may be affected with one or a number of clinical or subclinical diseases or in which the owner's complaint is that performance is suboptimal but the animals appear normal, has become a major and challenging task. This is particularly true in large dairy herds, large pig herds, beef feedlots, lamb feedlots and sheep flocks where the emphasis is on health management of the herd. Intensified animal agriculture may result in an increased frequency of herd **epidemics** or **outbreaks** of diseases such as pneumonic pasteurellosis, bloat, acute diarrhea in beef calves and peracute coliform mastitis in dairy cattle. Such well known diseases are usually recognizable and a definitive etiological diagnosis can usually be made and in some cases the disease can be controlled by vaccination. However, in some cases of herd epidemics of respiratory disease, salmonellosis, Johne's disease, for example, the veterinarian may have to make repeated visits to the herd in order to develop effective treatment and control procedures. The steps involved in the examination of the herd affected with a clinical disease or suboptimal performance are presented in Chapter 1.

VETERINARY TECHNICIANS

Veterinary technicians are now employed by veterinary practices to assist in a wide variety of tasks. They can collect and computerize animal health and production records from individual herds, collect laboratory samples and assist in the preparation of reports. Under the veterinary supervision they can do routine elective surgical procedures such as dehorning, castration, foot-trimming and vaccinations. The veterinarian is thus provided with more time to pursue the diagnosis and correction of health and production problems in the herd. In large commercial beef feedlots, veterinary technicians commonly identify and treat cattle affected with acute undifferentiated respiratory disease and the veterinarian will analyze the therapeutic responses, do necropsies and interpret the data, which have been stored in a computer.

VETERINARY EPIDEMIOLOGY

As animal agriculture continues to intensify, an increasing number of herd problems are evolving that have a multifactorial etiology and we are entering the era of the **epidemiological diagnosis**, in which the definitive etiology may not be determined but removal or modification of the risk factors may successfully and economically control the disease. For example, recent epidemiological observations revealed that certain skeletal abnormalities of beef calves were associated with the use of grass or clover silage as the sole diet of pregnant beef cows during the winter months in Canada. The precise etiology was undetermined but in a controlled clinical trial, supplementation of the silage with grain eliminated the abnormality. This is an example of a modern-day epidemiological diagnosis comparable to the observation by John Snow that cholera in humans was associated with the use of the community water pump, long before the causative bacterium was identified. Bovine spongiform encephalopathy, first recognized in the UK in 1986, has resulted in some excellent research in veterinary epidemiology, which has demonstrated its power in the investigation of a disease that has such important zoonotic implications.

It is clear that the next wave of development in food-producing-animal practice will be associated with the increased use of **applied and analytical epidemiology**. The tools of

epidemiology are now readily available to allow the veterinarian to identify and quantify the risk factors associated with the disease, to provide a more accurate prognosis, to accurately assess treatment responses and not depend on clinical impressions, to scientifically evaluate control procedures and to conduct response trials. There is a large and challenging opportunity for veterinarians to become involved in clinical research in the field where the problems are occurring. It will require that they become knowledgeable about the use of computerized databases. These now provide an unlimited opportunity to capture and analyze data and generate useful information, which heretofore was not considered possible. The technique of decision analysis is also a powerful tool for the veterinarian who is faced with making major decisions about treatment and control procedures.

COLLECTION AND ANALYSIS OF ANIMAL HEALTH DATA

With the shift in emphasis to the problems of the herd, the collection, analysis and interpretation of animal health and production data will be a major veterinary activity. Livestock producers must keep and use good records if the veterinarian is to make informed decisions about animal health and production. The once tedious and unpopular work of recording and analyzing animal health and production data is now done by the computer. Veterinarians will have to move in the direction of developing a computer-based animal health and production profile of each herd for which they are providing a service. Veterinary colleges will also have to provide leadership and provide undergraduate and graduate student education in the collection, analysis and interpretation of animal health data. This activity will include methods of informing the producer of the results and the action necessary to correct the herd problem and to improve production.

PUBLIC HEALTH AND FOOD SAFETY

Veterinarians have a major responsibility to ensure that the meat and milk produced by the animals under their care are free from pathogens, chemicals, antimicrobials and other drugs that may be harmful to humans. The prudent use of antimicrobials, including adherence to withdrawal times for meat and milk, are becoming major concerns of the veterinary associations such as the American Association of Bovine Practitioners and Swine Practitioners. Traditionally, veterinary public health was not an attractive career for veterinarians because it was perceived as an unimportant activity. However, because of the recent concern about the contamination of meat supplies by pathogens and **xenobiotics** (any substance foreign to an animal's biological system), and the potentially serious economic effects of such contamination on the export markets of a country, it is now clear that veterinarians, using a variety of testing techniques, will become involved in monitoring the use of veterinary drugs so that treated animals are not placed in the food-chain until the drugs have been excreted. The same principles apply to the contamination of milk supplies with antimicrobials, a major responsibility of the veterinarian.

ECONOMICS OF VETERINARY PRACTICE

The successful delivery of food-producing-animal practice will depend on the ability of the veterinarian to provide those services that the producer needs and wants at a price that is profitable to both the producer and veterinarian. Several constraints interfere with this successful delivery. Maximizing net profit is not a high priority for many farmers. Being independent and making a living on the farm are commonly ranked higher. Consequently, when veterinarians make recommendations to control a disease their subsequent enthusiasm for giving advice may be dampened if farmers do not adopt the control procedures even though the advice is based on good information about expected economic returns.

The frustrations that many veterinarians experience in attempting to get dairy producers to adopt the principles of an effective and economical mastitis control program are well known. In some cases, producers do not use modern methods of production and disease control because they are unaware of their importance. The variable financial returns that farmers receive for their commodities, particularly the low prices received during times of oversupply of meat and milk, may also influence whether they purchase professional veterinary service or attempt to do the work themselves.

VETERINARY EDUCATION

We have described our views on the state of food-producing-animal medicine and what it requires of veterinarians who practice it. Traditionally, veterinary colleges have provided undergraduate students with the knowledge and clinical skills necessary to enter veterinary practice and begin to engage in food-producing-animal practice. Field service units and large-animal in-clinics devoted to clinical teaching were an integral part of most veterinary colleges. The clinical caseload is for the students, clinicians and the paraclinical sciences such as microbiology, toxicology, clinical pathology and pathology. However, recently, it seems that veterinary colleges have not maintained their farm-animal teaching clinics and, in fact, some of these teaching clinics have ceased to exist. The demise of in-house food animal practice in veterinary teaching hospitals, as opposed to the care of agricultural animals from hobby farms, is contributed to by the increasing use of stringent biosecurity measures on medium- and large-scale operations. Animals brought to veterinary teaching hospitals for diagnosis and possible treatment cannot be returned to the farm because of the fear of introducing infectious disease. Regardless, the demise of in-house food-animal practice in universities should be of major concern to the veterinary profession, which should have an obligation to serve the veterinary needs of animal agriculture. Some veterinary colleges have developed extensive programs in which undergraduate students spend time in private veterinary practice to gain clinical experience. However, the failure to maintain and support viable farm-animal teaching clinics will diminish the clinical experience of clinicians and the paraclinical sciences, who have a primary responsibility for teaching. In addition, the lack of clinical cases will adversely affect the clinical research activities of clinicians. Clinicians must experience a critical number of clinical cases in order to maintain credibility as a veterinary scholar.

> *To study the phenomena of disease without books is to sail an unchartered sea, while to study books without patients is not to go to sea at all.*
>
> Sir William Osler,
> Books and Men. *Boston Surgical Journal*. 1901

The practicing veterinarian must become knowledgeable about various aspects of **farm animal management**, especially those that cause or contribute to clinical or subclinical disease and impaired animal production. Such veterinarians will become **species-industry specialists** who can provide totally integrated animal health and production management advice either to the dairy herd, the beef cow-calf herd, the beef feedlot, the pig herd or the sheep flock. To be able to do this veterinarians will need to undertake a postgraduate clinical residency program or develop the expertise on their own by diligent self-education in a

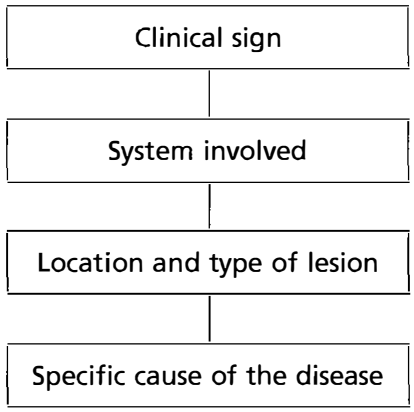
veterinary practice that is committed to the concept of a total animal health management and allows the veterinarian the time and the resources to develop the specialty.

OPTIMAL UTILIZATION OF THE FOOD-PRODUCING-ANIMAL PRACTITIONER

All that we have said in this introduction is related to enhancing and improving the performance of the professional food-producing-animal veterinarian. In developed countries this could mean greater utilization of each veterinarian by farmers and improved financial viability of their farming enterprises. In developing countries it could mean a greater volume of production at a time when malnutrition appears to be the fate of so many groups of the world community. These could be the outcomes if the world's agricultural situation was a stable one. As it is, there is currently a great upheaval in agriculture; developed countries are heavily overproduced and there is a sharp decline in farming as an industry and way of life. In developing countries, the decisions governing the health and welfare of animals and the people that depend on them often seem to depend more on political expediency than on the basic needs of humans and their animals. In these circumstances we do not feel sufficiently courageous and farsighted to predict our individual futures but with the hindsight of how far the human population and their attendant agricultural and veterinary professions have come in the past 50 years we are confident that you will have an opportunity to properly pursue the objectives and principles that we have described.

How to use this book

We would like you to get the most out of this book. To do that you should follow the directions below. And if you keep doing this every time you use the book you will develop a proper diagnostic routine of going from:



... and become what we wish for every one of you: a thinking clinician.

FOR EXAMPLE

A yearling bull has a sudden onset of dyspnea, fever, anorexia, abnormal lung sounds and nasal discharge.

Step 1 The bull's problem is dyspnea. Go to the index and find the principal entry for dyspnea.

Step 2 The discussion on dyspnea will lead you to respiratory tract dyspnea and cardiac dyspnea.

Step 3 Via the index consult these and decide that the system involved is the respiratory system and that the lungs are the location of the lesion in the system.

Step 4 Proceed to diseases of the lungs and decide on the basis of the clinical and other findings that the nature of the lesion is inflammatory and is pneumonia.

Step 5 Proceed to pneumonia, and consult the list of pneumonias that occur in cattle. Consult each of them via the index and decide that pneumonic pasteurellosis is the probable specific cause.

Step 6 Proceed to the section on pneumonic pasteurellosis determine the appropriate treatment for the bull and the chances of saving it.

Step 7 Don't forget to turn to the end of the section on pneumonic pasteurellosis and remind yourself of what to do to protect the rest of the herd from sharing the illness.

Guidelines for selection and submission of necropsy specimens for confirmation of diagnosis

In this edition we continue with the subheading *Samples for confirmation of diagnosis* to serve as a rough guideline for the collection of samples at necropsy. Several points must be emphasized with regard to this section. First and foremost, **collection of these samples is not advocated as a substitute for a thorough necropsy examination**. Furthermore, the samples listed are selected in order to confirm the diagnosis but a conscientious diagnostician should also collect samples that can be used to rule out other disease processes. Even the best of practitioners can make an incorrect tentative diagnosis but it is an even more humbling experience if there are no samples available to pursue alternate diagnoses. Also, recall that some diseases may be the result of several different etiological factors (e.g. neonatal diarrhea of calves) and the veterinarian who samples to confirm one of these factors, while not attempting to investigate others, has not provided a good service to the client.

A huge variety of veterinary diagnostic tests have been developed but each veterinary diagnostic laboratory (VDL) offers only a selected panel, chosen after consideration of a number of factors. Such factors may include: cost, demand, reliability, sensitivity and specificity, and the availability of appropriate technology at the lab. The array of diagnostic tests is constantly improving and it is beyond the scope of this text to list all the tests available for a given disease, or to recommend one test method to the exclusion of others. Under the samples for confirmation of diagnosis section we have merely listed some of the more common tests offered. Advances in molecular biology are providing exciting avenues for disease diagnosis, but many of these tests have limited availability in VDLs at present. For optimal efficiency in the confirmation of a diagnosis at necropsy, the practitioner must contact their VDL to determine what tests are offered and to obtain the preferred protocol for sample collection and submission to that particular laboratory. Most VDLs publish user guidelines, which include the tests available and the samples required. The guidelines listed below are broad, and individual VDLs may have very specific requirements for sample handling.

Several general statements can be made with regard to the submission of samples to VDLs:

- The samples should be accompanied by a clearly written and concise clinical history, including the signalment of the animal, as well as feeding and management information. Failure to provide this information deprives the owner of the full value of the expertise available from the laboratory staff
- If a potentially zoonotic disease is suspected, this should be clearly indicated in a prominent location on the submission form
- All specimens should be placed in an appropriate sealed, leakproof container and clearly labeled with a waterproof marker to indicate the tissue/fluid collected, the animal sampled and the owner's name. At some VDLs, pooling of tissues within a single bag or container is permitted for specific tests (such as virus isolation), but in general all fresh samples should be placed in separate containers. When packaging samples for shipment recall that condensation from ice packs and frozen tissues will damage any loose paper within the package; the submission sheet should be placed within a plastic bag for protection or taped to the outside of the shipping container
- Samples for histopathology can be pooled within the same container of 10% neutral-buffered formalin. An optimal tissue sample of a gross lesion should include the interface between normal and abnormal tissue. For proper fixation, tissue fragments should not be more than 0.5 cm in width and the ratio of tissue to formalin solution should be 1:10. If necessary, large tissues such as brain can be fixed in a larger container and then transferred to a smaller one containing only a minimal quantity of formalin for shipping to the laboratory. To speed fixation and avoid artifactual changes,

formalin containers should not be in direct contact with frozen materials during shipment.

In the *Samples for confirmation of diagnosis* section, the tests are listed under various discipline categories (bacteriology, virology, etc.). The appropriate sample(s) is noted, followed by the types of test that might be applied to these samples. The following is a list of these different tests, including any abbreviation used in this section of the text. A brief discussion of how the samples collected for each test should be handled is also provided. Again, it must be emphasized that this is by no means a complete listing of diagnostic tests available, and that different VDLs often have differing sample handling procedures.

- **Aerobic culture** = (CULT). These samples should generally be kept chilled during shipment. If a transit time of greater than 24 hours is anticipated the samples should be frozen, then packaged appropriately so that they are still frozen upon arrival at the VDL. Various bacterial species cannot be recovered using routine culture techniques and most of these are highlighted in the text by the phrase 'special culture requirements'
- **Agar gel immunodiffusion** = (AGID). A type of serological test. Chilled or frozen serum may be submitted
- **Anaerobic culture** = (ANAEROBIC CULT). Confirmation of the diagnosis requires that any swabs be transported in special transport media and that the VDL attempts to grow bacteria from the samples under anaerobic culture conditions. Transport requirements are as for (CULT) (aerobic culture) specimens
- **Analytical assay** = (ASSAY). This refers to a broad range of tests in which a substance is quantitatively measured. The substance to be assayed is listed in brackets, e.g. (ASSAY (Ca)) denotes a test for calcium levels. The method used to perform the assay is not listed but in general frozen samples may be submitted for most of these analytical assays.
- **Blood urea nitrogen** = (BUN). A useful test to determine degree of renal compromise. Sample can be shipped chilled or frozen
- **Bioassay** = (BIOASSAY). This typically refers to tests in which the sample material is administered to an animal under experimental conditions. Preserved material is inappropriate and some bioassays cannot be performed using samples which have been frozen. The VDL performing the test should be contacted for instructions prior to sample collection
- **Complement fixation** = (CF). A serological test. Ship chilled or frozen serum
- **Cytology** = (CYTO). Air-dried impression smears are usually adequate. Keep dry during transport
- **Direct smear** = (SMEAR). The type of test is usually given in brackets (e.g. (Gram)). Air-dried smears are usually adequate but must be kept dry during shipment
- **Enzyme-linked immunosorbent assay** = (ELISA). Chilled or frozen samples are usually acceptable. There are many variants of ELISA (e.g. antigen-capture, kinetic, indirect, direct, etc.) and the specific type used is not specified in this portion of the text
- **Electron microscopic examination** = (EM). Appropriate sample collection and handling varies with the specimen being examined. Most of the diagnostic specimens submitted to VDLs for EM are fecal samples, and these do not require any special preservative
- **Fecal floatation** = (FECAL). Sample can be fresh, chilled or frozen
- **Fluorescent Antibody Test** = (FAT). This may refer to either a direct or indirect method of antigen detection. Generally, cryostat sections are utilized and therefore the tissue received by the laboratory should still be frozen upon arrival to provide the best results. Freeze/thaw cycles should be avoided. If impression smears are being shipped, they should be kept dry
- **Fungal culture** = (FCULT). Special media is required. Transport as per (CULT) specimens
- **Immunohistochemical testing** = (IHC). Many of these tests can be performed on formalin-fixed material but in some instances frozen tissues must be delivered to the laboratory. In such instances the test is listed under a heading distinct from histology (e.g. virology, bacteriology, etc.)
- **Indirect hemagglutination** = (IHA). A serological test. Ship chilled or frozen serum
- **In-situ hybridization** = (IN-SITU HYBRID). Samples should be shipped chilled although some test methods can use formalin-fixed material. These tests utilize nucleic acid probes which bind with complementary nucleic acid sequences in the specimen. Although not widely used in routine diagnostics at present, these methods may gain more prominence as their use is refined
- **Virus isolation** = (ISO). Samples should be kept chilled during shipment or maintained in a frozen state if prolonged transit times are anticipated
- **Latex agglutination** = (LATEX AGGLUTINATION). Fresh, chilled or frozen samples are acceptable
- **Light microscopic examination** = (LM). Formalin-fixed tissues are preferred. The shipment of fresh tissues to the VDL permits more tissue autolysis prior to fixation, resulting in less useful specimens. If Bouin's fixative is available, it is the preferred preservative for eye globes.
- **Microagglutination test** = (MAT). A type of serologic test. Ship chilled or frozen serum.
- **Mycoplasmal culture** = (MCULT). These types of organism have specific growth requirements that are usually not met by standard bacteriological culture techniques. Transport as per (CULT) specimens. Culture swabs cannot be submitted in media containing charcoal or glycerol
- **Polymerase chain reaction** = (PCR). Tissues should be frozen and maintained in that state until arrival at the VDL. Swabs and fluids submitted for PCR testing should be chilled but not frozen. These tests are capable of detected minute quantities of nucleic acid, so if multiple animals are tested the samples should be 'clean' in order to avoid false-positives through cross-contamination (i.e. blood/tissue from one animal contaminating the sample from another)
- **Virus neutralization** = (VN). A serological test. Ship chilled or frozen serum.

PART 1

GENERAL MEDICINE

Clinical examination and making a diagnosis

1

Introduction

The focal point of any investigation of animal disease is the making of a diagnosis, and the critical part in making that decision is the clinical examination of the individual animal or group of animals. Therefore, it is appropriate that the first chapter of this book deals with this important subject.

However, before we begin that exercise, it is important that we be quite clear and agree upon what we mean by 'disease'. Let us assume that disease can be defined as 'inability to perform physiological functions at normal levels even though nutrition and other environmental requirements are provided at adequate levels'. When this definition is accepted, then not only does a clinically ill animal come into the area of examination but so also do those animals or herds that are not clinically ill but that do not perform as expected. As veterinarians working with food-producing animals and horses, we are required to recognize individual animals that are affected with a particular, recognizable pathological lesion, or biochemical or metabolic deficit, or nutritional deficiency, that results in recognizable clinical signs such as fever, dyspnea, convulsions or lameness. This is traditional veterinary medicine based on a transposition of attitudes and behavior from human medicine. However, it is also necessary for us to investigate disease that the owner recognizes simply as failure to perform or to reach predetermined objectives. This is not necessarily subclinical disease: it is recognizable clinically but perhaps only as poor performance, such as unthriftiness, without any specific system-oriented clinical signs. In other situations, the owner may not recognize any abnormality unless productivity is measured, e.g. milk production or growth rate per day.

There has been considerable emphasis on the clinical and laboratory examination of individual animals affected with clinical disease or that have not performed normally and the large body of information now available in laboratory medicine testifies to this preoccupation. Its greatest importance is in animals, such as companion and racing animals, that are kept as singles and, unless the diagnosis is simple and readily obvious, if a laboratory is available there may be a tendency to make one or more laboratory examinations. The more valuable the animal, the greater the tendency towards some laboratory work. Many biochemical, hematological and biophysical examinations of each body system can yield valuable clues about system or organ function, which usually lead to more accurate and detailed examination of that system or organ. In animals kept in herds or flocks these laboratory tests are also important but are equalled in importance overall by epidemiological investigations. There is little to be gained by this form of examination in animals kept as singles.

With a herd of animals affected with clinical disease, or which is failing to achieve expected objectives, an epidemiological investigation, in addition to the clinical examination of individual animals, may make a valuable contribution to the making of a diagnosis. This is not to suggest that clinical and laboratory examinations are deemphasized in the examination of herd problems. In some instances, the clinical and laboratory examinations assume major importance to ensure that animals in a herd that is not performing normally are in fact not clinically ill. But when the presenting complaint is poor performance, it is necessary to collect all the pertinent epidemiological data, including accurate production measurements, and to decide whether or not an abnormality is present and, if so, its magnitude. It is at this point that veterinarians become the arbiters of what is 'health' and what is 'illness'. In herd health programs this is a continuing and positive service provided by veterinarians to farmer clients.

In this chapter on clinical examination and making a diagnosis, we have described the standard procedure for the clinical examination of an individual animal followed by some guidelines for the examination of the herd. The level of the examination set out is sufficient to enable the clinician to determine the nature of the abnormality and the system involved. For more detailed examination it is recommended that subsequent chapters, which deal with individual systems, be consulted. Each of them sets out a method for a special examination of the particular system.

Clinical examination of the individual animal

A clinical examination has three parts:

- The animal
- The history
- The environment.

Inadequate examination of any of these may lead to error. The examination of the affected animal represents only a part of the complete investigation. Careful questioning of the owner or attendant can yield information about the diet or the prior diet, about recent vaccinations or surgery or about the introduction of animals into the group, that will provide the clues to a successful diagnosis. However, in certain instances, for example in lead poisoning of cattle, the most detailed examination of the animal and the most careful questioning of the owner may fail to elicit the evidence necessary for a correct diagnosis. Only a careful physical search of the environment for a source of lead can provide this information. Thus neglect of one aspect of the clinical examination can render valueless a great deal of work on the other aspects and lead to an error in diagnosis.

HISTORY-TAKING

In veterinary medicine, history-taking is often the most important of the three aspects of a clinical examination. The significance of the results obtained by

examination of the patient and the environment is liable to be modified by a number of factors. Animals are unable to describe their clinical symptoms; they vary widely in their reaction to handling and examination, and a wide range of normality must be permitted in the criteria used in a physical examination. These variations are much greater in some species than in others. Dairy cattle, horses, sheep and goats are usually easy to examine while beef cattle and pigs may be difficult to examine adequately under some conditions. A satisfactory examination of the environment may prove difficult because of lack of knowledge of the factors concerned or because of the examiner's inability to assess their significance. Problems such as the measurement of the relative humidity of a barn and its importance as a predisposing factor in an outbreak of pneumonia or the determination of pH of the soil with reference to the spread of leptospirosis can present virtually insuperable difficulties to the veterinarian in the field. On the other hand, a search for a specific factor such as a known poison may be relatively simple.

Nevertheless, history-taking is an important key to accurate diagnosis in veterinary medicine, and to be worthwhile it must be accurate and complete. Admittedly, human fallibility must be taken into consideration; there may be insufficient time, the importance of particular factors may not be appreciated, and there may be misunderstanding. Although these are excusable up to a point, failure to recognize the importance of the history can lead only to error. To avoid being misled, it is essential that the veterinarian assesses the accuracy of the history by careful examination of what the owner relates about his or her animals.

The history should suggest not only the diagnostic possibilities but also the probabilities. A 1-year-old heifer is unlikely to have clinical Johne's disease; an adult cow is more likely to have parturient paresis than a first-calf heifer, which in turn is more likely to have maternal obstetric paralysis than is the adult cow. The history may often indicate that special attention should be paid to the examination of a particular system in the animal, or a particular factor in the environment. For example, in hypovitaminosis-A in beef calves from 6–10 months of age, the animals may be seen when they are clinically normal and the only means of reaching a diagnosis may be a consideration of the history of the clinical findings and the nutritional status.

HISTORY-TAKING METHOD

Successful history-taking involves many veterinarian–client relationships, which must be learned by experience. Some suggestions are presented here as guidelines that may prove useful to the clinician.

The veterinarian should introduce himself or herself to the owner, and the usual greetings of the day will help to establish a veterinarian–client relationship. Asking the owner 'How can I help you today?' is an effective opening question, which provides the owner the opportunity to relate his or her concerns about the animals.

The owner or attendant must be handled with diplomacy and tact. The use of nontechnical terms is essential, since livestock owners are likely to be confused by technical expressions or reluctant to express themselves when confronted with terms they do not understand. Statements, particularly those concerned with time, should be tested for accuracy. Owners, and more especially herdsmen and agents, may attempt to disguise their neglect by condensing time or varying the chronology of events. If a detailed cross-examination of the owner seems likely to arouse some antagonism, it is advisable for the veterinarian to forego further questioning and be content with his or her own estimate of the dependability of the history. The clinician must try to separate owners' observations from their interpretations. A statement that the horse had a bout of bladder trouble may, on closer examination, mean that the horse had an attack of abdominal pain in which it assumed a posture usually associated with urination. Often, however, it is impossible to avoid the use of leading questions – 'Did the pigs scour?', 'Was there any vomiting?' – but it is necessary to weigh the answers in accordance with the general veracity of the owner.

Absence of a sign can only be determined by inquiring whether or not it occurred. Simply to ask for a complete history of what has happened almost invariably results in an incomplete history. The clinician must, of course, know the right questions to ask; this knowledge comes with experience and familiarity with disease. Owners seldom describe clinical signs in their correct time sequence; part of the clinician's task is to establish the chronology of events.

For completeness and accuracy in history-taking the clinician should conform to a set routine. The system outlined below includes patient data, disease history and management history. The order in which these parts of the history are taken will vary. In general it is best to take the disease history first. The psychological effect is good: the owner appreciates the desire to get down to the facts about his or her animal's illness.

PATIENT DATA

If records are to be kept at all, even if only for financial purposes, accurate identification of the patient is essential. An animal's previous history can be referred to, the disease status of a herd can be examined, specimens for laboratory examination can be dispatched with the knowledge that the results can be related to the correct patient. Accurate records are also necessary for the submission of accounts for veterinary services rendered and the details of the owner's address and of the animals examined and treated must be accurate. These points may have no importance in establishing the diagnosis but they are of primary importance in the maintenance of a successful practice.

The relevant data include:

- Owner's name and initials
- Postal address and telephone number
- Species, type, breed (or estimate of parentage in a crossbred)
- Sex, age, name or number, body weight
- If necessary, a description, including color markings, polledness and other identifying marks, of the patient.

Such a list may appear formidable but many of the points, such as age, sex, breed, type (use made of animal, e.g. beef, dairy, mutton, wool), are often of importance in the diagnosis. A case history of a particular animal may suggest that further treatment is likely to be uneconomic because of age, or that a particular disease is assuming sufficient importance in a herd for different control measures to be warranted.

Computers are now being used extensively in veterinary practices for recording the details of farm calls, the animals examined and treated, the amounts charged for travel and professional services, the costs of laboratory services, the drugs used and dispensed, and the diseases that occur on a particular farm on an ongoing basis. It is now possible for veterinary practices to provide regular and annual health reports to herd owners so that planned health management programs can be assessed and evaluated. The ability to retrieve and summarize this information on an individual farm basis is a major step forward in providing optimal veterinary service to livestock herds regardless of their size and complexity.

DISEASE HISTORY

History-taking will vary considerably depending on whether one animal or a group of animals is involved in the disease problem under examination. As a general rule, in large animal work, all disease states should be considered as herd problems until proved to be otherwise.

It is often rewarding to examine the remainder of a group and find animals that are in the early stages of the disease.

Present disease

Attempts should be made to elicit the details of the clinical abnormalities observed by the owner in the sequence in which they occurred. If more than one animal is affected, a typical case should be chosen and the variations in history in other cases should then be noted. Variations from the normal in the physiological functions such as intake of food or drink, milk production, growth, respiration, defecation, urination, sweating, activity, gait, posture, voice and odor should be noted in all cases. There are many specific questions that need to be asked in each case but they are too numerous to list here and for the most part they are variations on the questions already suggested.

If a number of animals are affected, information may be available from clinical pathological examinations carried out on living animals or necropsy examinations on fatal cases. The behavior of animals before death and the period of time elapsing between the first observable signs and death or recovery are important items of information. Prior surgical or medical procedures such as castration, docking, shearing, or vaccination may be important factors in the production of disease.

Morbidity, case fatality and population mortality rates

The morbidity rate is usually expressed as the percentage of animals that are clinically affected compared with the total number of animals exposed to the same risks. The case fatality rate is the percentage of affected animals that die. The population mortality rate is the percentage of all exposed animals that die. The estimates may be important in diagnosis because of the wide variations in morbidity, case fatality and population mortality rates that occur in different diseases. An equally important figure is the proportion of animals at risk that are clinically normal but show abnormality on the basis of laboratory or other tests.

Prior treatment

The owner may have treated animals before calling for assistance. Exact details of the preparations used and doses given may be of value in eliminating some diagnostic possibilities. They will certainly be of importance when assessing the probable efficiency of the treatment and the significance of clinical pathological tests, and in prescribing additional treatment. Drug withdrawal regulations now require that treated animals or their products, such as milk, be withheld from slaughter or market for varying lengths of time to allow drug residues to reach tolerable limits. This necessitates that owners reveal information about the drugs that they have used.

Prophylactic and control measures

It should be ascertained whether preventive or control procedures have already been attempted. There may have been clinical pathological tests, the introduction of artificial insemination to control venereal disease, vaccination, or changes in nutrition, management or hygiene. For example, in an outbreak of bovine mastitis careful questioning should be pursued regarding the method of disinfecting the cows' teats after each milking, with particular reference to the type and concentration of the disinfectant used and whether or not back-flushing of teat cups is practiced. Spread of the disease may result from failure of the hygiene barrier at any one of a number of such points. When written reports are available they are more reliable than the memory of the owner.

Previous exposure

The history of the group relative to additions is of particular importance. Is the affected animal an established member of the group, or has it been introduced, and if so how long ago? If the affected animal has been in the group for some time, have there been recent additions? Is the herd a 'closed herd' or are animals introduced at frequent intervals? Not all herd additions are potential carriers of disease – they may have come from herds where control measures are adequate, they may have been tested before or after sale or kept in quarantine for an adequate period after arrival, or they may have received suitable biological or antibiotic prophylaxis. Herd additions may have come from areas where a particular disease does not occur, although a negative history of this type is less reliable than a positive history of derivation from an area where a particular disease is enzootic.

A reverse situation may occur where imported animals have no resistance to endemic infection in the home herd, or have not become adapted to environmental stressors such as high altitudes, high environmental temperatures and particular feeding methods, or are not accustomed to poisonous plants occurring in the environment.

Transit

The possibility of infection during transit is always a potential risk and pre-sale certificates of health may be of little value if an animal has passed through a sale barn, a show or communal trucking yards while in transit. Highly infectious diseases may be transmitted via trucks, railroad cars or other accommodation contaminated by previous inhabitants. Transient introductions, including animals brought in for work purposes, for mating or on temporary grazing, are often overlooked as possible vectors of disease. Other sources of infection are wild fauna that graze over the same area as domestic livestock and inanimate objects such as human footwear, car tires and feeding utensils.

Culling rate

There may be considerable significance in the reasons for culling, and the number of animals disposed of for health reasons. Failure to grow well, poor productivity and short productive life will suggest the possible occurrence of a number of chronic diseases, including some associated with infectious agents, by nutritional deficiencies or by poisons.

Previous disease

Information elicited by questioning on previous history of illness may be helpful. If there is a history of previous illness, inquiries should be made on the usual lines, including clinical observations, necropsy findings, morbidity, case fatality rates, the treatments and control measures used and the results obtained. If necessary, inquiries should be made about herds from which introduced animals have originated and also about herds to which other animals from the same source have been sent.

MANAGEMENT HISTORY

The management history includes nutrition, breeding policy and practice, housing, transport and general handling. It is most important to learn whether or not there has been any change in the prevailing practice prior to the appearance of disease. The fact that a disease has occurred when the affected animals have been receiving the same ration, deriving from the same source over a long period, suggests that the diet is not at fault, although errors in preparation of concentrate mixtures, particularly with the present-day practice of introducing additives to feeds, can cause variations that are not immediately apparent.

Nutrition

The major objective in the examination of the nutritional history is to determine how the quantity and quality of the diet which the animals have been receiving compares with the nutrient requirements that have been recommended for a similar class of animal. In some situations it may be necessary to submit feed and water samples for analyses to assess quality.

Livestock at pasture

Pastured livestock present a rather different problem from those being stall-fed in that they receive a diet that is less controlled and thus more difficult to assess. The risk of parasitic infestation and, in some cases, infectious disease is much greater in grazing animals. Inquiries should be made about the composition of the pasture, its probable nutritive value with particular reference to recent changes brought about by rain or drought, whether rotational grazing is practiced, the fertilizer program and whether or not minerals and trace elements are provided by top-dressing or mineral mixtures. The origin of mineral supplements, particularly phosphates, which may contain excess fluorine, and homemade mixtures, which may contain excessive quantities of other ingredients, should receive attention. Actual examination of the pasture area is usually more rewarding than a description of it.

Hand-fed/stall-fed animals

Hand-fed or stall-fed animals are subjected to a more or less controlled feed supply but, because of human error, they are frequently exposed to dietary mistakes. Types and amounts of feeds fed should be determined. Examples of disease caused by inadequate hand-fed diets include: osteodystrophia fibrosa in horses on diets containing excess grain; azoturia in the same species when heavy-carbohydrate diets are fed during periods of rest, and lactic acid indigestion in cattle introduced to high-level grain diets too rapidly. The sources of the dietary ingredients may also be of importance. Grains from some areas are often much heavier and contain a much greater proportion of starch to husk than grains from other areas so that when feed is measured, rather than weighed, overfeeding or underfeeding may occur.

Because the digestive enzyme capacity of newborn farm animals is most efficient in the digestion of whole milk, the use of non-milk sources of carbohydrates and proteins in the formulation of milk replacers may result in indigestion and nutritional diarrhea.

Exotic diseases may be imported in feed materials: anthrax, foot-and-mouth disease and hog cholera are well-known examples.

Variations in the preparation of ingredients of rations may produce variable diets. Overheating, as in pelleting or the cooking of feeds, can reduce their vitamin content; contamination with lubricating oil can result in poisoning by chlorinated naphthalene compounds; pressure extraction of linseed can leave considerable residues of hydrocyanic acid in the residual oil cake.

Feeding practices may in themselves contribute to the production of disease. Pigs fed in large numbers with inadequate trough space or calves fed from communal troughs are likely to be affected by overeating or inanition, depending on their size and vigor. High-level feeding and consequent rapid growth may create deficiency states by increasing the requirement for specific nutrients.

In both hand-fed and grazing animals changes in diet should be carefully noted. Movement of animals from one field to another, from pasture to cereal grazing, from unimproved to improved pasture may all precipitate the appearance of disease. Periods of sudden dietary deficiency can occur as a result of bad weather or transportation, or during change to unfamiliar feeds. Rapid changes are more important than gradual alterations, particularly in pregnant and lactating ruminants when metabolic diseases, including those caused by hypocalcemia, hypoglycemia and hypomagnesemia, are likely to occur.

The availability of **drinking water** must be determined: salt poisoning of swine occurs only when the supply of drinking water is inadequate.

Reproductive management and performance

In the examination of a single animal the breeding and parturition history may suggest or eliminate some diagnostic possibilities. For example, pregnancy toxemia occurs in sheep in late pregnancy while acetonemia in dairy cows occurs primarily 2–6 weeks after parturition. Acute septic metritis is a possibility within a few days after parturition in any species but unlikely several weeks later.

Breeding history

The breeding history may be of importance with regard to inherited disease. The existence of a relationship between sires and dams should be noted. Hybrid vigor in crossbred animals should be considered when there is apparent variation in resistance to disease between groups maintained under similar environmental conditions. A general relationship between selection for high productivity and susceptibility to certain diseases is apparent in many breeds of animal and even in certain families. The possibility of genetotrophic disease, i.e. the inheritance of a greater requirement than normal of a specific nutrient, should be considered.

Reproductive history

The examination of the herd reproductive history involves comparing past and present reproductive performance with certain optimum objectives. The mean length of the interval between parturition and conception, the mean number of services per conception and the percentage of young animals weaned relative to the number of females that were originally exposed for breeding (calf or lamb crop, pigs weaned) are general measures of reproductive performance and efficiency.

Using cattle as an example, certain other observations may assist in determining the cause of failure to reach reproductive performance objectives. These are:

- Percentage of abortions
- Length of breeding season
- Percentage of females pregnant at specified times after the onset of breeding period
- Bull/cow ratio
- Size and topography of breeding pastures
- Fertility status of the females and males at breeding time.

The percentage of females that need assistance at parturition and the percentage of calves that die at birth are also indices of reproductive performance that are indicative of the level of reproductive management provided.

Climate

Many diseases are influenced by climate. Foot rot in cattle and sheep reaches its peak incidence in warm, wet summers and is relatively rare in dry seasons. Diseases spread by insects are encouraged when climatic conditions favor the propagation of the vector. Internal parasites are similarly influenced by climate. Cool, wet seasons favor the development of hypomagnesemia in pastured cattle. Anhidrosis in horses is specifically a disease of hot, humid countries. The direction of prevailing winds is of importance in many disease outbreaks, particularly in relation to the contamination of pasture and drinking water by fumes from factories and mines and the spread of diseases carried by insects.

General management

There are so many items in the proper management of livestock that, if neglected, can lead to the occurrence of disease that they cannot be related here; animal management in the prevention of disease is a subject in its own right and is dealt with in all parts of this book. Some of the more important factors include:

- Hygiene, particularly in milking parlors and in parturition and rearing stalls
- Adequacy of housing in terms of space, ventilation, draining, situation and suitability of troughs
- Opportunity for exercise
- Proper management of milking machines to avoid udder injury.

The class of livestock under consideration is also of importance; for example, enterotoxemia is most common in finishing lambs and pigs, parturient paresis in milking cows, obstructive urolithiasis in lambs and steers in feedlots and pregnancy toxemia in ewes used for fat lamb production.

EXAMINATION OF THE ENVIRONMENT

An examination of the environment is a necessary part of any clinical investigation because of the possible relationship between environmental factors and the incidence of disease. A satisfactory examination of the environment necessitates an adequate knowledge of animal husbandry and, with the development of species specialization, it will be desirable for the veterinarian to understand the environmental needs of a particular species or class of farm animal.

Depending on the region of the world, some animals are kept outside year round, some are housed for part of the year during the winter months, and some are kept under total confinement. For animals raised on pasture, the effects of topography, plants, soil type, ground surface and protection from extremes of weather assume major importance. For animals housed indoors, hygiene, ventilation and avoiding overcrowding are of major concern. Some of these items will be briefly presented here as guidelines. Each observation should be recorded in detail for preparation of reports for submission to the owners. Detailed records and even photographs of environmental characteristics assume major importance when poisonings are suspected and where litigation proceedings appear possible.

OUTDOOR ENVIRONMENT

Topography and soil type

The topography of grasslands, pastures and wooded areas can contribute to disease or inefficient production and reproduction. Flat, treeless plains offering no protection from wind predispose cattle to lactation tetany in inclement weather. Low, marshy areas facilitate the spread of insect-borne diseases and soil-borne infections requiring damp conditions, such as leptospirosis; Johne's disease and diseases associated with liver fluke infestation and lungworm pneumonia are more prevalent in such areas. Rough grasslands with extensive wooded areas can have an adverse effect on reproductive performance in beef herds because of the difficulty the bulls have in getting to the females during peak periods of estrus activity.

The soil type of a district may provide important clues to the detection of nutritional deficiencies; copper and cobalt deficiencies are most common on littoral sands and the copper deficiency/molybdenum excess complex usually occurs on peat soils. The surface of the ground and its drainage characteristics are important in highly intensive beef feedlots and in large dairy herds where fattening cattle and dairy cows are kept and fed under total confinement. Ground surfaces that are relatively impermeable and/or not adequately sloped for drainage can become a sea of mud following a heavy rainfall or snowstorm. Constant wetting of the feet and udders commonly results in outbreaks of foot rot and mastitis. Dirty udders increase the time required for udder washing prior to milking and can seriously affect a mastitis control program.

In some regions of the world, beef cows are calved in outdoor paddocks in the spring when it is wet and cold with an excess of surface water; this increases the spread of infectious disease and results in a marked increase in neonatal mortality. A lack of sufficient protection from the prevailing winds, rain, snow or the heat of the sun can seriously affect production and can exacerbate an existing disease condition or precipitate an outbreak. Dusty feedlots during the hot summer months may contribute to an increase in the incidence of respiratory disease or delay the response to treatment of disease such as pneumonia.

Stocking rate (population density)

Overcrowding is a common predisposing cause of disease. There may be an excessive buildup of feces and urine, which increases the level of infection. The relative humidity is usually increased and more difficult to control. Fighting and cannibalism are also more common in overcrowded pens than when there is adequate space for animals to move around comfortably. The detection and identification of animals for whatever reason (illness, estrus) can be difficult and inaccurate under crowded conditions.

Feed and water supplies

Pasture and feed

On pastures the predominant plant types, both natural and introduced, should be observed as they are often associated with certain soil types and may be the cause of actual disease; the high estrogen content of some clovers, the occurrence of functional nervous diseases on pastures dominated by *Phalaris aquatica* (syn. *P. tuberosa*) and perennial rye grass and the presence of selective absorbing 'converter' plants on copper-rich and selenium-rich soils are all examples of the importance of the dominant vegetation. The presence of specific poisonous plants, evidence of overgrazing and the existence of a bone-chewing or bark-chewing habit can be determined by an examination of the environment.

Vital clues in the investigation of possible poisoning in a herd may be the existence of a garbage dump or ergotized grass or rye in the pasture, or the chewing of lead-based painted walls in the barn, or careless handling of poisons in the feed area. The possibility that the forage may have been contaminated by environmental pollution from nearby factories or highways should be examined. In some cases the physical nature of the pasture plants may be important; mature, bleached grass pasture can be seriously deficient in carotene, whereas lush young pasture can have rachitogenic potency because of its high carotene content or it may be capable of causing hypomagnesemia if it is dominated by grasses. Lush legume pasture or heavy concentrate feeding with insufficient roughage can cause a serious bloat problem.

The feed supplies for animals raised in confinement outdoors must be examined for evidence of moldy feed, contamination with feces and urine and excessive moisture due to lack of protection from rain and snow. Empty feed troughs may confirm a suspicion that the feeding system is faulty.

Water

The drinking water supply and its origin may be important in the production of disease. Water in ponds may be covered with algae containing neurotoxins or hepatotoxic agents and flowing streams may carry effluent from nearby industrial plants. In a feedlot, water may suddenly become unavailable because of frozen water lines or faulty water tank valves. This should not go unnoticed if one recognizes the anxiety of a group of cattle trying to obtain water from a dry tank.

Waste disposal

The disposal of feces and urine has become a major problem for large intensified livestock operations. Slurry is now spread on pastures and may be important in the spread of infectious disease. Lagoons can provide ideal conditions for the breeding of flies, which can be troublesome to a nearby livestock operation. The inadequate disposal of dead animals may be an important factor in the spread of certain diseases.

INDOOR ENVIRONMENT

There are few aspects of livestock production that have aroused more interest, development and controversy in the last few years than the housing and environmental needs of farm animals. Several textbooks on the subject have been

written and only some of the important items will be mentioned here, with the aid of some examples. The effects of housing on animal health have not received the consideration they deserve, partly because of insufficient knowledge of animals' environmental needs and partly because there has been a failure to apply what is already known.

As a general statement, it can be said that inadequate housing and ventilation, overcrowding and uncomfortable conditions are considered to have detrimental effects on housed animals that make them not only more susceptible to infectious disease but also less productive. Moreover, this reduction in productive efficiency may be a greater cause of economic loss than losses caused by infectious disease. For this reason, the veterinarian must learn to examine and assess all aspects of an indoor environment, which may be the primary cause of, or a predisposing factor to, disease. By way of illustration, the major causes of preweaning mortality of piglets are chilling and crushing of piglets in the first few days of life, and not infectious disease. These physical causes are commonly related to a combination of poorly designed farrowing crates, slippery floors, inadequate heating and perhaps overcrowding of the farrowing facilities.

Hygiene

One of the first things to observe is the level of sanitation and hygiene, which is usually a reliable indicator of the level of management; poor hygiene is often associated with a high level of infectious disease. For example, the incidence of diarrhea in piglets may be high because the farrowing crates are not suitably cleaned and disinfected before the pregnant sows are placed in them. A similar situation applies for lambing sheds, calving pens and foaling boxes. An excessive buildup of feces and urine with insufficient clean bedding will result in a high level of neonatal mortality. The methods used for cleaning and disinfection should be examined carefully. The removal of dried feces from animal pens that have been occupied for several months is a difficult and laborious task and often not done well. Undue reliance may be placed on the use of chemical disinfectants.

The total length of time that animals have occupied a pen without cleaning and disinfection (occupation time) should be noted. As the occupation time increases, there is a marked increase in the infection rate and the morbidity and mortality from infectious disease often increase.

Ventilation

Inadequate ventilation is considered to be a major risk factor contributing to the severity of swine enzootic pneumonia in finishing pigs. The primary infection has a minimal effect on the well-housed pig, but inadequate ventilation results in overheating of the barn in the summer months and chilling and dampness during the winter months, commonly resulting in subclinical and clinical pneumonia, which severely affects productive efficiency. Similarly, in young calves, which are raised indoors in most of the temperate zones of the world, protection from the cold during the winter is necessary. The effects of enzootic pneumonia of housed calves are much more severe when ventilation is inadequate than when the calves are comfortable and have clean, fresh air.

The evaluation of the adequacy of ventilation of a farm animal barn that is filled to economic capacity with animals is a difficult task and a major subject. Ventilation is assessed by a determination of the number of air changes per unit of time, the relative humidity during the day and night, the presence or absence of condensation on the hair coats of the animals or on the walls and ceilings, the presence of drafts, the building and insulation materials used, the positions and capacities of the fans and the size and location of the air inlets. The measurement of the concentration of noxious gases in animal barns, such as ammonia and hydrogen sulfide, may be a valuable aid in assessing the effectiveness of a ventilation system.

Animals raised indoors are frequently overcrowded, which may predispose to disease, and measurements of population density and observations of animal behavior in such conditions assume major importance. When pigs are raised indoors in crowded conditions with inadequate ventilation, their social habits may change drastically and they begin to defecate and urinate on the clean floor and on their pen-mates rather than over the slatted floor over the gutter. This can result in outbreaks of diseases that are transmitted by the fecal–oral route.

Flooring

The quality of the floor is often responsible for diseases of the musculoskeletal system and skin. Poorly finished concrete floors with an exposed aggregate can cause severe foot lesions and lameness in adult swine. Recently calved dairy cows are very susceptible to slipping on poor floors in dairy barns, a common cause of the downer cow syndrome. Loose-housing systems, particularly those with slatted floors, have resulted in a new spectrum of diseases of the feet of cattle because of the sharp edges of some of the slats. The quality and quantity of bedding used should be noted. Bedding is now rarely used in intensified swine operations. The use of sawdust or shavings in loose-housing systems for dairy cattle may be associated with outbreaks of coliform mastitis. Wet bedding, particularly during the winter months, is commonly associated with endemic pneumonia in calves.

Floor plan

The floor plan and general layout of an animal house must be examined for evidence that the routine movements of animal attendants, the movements of animals and feeding facilities may actually be spreading disease. Communal gutters running through adjacent pens may promote the spread of disease through fecal or urinary contamination. The nature of the partitions between pens, whether solid or open grid type, may assist the control or spread of infectious disease. The building materials used will influence the ease with which pens, such as farrowing crates and calf pens, can be cleaned and disinfected for a new batch of piglets or calves.

Lighting

The amount of light available in a barn should be noted. With insufficient light it may be difficult to maintain a sufficient level of sanitation and hygiene, sick animals may not be recognized early enough, and in general errors in management are likely to occur.

In the investigation of a herd problem of mastitis in dairy cattle the veterinarian should visit the farm at milking time and observe how the cows are prepared for milking, examine the teats and udders before and after they are washed, observe the use of the milking machine, and the level of sanitation and hygiene practiced. Several successive visits may be necessary to reveal possible weakness in a mastitis control program.

EXAMINATION OF THE PATIENT

A complete clinical examination of an animal patient includes, in addition to history-taking and an examination of the environment, physical and laboratory examinations. A complete clinical examination of every patient is unnecessary because of the simplicity of some diseases. However, a general clinical examination of every patient is necessary and the inexperienced clinician should spend as much time and effort as is practicable and economical in carrying it out. This will help to avoid the sort of embarrassing error in which a calf is operated on for umbilical hernia when it also has a congenital cardiac defect.

As **learned** experience develops, the clinician will know the extent to which a

clinical examination is necessary. All the laboratory tests that are likely to be informative and that are practical and economical should be used. Because of the cost of laboratory tests, the clinician must be selective in the tests used. The most economical method is to examine the patient and then select those laboratory tests that will support or refute the tentative clinical diagnosis. In this section a system for the examination of a patient is outlined in a general way. There is a great deal of difference between species in the ease with which this examination is done and the amount of information that can be collected. Additional detailed examination techniques are described under the individual body systems.

The examination of a patient consists of a **general inspection** done from a distance (the **distant examination**, and the particular **distant examination of body regions**), followed by a **close physical examination** of all body regions and systems. Only the major body systems that are routinely examined are presented here as part of the general examination.

GENERAL INSPECTION (DISTANT EXAMINATION)

The importance of a distant examination of the animal cannot be overemphasized, and yet it is often overlooked. Apart from the general impression gained from observation at a distance, there are some signs that can best be assessed before the animal is disturbed. The proximity of the examiner is particularly disturbing to animals that are unaccustomed to frequent handling.

Behavior and general appearance

The general impression of the health of an animal obtained by an examination from a distance should be assessed according to the following.

Behavior

Separation of an animal from its group is often an indication of illness. The behavior is also a reflection of the animal's health. If it responds normally to external stimuli, such as sound and movement, it is classified as **bright**. If the reactions are sluggish and the animal exhibits relative indifference to normal stimuli, it is said to be **dull** or **apathetic**. Cattle with carbohydrate engorgement are commonly reluctant to move unless coaxed. A pronounced state of indifference in which the animal remains standing and is able to move but does not respond at all to external stimuli is the **'dummy' syndrome**. This occurs in subacute lead poisoning, listeriosis and some cases of acetonemia in cattle, and in encephalomyelitis and hepatic cirrhosis in horses. The terminal stage of apathy or depression is **coma**, in which the animal is unconscious and cannot be roused.

Excitation states

Excitation states vary in severity. A state of anxiety or apprehension is the mildest form: here the animal is alert and looks about constantly but is normal in its movements. Such behavior is usually expressive of moderate constant pain or other abnormal sensation, as in early parturient paresis or in recent blindness. A more severe manifestation is restlessness, in which the animal moves about a good deal, lies down and gets up and may go through other abnormal movements such as looking at its flanks, kicking at its belly and rolling and bellowing. Again, this demeanor is usually indicative of pain.

More extreme degrees of excited demeanor include **mania** and **frenzy**. In mania, the animal performs abnormal movements with vigor. Violent licking at its own body, licking or chewing inanimate objects and pressing forward with the head are typical examples. In frenzy, the actions are so wild and uncontrolled that the animals are a danger to anyone approaching them. In both mania and frenzy there is usually excitation of the brain, as in rabies, acute lead poisoning and some cases of nervous acetonemia.

Voice

Abnormality of the voice should be noted. It may be hoarse in rabies or weak in gut edema; there may be continuous lowing in nervous acetonemia or persistent bellowing indicative of acute pain. Soundless bellowing and **yawning** are commonly seen in rabid cattle and yawning is a common sign in animals affected with hepatic insufficiency.

Eating

The appetite of the animal can be assessed by observing its reaction to the offering of feed or by the amount of feed available that has not been eaten. It is important to determine the total amount of feed that the animal is eating per day. In a patient that has retained its appetite, there may be abnormality of **prehension**, **mastication** or **swallowing** and, in ruminants, of belching and regurgitation.

Prehension may be interfered with by inability to approach feed, paralysis of the tongue in cattle, in cerebellar ataxia, osteomyelitis of cervical vertebrae and other painful conditions of the neck. When there is pain in the mouth, prehension may be abnormal and affected animals may be able to take only certain types of feed. Mastication may be slow, one-sided or incomplete when mouth structures, particularly teeth, are affected. Periodic cessation of chewing when feed is still in the mouth occurs commonly in the 'dummy' syndrome, when there are space-occupying lesions of the cranium or an encephalomyelitis exists.

Swallowing may be painful because of inflammation of the pharynx or esophagus, as is found in strangles in the horse,, in calf diphtheria, and where improper use of bailing and drenching guns or bottles has caused laceration of the pharyngeal mucosa. Attempts at swallowing followed by coughing up of feed or regurgitation through the nostrils can also be the result of painful conditions but are most likely to be due to physical obstructions such as esophageal diverticula or stenosis, a foreign body in the pharynx, or paralysis of the pharynx. It is important to differentiate between material that has reached the stomach and ingesta regurgitated from an esophageal site. Partial esophageal obstruction resulting in difficult swallowing is usually manifested by repeated swallowing movements, often with associated flexion of the neck and grunting.

In ruminants there may be abnormalities of **rumination** and **eructation**. Absence of cudding occurs in many diseases of cattle and sheep; violent efforts at regurgitation with grunting suggests esophageal or cardiac obstruction. There may be inability to control the cud – 'cud-dropping' – due to pharyngeal paralysis or painful conditions of the mouth. Failure to eructate is usually manifested by the appearance of bloat.

Defecation

In constipation and rectal paralysis or stenosis, the act of defecation may be difficult and be accompanied by straining or tenesmus. When there is abdominal pain or laceration of the mucocutaneous junction at the anus, defecation may cause obvious pain. Involuntary defecation occurs in severe diarrhea and when there is paralysis of the anal sphincter. Consideration of frequency, volume and character of feces is given later under the section on special examination of the digestive tract. Constipation must not be mistaken for scant feces, particularly in mature cattle with diseases of the forestomachs and failure of movement of ingesta in a caudad direction.

Urination

This may be difficult when there is partial obstruction of the urinary tract, and painful when there is inflammation of the bladder or urethra. In cystitis and urethritis, there is increased frequency with the passage of small amounts of fluid, and the animal remains in the urination posture for some time after the flow ceases. Incontinence, with constant dribbling of urine, is usually due to partial obstruction of the urethra or paralysis of its sphincter. If the animal urinates during

the visual inspection, a sample of urine should be obtained, examined grossly and submitted for urinalysis.

Posture

Abnormal posture is not necessarily indicative of disease, but when associated with other signs it may indicate the site and severity of a disease process. One of the simplest examples is resting of a limb in painful conditions of the extremities; if a horse continually shifts its weight from limb to limb it may indicate the presence of laminitis or early osteodystrophia fibrosa. Arching of the back with the limbs tucked under the body usually indicates mild abdominal pain; downward arching of the back and 'saw horse' straddling of the legs is characteristic of severe abdominal pain, usually spasmodic in occurrence; a 'dog-sitting' posture in the horse associated with rolling and kicking at the belly is usually associated with abdominal pain and pressure on the diaphragm, such as occurs in acute gastric dilatation after engorgement on grain. This posture is commonly adopted by normal cattle but will occur in painful conditions of the pelvic limbs such as degenerative osteoarthritis in young cattle. Abduction of the elbows is usually synonymous with chest pain or difficulty in breathing. Elevation and rigidity of the tail, and rigidity of the ears and limbs, are good indications of tetanus in animals. The carriage of the tail in pigs is a useful barometer of their state of health. Sheep that are blind, as in early pregnancy toxemia, are immobile but stand with the head up and have an expression of extreme alertness.

When the animal is recumbent, there also may be abnormalities of posture. In cattle affected by dislocation of the hip or by sciatic nerve paralysis, the affected limb is not held flexed next to the abdomen but sticks straight out in an awkward position; unilateral pain in the chest may cause an animal to lie habitually on the other side; a weak hindleg may be kept under the animal. The head may be carried around towards the flank in parturient paresis in cows and in colic in horses. Sheep affected with hypocalcemia, and cattle with bilateral hip dislocation, often lie in sternal recumbency with the hindlegs extended behind in a frog-like attitude. Inability or lack of desire to rise are usually indicative of muscle weakness or of pain in the extremities as in enzootic muscular dystrophy or laminitis.

Gait

Movements of the limbs can be expressed in terms of rate, range, force and direction of movement. Abnormalities may occur in one or more of these categories. For example, in true cerebellar ataxia all qualities of limb movement are affected. In louping-ill in sheep it is the range and force that are excessive, giving a high-stepping gait and a bounding form of progression; in arthritis, because of pain in the joints, or in laminitis, because of pain in the feet, the range is diminished and the patient has a shuffling, stumbling walk. The direction of progress may be affected. Walking in circles is a common abnormality and is usually associated with rotation or deviation of the head; it may be a permanent state as in listeriosis or occur spasmodically as in acetonemia and pregnancy toxemia. Compulsive walking or walking directly ahead regardless of obstructions is part of the 'dummy' syndrome mentioned earlier and is characteristic of encephalomyelitis and hepatic insufficiency in the horse.

Body condition

The animal may be in normal bodily condition, or obese, thin or emaciated. The difference between thinness and emaciation is one of degree: the latter is more severe but there are additional signs that are usually taken into consideration. In an emaciated (cachectic) animal the coat is poor, the skin is dry and leathery and work performance is reduced. Thin animals, on the other hand, are physiologically normal. The difference between fatness and obesity is of the same order. Most beef cattle prepared for the show-ring are obese. In order to inject some degree of numerical assessment it is now customary in all farm animal species and in horses to use body condition on a scale of 1–5 or preferably 1–10.

Body conformation

The assessment of conformation or shape is based on the symmetry and the shape and size of the different body regions relative to other regions. An abdomen that is very large relative to the chest and hindquarters can be classified as an abnormality of conformation. To avoid repetition, points of conformation are included in the description of body regions.

Skin

Skin abnormalities can usually be seen at a distance. They include changes in the hair or wool, abnormal sweating, the presence of discrete or diffuse lesions, evidence of soiling by discharges and of itching. The normal luster of the coat may be absent: it may be dry as in most chronic debilitating diseases or excessively greasy as in seborrheic dermatitis. In debilitated animals the long winter coat may be retained past the normal time. Alopecia may be evident: in hyperkeratosis it is diffuse; in ringworm it may be diffuse but more commonly occurs in discrete areas. Sweating may be diminished, as in anhidrosis of horses; patchy as in peripheral nerve lesions; or excessive as in acute abdominal pain. Hypertrophy and folding of the skin may be evident, hyperkeratosis being the typical example. Discrete skin lesions range in type from urticarial plaques to the circumscribed scabs of ringworm, pox and impetigo. Diffuse lesions include the obvious enlargements due to subcutaneous edema, hemorrhage and emphysema. Enlargements of lymph nodes and lymphatics are also evident when examining an animal from a distance.

INSPECTION OF BODY REGIONS (PARTICULAR DISTANT EXAMINATION)

As a general rule, as much of a clinical examination as possible should be carried out before the animal is handled. This is partly to avoid unnecessary excitement of the patient but also because some abnormalities are better seen at a distance and in some cases cannot be discerned at close range. The general appearance of the animal should be noted and its behavior assessed. Some time should also be devoted to an inspection of the various body regions – a particular distant examination.

Head

The facial expression may be abnormal. The rigidity of tetanus, the cunning leer or maniacal expression of rabies and acute lead poisoning are cases in point. The symmetry and configuration of the bony structure should be examined. Doming of the forehead occurs in some cases of congenital hydrocephalus and in chondrodysplastic dwarfs, and in the latter there may be bilateral enlargement of the maxillae. Swelling of the maxillae and mandibles occurs in osteodystrophia fibrosa; in horses swelling of the facial bones is usually due to frontal sinusitis; in cattle enlargement of the maxilla or mandible is common in actinomycosis. Asymmetry of the soft structures may be evident and is most obvious in the carriage of the ears, degree of closure of the eyelids and situation of the muzzle and lower lip. Slackness of one side and drawing to the other are constant features in facial paralysis. Tetanus is accompanied by rigidity of the ears, prolapse of the third eyelid and dilatation of the nostrils.

The carriage of the head is most important: rotation is usually associated with defects of the vestibular apparatus on one side, deviation with unilateral involvement of the medulla and cervical cord; opisthotonos is an excitation phenomenon associated with tetanus, strychnine poisoning, acute lead poisoning, hypomagnesemic tetany, polioencephalomalacia and encephalitis.

The eyes merit attention. Visible discharge should be noted; protrusion of the eyeball, as occurs in orbital lymphomatosis, and retraction of the bulb, as occurs commonly in dehydration, are important findings; spasm of the eyelids and excessive blinking usually indicate pain or peripheral nerve involvement; prolapse of the nictitating membrane usually characterizes central nervous system derangement, generally tetanus.

Dilatation of the nostrils and nasal discharge suggest the advisability of closer examination of the nasal cavities at a later stage. Excessive salivation or frothing at the mouth denotes painful conditions of the mouth or pharynx or is associated with tremor of the jaw muscles due to nervous involvement. Swellings below the jaw may be inflammatory, as in actinobacillosis and strangles, or edematous, as in acute anemia, protein starvation or congestive heart failure. Unilateral or bilateral swelling of the cheeks in calves usually indicates necrotic stomatitis.

Neck

If there is enlargement of the throat this region should be more closely examined later to determine whether the cause is inflammatory and whether lymph nodes, salivary glands (or guttural pouches in the horse) or other soft tissues are involved. Goiter leads to local enlargement located further down the neck. A jugular pulse, jugular vein engorgement and edema should be looked for and local enlargement due to esophageal distension should be noted.

Thorax

The respiration should be examined from a distance, preferably with the animal in a standing position, as recumbency is likely to modify it considerably. Allowance should be made for the effects of exercise, excitement, high environmental temperatures and fatness of the subject: obese cattle may have respiratory rates two to three times that of normal animals. The rate, rhythm, depth and type of respiration should be noted.

Respiratory rate

In normal animals under average conditions the rate should fall within the following limits:

- Horses, 8–16/min
- Cattle, 10–30/min
- Sheep and pigs, 10–20/min
- Goats, 25–35/min.

An increased respiratory rate is designated as polypnea, decreased rate as oligopnea and complete cessation as apnea. The rate may be counted by observation of rib or nostril movements, by feeling the nasal air movements or by auscultation of the thorax or trachea. A significant rise in environmental temperature or humidity may double the normal respiratory rate. Animals that are acclimatized to cold outdoor temperatures are susceptible to heat stress when exposed suddenly to warmer temperatures. When brought indoors the respiratory rate may increase to six or eight times the normal, and panting open-mouth breathing may be evident within 2 hours.

Respiratory rhythm

The normal respiratory cycle consists of three phases of equal length: inspiration, expiration and pause; variation in the length of one or all phases constitutes an abnormality of rhythm. The breathing pattern of the neonatal foal is markedly different from that of the adult horse, and similar to that of other neonates. It has a higher respiratory rate, a higher airflow rate, and a higher minute ventilation on a body weight basis. In addition, in the standing neonatal foal, both the inspiratory and expiratory airflow patterns are essentially monophasic, whereas the adult horse typically has a biphasic inspiratory and expiratory airflow pattern. The transition from monophasic to biphasic flow patterns occurs within the first year of life.

Prolongation of phases

Prolongation of inspiration is usually due to obstruction of the upper respiratory tract; prolongation of the expiration is often due to failure of normal lung collapse, as in emphysema. In most diseases of the lungs there is no pause and the rhythm consists of two beats instead of three. There may be variation between cycles: Cheyne–Stokes respiration, characteristic of advanced renal and cardiac disease, is a gradual increase and then a gradual decrease in the depth of respiration; Biot's breathing, which occurs in meningitis affecting the medullary region, is characterized by alternating periods of hyperpnea and apnea, the periods often being of unequal length. Periodic breathing also occurs commonly in animals with electrolyte and acid–base imbalances – there are periods of apnea followed by short bursts of hyperventilation.

Respiratory depth

The amplitude or depth of respiratory movements may be reduced in painful conditions of the chest or diaphragm and increased in any form of anoxia. Moderate increase in depth is referred to as hyperpnea and labored breathing as dyspnea. In dyspnea, the accessory respiratory movements become more prominent: there is extension of the head and neck, dilatation of the nostrils, abduction of the elbows and breathing through the mouth plus increased movement of the thoracic and abdominal walls. Loud respiratory sounds, especially grunting, may also be heard.

Type of respiration

In normal respiration there is movement of the thorax and abdomen. In painful conditions of the thorax, e.g. acute pleurisy, and in paralysis of the intercostal muscles, there is relative fixation of the thoracic wall and a marked increase in the movements of the abdominal wall; there also may be an associated pleuritic ridge caused by thoracic immobility with the thorax expanded. This syndrome is usually referred to as an abdominal-type respiration. The reverse situation is thoracic-type respiration, in which the movements are largely confined to the thoracic wall, as in peritonitis, particularly when there is diaphragmatic involvement.

Thorax symmetry

This can also be evaluated by inspection. Collapse or consolidation of one lung may lead to restriction of movements of the thoracic wall on the affected side. The 'rachitic rosary' of enlarged costochondral junctions is typical of rickets.

Respiratory noises or stridors

These include:

- Coughing – due to irritation of the pharynx, trachea and bronchi
- Sneezing – due to nasal irritation
- Wheezing – due to stenosis of the nasal passages
- Snoring – when there is pharyngeal obstruction, as in tuberculous adenitis of the pharyngeal lymph nodes
- Roaring – in paralysis of the vocal cords
- Grunting – a forced expiration against a closed glottis, which happens in many types of painful and labored breathing.

An important part of the clinical examination of a horse that produces an externally audible noise, usually a grunt, while working is to determine when the noise occurs in the respiratory cycle. This can be related to limb movements, expiration occurring as the leading foot hits the ground at the canter or gallop. Flexion of the head by the rider will exacerbate the noise.

Abdomen

Variations in abdominal size are usually appreciated during the general inspection of the animal. An increase in size may be due to the presence of excessive feed, fluid, feces, flatus or fat, the presence of a fetus or a neoplasm. Further differentiation is usually possible only on close examination. In advanced pregnancy, fetal movements may be visible over the right

flank of cattle. In severe distension of the intestines with gas, the loops of intestine may be visible in the flank, especially in calves. Intestinal tympany usually results in uniform distension of the abdomen whereas fluid tends to result in increased distension ventrally.

The term 'gaunt' is used to describe an obvious decrease in the size of the abdomen. It occurs most commonly in starvation, in severe diarrhea and in many chronic diseases where appetite is reduced. An umbilical hernia, omphalophlebitis, or dribbling of urine from a previous urachus may be apparent on visual inspection of the ventral abdominal wall. Ventral edema is commonly associated with approaching parturition, gangrenous mastitis, congestive heart failure, infectious equine anemia, and rupture of the urethra due to obstructive urolithiasis. A grossly enlarged asymmetrical swelling of the flank may suggest herniation of the abdominal wall. Ruminal movements can be seen in the left paralumbar fossa and flank of cattle but a complete examination of the rumen requires auscultation, palpation and percussion, which are described later.

External genitalia

Gross enlargements of the preputial sheath or scrotum are usually inflammatory in origin but varicocele or tumors can also be responsible. Degenerative changes in the testicles may result in a small scrotum. Discharges of pus and blood from the vagina indicate infection of the genitourinary tract.

Mammary glands

Disproportionate size of the udder suggests acute inflammation, atrophy or hypertrophy of the gland. These conditions can be differentiated only by further palpation and examination of the milk or secretions.

Limbs

General abnormalities of posture and gait have been described. Symmetry is important and comparison of the various aspects of pairs of limbs should be used when there is doubt about the significance of an apparent abnormality. Enlargement or distortion of bones, joints, tendons, sheaths and bursae should be noted and so should any enlargement of peripheral lymph nodes and lymphatic vessels.

CLOSE PHYSICAL EXAMINATION

Some of the techniques used in making a close physical examination are set out below.

Palpation

Direct palpation with the fingers or indirect palpation with a probe is aimed at determining the size, consistency, temperature and sensitivity of a lesion or organ. Terms used to describe palpation findings include the following:

- Doughy – when the structure pits on pressure, as in edema
- Firm – when the structure has the consistency of normal liver
- Hard – when the consistency is bone-like
- Fluctuating – when the structure is soft, elastic and undulates on pressure but does not retain the imprint of the fingers
- Tense – when the structure feels like a viscus distended with gas or fluid under some considerable pressure
- Emphysematous – when the structure is puffy and swollen, and moves and crackles under pressure because of the presence of gas in the tissue.

Percussion

In percussion, the body surface is struck so as to set deep parts in vibration and cause them to emit audible sounds. The sounds vary with the density of the parts set in vibration and may be classified as follows:

Resonant – the sound emitted by organs containing air, e.g. normal lung
Tympanitic – a drum-like note emitted by an organ containing gas under pressure such as a tympanitic rumen or cecum
Dull – the sound emitted by solid organs such as heart and liver.

Percussion can be performed with the fingers using one hand as a plexor and one as a pleximeter. In large animals a pleximeter hammer on a pleximeter disk is recommended for consistency.

The quality of the sound elicited is governed by a number of factors. The strength of the percussion blow must be kept constant as the sound volume increases with stronger percussion. Allowances must be made for the thickness and consistency of overlying tissues. For example, the thinner the thoracic wall, the more resonant the lung. Percussion on a rib must not be compared with percussion on an intercostal space. The size and body condition score of the animal are also important considerations. The technique may be relatively ineffective in a fat animal. Pigs and sheep are of a suitable size but the fatness of the pig and the wool coat of the sheep plus the uncooperative nature of both species make percussion impracticable. In mature cattle and horses the abdominal organs are too large and the overlying tissue too thick for satisfactory outlining of organs or abnormal areas, unless the observer is highly skilled. The lungs of cattle and horses can be satisfactorily examined by percussion but this requires practice and experience to become skillful and accurate.

Percussion is a valuable aid in the diagnosis of diseases of the lungs and abdominal viscera of all large animals. Increased dullness over the thorax indicates consolidation of the lung, a pleural effusion, or space-occupying lesion such as tumor or abscess. Increased resonance over the thorax suggests emphysema or pneumothorax.

Ballottement

Ballottement is a technique used to detect floating viscera or masses in the abdominal cavity. Using the extended fingers or the clenched fist the abdominal wall is palpated vigorously with a firm push to move the organ or mass away and then allow it to rebound on to the fingertips. Ballottement of a fetus is a typical example; the fetal prominences can be easily felt by pushing the gravid uterus through the abdominal wall over the right flank in pregnant cattle. Impaction of the abomasum, large tumors and abscesses of the abdominal cavity may also be detected by ballottement. Ballottement and auscultation of the flanks of cattle is also useful to detect fluid-splashing sounds. Their presence on the left side suggests carbohydrate engorgement and excessive quantities of fluid in the rumen, or left-side displacement of the abomasum. Over the right flank, fluid-splashing sounds may indicate intestinal obstruction, abomasal volvulus, cecal dilatation and torsion, and paralytic ileus.

Ballottement and auscultation of the abdomen of the horse with colic may elicit fluid-splashing sounds indicative of intestines filled with fluid, as in intestinal obstruction or paralytic ileus. A modification of the method is tactile percussion, when a cavity containing fluid is percussed sharply on one side and the fluid wave thus set up is palpated on the other. The sensation created by the fluid wave is called a fluid thrill. It is felt most acutely by the palm of the hand at the base of the fingers. Diseases that cause ascites and accumulation of fluid in the peritoneal cavity are examples where this technique is useful.

Auscultation

Direct listening to the sounds produced by organ movement is performed by placing the ear to the body surface over the organ. Indirect auscultation by a stethoscope is the preferred technique. A considerable amount of work has been done to determine the most effective stethoscopic equipment, including investigation of such things as the shape and proportions of bell chest pieces, the thickness of rubber tubes and the diameter

and depth of phonendoscope chest pieces. A comparatively expensive unit from a reputable instrument firm is a wise investment. For large animal work, a stethoscope with interchangeable 5 cm diameter phonendoscope and rubber (to reduce hair friction sounds) bell chest pieces is all that is required. The details of the sounds heard on auscultations of the various organs are described in their respective sections. Auscultation is used routinely to assess heart sounds, lung sounds and gastrointestinal sounds.

Percussion and simultaneous auscultation of abdomen

Percussion and simultaneous auscultation of the left and right sides of the abdomen is a useful technique for examination of the abdomen of large animals. The stethoscope is placed over the area to be examined and the areas around the stethoscope and radiating out from it are percussed. This is a valuable diagnostic aid for the detection and localization of a gas-filled viscus in the abdomen of cattle with left-side displacement of the abomasum, right-side dilatation and volvulus of the abomasum, cecal dilatation and torsion, intestinal tympany associated with acute obstruction or paralytic ileus, or pneumoperitoneum.

Simultaneous percussion and auscultation of the abdomen of the horse with colic is useful to detect pings indicative of intestinal tympany associated with intestinal obstruction or paralytic ileus. In diaphragmatic hernia the presence of gas-filled intestines in the thorax may be determined by this method. To elicit the diagnostic 'ping', it is necessary to percuss and auscultate side by side and to percuss with a quick, sharp, light and localized force. The obvious method is a quick tap with a percussion hammer or similar object. Another favored method is a 'flick' with the back of a forefinger suddenly released from behind the thumb. A gas-filled viscus gives a characteristic clear, sharp, high-pitched 'ping' which is distinctly different from the full, low-pitched note of solid or fluid-filled viscera. The difference between the two is so dramatic that it is comparatively easy to define the borders of the gas-filled viscus.

The factors that determine whether a 'ping' will be audible are the force of the percussion, the size of the gas-filled viscus and its proximity to the abdominal wall. The musical quality of the ping is dependent on the thickness of the wall of the viscus (e.g. rumen, abomasum, small or large intestines) and the amount and nature of the fluid and gas in the intestines or viscus.

Succussion

This technique, which involves moving the body from side to side to detect the presence of fluid, is an adaptation of the above method. By careful auscultation while the body is moved, free fluid in the intestines or stomach will result in fluid-splashing or tinkling sounds.

Other techniques

Special physical techniques including biopsy and paracentesis are described under special examination of the various systems to which they apply. With suitable equipment and technique, one of the most valuable adjuncts to a physical examination is a radiographic examination. The size, location and shape of soft tissue organs are often demonstrable in animals of up to moderate size. Radiology, other than of limbs and neonates, is not commonly practiced in larger animals. Ultrasound appears to have much more general application but will require its own textbook.

SEQUENCE USED IN THE CLOSE PHYSICAL EXAMINATION

The close physical examination should be performed as quietly and gently as possible to avoid disturbing the patient and thus increasing the resting heart and respiratory rates. At a later stage it may be necessary to examine certain body systems after exercise, but resting measurements should be carried out first. If possible the animal should be standing, as recumbency is likely to cause variation in heart and pulse rates, respiration and other functions.

The sequence used in the close physical examination will vary with the species being examined, the results of the distant examinations, the history obtained, and the diagnostic hypotheses that the clinician has generated. The various parts of the close physical examination that are described here can be modified according to individual circumstances but it is important to do a thorough clinical examination based on the circumstances.

Following the distant examination, and the particular distant examination, it is recommended that the vital signs be determined before the animal is handled for examination of body regions such as the oral cavity.

In general, an appropriate sequence for the close physical examination would be as follows:

- Vital signs: temperature, heart and pulse rates, respirations, state of hydration
- Thorax: heart sounds (rate, rhythm, intensity); lung sounds
- Abdomen: nasogastric intubation
- Head and neck: including eyes, oral cavity, facial structures, and the jugular veins
- Rectal examination
- Urinary tract
- Reproductive tract
- Mammary gland
- Musculoskeletal system
- Nervous system
- Skin: including ears, hooves and horns.

The important principle is to determine the vital signs before handling and examining other body systems, which may distort the vital signs. The sequence that follows taking the vital signs can vary, based on individual circumstances, the urgency of the case, if any, and the ease of doing the particular examinations. For example, it may be very important to pass a nasogastric tube as one of the first diagnostic techniques in a horse with severe colic associated with gastric distension. When presented with a lactating dairy cow with peracute mastitis, the sequence will be recording the temperature, heart rate and sounds, respirations and status of the lungs, status of the rumen, followed by careful examination of the mammary gland. The close physical examination of each body region or body systems is outlined below.

Vital signs

Temperature

Normally the temperature is taken per rectum. When this is impossible the thermometer should be inserted into the vagina. Ensure that the mercury column is shaken down, moisten the bulb to facilitate entry and, if the anus is flaccid or the rectum full of hard feces, insert a finger also to ensure that the thermometer bulb is held against the mucosa. When the temperature is read immediately after defecation, or if the thermometer is stuck into a ball of feces or is left in the rectum for insufficient time, a false, low reading will result.

As a general rule the thermometer should be left in place for 2 minutes. If there is doubt as to the accuracy of the reading, the temperature should be taken again. The normal average temperature range for the various species at average environmental temperature is as shown in Table 1.1.

The reference values in Table 1.1 indicate the average resting temperature

Table 1.1 Normal average temperatures with critical points

Species	Normal temperature	Critical point
Horse	38.0°C (100.5°F)	39.0°C (102.0°F)
Cattle	38.5°C (101.5°F)	39.5°C (103.0°F)
Pig	39.0°C (102.0°F)	40.0°C (103.5°F)
Sheep	39.0°C (102.0°F)	40.0°C (104.0°F)
Goat	39.5°C (103.0°F)	40.5°C (105.0°F)

Temperature conversions are approximate.

for the species and the critical temperature above which hyperthermia can be said to be present. Normal physiological variations occur in body temperature and are not an indication of disease: a diurnal variation of up to 1°C (2°F) may occur, with the low point in the morning and the peak in the late afternoon. There may be a mild rise of about 0.6°C (1°F) in late pregnancy, but a precipitate although insignificant decline just before calving is not uncommon in cows and ewes and lower temperatures than normal occur just before estrus and at ovulation – the degree of change (about 0.3°C; 0.6°F) is unlikely to attract clinical attention.

In sows the body temperature is subnormal before farrowing and there is a significant rise in body temperature coinciding with parturition. This rise is commonly high enough to exceed the critical temperature of 40°C and may be considered erroneously as evidence of disease. The elevation of temperature that occurs in sows at the time of parturition, of the order of 1°C, is maintained through lactation and disappears at weaning.

High environmental humidity and temperature and exercise will cause elevation of the temperature; the deviation may be as much as 1.6°C (3°F) in the case of high environmental temperatures and as much as 2.5–3°C (4.5°F) after severe exercise; in horses, after racing, 2 hours may be required before the temperature returns to normal.

If animals that have been acclimatized to cold outside temperatures are brought indoors to a warmer temperature their body temperatures may exceed the critical temperature within 2–4 hours. Marked temperature variations are an indication of a pathological process:

- **Hyperthermia** is simple elevation of the temperature past the critical point, as in heat stroke
- **Fever** or **pyrexia** is the state where hyperthermia is combined with toxemia, as in most infectious diseases
- **Hypothermia**, a subnormal body temperature, occurs in shock, circulatory collapse (as in parturient paresis and acute rumen impaction of cattle), hypothyroidism and just before death in most diseases.

Pulse

The pulse should be taken at the middle coccygeal or facial arteries in cattle, the facial artery in the horse and the femoral artery in sheep and goats. With careful palpation a number of characters may be determined, including rate, rhythm, amplitude, tone, maximum and minimum pulse pressures and the form of the arterial pulse. Some of these characters are more properly included in special examination of the circulatory system and are dealt with under that heading.

Table 1.2 Resting pulse rates

Species	Pulse rate per minute
Adult horses	30–40
Foals up to 1 year	70–80
Adult cattle	60–80
Young calves	100–120
Sheep and goats	70–90

Rate

The pulse rate is dependent on the heart alone and is not directly affected by changes in the peripheral vascular system. The pulse rate may or may not represent the heart rate; in cases with a pulse deficit, where some heartbeats do not produce a pulse wave, the rates will differ. Normal resting rates (per minute) for the various species are shown in Table 1.2.

Although there are significant differences in rate between breeds of dairy cow, and between high- and low-producing cows, the differences would not be noticeable to a clinician performing a routine examination. In newborn thoroughbred foals the pulse rate is 30–90 in the first 5 minutes, then 60–200 during the first hour, and then 70–130 during the first 48 hours after birth. Draught horses have heart rates slightly higher than those quoted, which are based on a light horse population. The pulse is not readily palpable in the pig but the comparable heart rate is 60–100 per minute. The same techniques are used in intensive clinical examinations for horses afflicted with the poor performance syndrome.

Bradycardia, or marked slowing of the heartbeat, is unusual unless there is partial or complete heart block, but it does occur in cases of space-occupying lesions of the cranium, in cases of diaphragmatic adhesions after traumatic reticulitis in cattle, or when the rumen is much emptier than normal.

Tachycardia, or increased pulse rate, is common and occurs in most cases of septicemia, toxemia, circulatory failure and in animals affected by pain and excitement. Counting should be carried out over a period of at least 30 seconds.

Rhythm

The rhythm may be regular or irregular. All irregularities must be considered as abnormal except sinus arrhythmia, the phasic irregularity coinciding with the respiratory cycle. There are two components of the rhythm, namely the time between peaks of pulse waves and the amplitude of the waves. These are usually both irregular at the one time, variations in diastolic filling of the heart causing variation in the subsequent stroke volume. Regular irregularities occur with constant periodicity and are usually associated with partial heart block. Irregular irregularities are due to ventricular extrasystoles or atrial fibrillation. Most of these irregularities, except that due to atrial fibrillation, disappear with exercise. Their significance lies chiefly in indicating the presence of myocardial disease.

Amplitude

The amplitude of the pulse is determined by the amount of digital pressure required to obliterate the pulse wave. It is largely a measure of cardiac stroke volume and may be considerably increased, as in the 'water hammer' pulse of aortic semilunar valve incompetence, or decreased, as in most cases of myocardial weakness.

State of hydration

The state of hydration is assessed by inspection of the eyes for evidence of dehydration and evaluating the elasticity of the skin. Dehydration is characterized by sunken eyes of varying degrees, and the skin will 'tent' when lifted with the fingers and remain tented for varying lengths of time.

EXAMINATION OF BODY REGIONS

After the examination of the temperature, pulse and respirations the physical examination proceeds with an examination of the various body regions.

Thorax

Examination of the thorax includes palpation, auscultation and percussion of the cardiac area (precordium) and the lung area. The wide variations between species in the thickness of the thoracic wall, the size of the animal and the respiratory rate require careful and methodical examination. For example, in the adult horse the thick thoracic wall and the normally slow respiratory rate contribute to an almost soundless respiration on auscultation of the thorax. There is, too, the need to detect minor pulmonary lesions, which may reduce the work performance of the horse only slightly but, because of the importance of perfect fitness in a racing animal, may have major significance. Another important factor that emphasizes the care that must be taken with the examination of the respiratory system of the horse is the ability of racing animals to compensate for even major pulmonary lesions from their immense functional reserve. Because of this, one is likely to encounter horses with massive pulmonary involvement and yet with little obvious impairment of respiratory function.

Cardiac area

Auscultation of the heart is aimed at determining the character of normal heart

sounds and detecting the presence of abnormal sounds. Optimum auscultation sites are the fourth and fifth intercostal spaces and, because of the heavy shoulder muscles that cover the anterior border of the heart, the use of a flat phonendoscope chest piece pushed under the triceps muscles is necessary. Extension of the forelimb may facilitate auscultation if the animal is quiet. Areas where the various sounds are heard with maximum intensity are not directly over the anatomical sites of the cardiac orifices, because conduction of the sound through the fluid in the chamber gives optimum auscultation at the point where the fluid is closest to the chest wall.

The first (systolic) sound is heard best over the cardiac apex, the tricuspid closure being most audible over the right apex and mitral closure over the left apex. The second (diastolic) sound is heard best over the base of the heart, the aortic semilunar closure posteriorly and the pulmonary semilunar anteriorly, both on the left side.

In auscultation of the heart, the points to be noted are the rate, rhythm, intensity and quality of sounds and whether abnormal sounds are present. Comparison of the heart and pulse rates will determine whether there is a pulse deficit due to weak heart contractions failing to cause palpable pulse waves; this is most likely to occur in irregular hearts. Normally the rhythm is in three time and can be described as

LUBB – DUPP – pause,

the first sound being dull, deep, long and loud and the second sound sharper and shorter. As the heart rate increases the cycle becomes shortened, mainly at the expense of diastole and the rhythm assumes a two-time quality. More than two sounds per cycle is classified as a 'gallop' rhythm and may be due to reduplication of either the first or second sounds. Reduplication of the first sound is common in normal cattle and its significance in other species is discussed under diseases of the circulatory system.

The rhythm between successive cycles should be regular except in the normal sinus arrhythmia associated with respiration. With irregularity, there is usually variation in the time intervals between cycles and in the intensity of the sounds – louder sounds coming directly after prolonged pauses and being softer than normal sounds after shortened intervals, as in extrasystolic contractions. The intensity of the heart sounds may vary in two ways, absolutely or relatively: absolutely when the two sounds are louder than normal, and relatively when one sound is increased compared to the other in the cycle. For example, there is increased absolute intensity in anemia and in cardiac hypertrophy.

The intensity of the first sound depends on the force of ventricular contraction and is thus increased in ventricular hypertrophy and decreased in myocardial asthenia. The intensity of the second sound depends upon the semilunar closure, i.e. on the arterial blood pressure, and is therefore increased when the blood pressure is high and decreased when the pressure is low.

Abnormal sounds may replace one or both of the normal sounds or may accompany them. The heart sounds are muffled when the pericardial sac is distended with fluid. Sounds that are related to events in the cardiac cycle are murmurs or bruits and are caused mainly by endocardial lesions such as valvular vegetations or adhesions, by insufficiency of closure of valves and by abnormal orifices such as a patent interventricular septum or ductus arteriosus. Interference with normal blood flow causes the development of turbulence with resultant eddying and the creation of murmurs. In attempting to determine the site and type of the lesion it is necessary to identify its time of occurrence in the cardiac cycle: it may be presystolic, systolic or diastolic and it is usually necessary to palpate the arterial pulse and auscultate the heart simultaneously to determine accurately the time of occurrence. The site of maximum audibility may indicate the probable site of the lesion, but other observations, including abnormalities of the arterial pulse wave, should be taken into account. In many cases of advanced debility, anemia and toxemia, soft murmurs can be heard that wax and wane with respiration (hemic murmurs) and are probably due to myocardial asthenia. In cases of local pressure on the heart by other organs, for example in diaphragmatic hernia in cattle, loud systolic murmurs may be heard, probably due to distortion of the valvular orifices.

Abnormal sounds not related to the cardiac cycle include pericardial friction rubs, which occur with each heart cycle but are not specifically related to either systolic or diastolic sounds. They are more superficial, more distinctly heard than murmurs and have a to-and-fro character. Local pleuritic friction rubs may be confused with pericardial sounds, especially if respiratory and cardiac rates are equal.

Palpation of the heart beat has real value: the size of the cardiac impulses can be assessed and palpable thrills may on occasion be of more value than auscultation of murmurs. It is best carried out with the palm of the hand and should be performed on both sides. An increased cardiac impulse, the movements of the heart against the chest wall during systole, may be easily seen on close inspection of the left precordium and can be felt on both sides. It may be due to cardiac hypertrophy or dilatation associated with cardiac insufficiency or anemia or to distension of the pericardial sac with edema or inflammatory fluid. Care should be taken not to confuse a readily palpable cardiac impulse due to cardiac enlargement with one due to contraction of lung tissue and increased exposure of the heart to the chest wall.

Normally, the heart movements can be felt as distinct systolic and diastolic thumps. These thumps are replaced by thrills when valvular insufficiencies or stenoses or congenital defects are present. When the defects are large the murmur heard on auscultation may not be very loud but the thrill is readily palpable. Early pericarditis may also produce a friction thrill. The cardiac impulse should be much stronger on the left than the right side and reversal of this situation indicates displacement of the heart to the right side. Caudal or anterior displacement can also occur.

Percussion to determine the boundaries of the heart is of little value in large animal work because of the relatively large size of the heart and lungs and the depth of tissue involved. The area of cardiac dullness is increased in cardiac hypertrophy and dilatation and decreased when the heart is covered by more than the usual amount of lung, as in pulmonary emphysema. More detailed examination of the heart by electrocardiography, radiographic examination, test puncture and blood pressure are described under diseases of the heart.

Lung area

Auscultation, percussion and **palpation** are the major methods used for examination of the lungs.

The lung area available for satisfactory auscultation is slightly larger than that available for percussion. The normal breath sounds are heard over most of the lungs, particularly in the middle third anteriorly over the base of the lung, and consist of a soft, sipping VEE–EFF, the latter, softer sound occurring at expiration. The sounds are heard with variable ease depending on the thickness of the chest wall and the amplitude of the respiratory excursion. In well-fleshed horses and fat beef cattle the sounds may not be discernible at rest. The amplitude or loudness of the breath sounds is increased in dyspnea and in early pulmonary congestion and inflammation. The amplitude of the breath sounds is decreased or totally inaudible when there is pleural effusion, and in space-occupying lesions

in the lung or pleural cavity. Abnormal lung sounds include crackles, wheezes and pleuritic friction rubs. They are the result of interference with the free movement of air in and out of the lungs, and of the presence of lesions that interfere with the normal movement of the lung and thus create additional respiratory sounds, which are an indication of disease. The descriptions and interpretations of the normal and abnormal lung sounds, and other respiratory noises are described in Chapter 10.

The intensity of abnormal lung sounds may be increased and their clarity improved by measuring the rate and depth of respirations with forced mild exercise such as walking for a few minutes followed by immediate auscultation. If exercise is undesirable the occlusion of both nostrils for 30–45 seconds will be followed by some deep inspirations and accentuation of abnormal lungs. An alternative maneuver which is effective in both horses and cattle is to pull a plastic bag over the muzzle and lower face. When respiratory movements become exaggerated the bag is removed and the lungs auscultated immediately.

Sounds of peristalsis are normally heard over the lung area on the left side in cattle and in horses. In cattle, these sounds are due to reticular movement and in horses to movements of the colon. Their presence is not of much significance in these species unless there are other signs. In cattle, too, sounds of swallowing, eructation and regurgitation may be confused with peristaltic sounds; ruminal movements and the esophagus should be observed for the passage of gas or a bolus to identify these sounds. Other techniques for examination of the thorax are described under diseases of the respiratory system (Ch. 10).

Palpation of the thoracic wall may reveal the presence of a pleuritic thrill, bulging of the intercostal spaces when fluid is present in the thoracic cavity, or narrowed intercostal spaces and decreased rib movement over areas of collapsed lung.

Percussion may be by the usual direct means, or indirectly by tracheal percussion when the trachea is tapped gently and the sound is listened for over the lung area. By direct percussion within the intercostal spaces the area of normal lung resonance can be defined and abnormal dullness or resonance detected. Increased dullness may indicate the presence of a space-occupying mass, consolidated lung, edematous lung or an accumulation of fluid. In a pleural effusion the upper limit of the area of dullness can be determined by percussion and the **fluid line** can be delineated and identified and used to assess the progress of therapy.

An overloud normal percussion note is obtained over tissue containing more air than usual, e.g. emphysematous lung. A definite tympanitic note can be elicited over pneumothorax or a gas-filled viscus penetrating through a diaphragmatic hernia. For percussion to be a satisfactory diagnostic aid, affected areas need to be large with maximum abnormality, and the chest wall must be thin.

Abdomen

Clinical examination of the abdomen includes:

- **Visual inspection** of the abdominal contour for evidence of distension or gauntness
- **Auscultation** of the gastrointestinal sounds
- **Palpation** and **percussion** through the abdominal wall
- **Rectal palpation**
- **Passage of the nasogastric tube**
- **Paracentesis** of the abdomen.

Auscultation

Auscultation of the abdomen is an essential part of the clinical examination of cattle, horses and sheep. It is of limited value in pigs. The intestinal or stomach sounds will indicate the nature of the intraluminal contents and the frequency and amplitude of gastrointestinal movements, which are valuable aids in clinical diagnosis. The intensity, duration and frequency of the sounds should be noted. All these characteristics will be increased in animals that have just eaten or immediately following excitement.

Auscultation of the rumen of cattle and sheep

This is a very useful part of the clinical examination. In normal animals there are 1–2 primary contractions per minute, involving the reticulum and the dorsal and ventral sacs of the rumen; the frequency depends on the amount of time that has elapsed since feeding and the type of food consumed. Secondary contractions of the dorsal and ventral sacs of the rumen occur at about 1 per minute and are commonly associated with eructation. The examination is made in the left paralumbar fossa and a normal sequence of sounds consists of a lift of the flank with a fluid gurgling sound, followed by a second more pronounced lift accompanied by a booming, gassy sound. Auscultation over the lower left ribs will reveal the fainter fluid sounds of reticular contractions just prior to the contractions of the dorsal and ventral ruminal sacs described above. The reticular and ruminal sounds are the predominant abdominal sounds in the normal ruminant.

A grunt, detectable by auscultation over the trachea, may occur during the reticular contraction phase of a primary contraction in cattle with traumatic reticuloperitonitis. The factors that result in a decrease in the intensity and frequency of ruminal sounds are discussed in detail in Chapter 6.

The intestinal sounds that are audible on auscultation of the right flank of cattle and sheep consist of frequent faint gurgling sounds, which are usually difficult to interpret. The contraction of the abomasum and the intestines result in a mixture of sounds that are difficult to distinguish.

Intestinal sounds of the horse

These sounds are clearly audible and their assessment is one of the most vital parts of the clinical examination and surveillance of the horse with suspected abdominal disease. Over the right and ventral abdomen there are the loud, booming sounds (borborygmi) of the colon and cecum, which are at peak intensity about every 15–20 seconds. Over the left abdomen there are the much fainter rushing fluid sounds of the small intestines. An increase in the intensity and frequency of sounds with a distinct fluid quality are heard in enteritis and loud, almost crackling, sounds in spasmodic colic. In impaction of the large intestine there is a decrease in the intensity and frequency of the borborygmi, and in thromboembolic colic due to verminous aneurysm and infarction of the colon there may be complete absence of sounds. In intestinal obstruction the intestinal sounds due to peristalsis are markedly decreased and usually absent and fluid tinkling sounds occur infrequently. In intestinal stasis in the horse, auscultation in the right flank often detects the tinkling sound of fluid dropping from the ileocecal valve through gas into the dorsal sac of the cecum.

Palpation and percussion through the abdominal wall

Because of the thickness and weight of the abdominal wall in mature cattle and horses, deep palpation of viscera and organs through the abdominal wall has limited value in these species compared to its usefulness in small animals. No viscera or organ, with the exception of the fetus, can be palpated with certainty through the abdominal wall in the horse. In cattle, the rumen and its contents can usually be palpated in the left paralumbar fossa. Ruminal distension is usually obvious while an inability to palpate the rumen may be due to a small, relatively empty rumen or to medial displacement, as in left-side displacement of the abomasum.

Percussion and simultaneous auscultation

In left-side displacement of the abomasum, percussion and simultaneous auscultation over the upper third of the costal arch between the 9th and 12th ribs of the left side will elicit the typical high-pitched musical-quality sounds or ping. These may be mistaken for similar sounds present in ruminal atony. A markedly enlarged liver in a cow may be palpable by ballottement immediately behind the right costal arch. Using a combination of palpation, percussion and simultaneous auscultation over the right paralumbar fossa and caudal to the entire length of the right costal arch it may be possible to detect any of the following in cattle:

- Dilatation and torsion of the abomasum
- Cecal dilatation and torsion
- Impaction of the abomasum and omasum
- Intestinal obstructions, including torsion of the coiled colon.

Percussion and auscultation over viscera that are distended with fluid and gas may be undertaken and the size and location of the tympanitic area will provide some indication of the viscera likely to be involved.

Tactile percussion of the abdomen

This technique aids detection of an excessive quantity of fluid in the peritoneal cavity: ascites due to a ruptured bladder, transudate in congestive heart failure and exudate in diffuse peritonitis. A sharp blow is struck on one side of the abdomen and a fluid wave, a 'blip' or undulation of the abdominal wall, can be seen and felt on the opposite side of the abdomen. The peritoneal cavity must be about one-third full of fluid before a fluid wave can be elicited.

Abdominal pain

The location of abdominal pain may be located by deep external palpation of the abdominal wall in cattle. Deep palpation with a firm uniform lift of the closed hand or with the aid of a horizontal bar held by two people under the animal immediately caudal to the xiphoid sternum is a useful aid for the detection of a grunt associated with traumatic reticuloperitonitis in cattle. Superficial pain may be elicited by a firm poke of the hand or extended finger in cattle or horses. In cattle, pain may be elicited over the right costal arch when there are liver lesions or generally over the abdomen in diffuse peritonitis.

The response to palpation of a focus of abdominal pain in cattle is a 'grunt' which may be clearly audible without the aid of a stethoscope. However, if there is doubt about the audibility of the grunt, the simultaneous auscultation of the trachea will detect a perceptible grunt when the affected area is reached. In calves with abomasal ulceration, a focus of abdominal pain may be present on deep palpation over the area of the abomasum.

In cases of severe abdominal distension (ruminal tympany in cattle, torsion of the large intestine) it is usually impossible to determine, by palpation and percussion, the viscera that are distended. Pneumoperitoneum is rare and thus gross distension of the abdomen is usually due to distension of viscera with gas, fluid or ingesta. A combination of rectal examination, passage of a stomach tube, paracentesis and exploratory laparotomy may be necessary to determine the cause.

The abdomen of pigs is difficult to examine by palpation because pigs are seldom sufficiently quiet or relaxed and the thickness of the abdominal wall limits the extent of deep palpation. In late pregnancy in sows the gravid uterus may be ballotted but it is usually not possible to palpate fetal prominences.

In sheep, the rumen, impacted abomasum and the gravid uterus are usually palpable through the abdominal wall. Positioning the sheep on its hindquarters will shift the viscera to a more easily palpable position.

Nasogastric intubation

An important part of the examination of the abdomen and gastrointestinal tract of large animals, especially cattle and horses, is the passage of the nasogastric tube into the rumen of cattle and into the stomach of horses. Gastric reflux occurs commonly in the horse with colic and it is important to determine if the stomach is distended with fluid and to relieve it as necessary. This topic is presented in detail in the chapter dealing with equine colic. In cattle, when disease of the rumen is suspected, the nasogastric tube is passed into the rumen to relieve any distension and to obtain a sample of rumen juice for determination of rumen pH and the presence or absence of rumen protozoa.

Head and neck

Eyes

Any discharge from the eyes should be noted: it may be watery in obstruction of the lacrimal duct, serous in the early stages of inflammation and purulent in the later stages. Whether the discharge is unilateral or bilateral is of considerable importance; a unilateral discharge may be due to local inflammation, a bilateral discharge may denote a systemic disease. Abnormalities of the eyelids include abnormal movement, position and thickness. Movement may be excessive in painful eye conditions or in cases of nervous irritability including hypomagnesemia, lead poisoning and encephalitis. The lids may be kept permanently closed when there is pain in the eye or when the eyelids are swollen, as for instance in local edema due to photosensitization or allergy. The membrana nictitans may be carried across the eye when there is pain in the orbit or in tetanus or encephalitis. There may be tumors on the eyelids.

Examination of the conjunctiva

This examination is important because it is a good indicator of the state of the peripheral vascular system. The pallor of anemia and the yellow coloration of jaundice may be visible, although they are more readily observed on the oral or vaginal mucosa. Engorgement of the scleral vessels, petechial hemorrhages, edema of the conjunctiva as in gut edema of pigs or congestive heart failure, and dryness due to acute pain or high fever are all readily observable abnormalities.

Corneal abnormalities

These include opacity, varying from the faint cloudiness of early keratitis to the solid white of advanced keratitis, often with associated vascularization, ulceration and scarring. Increased convexity of the cornea is usually due to increased pressure within the eyeball and may be due to glaucoma or hypopyon.

Size of the eyeball

Eyeball size does not usually vary but protrusion is relatively common and when unilateral is due in most cases to pressure from behind the orbit. Periorbital lymphoma in cattle, dislocation of the mandible and periorbital hemorrhage are common causes. Retraction of the eyeballs is a common manifestation of reduction in volume of periorbital tissues, e.g. in starvation when there is disappearance of fat and in dehydration when there is loss of fluids.

Abnormal eyeball movements

Abnormal movements occur in nystagmus due to anoxia or to lesions of the cerebellum or vestibular tracts. In nystagmus there is periodic, involuntary movement with a slow component in one direction and a quick return to the original position. The movement may be horizontal, vertical or rotatory. In paralysis of the motor nerves to the orbital muscles there is restriction of movement and abnormal position of the eyeball at rest.

Examination of the deep structures

Assessment of the deep structures of the eye necessitates an ophthalmoscope but gross abnormalities may be observed by direct vision. Pus in the anterior chamber, hypopyon, is usually manifested by yellow to white opacity often with a

horizontal upper border obscuring the iris. The pupil may be of abnormal shape or abnormal in position due to adhesions to the cornea or other structures. An abnormal degree of dilatation is an important sign, unilateral abnormality usually suggesting a lesion of the orbit.

Bilateral excessive dilatation (mydriasis) occurs in local lesions of the central nervous system affecting the oculomotor nucleus, or in diffuse lesions including encephalopathies, or in functional disorders such as botulism and anoxia. Peripheral blindness due to bilateral lesions of the orbits may have a similar effect. Excessive constriction of the pupils (miosis) is unusual unless there has been overdose with organic phosphatic insecticides or parasympathomimetic drugs. Opacity of the lens is readily visible, especially in advanced cases.

Vision tests

Several tests of vision and of ocular reflexes are easily carried out, and when warranted should be done at this stage of the examination. Tests for blindness include the menace reflex and an obstacle test. In the former a blow at the eye is simulated, care being taken not to cause air currents. The objective is to elicit the eye preservation reflex manifested by reflex closure of the eyelids. This does not occur in peripheral or central blindness and in facial nerve paralysis there may be withdrawal of the head but no eyelid closure. An obstacle test in unfamiliar surroundings should be arranged and the animal's ability to avoid obstacles assessed. The results are often difficult to interpret if the animal is nervous. A similar test for night-blindness (nyctalopia) should be arranged in subdued light, either at dusk or on a moonlit night. Nyctalopia is one of the earliest indications of avitaminosis-A. Total blindness is called amaurosis, partial blindness is called amblyopia. The pupillary light reflex – closure and dilatation of the iris in response to lightness and darkness – is best tested with a strong flashlight.

Nostrils

Particular attention should be paid to the odor of the nasal breath. There may be a sweet sickly smell of ketosis in cattle or a fetid odor, which may originate from any of a number of sources including gangrenous pneumonia, necrosis in the nasal cavities or the accumulation of nasal exudate. Odors originating in the respiratory tract are usually constant with each breath and may be unilateral. The sour smell of alimentary tract disturbance is detectable only periodically, coinciding with eructation. Odors originating in the mouth from bad teeth or from necrotic ulcers associated with *Fusobacterium necrophorum* in calves may be smelled on the nasal breath but are stronger on the oral breath.

In certain circumstances it may be important to note the volume of the breath expelled through the nostrils: it may be the only way of determining whether the animal is breathing and, in some cases, of counting the respiratory rate. Variation in volume between nostrils, as felt on the hands, may indicate obstruction or stenosis of one nasal cavity. This can be examined further by closing off the nostrils one at a time; if obstruction is present in one nostril, closure of the other causes severe respiratory embarrassment.

Any nasal discharge that is present should receive special attention and its examination should be carried out at the same time as an inspection of the nasal mucosa. Discharges may be restricted to one nostril in a local infection or be bilateral in systemic infection. The color and consistency of the exudate will indicate its source. In the early stages of inflammation the discharge will be a clear, colorless fluid, which later turns to a white to yellow exudate as leukocytes accumulate in it. In Channel Island cattle the color may be a deep orange, especially in allergic rhinitis. A rust or prune juice color indicates blood originating from the lower respiratory tract, as in pneumonia and in equine infectious anemia in the horse. Blood clots derived from the upper respiratory tract or pharynx may be present in large quantities, or appear as small flecks. In general, blood from the upper respiratory tract is unevenly mixed with any discharge, whereas that from the lower tract comes through as an even color.

The consistency of the nasal discharge will vary from watery in the early stages of inflammation, through thick, to cheesy in longstanding cases. Bubbles or foam may be present. When the bubbles are coarse it signifies that the discharge originates in the pharynx or nasal cavities; fine bubbles originate in the lower respiratory tract. In all species, vomiting or regurgitation caused by pharyngitis or esophageal obstruction may be accompanied by the discharge of food material from the nose or the presence of food particles in the nostrils. In some cases the volume of nasal discharge varies from time to time, often increasing when the animal is feeding from the ground, leading to infection of cranial sinuses.

Inflammation of the nasal mucosa varies from simple hyperemia, as in allergic rhinitis, to diffuse necrosis, as in bovine malignant catarrh and mucosal disease, to deep ulceration as in glanders. In hemorrhagic diseases variations in mucosal color can be observed and petechial hemorrhages may be present.

Mouth

Excessive salivation, with ropes of saliva hanging from the mouth and usually accompanied by chewing movements, occurs when a foreign body is present in the mouth and also in many forms of inflammation of the oral mucosa or of the tongue. Actinobacillosis of the tongue, foot-and-mouth disease and mucosal disease are typical examples. Excessive salivation may also occur in diseases of the central nervous system, as in acute lead poisoning in young cattle. Hypersalivation is a characteristic sign in epidermic hyperthermia associated with the mycotoxins of *Acremonium coenophialum* and *Claviceps purpurea* and by the fungus *Rhizoctonia leguminicola* sometimes found on red clover. Dryness of the mouth occurs in dehydration and poisoning with belladonna alkaloids, or when high levels of urea are fed.

Abnormalities of the buccal mucosa include local lesions, hemorrhages in purpuric diseases, the discolorations of jaundice and cyanosis and the pallor of anemia. Care must be taken to define the exact nature of lesions in the mouth, especially in cattle; differentiation between vesicles, erosive and ulcerative lesions is of diagnostic significance in the mucosal diseases of this species.

Teeth

Examination of the teeth for individual defects is a surgical subject but a general examination of the dentition can yield useful medical information. Delayed eruption and uneven wear may signify mineral deficiency, especially calcium deficiency in sheep; excessive wear with mottling and pitting of the enamel is suggestive of chronic fluorosis.

Tongue

The tongue may be swollen by local edema or by inflammation as in actinobacillosis of cattle, or shrunken and atrophied in post-inflammatory or nervous atrophy. Lesions of the lingual mucosa are part of the general buccal mucosal response to injury.

Pharynx

Examination of the pharyngeal region in large animals requires some dexterity and the use of a speculum of appropriate size. The oral cavity and pharynx of calves, lambs and goat kids is examined by holding the mouth open, depressing the base of the tongue with the fingers or a tongue depressor and viewing the pharynx, the glottis and the proximal part of the larynx and arytenoid cartilages. In adult cattle, a metal or Plexiglass cylindrical speculum, 45 cm in length and 4 cm in diameter,

placed in the oral cavity and over the base of the tongue will allow viewing of the pharynx and the larynx. Foreign bodies, diffuse cellulitis and pharyngeal lymph node enlargement can also be detected by this means. The use of a speculum wedged between the upper and lower molar teeth in cattle allows manual exploration and evaluation of lesions of the pharynx and proximal part of the larynx. In the horse, the pharynx cannot be viewed from the oral cavity and manual exploration of the pharynx requires general anesthesia. Endoscopy is a useful method of examination in this species, and the modern fiberoptiscope has made it possible to visualize lesions in the posterior nares and pharynx–esophagus, larynx–trachea in the standing, conscious horse or ox.

Submaxillary region

Abnormalities of the submaxillary region that should be noted include enlargement of lymph nodes due to local foci of infection, subcutaneous edema as part of a general edema, local cellulitis with swelling and pain, enlargement of salivary glands or guttural pouch distension in the horse. Thyroid gland enlargement is often missed or mistaken for other lesions, but its site, pulsation and surrounding edema are characteristic.

Neck

The most important part of the examination of the neck of cattle and horses is to determine the state of the jugular veins. Bilateral engorgement of the jugular veins may be due to obstruction of the veins by compression or constriction, or to right-side congestive heart failure. A jugular pulse of small magnitude moving up the jugular vein about one-third of the way up the neck is normal in most animals but it must be differentiated from a transmitted carotid pulse, which is not obliterated by compression of the jugular vein at a lower level. Variations in size of the vein may occur synchronously with deep respiratory movements but bear no relation to the cardiac cycles. When the jugular pulse is associated with each cardiac movement it should be determined whether it is physiological or pathological. The physiological pulse is presystolic and due to atrial systole, and is normal. The pathological pulse is systolic and occurs simultaneously with the arterial pulse and the first heart sound; it is characteristic of an insufficient tricuspid valve.

Local or general enlargement of the esophagus associated with vomiting or dysphagia occurs in esophageal diverticulum, stenosis and paralysis, and in cardial obstructions. Passage of a stomach tube or probang can assist in the examination of esophageal abnormalities.

Tracheal auscultation is a useful diagnostic aid. Normally, the sounds that are audible are louder and more distinct than breath sounds audible over the lung. In upper respiratory tract disease such as laryngitis and tracheitis, the sounds are louder and harsher and may be whistling in the presence of stenosis. Very loud stenotic tracheal sounds are characteristic of calves with tracheal collapse. Abnormal tracheal sounds, regardless of their cause, are usually transferred down the major bronchi and are audible on auscultation over the thorax, primarily during inspiration. They are commonly confused with abnormal lung sounds due to pneumonia, but in pneumonia the abnormal sounds are usually present both on inspiration and on expiration.

Rectal examination

Rectal exploration of the abdomen is a vital part of the complete examination of the abdomen of large animals, especially cattle and horses. Abnormalities that are completely unexpected may be present and may be the cause of illness in animals in which no other significant clinical abnormalities were detected on clinical examination. Special care is necessary to avoid injuring the patient and causing it to strain. Suitable lubrication and avoidance of force are the two most important factors. Rectal examination enables observations to be made on the alimentary, urinary and genital tracts and on the vessels, peritoneum and pelvic structures. The amount and nature of the feces in the rectum should be determined.

Palpable abnormalities of the digestive tract include paralysis and ballooning of the rectum, distension of the loops of the intestine with fluid or gas, the presence of hard masses of ingesta as in cecal and colonic impactions in the horse, and intestinal obstruction due to volvulus, intussusception or strangulation. The detection of tight bands of mesentery leading to displacement segments may be a valuable guide. In cattle, the caudal sacs of the rumen are readily palpable. When the rumen is distended as in bloat or vagus indigestion they may push well into the pelvis or be only just within reach when the rumen is empty. A distended abomasum may be felt in the right half of the abdomen in cases of abomasal torsion and occasionally in vagus indigestion. In healthy animals there is little to feel because of the space occupied by normal intestines. Palpable objects should be carefully examined.

The left kidney in the cow can be felt in the midline and distinct lobulations are evident. In the horse, the caudal pole of the left kidney is easily palpable, but the right kidney is not. There may be abnormalities of size in pyelonephritis, hydronephrosis and amyloidosis, and pain on pressure in pyelonephritis. The ureters are not normally palpable nor is the empty bladder. A distended bladder or chronic cystitis with thickening of the wall can be felt in the midline at the anterior end of the pelvic cavity. Abnormalities of the bladder and ureters in cattle are also palpable through the ventral aspects of the vagina. Large calculi have a stone-like hardness and are occasionally observed in horses in the same position. Pain with spasmodic jerking of the penis on palpation of the urethra occurs in urinary obstruction due to small calculi, cystitis and urethritis. Enlarged, thickened ureters such as occur in pyelonephritis can be felt between the kidney and the bladder.

On the peritoneum and mesentery one may feel the small, grape-like lesions of tuberculosis, the large, irregular, hard masses of fat necrosis and the enlarged lymph nodes of lymphomatosis. The abdominal aorta is palpable, and in horses the anterior mesenteric artery and some of its branches can be felt. This may be an important examination if a verminous aneurysm is suspected, in which case the vessels are thickened but still pulsate, have an uneven rough surface and may be painful. In horses the caudal edge of the spleen is usually palpable in the left abdomen. During a rectal examination in a horse it is advantageous in some cases to palpate the inguinal ring from inside the abdomen and, by pushing the other hand between the horse's thighs, to palpate the external ring simultaneously. It is then easier to decide whether any abnormal structures are passing through the ring.

Feces and defecation

Examination of the feces may provide valuable information on the digestive and motor functions of the tract. They should be examined for volume, consistency, form, color, covering, odor and composition. Note should be made of the frequency and the time taken for material to pass through the tract. Laboratory examinations may be advisable to detect the presence of helminth eggs, occult blood, bile pigments, pathogenic bacteria or protozoa.

The volume of feces is usually described scant, normal or copious but, in certain circumstances, it may be advisable to weigh or measure the daily output. The normal output for each species is as follows:

- Horses: 15–20 kg/day
- Cattle: 25–45 kg/day
- Pigs: 1–2.5 kg/day
- Sheep and goats: 0.5–1 kg/day

There is an increased bulk when much fiber is fed or during attacks of diarrhea. The consistency and form of the feces varies with each species and varies widely within a normal range, depending particularly on the nature of the food. Variations in consistency not explainable by changes in the character of the feed may indicate abnormalities of any of the functions of the tract. The consistency is more fluid in diarrhea and less fluid than normal in constipation. The consistency and form of the feces may provide some indication of the location of the dysfunction of the gastrointestinal tract. In general, large quantities of liquid feces suggest a dysfunction of the small intestine where normally most of the fluid is absorbed. If the feces contain large quantities of undigested feed this suggests overfeeding, incomplete mastication, a digestive enzyme deficiency or an acute disorder of the small intestine or stomachs. Large quantities of soft feces that contain well-digested ingesta suggest a dysfunction of the large intestine. However, these are only guidelines and are subject to error.

Color of the feces This also varies widely with the color of the food, but feces of a lighter color than normal may be caused by an insufficient secretion of bile or by simple dilution of the pigments, as occurs in diarrhea. The effect of blood on the appearance of feces has already been described. Discoloration by drugs should be considered when the animal is undergoing treatment.

Fecal odor This depends largely on the nature of the food eaten but in severe enteritis the odor is characteristically one of putrefaction.

Composition The composition of the feces should be noted. In herbivorous animals, there is always a proportion of undigested fiber but excessive amounts suggest incomplete digestion due to, for example, bad teeth and faulty mastication. Excessively pasty feces are usually associated with a prolonged sojourn in the tract such as occurs in vagal indigestion or abomasal displacement in cattle. Foreign material of diagnostic significance includes sand or gravel, wool, and shreds of mucosa. Mucus is a normal constituent but, in excessive amounts, indicates either chronic inflammation, when it is associated with fluid, copious feces, or constipation when the feces are small in volume and hard. Mucosal shreds or casts always indicate inflammation.

Frequency of defecation Frequency and the length of sojourn in the gastrointestinal tract are usually closely allied, increased frequency and decreased sojourn occurring in diarrhea and the reverse in constipation. Most animals defecate eight to 12 times a day but the sojourn varies widely with the species. Omnivores and carnivores with simple stomachs have an alimentary sojourn of 12–35 hours. In ruminants it is 2–4 days and in horses 1–4 days, depending on the type of feed.

Other observations

Observation of other acts associated with the functions of the alimentary tract may provide information of diagnostic value. Prehension, mastication, swallowing, vomiting and defecation should be observed and an attempt made to analyze the behavior of the animal when there is evidence of abdominal pain.

Paracentesis of the abdomen

Paracentesis of the abdomen includes obtaining a sample of peritoneal fluid when peritonitis or inflammation of the serosae of the intestines or other viscera of the abdomen is suspected. Aspiration of fluid from a distended abdominal viscus is also possible and may aid in the diagnosis.

Urinary system

Examination of the urinary tract consists of observations of the **act of urination**, evidence of **difficult** and **painful urination**, **abnormal urine**, collection of urine and urinalysis, and, depending on the species, **palpation** of the **kidneys, bladder and urethra**. Details of the examination of the urinary tract are presented in Chapter 11.

Reproductive tract

Examination of the reproductive tract is usually carried out at this stage but is not discussed here because it is dealt with adequately in texts on diseases of the genital system. In the immediate postpartum period, the vagina, cervix and uterus should be examined thoroughly for evidence of gross abnormalities such as metritis, retained placenta and ruptured uterus, which may be the cause of illness not obvious on examination of other body systems.

Mammary gland

The mammary gland(s) of all species is examined by inspection and palpation of the udder and teats, and gross examination of the milk or abnormal secretions of the glands. Details of this examination are presented in Chapter 15.

Musculoskeletal system and feet

Examination of the musculoskeletal system and feet is necessary when there is lameness, weakness, or recumbency. Inspection of the gait during the walk and trot is used to determine the origin of the lameness. The muscles, joints, ligaments, tendons, and bones are inspected and palpated to determine abnormalities associated with lameness, weakness or recumbency. The feet are examined by inspection, palpation and the trimming of hooves in farm animals to identify lesions associated with lameness. Medical imaging is commonly used to define lesions not readily recognizable by routine clinical examination. Details of examination of the musculoskeletal system and feet are presented in Chapter 13.

Nervous system

In routine veterinary practice, veterinarians will commonly include several components of a neurological examination in a complete clinical examination. Most often a diagnosis and differential diagnosis can be made from consideration of the history and the clinical findings. However, if the diagnosis is uncertain it may be necessary to conduct a complete neurological examination, which may uncover additional clinical findings necessary to make a diagnosis and give a prognosis.

A complete neurological examination includes examination of the mental status, head and posture, cranial nerve function, gait and posture, function of the neck and forelimbs, function of the trunk and hindlimbs, palpation of the bony encasement of the central nervous system, examination of cerebrospinal fluid, medical imaging of the bony skeleton of the head and vertebral column. The details of the neurological examination are presented in Chapter 12.

Skin including ears, hooves and horns

A systematic method for the examination of the skin is necessary to avoid misinterpretation of the lesions. Inspection of the behavior of the animal and of the skin and hair, and palpation and smelling of the skin are the most common physical methods used for clinical examination of the skin. The important prerequisites for an adequate examination of the skin are good lighting such as natural light or daytype lamps, clipping the animal's hair when necessary to adequately visualize lesions, magnification of the lesions with a hand lens to improve visualization of the changes, and adequate restraint and positioning of the animal. Palpation can be used to assess the consistency of lesions, the thickness and elasticity of skin, and to determine the presence of pain associated with diseases of the skin.

Close inspection and palpation of the skin and hair coat are necessary to identify and characterize lesions. Magnifying spectacles or an illuminated magnifying glass may prove useful. The dorsal aspect of the body is inspected by viewing it from the rear, as elevated hairs and patchy alopecia may be more obvious from that

angle. All parts of the head including the nose, muzzle and ears are examined. The lateral trunk and the extremities are then examined. The feet of large animals need to be picked up to examine the interdigital clefts and parts of the coronary bands. The skin of the udder and teats of cattle, sheep and goats, and horses must be observed. The ventral aspect of the body is carefully examined using a source of light to illuminate the underside of adult cattle and horses. The external and internal aspects of the ears, and the hooves and horns must be examined by inspection and palpation.

Every centimeter of the skin needs to be examined for the presence of lesions in different stages of development. The **visual**, **tactile** and **olfactory senses** are used to see, feel and smell the lesions. The presence or absence of some ectoparasites can be determined by direct inspection. For example, lice and ticks of cattle are usually easily visible. The odor of the skin in some diseases may be abnormal; dermatophilosis in cattle is characterized by a foul and musty odor. Parting the hairs with the fingers or by gently blowing them is necessary to evaluate the length of the hair shafts. Broken hairs, changes in hair color and the accumulation of exudative material on hair shafts are noted. The texture and elasticity of the skin must be assessed by rolling the skin between the fingers. Careful digital palpation of the hair coat which appears normal on visual inspection may reveal underlying lesions such as pustules which may be covered by the hair coat. In some cases, tufts of hairs may be seen protruding through an accumulation of exudate. A combination of visual inspection of the wool coat of sheep is done carefully and systematically by parting the wool coat and evaluating the condition of the wool fibers and the underlying skin. The hair coat should not be clipped, groomed or washed before the lesions have been identified and characterized.

DIAGNOSTIC ULTRASONOGRAPHY

Diagnostic ultrasonography in animals is the continuation of the clinical examination

Ultrasonography has developed into a valuable imaging technique in almost all animal species because of the rapid development of technically improved portable units and their potential use at any given location, which is important in farm animals not being examined in a veterinary clinic. It is indeed a continuation of the clinical examination.[1]

The ultrasonographic examination is unique in its patient application because it is a dynamic examination technique with no risk to the patient or the sonographer. It is a continuation of the clinical examination. Ultrasonography is noninvasive, and well tolerated in unsedated animals. It enables serial examinations to monitor the progression of an abnormality or response to treatment. Ultrasonography requires considerable skill and experience to make a diagnosis. Some practitioners may hesitate before investing considerable resources in an ultrasound machine if they feel it will not be used regularly and if they believe they do not have enough time for the examination. Continuing education courses and workshops are becoming more common and they provide excellent training and the latest concepts. When employed correctly, ultrasonography is of great benefit to every veterinary clinician and practitioner in continuing the clinical examination. Ultrasonography can be valuable in examining the contents of cavitary lesions, synovial cavities, cysts or other fluid-filled lesions for the presence of liquid, semisolid or solid contents and/or effusion. Centesis of synovial cavities or body cavities, and biopsy of organs such as liver or kidney are now frequently done as part of the clinical examination. Ultrasonography enables accurate needle placement following ultrasonographic examination of the designated structure, assisting with the measurement of the distance from the skin surface to the structure when, for example, a freehand biopsy technique is to be performed.

The literature on the history of the development, advances and application of ultrasound in animals has been reviewed.[2]

When a pulse of ultrasound is directed into a substance, varying amounts are reflected back to the source according to the material encountered and the returning signal conveys information regarding the structures it has penetrated. Real-time brightness or 'B' mode imaging is currently the form of ultrasound most commonly used. Examination of moving structures such as the heart required a technique known as time motion or 'M' mode ultrasound.

During a routine ultrasound examination, real-time B mode provides information regarding the physical form and structure of tissues, allows subjective assessment of movement such as peristaltic contractions within the intestine and provides an overview that guides the application of other ultrasound modes. M mode is now an integral part of echocardiographic examinations and all modern ultrasound machines are equipped with this capability.

The benefits of ultrasound as a veterinary diagnostic imaging procedure are numerous.[2] Routine examinations have no harmful biological effects. It is a safe procedure for the animal, the operator and nearby personnel, allowing it to be done in any location without the need for specific safety precautions.

The ability of ultrasound to distinguish fluid from soft tissue and differentiate between soft tissues on the basis of their composition makes it more suited than radiography for examining soft tissue structures. Ultrasonography can often provide information that was previously only available through exploratory laparotomy. Ultrasound is limited by its inability to penetrate gas-filled or bony structures; therefore 'acoustic windows' must be found that avoid the interposition of bone or gas between the transducer and the region of interest, although this can often be achieved by judicious positioning of the patient. Transcutaneous examinations in animals require removal of the hair overlying the region of interest by clipping, as the beam cannot penetrate the air trapped between the hairs.

Examples of the use of ultrasonography in bovine practice include the diagnosis of gastrointestinal disease,[3] diseases of the mammary gland,[4] thoracic disease,[5] splenic disease,[6] ruptured gall bladder in cows[7] and the blood flow patterns in the common carotid artery and external jugular vein for cardiac and blood vessel disease.[8]

The use of ultrasonography as a reproductive management aid in dairy cattle practice represents a major advance in understanding reproductive biology in cattle.[9] The literature on the veterinary ultrasound equipment, imaging the bovine ovary (ovarian follicles, corpora lutea, ovarian cysts), the bovine uterus (early pregnancy diagnosis, early embryonic loss, identification of cows carrying twins, determination of fetal sex) and the diagnostic limitations of ultrasonic imaging has been reviewed.[9] Because nonpregnancy can be established 7–14 days earlier after artificial insemination (AI) using ultrasound compared with rectal palpation, nonpregnant cows can be detected earlier and returned to AI service, thereby improving the pregnancy rate through an increased AI service rate.

The use of ultrasonography to examine various body systems is described briefly in their respective chapters in the General Medicine part of the textbook. Readers are encouraged to consult the publications listed under Review Literature and References, and textbooks dealing with ultrasonography. Short courses and laboratory workshops are now commonplace and readily available and highly recommended. The development of extension education programs to train bovine practitioners is a critical step toward rapid implementation of this technology into the dairy industry.

Making a diagnosis

The practice of clinical veterinary medicine consists of two major facets: the making of a diagnosis and the provision of treatment and control measures. For treatment and control to be of optimum value the diagnosis must be as accurate as possible, so that diagnosis is the crux of all medical problems.

A diagnosis is the identification of the disease affecting the patient, and to be complete should include three parts:

- The specific cause
- The abnormality of structure or function produced by the causative agent, and which is inimical to normal body processes
- The clinical manifestation of that abnormality produced by the causative agent.

For recording purposes the animal species should also be included, for example, 'equine *Rhodococcus equi* pneumonia and lung abscess'. Many diagnoses fall short of this objective because of lack of confirmatory laboratory assistance. So clinical signs (such as bovine chronic diarrhea) or necropsy lesions (such as bovine polioencephalomalacia) are often used.

DIAGNOSTIC METHODS

At least five distinctly recognizable methods are used and they are presented here in order of increasing complexity. As a general rule the experienced clinician uses more of the simpler strategies, the novice clinician more of the complex ones. This is because the simple method omits several steps in the clinical reasoning process – the sort of appropriate and safe 'cutting of corners' that it is possible to carry out with confidence only after gaining wide experience and after paying a good deal of attention to assessing one's own personal competence as a clinician and especially as a diagnostician.

METHOD 1: THE SYNDROME OR PATTERN RECOGNITION

In the first few moments of viewing the patient, e.g. the pain-generated behavior of a horse with abdominal pain or the skin lesions of ecthyma in a sheep or papillomatosis in a cow, the diagnosis is made instantaneously and reflexly. The same experience may occur while taking the history: one may have to rely entirely on the history in the case of a cow having an epileptic seizure to be able to diagnose it. This recognition is based on the comparison of the subject case and previous cases in the clinician's memory and the one is recognized as a replica of the other. There is no need to seek further supporting advice and the definitive diagnosis is made then and there. In the hands of the wise and experienced clinician the method is quick and accurate.

METHOD 2: HYPOTHETICO-DEDUCTIVE REASONING

As soon as the client begins to relate the presenting signs, usually commencing with the key clinical sign, the clinician begins to draw up a short list of diagnostic possibilities, usually three or four. This is the process of generating multiple plausible **hypotheses** from initial cues. The clinician then begins to ask questions and conduct clinical examinations that test the hypotheses. The questions and examinations may be directed at supporting or discounting the tentative diagnoses (the confirm/exclude technique) but they may lead to the addition of more hypotheses and the deletion of some others. (The questions used here are search ones, aimed at supporting a hypothesis, and are distinctly different from scanning questions, which are 'fishing' expeditions looking for more key signs about which to ask search questions.) This process of hypothesis and deduction is continued until one diagnosis is preferred to the others. The original list of hypotheses may be expanded but not usually to more than seven, and in the final stages is usually reduced to two or three. These are then arranged in order of preference and become the list of **diagnostic possibilities**.

In farm animal medicine there is usually a general absence of both hard primary data and ancillary data such as clinical pathology, so that the clinician may be in the position of having to provide treatment for two or three possible illnesses. An example is the parturition syndrome of recently calved dairy cows in which the treatment of subacute mastitis, metritis and acetonemia is standard procedure because the clinician is uncertain about which disease is most accountable for the illness. In the more resourceful arena of a veterinary teaching hospital it may still be necessary to proceed in this way in the first instance but then to narrow down the list of hypotheses when additional information is received from the laboratory. This polypharmacy approach has a number of disadvantages, among which are included the additional expense and the increased possibility of contamination of food products of animal origin by medications, especially antibiotics and sulfonamides, and with resistant strains of bacteria.

One of the important characteristics of this strategy is the dependence on the selection of a critical or key clinical sign or cue on which to base the original hypotheses. The selection of the key sign and additional supporting clinical findings is done instinctively by experienced clinicians on the basis of prior experience in similar situations. For novice clinicians it may be necessary to examine two or more key signs.

METHOD 3: THE ARBORIZATION OR ALGORITHM METHOD

This is really an extension of method 2 but the hypothetico-deductive reasoning method is formalized and carried out according to a preplanned program. The hypothetico-deductive reasoning method depends on the clinician remembering and being aware of an all-inclusive list of diagnostic possibilities in the case under consideration. Because memory is unreliable and impressionistic the method is subject to error by omission. The arborization or algorithmic method similarly approaches a listed series of diagnoses and examines each one in turn with supporting or disproving questions; if they pass the proving test they stay in, if they fail it they are deleted. For example, a key sign of red urine in a cow promotes the question: *Has the cow had access to plant substances that color the urine red?* If the answer is no, the next question is: *Is the red color caused by hemoglobinuria or hematuria?* If the answer is hemoglobinuria, all the diagnoses on the hematuria branch of the algorithm are deleted and the questioner proceeds to the next question, which will attempt to determine whether the cow has postparturient hemoglobinuria or any one of a number of diseases characterized by intravascular hemolysis.

Provided that the list of possible diagnoses is complete and is frequently updated

as new diagnoses become available – and, just as importantly, as new ways of supporting or discounting each hypothesis are added as soon as they are published – the method works well. These algorithms are eminently suited to computerization and can be made available by the supply of floppy disks or by access to a central database via a modem, the online database, or dial-up information system.

The arborization method is well suited to the clinician who has not had the necessary experience for the memorization of long lists of potential diagnoses and the critical tests that confirm or exclude each of them. Because the algorithms are likely to include **all** the recorded diagnoses that have that particular key sign, error by omission is not a risk. Thus they are also valuable to the specialist, who is less able to afford an omission than the general practitioner and certainly cannot really afford to miss even the most obscure and unlikely diagnosis. Another major advantage is that they provide a system of tests that should be performed and clinical findings that should be searched for – which is really a form of clinical protocol, acting as a reminder of the sequential diagnostic steps to be taken. The arrangement of the algorithm represents the clinical reasoning of the person who designed it and it should have considerable merit, assuming that the designer was an expert. This characteristic does arouse the comment that the method does away with the need for the clinicians to do their own clinical reasoning. That may be so, but the interests of optimum clinical care of patients are probably better served by having first-year interns apply the clinical reasoning of a specialist and as a consequence achieve significantly better results.

METHOD 4: THE KEY ABNORMALITY METHOD

This is a more time-consuming method than the previous ones and requires that clinicians rely on their knowledge of normal structure and function to select the key abnormality or clinical cue. The method consists of five steps and is summarized in Figure 1.1.

Determination of the abnormality of function present

Disease is abnormality of function which is harmful to the animal. The first step is to decide what abnormality of function is present. There may of course be more than one and some clinically insignificant abnormalities may be present, e.g. a physiological cardiac murmur in a newborn foal. Definition of the abnormality is usually in general terms such as paralysis, state of the alimentary tract, hypoxia, respiratory insufficiency, nervous shock and so on. These terms are largely clinical, referring to abnormalities of normal physiological function, and their use requires a foreknowledge of normal physiology. It is at this point that the preclinical study of physiology merges into the clinical study of medicine.

The necessary familiarity with the normal, combined with observation of the case in hand, makes it possible to determine the physiological abnormality that may be, e.g. hypoxia. The next step is to determine the body system or body as a whole or organ involved in the production of the hypoxia.

Determination of the system or body as a whole or organ affected

Having made a careful physical examination and noted any abnormalities, it is

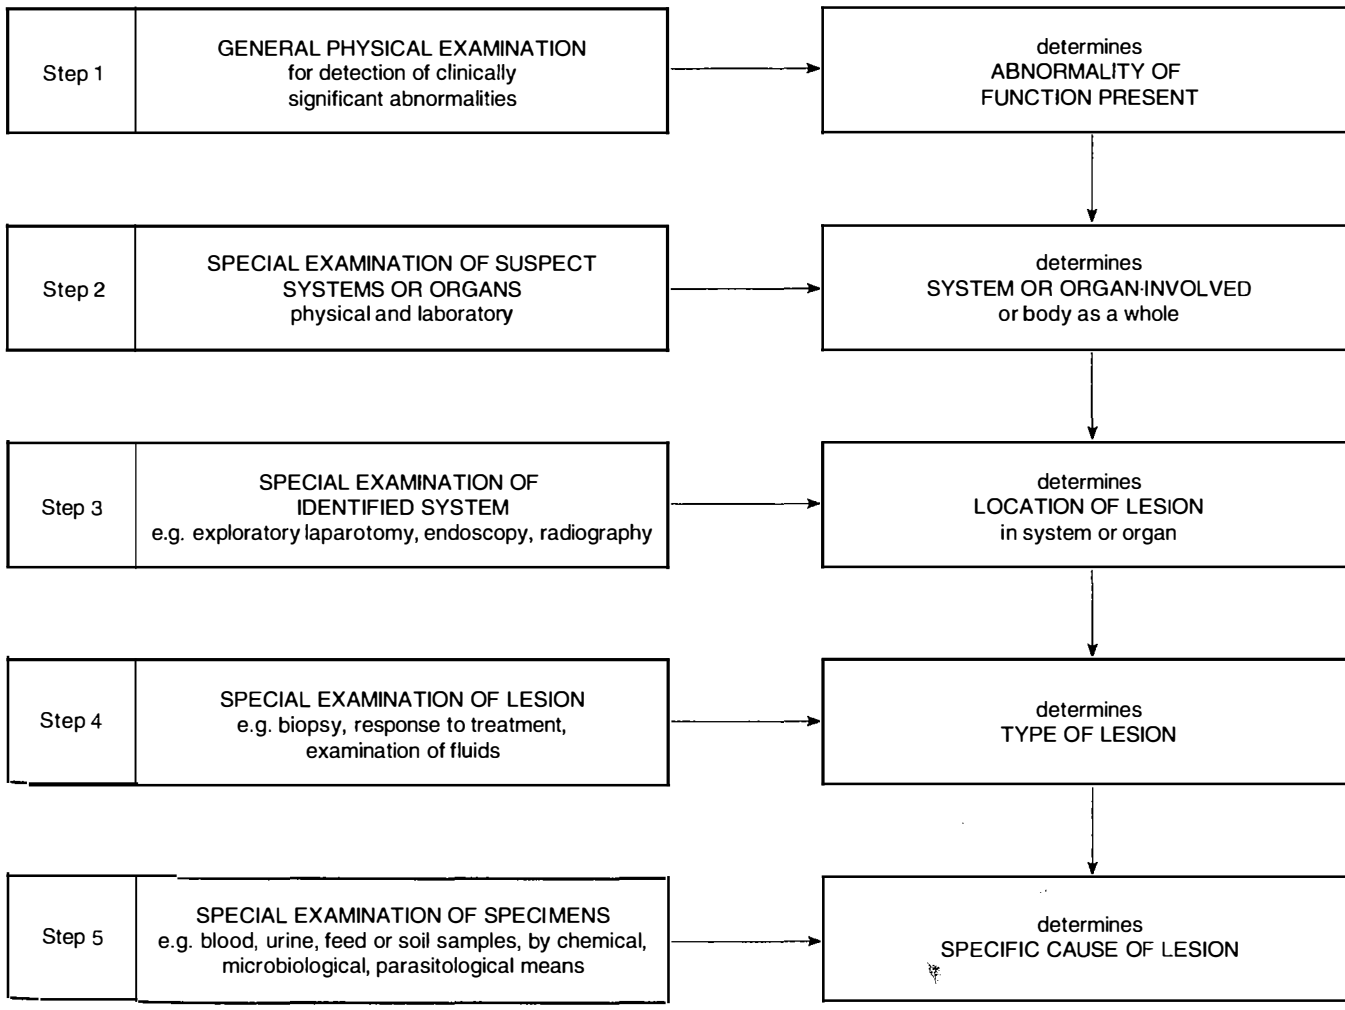

Fig. 1.1 Making a diagnosis.

then possible to consider which body system or organ is the cause of the abnormality. In some cases the body as a whole may be involved. This may not be difficult with some systems: for example, hypoxia may be due to failure of the respiratory or circulatory systems and examination of these is not difficult. However, special problems arise when attempting to examine the nervous system, the liver, kidney, endocrine glands, spleen and hemopoietic systems. Here, routine physical examination by palpation, auscultation and percussion is not very rewarding: special ancillary examination techniques with the aid of a laboratory are usually necessary. These are described under special examination methods for the various systems. As a guiding principle, all functions of the organ under examination should be observed and any abnormalities noted. For example, if the integrity of the central nervous system is to be examined, the clinician would look for abnormalities of mental state, gait, posture, muscle and sphincter tone and involuntary movements, abnormal posture and paralysis. Knowing the normal physiological functions of systems, one looks for aberrations of them.

When only simple physical examination is available it may be extremely difficult to choose between two or more systems as the possible location of the abnormality. For example, in an animal that is unable to rise from the recumbent position it may be difficult to decide whether the nervous system or the musculoskeletal system or generalized weakness from a systemic illness is the origin of the clinical recumbency. If special diagnostic techniques and laboratory evaluations are inconclusive or not available, it may be necessary to resort to probability as a guide. For example, paresis due to diseases of the muscles is most common in young calves, lambs and foals and generally uncommon in mature farm animals, with the exception of the myopathy associated with the downer cow syndrome in dairy cattle. However, paresis is common in mature cows affected with parturient hypocalcemia, peracute coliform mastitis and acute diffuse peritonitis.

Determination of the location of the lesion within the system or organ affected

The location of the lesion within the body system involved is not always obvious and may require special physical and laboratory examination techniques. For example, a detailed neurological examination may be necessary to localize the lesion in an animal with manifestation of disease of the nervous system. This may be combined with radiographic techniques such as myelography. An exploratory laparotomy with or without biopsy techniques may be necessary to determine the location of an intestinal lesion thought to be the cause of chronic diarrhea. Endoscopy is rapidly becoming standard practice for the localization of lesions of the respiratory tract of the horse. Radiography is often necessary to localize lesions of the musculoskeletal system and diseases of the feet of horses and cattle.

Determination of the type of lesion

The abnormality observed may be produced by lesions of different types. In general, lesions can be divided into anatomical or physical lesions and functional disturbances. The physical lesions can be further subdivided into inflammatory, degenerative or space-occupying. These classifications are not mutually exclusive, as a lesion may be both inflammatory and space-occupying: abscesses in the spinal cord or lung are typical examples. In these circumstances it is necessary to modify the diagnosis and say that such and such a lesion is space-occupying and may or may not be inflammatory.

The differentiation between functional disturbances and physical lesions is often extremely difficult because the abnormalities produced may be identical. For example, in a case of hypomagnesemia in a cow there is no physical lesion but differentiation from the encephalitis of furious rabies may be impossible. As a rule, functional disturbances are transient, often recurrent or fluctuating and are readily reversible by treatment, whereas structural lesions cause changes that are relatively static or at least change slowly and are affected only gradually by treatment. This is by no means a regular rule: the acute abdominal pain of intestinal obstruction usually fluctuates but the lesion is a physical one, whereas the paralysis of parturient paresis in cattle is static but the disturbance is functional only.

Differentiation between inflammatory, degenerative and space-occupying lesions is usually simpler. The latter produce signs characteristic of pressure on surrounding organs and can often be detected by physical means. Inflammatory lesions are characterized by heat, pain, swelling and a local or general leukocytosis and, in severe cases, a systemic toxemia. A total white blood cell count and differential is a **sensitive** but **nonspecific** test for the presence of an infection. A leukopenia, neutropenia and a degenerative left shift suggests a severe infection. A neutrophilia and regenerative shift suggests an active chronic infection. The most common infections of cattle, which are often not readily obvious, are in the thoracic and abdominal cavities (pleuritis, pulmonary abscesses, pericarditis and peritonitis). Degenerative lesions produce the same loss or abnormality of function as lesions of the other types but are not usually accompanied by evidence of inflammation unless they are extensive. If the lesion is accessible, biopsy should be considered as a means of determining its nature.

Determination of the specific cause of the lesion

If in the system involved, the nature of the abnormality and the type of lesion can be satisfactorily determined, it then remains to decide on the specific causative agent. If, for example, it could be said that a particular case of paralysis in a calf was caused by a degenerative lesion of the musculature, only a few specific etiological agents would have to be considered to make a final diagnosis. In many, if not most cases it is impossible to go beyond this stage without additional techniques of examination, particularly laboratory examinations, and it is a general practice to make a diagnosis without this confirmatory evidence because of limitations of time or facilities.

It is at this stage that a careful history-taking and examination of the environment show their real value. It is only by a detailed knowledge of specific disease entities, the conditions under which they occur, the epidemiology and the clinical characteristics of each disease that an informed judgment can be made with any degree of accuracy. If the diagnostic possibilities can be reduced to a small number, confirmation of the diagnosis by laboratory methods becomes so much easier because there are fewer examinations to be made and confirmation by response to treatment is easier to assess. If it is necessary to treat with a great many drugs serially or in combination to achieve a cure, the expense is greater and the satisfaction of both the client and the veterinarian is diluted in proportion to the range of treatments. Accuracy in diagnosis means increased efficiency, and this is the final criterion of veterinary practice.

METHOD 5: THE DATABASE METHOD

The basis of this method (also called the **Weed** or **problem-oriented method**, is to conduct a complete clinical and clinicopathological examination of the patient in order to acquire a comprehensive patient database. The problems (key signs) in this database are then matched with the diagnostic database, in which collections of signs or syndromes are labeled with diagnoses, to select the best fit with the patient's data.

This method also uses the **problem-oriented veterinary medical record**

system, which is an excellent system for the daily recording of clinical and laboratory data in an orderly, systematic and consistent manner that can be easily followed by clinicians and their colleagues. This system is now used widely by veterinary teaching hospitals. The system has four components based on the four phases of veterinary medical action:

- Database
- Problem list
- Initial plans
- Progress notes.

The progress notes are created daily and divided into four parts known collectively by the acronym SOAP to designate:

- S: subjective information
- O: objective data
- A: assessment of problem
- P: plans, which may include diagnostic, therapeutic or client education.

The method requires that clinicians be very painstaking in their examination and recording. It places great demands on the time spent by clinicians and clinical pathologists, on laboratory resources and on clinical record storage. Much of the data has no diagnostic significance because the diagnostic decisions are made largely on the presence or absence of relatively few key signs. It also has the disadvantage that there is a tendency to make the patient fit a category. It is the opposite of the **key abnormality** method, in which only the signs and other indicants relevant to the proposed diagnosis are sought and recorded. Because of its requirement of time and data recording and storage this method is not suitable for use in food animal medicine, where speed is a vital component of the diagnostic process. As mentioned earlier, however, it is an excellent system for the teaching of clinical veterinary medicine.

The method is really an expanded version of the hypothetico-deductive method, where the hypotheses are made sequentially as further information becomes available. In the database method all the hypotheses are pursued in parallel because all the possible data have been collected into the patient's database. The source of error in the method is the possibility of undue importance being attached to a chance abnormality in, say, the clinical biochemistry. If the abnormality cannot be matched to a clinical sign, it should be weighted downwards in value or marked for comment only. The same error may result from inclusion of a sign that is important, e.g. diarrhea, but that happens to be present at low intensity.

INTERPRETATION OF LABORATORY DATA

WHEN TO COLLECT LABORATORY DATA

Collection of a full history and performance of a purposeful physical examination are the most powerful tools available to the veterinarian in determining the nature of an animal's disease and its likely cause. However, laboratory data, including results of clinical, biochemical, hematologic, serologic, radiographic, electrocardiographic, ultrasonographic and other examinations, are often obtained from individual animals or groups of animals. The reasons for collecting laboratory data can be summarized as:

- To confirm the presence or cause of a disease
- To assess the severity of a disease
- To predict the clinical course of a disease or to determine a prognosis
- To estimate the likely response to therapy
- To determine the response to therapy or monitor progression of a disease
- To satisfy regulatory requirements
- To determine the disease or immune status of an animal, herd or flock.

Collection of laboratory data should not be viewed as a fishing expedition performed in the hope that 'something will turn up'. The decision to collect laboratory data should always be made with one or more of the above aims, with the intention that the data collected will answer a particular, clearly stated question. It is very easy, when faced with a sick animal with clinical signs that are not clearly diagnostic or indicative of the organ system involved, to request a 'serum biochemical profile' and complete blood count without having a clear idea of the usefulness of the information provided by the results of these tests. While the usefulness of these tests in most cases is very clear, the results of the tests are most informative when used to address a particular question, for instance: does the animal have evidence of kidney disease?

A test should never be performed unless one can anticipate all the likely results and provide a meaningful interpretation for each. Collecting laboratory data for the sake of running a test or as an act of diagnostic desperation is wasteful of resources and will not, in all likelihood, contribute to management of the animal or group of animals. It is more likely that the results of the test will be uninterpretable and will muddy the diagnostic picture.

PROPERTIES OF DIAGNOSTIC TESTS

The following properties of a test, and of the population to which it is applied, should be known before it is considered to be reliable:

- The test should be developed and validated in the population of interest. Tests developed in one population might not be valid in an animal from another population. For instance, tests developed for use in one species might not be reliable if used in another species
- You should know how accurate the test is in the situation in which you intend to use it
- The **specificity** of the test, i.e. the ability of a positive result of the test to rule in the disease of interest, should be known. While this is a property of the test that is usually independent of the prevalence of the disease in the population being tested, this might not always be the case
- The **sensitivity** of the test, i.e. the ability of a negative result of the test to rule out the disease of interest, should be known. While this is a property of the test that is usually independent of the prevalence of the disease in the population being tested, this might not always be the case
- The pre-test likelihood of the disease in the population should be known. This permits calculation of post-test odds of the animal having (**positive predictive value**) or not having (**negative predictive value**) the disease for which it is being tested
- The likelihood ratios of the various test results should be known for the population of animals being tested
- The reliability of the laboratory performing the test should be known. There should be considerable confidence in the quality control of the laboratory such that test results are repeatable and reliable
- Are the references ranges (values in animals without the disease or condition of interest) known and with what certainty are they known? The meaning of an abnormal test result should be clear
- The test should allow you to rule in or rule out one of the differential diagnoses, in the instance in which a test is being used for diagnostic, as opposed to monitoring or other purposes
- All test results should be interpretable. In other words, all results should provide information that will be of use in diagnosis or monitoring.

Utility

To be useful, a diagnostic test must be accurate. An accurate test reliably

differentiates between normal and diseased animals, thereby contributing to effective management of the animal or its disease. Inaccurate diagnostic tests provide unreliable data, which in the best scenario are useless and in the worst scenario cause mismanagement of the animal or its disease. The diagnostic accuracy of a test should be known before it is used extensively and a test of unknown diagnostic accuracy should be assumed to be inaccurate until proven otherwise.

The usefulness of a test to a veterinarian depends on a number of factors. Firstly, the test must be accurate, as discussed above. Secondly, it should be technically feasible and reliable, i.e. the test must be readily performed and its characteristics (listed above) must be known. A test that cannot be readily performed has minimal usefulness and unreliable tests are inaccurate. For testing of analytes, such as serum biochemical analysis or serology, it is important that the analysis yields results that are accurate and precise. Laboratory tests that are accurate yield results that are the same (or very close to) the true value of the variable being measured. Precise tests yield results that have very little variability around the expected value. Note that a test can be precise without being accurate, i.e. it has little variability but yields a value that is different from the actual value. Tests that are inaccurate or are highly variable (have poor precision) are not useful because the results are unreliable.

Thirdly, the test must have diagnostic utility in that the results of the test should enable the veterinarian to make a decision that will affect the subsequent management of the animal or its disease. If the results of the test will not alter the animal's management or treatment of its disease nor improve its production or prognosis, then the test has no diagnostic utility and should not be performed. The diagnostic utility depends on the characteristics of the test in the population of animals being tested. The important characteristics, which should be known before the test is widely used, are the sensitivity and specificity of the test and the likelihood ratios associated with the possible results, in the population in which it will be used. That a test has sensitivity and specificity implies that there is a range of values expected in normal animals, the so-called 'reference range'.

Reference range (Interval)

An important aspect of evaluating laboratory data is to decide whether or not the result of a test is consistent with the animal being healthy or diseased. Healthy animals are assumed to have values within a certain range, whereas diseased animals may have values that differ from that expected in a healthy animal. The range of values in healthy animals is often referred to as being the 'normal range' although, because of the statistical connotation of this term, 'reference range' or 'reference interval' is preferred.

The reference range represents the range of values of a test that are expected in a group of healthy animals. Animals with values outside the reference range are at increased risk of having the disease, compared to animals with values within the reference range. The actual increase in risk of being diseased depends on the way in which the reference range was determined, the sensitivity and specificity of the test and the prevalence of the disease in the population from which the animal was selected. Calculation of likelihood ratios, both positive and negative, is a useful means of quantitatively assessing the results of a test.

The reference range for a particular test is usually developed by collecting values from a large number of healthy or 'normal' animals and performing a statistical analysis of the values. For variables that have a range of possible values (e.g. serum urea nitrogen concentration), as opposed to being either present or absent (e.g. seropositive or seronegative for antibodies to a disease), the range of values in normal animals will have a characteristic spread. For the range of values of the variable in normal animals, an upper and a lower value are chosen that represent the upper and lower limits of the reference range. These values are usually chosen to include 95% of the values from normal animals, calculated as the mean value for the population of normal animals plus or minus 2 standard deviations, or as the 2.5–97.5 percentile range.

Problems with reference ranges

There are problems with using the reference range of normal animals to diagnose diseased animals. Firstly, 5% of normal animals will have values for the test that are outside the reference range and may be incorrectly diagnosed as being diseased (**false positive**). Although a 5% false-positive rate is very low, the error is compounded when batteries of tests are run at the same time. This is a potentially serious problem when interpreting data from a serum biochemical profile analysis, in which 20 or more analytes may be measured simultaneously from one animal. The risk of the value of any one analyte being outside the normal range is only 5%, but when 20 analytes are measured simultaneously the chance of finding one analyte of the 20 with a value outside the reference range is almost 66% ($100(1-0.95^{20})$).

This problem can be mitigated in several ways. Firstly, serum biochemical profiles often contain more than one variable that is indicative of a particular disorder. If disease affecting a particular organ system is present, then there should be appropriate changes in all variables indicative of disease in this system. For instance, most serum biochemical profiles measure both serum creatinine and urea nitrogen concentrations. An elevation in the serum urea nitrogen concentration may be indicative of renal disease, but if the serum creatinine concentration is not also increased, then the likelihood of important renal dysfunction is much less than if both analytes were above the reference range. Secondly, disease may be associated only with marked increases in value of the variable such that unusually low values could be disregarded. For example, a serum creatinine concentration below the reference range is very unlikely to indicate the presence of renal disease, and a serum creatine kinase activity below the reference range has almost no diagnostic value. Thirdly, the extent to which the variable is outside the reference range should be considered. A small difference from the reference range is much less likely to indicate the presence of disease than is a much larger difference – calculation of likelihood ratios is one way of expressing this effect of variables that are markedly abnormal.

Another problem with using the reference range to detect disease is that not all diseased animals will have a value for the variable of interest that is outside the normal range. Some diseased animals will have values of useful variables that are within the reference range and these animals may be falsely diagnosed as not having the disease (**false negative**). This problem can be mitigated by reducing the size of the reference range, although this will increase the false-positive rate, or by measuring other variables that are also useful in detecting the suspected disease. For instance, an animal with liver disease may have a value of the serum activity of a hepatic enzyme that is within the reference range suggesting the lack of liver disease (a false-negative result). However, the same animal may have marked increases in serum bilirubin and bile acid concentrations, findings strongly suggestive of liver disease.

Sensitivity and specificity

The sensitivity of a test is a measure of the test's ability to detect animals that are diseased and its numerical value represents the proportion of animals with

Table 1.3 Method for determining sensitivity, specificity, likelihood ratio for positive and negative tests, positive predictive value and negative predictive value of a test

	True disease status	
	Disease present	**Disease absent**
Test positive	True positive (TP)	False positive (FP)
Test negative	False negative (FN)	True negative (TN)

Sensitivity = (TP/[TP + FN]) × 100
Specificity = (TN/[FP + TN]) × 100
Likelihood ratio positive test = Sensitivity/(1 – Specificity)
Likelihood ratio negative test = Specificity/(1 – Sensitivity)
Positive predictive value = TP/(TP + FP)
Negative predictive value = TN/(TN + FN)

the disease that are detected by the test (Table 1.3). A test with high sensitivity will detect most diseased animals within a population.

The specificity of a test is a measure of the test's ability to detect animals that are not diseased and its numerical value represents the proportion of normal animals detected by the test. A highly specific test will rule out the disease in most normal animals. Stated another way, a negative result for a test with high sensitivity effectively rules out the disease being tested for, whereas a positive test result for a test of high specificity effectively rules in the disease for which the animal is being tested.

Sensitivity and specificity are intrinsic properties of the test and their values are not influenced by the likelihood before the animal is tested that it has the disease for which it is being tested. The ability of a test to detect whether an animal has a particular disease depends on the likelihood that the animal has the disease at the time it is tested (the prevalence of disease in the population from which the animal being tested is drawn) as well as on the sensitivity and specificity of the test. The sensitivity and specificity can be combined to produce a single number, the likelihood ratio.

Likelihood ratio

The likelihood ratio is an overall measure of the efficiency of the diagnostic test, combining both sensitivity and specificity (Table 1.3) and permitting the calculation of post-test odds of the disease from the pre-test odds of disease. The likelihood ratio is a quality of the test and is not influenced in most instances by the prevalence of the disease in the population. The likelihood ratio is useful for quantifying the post-test odds of an animal having the disease. For instance, in hospitalized neonatal foals, a positive stall-side test for failure of transfer of passive immunity has a likelihood ratio of 4.86. A foal with pretest probability of having the disease of 50% that has a positive test (i.e. indicative of lack of passive immunity) therefore has a post-test probability of having the disease of 81%.[1]

Positive and negative predictive value

The combined effects on the ability of the test to correctly detect diseased or healthy animals of (a) the prevalence of the disease and (b) the sensitivity and specificity of the test can be calculated and are called the positive predictive value (PPV) and negative predictive value (NPV) respectively. These are important values because they determine the usefulness of the test in detecting diseased, or normal, animals. The positive predictive value is the likelihood that a positive test is from an animal with the disease. The negative predictive value is the likelihood that a negative test is from an animal that does not have the disease.

Both the PPV and NPV are inextricably linked to the prevalence of the disease in the population being tested. Reports of the PPV and NPV are therefore only useful for populations of animals similar to those in which the values of these variables was determined, especially with regard to the prevalence of the disease in the population. The prevalence of the disease can also be viewed as the probability that an animal selected at random from the population has the disease – it is the pretest probability of disease in the animal. For a test of given sensitivity and specificity, the likelihood that a positive test correctly predicts the presence of disease (the PPV) increases as the proportion of diseased animals in the population increases (the disease has higher prevalence). Conversely, the NPV increases as the prevalence of the disease decreases.

The effect of changes in prevalence on the PPV and NPV of two tests with differing sensitivities and specificities is illustrated in Table 1.4. The probability that either test will detect the presence of disease in an animal with a high pretest likelihood of having the disease is very high. Similarly, the probability that a negative result is indicative of the absence of disease in an animal from a population with very low prevalence of disease is also very high. Importantly, the ability of a very good test (sensitivity and specificity both 95%) to correctly predict the presence of disease in an animal with a positive test from a population with a low prevalence (1% of animals affected) of the disease is very poor. Applied to an individual animal, this means that even a very good test is likely to yield an incorrect result in an animal that is unlikely to have the disease.

Conversely, although the test result is very unlikely to be incorrect, a positive result in an animal with a very high pretest probability of having the disease yields little further information. The test result does not increase the likelihood of the animal having the disease by very much. The diagnostic test has its greatest utility when the pretest probability of disease is approximately 50% and the increase in PPV and NPV is much greater for a test with higher sensitivity and specificity.

The pre-test probability of disease, and thus the positive predictive value of the test, can be increased by selecting animals to be tested through careful physical examination and collection of an appropriate history. The PPV of a test in an animal that has signs of the disease being tested for is much higher than the PPV of a test in an animal without signs of the disease. Testing clinically normal animals

Table 1.4 Effect of changes in prevalence (pretest probability of disease) on the positive predictive value (PPV) and negative predictive value (NPV) of tests with 95% sensitivity and specificity (Test A) and 60% sensitivity and specificity (Test B)

Prevalence or pretest probability of disease (%)	Test A PPV (%)	NPV (%)	Test B PPV (%)	NPV (%)
1	17	99	1	99
10	67	99	14	92
25	85	98	33	82
50	95	96	60	60
75	98	86	83	31
90	99	65	94	12
99	99	19	99	1

is more likely to yield false-positive than true-positive results and such indiscriminate testing is not wise.

COMPUTER-ASSISTED DIAGNOSIS

In the 1980s there was considerable interest in computer-assisted diagnosis. The entry of the clinical and laboratory data from a patient into a computer program could yield a differential diagnosis list of diseases in order of highest to lowest probability. However, despite over 20 years of activity and interest in the use of computers for diagnosis, the impact of computer-assisted diagnosis in medical practice has been slight. Computerized programs have been useful in circumscribed areas such as the differential diagnosis of abdominal pain in humans and the diagnosis and treatment of meningitis. However, no program developed for use in a specific localized area of the body has been successfully adapted for generalized use. Theoretically, the computer could be expected to be useful to aid the clinician with the workup in order to make multiple and complex diagnoses.

Research on clinical decision-making has confirmed the importance of creating the list of differential diagnoses or diagnostic hypotheses. A clinician faced with a diagnostic problem must use clinical findings to develop a list of possible diagnoses. With a knowledge of the epidemiological and clinical characteristics of each disease, the veterinarian can confirm or exclude certain diagnostic possibilities. Diagnostic acumen depends on the ability to recognize the most important clinical abnormalities and to generate a list of differential diagnoses – a task that becomes more efficient with experience.

Specialists can generate many differential diagnoses in a narrow area of expertise, but the breadth of knowledge required in general practice makes it difficult for generalists to keep current on rare or unusual conditions. If a disease is not considered by the clinician faced with a presenting problem, it is frequently overlooked as a possibility and may not be 'stumbled-on' during the diagnostic process. This problem is complicated in veterinary education by the common practice of teaching according to disease entity. All the nosology of a disease is presented in a standard format but the information must then be used in reverse order in clinical practice: the clinician generates a list of diseases based on the history and clinical findings. Textbooks that feature lists of differential diagnoses for animals with similar clinical findings assist in this task, but rapidly become outdated because of the many major and minor clinical findings that can be associated with a disease. The large storage capacity of computer databases and the ease of access to stored data makes the computer useful for handling this sort of information.

The success of a computer-assisted diagnosis will depend first on the clinician determining the important finding or **forceful feature** or **pivot** of the case, which can be useful in separating possible look-alike diseases. The second most important requirement is to know the propensity for a certain clinical finding to occur in a disease syndrome. The algorithm is the center of a computer-aided diagnostic system. Statistical algorithms calculate the most likely diagnosis from explicit statistical analysis of disease probabilities and the frequency of clinical findings in a particular disease.[1] A statistical algorithm is based on the Bayes theorem. The posterior probability that an animal has a given disease can be calculated if one has access to:

- The incidence (prior probability) of the disease
- The probability of a given clinical finding if the animal has the disease
- The probability of the same clinical finding occurring if the animal has the disease.

After receiving the data, the computer uses this theory to calculate the likelihood of various diseases. However, a major problem of a Bayesian system is the non-availability of an order of probabilities of the incidence of diseases and clinical findings associated with them. There is a need in veterinary medicine to generate comprehensive databases from which the probabilities of incidence and clinical finding for each disease can be determined from actual clinical practice.

In spite of these limitations, some progress is being made in the development of computer-assisted diagnosis in veterinary medicine. One computer-assisted diagnostic system for veterinary medicine was developed at the College of Veterinary Medicine, Cornell University, Ithaca, NY. The CONSULTANT program designed by M. E. White and J. Lewkowicz[2] is available on the Internet at: http://www.vet.cornell.edu. The Web version of the CONSULTANT program is based on the 1996 database. Direct access to the most current database of CONSULTANT at the College is possible using dial-in or telnet.

The data bank contains a description of several thousand diseases of dogs, cats, horses, cattle, sheep, pigs and goats. For each disease, there is a short description, including information on diagnostic testing, a list of current references, and a list of the clinical findings that might be present in the disease. The clinician enters one or more of the clinical findings present in a patient. The computer supplies a list of the diseases in which that clinical finding or combination of clinical findings are present. The complete description can be retrieved for any disease in the list of differential diagnoses. The program is available by long-distance telephone and a modem. A major limitation of the program to date is that the list of differential diagnoses is not in order of probability from highest to lowest. This is because the program does not include the probability of incidence and clinical findings for each disease, information that, as mentioned earlier, is not yet available.

Experience with the Cornell CONSULTANT program has shown that computer-assisted diagnosis is not used in day-to-day management of routine cases but is used primarily when faced with an unusual problem, to provide assurance that a diagnosis was not overlooked. Computerized databases also offer a mechanism for the generalist to search through a complete list of differential diagnoses compiled from the recorded experience of many specialists and kept current as new information is published. Practitioners feel that having access to CONSULTANT is also a significant part of continuing education and a source of references. Experience with a computer-assisted diagnostic system has also confirmed the importance of an accurate history and an adequate clinical examination. If an important clinical finding is not detected, or not adequately recognized – for example, mistaking weakness of a limb for lameness due to musculoskeletal pain – the computer program will be ineffective. Disagreement between observers about the meaning of a clinical finding will also continue to be a problem as computer-assisted diagnosis becomes more widely used.

At the present time, the most important service the computer can provide in making a diagnosis is the generation of a hypothesis through the generation of a list of differential diagnoses, and access to further information. Computers will probably not be able to make a definitive etiological diagnosis but they are able to remind the user of diagnoses that should be considered and to suggest the collection

of additional data that might have diagnostic value.

Prognosis and therapeutic decision-making

The dilemma of whether or not to administer a certain drug or perform a certain operation in an animal patient with or without an established diagnosis, or when the outcome is uncertain, is familiar to veterinarians. Owners of animals with a disease, or merely a minor lesion, expect to receive a reasonably accurate prediction of the outcome and the cost of treatment, but often considerable uncertainty exists about the presence or absence of a certain disease, or its severity, because confirmatory diagnostic information is not available.

The information required for a reasonably accurate prognosis includes:

- The expected morbidity and case fatality rates for the disease
- The stage of the disease
- Whether or not a specific treatment or surgical operation is available or possible
- The cost of the treatment.

If success is dependent on prolonged and intensive therapy, the high cost may be prohibitive to the owner, who then may select euthanasia of the animal as the optimal choice. Veterinarians have an obligation to keep their clients informed about all the possible outcomes and the treatment that is deemed necessary, and should not hesitate to make strong recommendations regarding the treatment or disposal of a case. There are also different levels of outcome, which may affect the prognosis and therapeutic decision-making. In the case of breeding animals, mere survival from a disease is insufficient and treatment is often not undertaken if it is unlikely that it will result in complete recovery and return to full breeding capacity. Slaughter for salvage may be the most economical choice. In other cases, e.g. a pleasure horse, the return of sufficient health to permit light work may satisfy the owner.

DECISION ANALYSIS

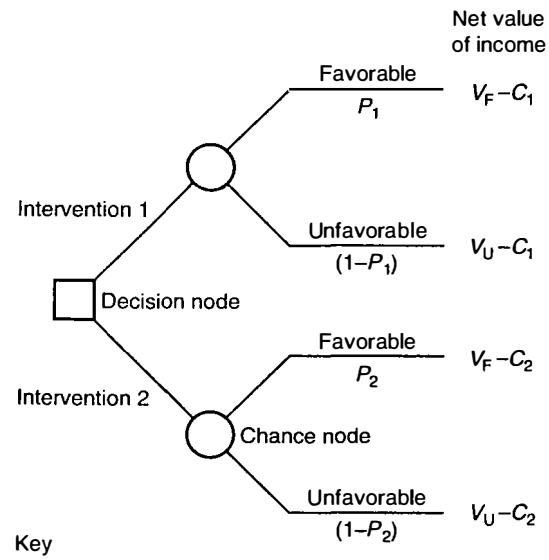
Veterinarians must routinely make decisions that have economic consequences for the client and the veterinarian. Questions such as whether to vaccinate or not, whether to treat an animal or recommend slaughter for salvage value, whether or not to perform surgery, or even which surgical procedure to use to correct a case of left-side displacement of the abomasum, are common.[3] Many of these questions are complex, requiring several successive decisions, and each decision may have more than one outcome. Clinical decisions are not only unavoidable but also must be made under conditions of uncertainty. This uncertainty arises from several sources and include the following:

- Errors in clinical and laboratory data
- Ambiguity of clinical data and variations in interpretations
- Uncertainty about the relationships between clinical information and presence of disease
- Uncertainty about the effects and costs of treatment
- Uncertainty about the efficacy of control procedures such as vaccination or the medication of feed and water supplies in an attempt to control an infectious disease.

The process of selecting a management plan from a range of options involves a mental assessment of the available options and their probable outcomes. Decision analysis provides a framework for handling complex decisions so that they can be more objectively evaluated. Decision analysis is a systematic approach to decision-making under conditions of uncertainty. Because the technique can be so useful in sorting out complex questions associated with the treatment and control of disease in individual animals and in herds, it is almost certain to become more commonly used by large-animal practitioners.

Decision analysis involves identifying all available choices and the potential outcomes of each, and structuring a model of the decision, usually in the form of a decision tree. Such a tree consists figuratively of nodes, which describe choices and chances, and outcomes. The tree is used to represent the strategies available to the veterinarian and to calculate the likelihood that each outcome will occur if a particular strategy is employed. A probability value must be assigned to each possible outcome, and the sum of the probabilities assigned to the branches must equal 1.0. Objective estimates of these probabilities may be available from research studies or from a veterinarian's own personal records or it may be necessary to use subjective estimates. The monetary value associated with each possible outcome is then assigned, followed by calculation of the expected value at each node in the tree. At each decision node the value of the branch with the best expected value is chosen and that becomes the expected value for that node. The expected value establishes a basis for the decision. An example of a decision tree without probability values assigned is shown in Figure 1.2.[4]

In the decision tree, choices such as the decision to use intervention no. 1 or intervention no. 2 are represented by squares, called **decision nodes**. Chance events, such as favorable or unfavorable outcomes, are represented by circles called **chance nodes**. When several



Key
P_1 = Prognosis for a favorable outcome following intervention 1
P_2 = Prognosis for a favorable outcome following intervention 2
V_F = Revenue obtained from a favorable outcome
V_U = Revenue obtained from an unfavorable outcome
C_1 = Cost of intervention 1
C_2 = Cost of intervention 2

Fig. 1.2 A decision tree for choosing between two interventions. (With permission from Fetrow J et al. J Am Vet Med Assoc 1985; 186:792–797.)

decisions are made in sequence, the decision nodes must be placed from left to right in the same order in which the decisions would have to be made, based on information available at that time. The tree may become very complicated, but the basic units of choice and chance events represented by squares and circles remain the same. Lines, or **branches**, follow each node and lead to the next event. The branches following each decision node must be exhaustive; for example, they must include all possible outcomes, and the outcomes must be mutually exclusive.[3] After each chance node there is a probability that an event occurs. The probabilities following a chance node must add up to 1.0. The probabilities are placed on the tree following the chance node. The expected outcomes (V_F and V_U in Fig. 1.2) are entered at the far right of the tree. The outcomes represent the value that would result if the events preceding them on the tree were to take place, and must include the costs of the intervention.

When a complete tree accurately representing the problem has been constructed, the next step is to solve it for the best decision to follow. This is done by starting at the right of the tree, where outcome values are multiplied by the probabilities of outcome at the preceding chance node. The figures derived from this procedure are added together to obtain the equivalent of a weighted average value at the chance node, known as the **expected value**, which by convention is circled with an oval. This procedure is repeated from right to left on the tree at each chance node. When a decision node is reached when moving from right to left, the most profitable path is chosen and a double bar is drawn across the branches leading to the lesser cost-effective decisions. When the first decision node at the left of the tree is reached, a single path will remain that leads from left to right and has not been blocked by double bars. This path represents the best way to handle the problem according to the available information, including the outcome at the end of that path.

An example of the construction and use of a decision tree to assist in deciding at what day postpartum an ovarian cyst should be treated, as opposed to waiting for spontaneous recovery, is illustrated in Figure 1.3.[4] In structuring the problem, over time, the clinician knows that the cyst can be treated or left to be treated later. Retreatment is possible if the first treatment is ineffective. The structure must include all alternatives. The other information needed to solve the problem includes:

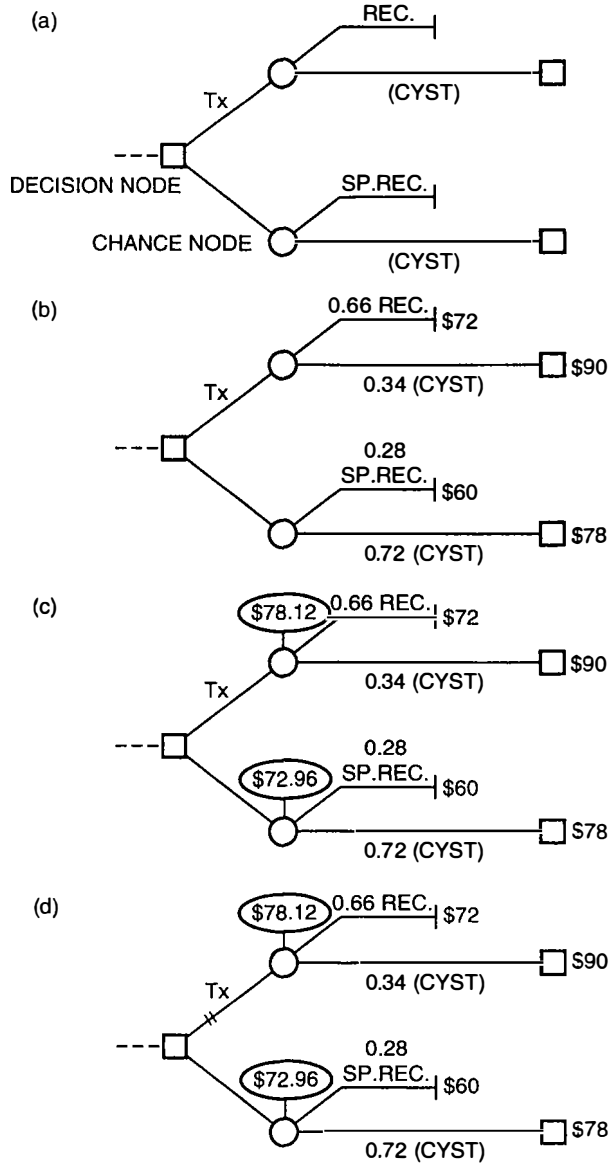


Fig. 1.3 Example of the construction and use of a decision tree. The sources of probabilities and dollar values are discussed in the text. (a) The skeleton of the decision tree with a decision (treat Tx versus do not treat) and chance outcomes (recovery (REC) or spontaneous recovery (SPREC) versus continued cyst (CYST)). (b) Probabilities and previously calculated outcome values are placed on the tree. (c) Expected costs of decision alternatives have been calculated and written in balloons above the chance nodes. (d) At this decision node, the correct choice is no treatment because it is cheaper ($72.96 v $78.12). Double bars mark the pathway that is not chosen (treatment). The value $72.96 is then the outcome cost for this decision node. The value is used in the calculation of the best alternative to the previous decision node, as the process is repeated from right to left (not shown). (With permission from White ME, Erb HN. Comp Cont Educ Pract Vet 1982; 4:S426–S430.)

- The incidence or chances of spontaneous recovery
- The response to treatment, both initially and following repeated treatments
- When the response occurs
- The cost of treatment and the cost of the disease.[4]

The critical factor in each tree is the probability value for each possible outcome. The monetary value of each outcome can be estimated on a daily basis but, unless the probability of the outcome can be assessed as accurately as possible, the decision analysis will be unreliable. Decision analysis has been used to determine the cost-effectiveness of heat mount detectors, the time at which to treat bovine ovarian cysts, the effectiveness of three alternative approaches to the control of *Haemophilus* meningoencephalitis in feedlot cattle, the

economically optimal control strategy among several alternatives for the control of infection with *Brucella ovis* in a sheep flock[5] and the relative merits of testing or not testing calves entering a feedlot with a metabolic and cellular profile test as predictors of performance in the feedlot. Decision analysis can now be done on microcomputers which makes the process highly suitable for assisting the veterinarian in daily decision-making.

The details of the steps used in decision analysis of several different problems in food-animal practice have been described and the reader is referred to the publications for further information.[4] There are some limitations to using decision analysis in animal health programs:[6] the technique requires time and effort, which practitioners are reluctant to provide unless the benefits are obvious. The estimates of the probabilities associated with the respective branches of the tree are seldom readily available.

A number of techniques that can be used to derive these probabilities and incorporate them in decision-making have been recorded. The rapidly developing use of analytical veterinary clinical epidemiology can now provide the tools to generate the numerical data necessary to make reliable decisions. There is a need to apply epidemiological principles to prospective clinical studies to determine the most effective therapy or the efficacy of control procedures for the commonly occurring economically important diseases of food-producing animals. The inputs and outputs of a given strategy may not have a market value, or the market value may not be an appropriate measure, or they may not be tangible or measurable in the usual monetary units. For example, the market value of a dairy cow may not represent the true or real value of the cow to the farmer. The farmer may consider the value of the cow in relation to cattle replacement determinants such as herd size, the availability of replacements and the genetic potential of the animal. The final selection of one option or the other is usually a complex process that will also vary from individual to individual depending on the decision criterion used.

In summary, decision analysis provides a systematic framework for making rational decisions about major questions in animal health and it is hoped that some veterinarians will adopt the technique for field use.

Examination of the herd

The examination of the herd assumes importance where there are outbreaks of disease or problems of herd productivity due to subclinical disease. The purpose of a herd examination is to define the exact nature of the problem and to identify those dysfunctions within the herd environment that are associated with its occurrence. The ultimate objective in the examination of a herd is to establish strategies for the treatment, correction and control of the disease problem at the herd level. This may involve strategies to increase the resistance of the animals or strategies that change adverse factors in the herd environment.

There are a number of ways in which these objectives can be achieved and they are not mutually exclusive. The methods for examination of the herd include:

- Initial definition of the problem to be examined
- Clinical examination of individual animals in the herd
- Analysis of records of performance and disease
- Examinations of the environment of the herd
- Laboratory examination of animal; nutritional and environmental sampling
- Necropsy examinations of dead or sacrificed animals
- Descriptive and analytical epidemiological examinations.

Methods for correction of the problem include:

- Treatment of individual sick animals
- Selective or strategic prophylactic medication of the impacted group
- Immunoprophylaxis
- Alterations to the nutrition, the environment or the management of the herd or of selected groups within it.

One, or several, of these methodologies may be used in dealing with herd problems depending upon the nature of the disease under consideration.

Herd examinations can be expensive and in clinical settings the depth of investigation must be justified by the degree of economic importance of the problem. Some diseases are well defined, they are easily and definitively recognized by clinical or postmortem examination, their determinants are well established, and there are established effective methods for their control. In these instances a herd examination in a clinical setting would be limited to the initial examinations that establish the diagnosis and to the implementation of corrective strategies.

Other diseases are less well defined. There may be several determinants of their occurrence and consequently all facets of the examination methods may be needed to determine the most appropriate method for control. It is for this type of disease that **epidemiological investigations** are of particular importance and, where there is an economic justification, an in-depth epidemiological investigation should be considered in order to determine the appropriate method of intervention.

APPROACH TO HERD EXAMINATION

The previous sections have discussed the approach to clinical examination of the individual animal and the methods for determining the presence of system dysfunction and of reaching a diagnosis as to cause. Basically, these consist of a physical examination to assess the function of each body system coupled with laboratory or other ancillary diagnostic methods and information that can assist in this assessment and in the establishment of cause. In the individual animal, disease is usually diagnosed and classified by the system involved and the inciting agent as, for example, pneumonia associated with *Histophilus somni*, myopathy caused by a deficiency of selenium. Subsequent treatment is based on this knowledge and usually consists of therapy directed against the cause and therapy aimed at correcting the system dysfunction.

The approach to the examination of the herd has a similar logical and systematic approach but it is obviously expanded beyond the examination of individual animals and involves different systems. It also involves different approaches to the cause of disease. Herd examinations are conducted because there is an outbreak of disease or a problem of production inefficiency. By definition this involves a group or a population of animals. Most outbreaks of disease and problems of production inefficiency in

groups of animals result from faults or dysfunctions in the complex of interactions that occur within groups of animals and between the groups of animals and their management, environment and nutrition. The characteristics of the group of animals that are affected thus become a focus of the examination and the management, environment and nutrition are the broad systems that are examined in relation to this group of animals. In the examination of the herd one is asking the following questions:

- What is the disease problem that is present?
- What are the characteristics of the animals that are involved?
- Why has this group of animals developed the disease?
- Why are they at increased risk in relation to others within the herd?
- What are the factors in their management, nutrition or other environment that have led to this increased risk?
- What intervention strategies can be used to correct the problem?

A major objective of the examination is to establish a diagnosis of cause. In particular, the objective is to establish a diagnosis of cause that can be altered by an intervention. The diagnosis of cause in a herd disease problem is often different from the diagnosis of cause established in the examination of an individual. Disease occurrence in groups of animals is often multifactorial in cause and the result of the interaction of several risk factors, which may be characteristics of the animals, their environment or of an inciting agent. In the context of the herd the cause or 'etiology' of a disease can be a management fault. In making a diagnosis of cause, the clinician establishes and ranks the major determinants of the problem from among the various risk factors.

Examples of multifactorial etiology of a disease

The examination of an individual animal that is representative of a group of young calves with respiratory disease may lead to a diagnosis of pneumonia associated with *Histophilus somni*. The diagnosis of the cause of the same problem following a herd examination that evaluates the numerous risk factors for pneumonia in calves might be:

- Inadequate ventilation in the calf house
- Failure of adequate passive transfer of colostral immunoglobulins
- Most probably, a combination of the above two, plus other additional factors.

In making a diagnosis of cause, the clinician establishes and ranks the major determinants of the problem from among the various risk factors.

With many diseases one progresses to an examination of cause in the herd using knowledge of recognized risk factors for the disease. These risk factors usually have a logical relation to the disease being examined, as with the example of calf pneumonia. With other diseases the logic of these relationships may be less apparent. This occurs particularly with newly developing or recently recognized diseases, where the pathogenesis of the disease is poorly understood but epidemiological examinations have established certain relationships that have a causal association. The definition of circumstances of occurrence for a disease can lead to a method of control even though the cause of the disease, in the traditional sense, is not known and the relationship between the inciting or associated circumstance and the disease is obscure. A current example would be the developing recognition of an association between dry cow nutrition in dairy cattle and metabolic and infectious diseases that occur early in lactation.

Example of the control of a disease without knowledge of its etiological cause

It is now known that facial eczema in sheep is a toxicosis from fungal toxins produced on pastures. However, long before the toxic nature of this disease was fully understood, the epidemiological circumstances of its occurrence were defined and it was prevented by removing sheep from pastures that had risk for the disease during predicted risk periods factors.

Problems of disease and production inefficiency encountered in herds can present a considerable challenge in diagnosis and correction. In part this is because disease in groups or herds is commonly multifactorial in cause and, for this reason, in an examination of the herd, all the factors that influence the behavior of a disease in that herd assume importance. The obvious approach is a quantitative definition of the disease and a quantitative examination of the relative importance of these risk factors. However, this approach can be difficult in practice.

In clinical settings there is usually no difficulty in achieving a quantitative definition of the animals affected and their characteristics. In large, well-recorded herds it is usually possible to conduct a quantitative examination of risk factors if the records contain information that relates to them. In small herds, a quantitative examination of the relative importance of risk factors may be limited by low numbers of animals. Knowledge of risk factors and their relative importance in disease causation is improving with epidemiological research studies that involve large numbers of animals and several herds. The role of the clinician in the approach to a herd disease problem is to know and to be able to detect these established influences, to be able to quantify them where possible, and to be able to choose from among them those that are most subject to correction by intervention from both a practical and an economic standpoint.

EXAMINATION STEPS

There is no single protocol that can be used for the examination of the herd as this will depend both upon the type of disease problem and the type of herd. For example the methods of examination that would be used in the examination and definition of a problem of ill-thrift in a flock of weaned lambs would be different from those used for a problem of lameness in dairy cattle. Most herd investigations will follow certain broad principles and steps, and these are outlined in Figure 1.4. A given herd examination would not necessarily follow all the steps in this illustration nor would it necessarily proceed in the exact order given. However, the general principles apply to most investigations.

Step 1: Defining the abnormality

It is essential first to define the abnormality in either clinical or subclinical terms. This definition must be accurate, as this step of the examination determines the focus of the examination and the types of cases that will be included in the examination and analytical procedures. A **case** is defined as an animal or a group of animals that have the characteristics of the disease or a defined deviation from targets of production. With some investigations the problem will have obvious clinical manifestations and the primary definition of cases will be made by clinical examination of affected individuals. With others the primary complaint may be lowered production in the absence of clinical disease. An apparent problem in production efficiency can be focused by the examination of records. In many herds this will prove to be an immediate major limitation to the investigation because of a lack of sufficient records on reproduction, production and associated management to define the complaint. In these circumstances the criteria of the production inefficiency that will be

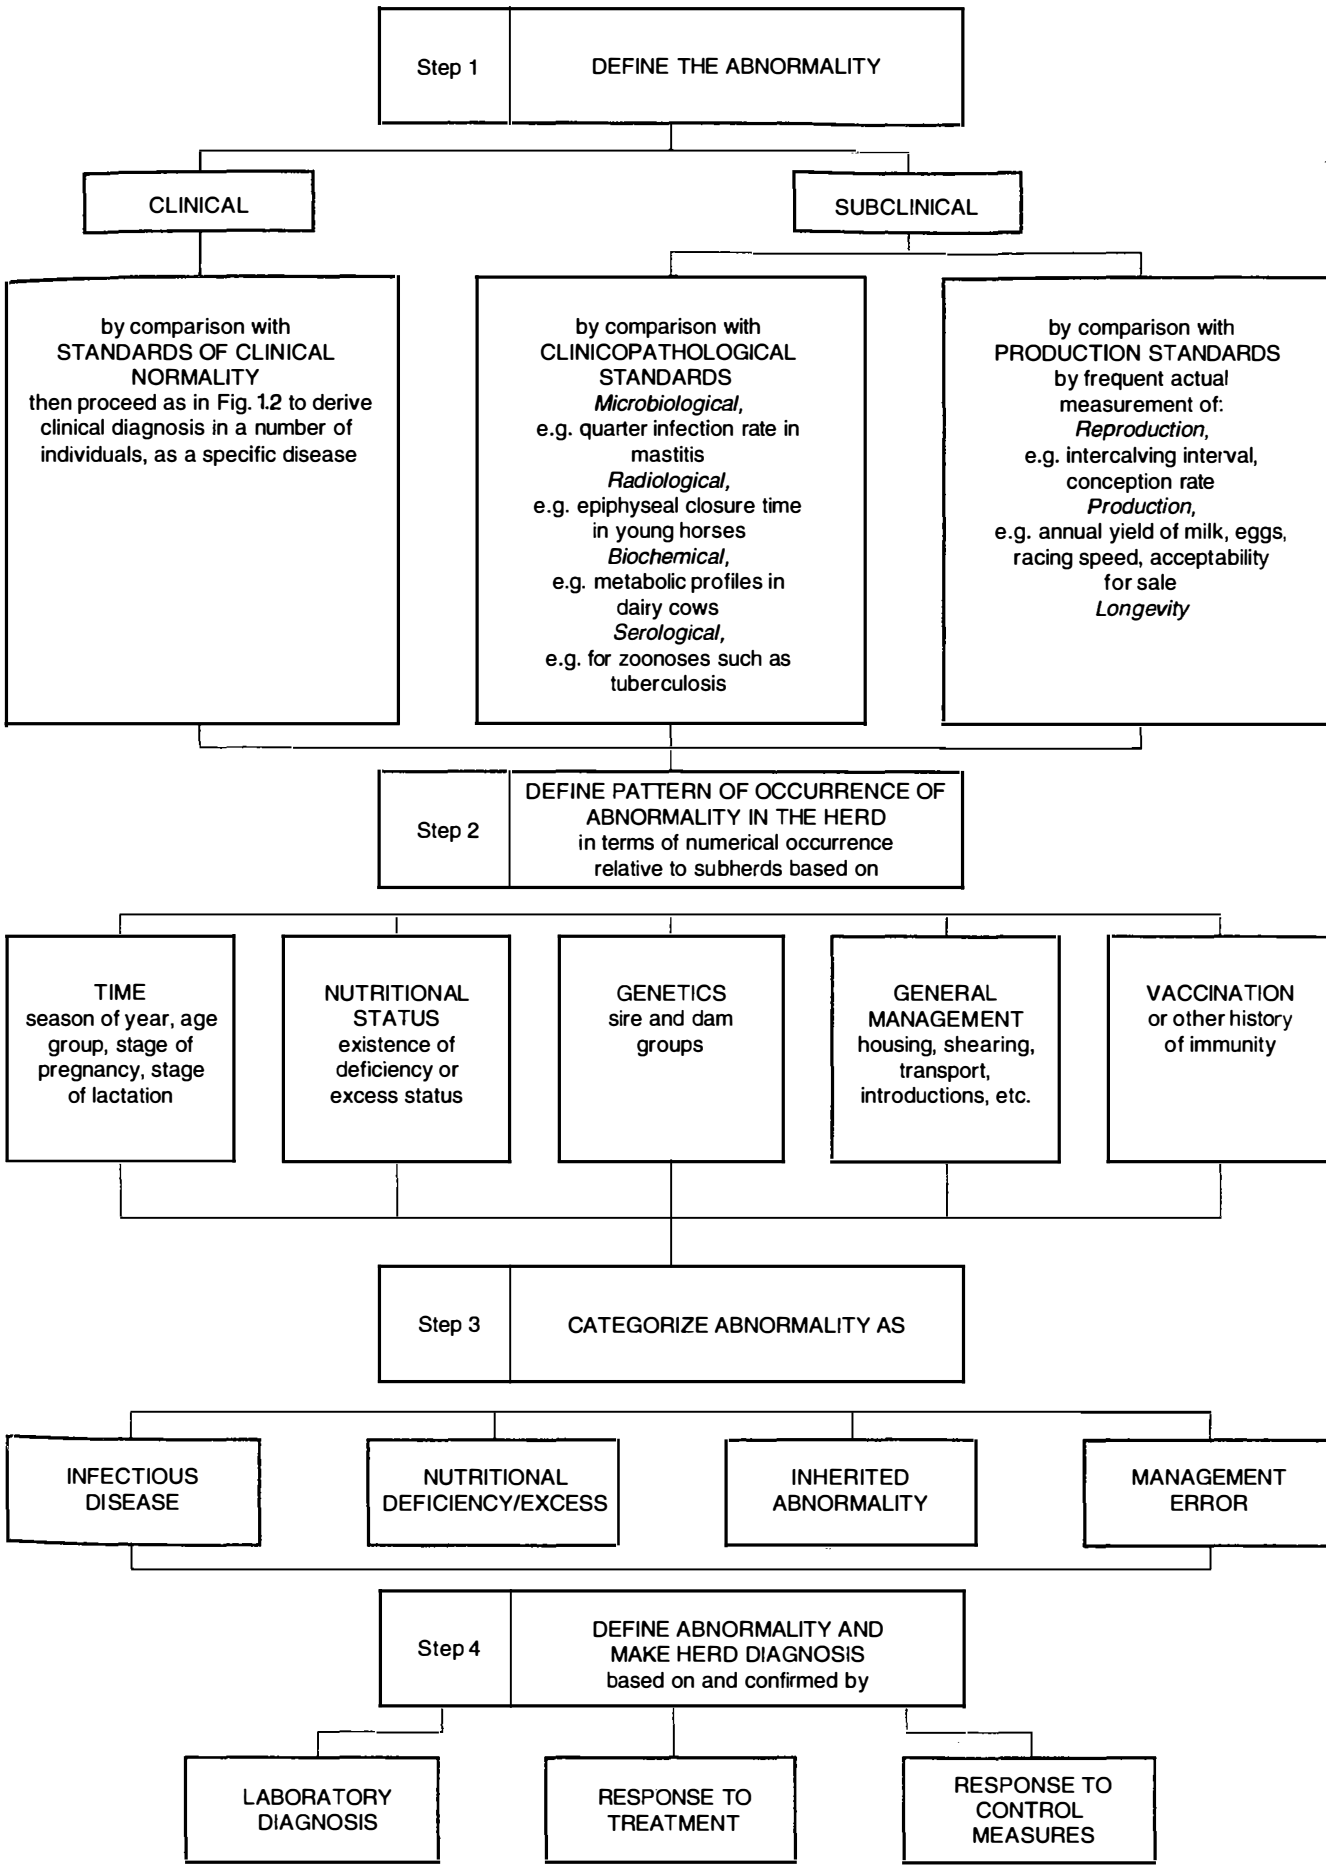

Fig. 1.4 Examination of the herd with the objective of making a diagnosis.

considered in the examination will need to be determined and some form of measurement established.

Step 2: Defining the pattern of occurrence and risk factors

This step of the examination is often conducted in conjunction with step 1 above. It has the purpose of defining the characteristics of the animals that are affected in the disease problem and that have been established as cases, and of determining differences between them, as individuals or as a group, and the non-affected animals within the herd. These differences may be attributes of the animals themselves or of environmental influences that affect them.

The initial examination is usually directed towards the determination of the characteristics of the animals involved and the **temporal** (when) and **spatial** (where) patterns of the disease. In general, the information that allows these examinations is collected at the same time and consists of such factors as:

- A listing of the cases that have occurred
- The date when disease was first observed in each case
- The age, breed and other individual information for each case, which may include such information as source, family association, vaccination history, previous medication
- Management group membership, which may be pen membership, milking string, pastoral group, etc.
- Type of ration and nutritional data
- Management and other environmental information that is relevant to the problem.

In order to compute **risk group analysis** the number of animals present in both sick and well groupings must be recorded, as must be any similarities and differences in their management and environment. After the identity of the abnormality has been established, all the available clinical, production and laboratory data are examined according to the affected subgroups in the herd and according to time occurrence, management differences, nutritional and environmental influences and factors such as vaccination history.

In most herd examinations the analysis of these data is restricted to a cross-sectional study. Prevalence rates within the various groups are calculated and the population at risk can be determined. Animals or groups can be examined as those with and without disease and those with and without hypothesized risk factors, using a 2 × 2 contingency table generated for each variable. Relative risk, odds ratios or rate ratios can be calculated as a measure of association of the variable with chi-square and Mantel–Haenszel procedures used for evaluation of the significance of the risk. This attempts to determine if any associations exist between certain groups of animals and those factors that can influence the behavior of disease.

In some herds, where there has been extensive historical recording, it may be possible to examine the nature of the problem on the basis of a case-control study. However, in most herds this will not be possible because of the paucity of recording of factors of importance to the definition of the disease problem. With problems that are of obvious continuing importance to the economic viability of the herd it may be necessary to establish recording systems that allow a prospective examination of the problem.

Temporal pattern

The temporal pattern of distribution of a disease in a population can be of importance in suggesting the type of disease that is occurring and its possible causes. Temporal recording and graphing of cases is of value in indicating possible portals of entry of an infectious agent or sources of a toxic influence. For this analysis the temporal occurrence of the disease is determined by the collection and graphing of the time of onset of clinical cases (hours, days, weeks) and by relating this information to management or environmental changes.

Generally two types of epidemic curve are graphed. A **point source** epidemic curve is characterized by a rapid increase in the number of cases over a short period of time. This type of epidemic curve occurs when all the animals in a population are exposed at the one time to a common agent. Generally this will be a poison or a highly infectious agent, with many animals becoming affected at approximately the same time and, depending on the variation in the incubation period, a sharply rising or a bell-shaped curve of short time duration. The graphing of a sporadic outbreak suggests the occasional introduction of a disease agent into a susceptible population or the sporadic occurrence of factors suitable to the clinical manifestation of an endemic agent, as opposed to the relatively continual occurrence of an endemic disease.

When the infection has to be transferred from animal to animal after undergoing multiplication in each, delay results and the epidemic curve develops a flatter bell-shaped occurrence of much longer duration and with varying peaks depending upon temporal differences in, and opportunities for, transmission. This is known as a **propagative** epidemic. Whereas the occurrence and identification of an index case has considerable value in epidemiological examinations of this nature, it commonly cannot be identified in veterinary clinical settings.

Spatial examination

The spatial examination of a disease problem requires the gathering of information on affected and nonaffected animals in relation to areas of the housing environment, or pastures, or animal movements. A cluster of cases associated with a specific area may indicate the source of the problem. This is best analyzed by plotting the frequency of cases on maps of the environment that include possible risk factors such as pen locations within buildings, buildings themselves, water sources, pastures, rubbish dumps, roads, implement storage areas, etc. When spatial associations are established, further detailed examination of the location is indicated.

Step 3: Defining the etiological group

Following characterization of the abnormality according to groups within the herd, and having made comparisons of the prevalence rates between groups, it may be possible to discern to which etiological category the abnormality most logically belongs. In many instances considerable difficulty may be encountered in deciding in which of the general areas of etiology the major determinant is located. In so many cases herd problems are not the result of a single error but are multifactorial, with several determinants contributing to a greater or lesser degree, and the problem may fall in several categories.

An example might be a problem of mortality in calves where examinations have determined that population mortality rates are highest in the winter period, that most mortality occurs between 4 days and 1 month of age, that calves that die early in this period have septicemia, or have scours associated with rotavirus and cryptosporidial infections, that the body condition scores of the calves fall during the third and fourth weeks of life and that calves that die later in the time period appear to die of starvation. Probable causes include improper feeding of colostrum, a poor environment leading to a high infection pressure and possibly also to excess cold exposure, malnutrition resulting either from the residual effects of enteric disease on intestinal absorption of nutrients or from an inadequate caloric intake or both. This complex could be placed in the categories of infectious disease, nutritional disease and also in the category of management error; further definition is the next step.

The use of **path models** that summarize current knowledge of the causality of the disease under consideration can help in this aspect of the herd examination. Path models specific to the problem at hand can be constructed and can show the interrelationships between various risk factors and give some indication of the dependence of any one factor on the occurrence of another. This information can be used to estimate the relative contributions of the various etiological categories and to give guidance as to the area where intervention is most likely to be effective.

Step 4: Defining the specific etiology

The final step is to select the probable most important determinant or combination of determinants from within one or more of the general areas and to make corrective interventions based on this diagnosis. In many instances the primary cause may be clear and the correction, be it alterations in nutrition, alterations in management, vaccination, etc., can be made at this stage. In other cases further prospective examinations may be conducted for a better definition before an intervention is attempted. In the example above, failure of passive transfer of colostral immunoglobulins and inadequate caloric intake would have been suspect or even identified as underlying determinants of the problem. However, with most farm recording systems there is likely to be no available data that would help delineate the specific reasons, and the specific management deficiencies that require correction, and so a prospective study to establish these would need to be established.

It can be very difficult to obtain a clearly defined diagnosis of cause of disease in a herd, because of its complexity, but the known important relationships are given for the individual diseases in the special medicine section. Methods for practical clinical quantitative assessment of the level of management expertise or, more importantly, the intensity with which it is applied, are not available. Consequently this must be assessed qualitatively for most management practices. Surrogates such as the percentage of cows presented for pregnancy diagnosis but not pregnant, bulk tank somatic count, rates of failure of passive transfer of colostral immunoglobulins, etc., can give some indication.

TECHNIQUES IN EXAMINATION OF THE HERD OR FLOCK

Set out below are some of the techniques used in examining a group or herd of animals. Any one or combination of the techniques may be used at the one time, depending on the nature of the problem, the availability of support facilities such as diagnostic laboratories and data analysis laboratories, and their cost.

CLINICAL EXAMINATION

A clinical examination is essential if clinical illness is a feature of the disease; a representative sample of animals should be examined. The importance of this component of the examination cannot be overemphasized. Where there is clinical disease an accurate definition by clinical examination may lead to a diagnosis of a disease with known and specific determinants and further examination of the herd can focus specifically on these factors. Where clinical examination does not lead to a finite definition of the cause of the disease but gives a diagnosis of a disease of multifactorial determinants, the examination will still lead to the identification of risk factors that need to be included in the herd examination.

Recording the findings is important and is greatly assisted by a structured report form so that the same clinical features are recorded for each animal. Commonly, clinically affected animals are enrolled as cases in an investigation on the basis of the presence of certain defined signs or clinical abnormalities and a recording form aids in this selection. This is especially important where several veterinarians in a practice may be involved in the herd examination over time.

Selection of the animals to be examined is vital. This should not be left to the farmer because that selection may be biased to include the sickest, the thinnest and the oldest, and not necessarily the animals that are representative of the disease under examination. This is particularly important if a group of animals is to be brought from the farm to a central site for detailed clinical examination as part of the workup of the problem. Strict instructions should be given to the owner to select 10–12 animals as a minimum. The groups should include eight sick animals, if possible four advanced and four early cases, and four normal animals as controls. If the situation permits it, the inclusion of animals that can be sacrificed for necropsy examination is an advantage. Ideally, unless facilities will not allow it, the clinical examinations should be on the farm and the veterinarian should select the animals for examination.

In outbreaks of disease where there is mortality, necropsy examination and associated sampling is an extremely valuable investigative and diagnostic tool. Necropsy examination should not be ignored as the primary method of establishing a diagnosis of problems of disease or production inefficiency in larger herds and flocks. With many diseases in swine herds and larger sheep flocks the costs associated with the sacrifice of a few animals for this purpose are by far outweighed by the benefits of an early and accurate diagnosis and the ability to intervene quickly with corrective strategies. Even in cattle herds, owners are willing to sacrifice affected cattle if by so doing they can facilitate a more accurate definition of their problem. It must also be recognized that some diseases cannot be accurately defined on the basis of their clinical manifestation and epidemiology and a necropsy is required as part of the examination system.

SAMPLING AND LABORATORY TESTING

Laboratory examination is conducted for a number of legitimate reasons. It may be conducted to aid in the establishment of a diagnosis or it may be conducted following the establishment of a diagnosis to aid in the definition of risk factors or in the evaluation or the efficacy of treatment and control strategies.

The validity of laboratory testing in the investigation of disease is only as good as the quality and relevance of the samples that are submitted. The samples submitted must be appropriate to the question that is being asked of them. Frequently samples that can be most conveniently obtained are not the best for this purpose and a **sampling strategy** specifically directed to the question may need to be established.

Laboratory analysis of samples is expensive and should not be undertaken unless there is a specific objective. Before submitting samples for examination the following questions should be asked:

- Is the sampling strategy structured to answer specific questions or is it a random 'fishing expedition'?
- Have you established a sampling strategy that will allow a comparison of animals in your 'at risk' category with those believed not at risk for the disease or the exposure factor?
- Is there a 'gold standard' for the analysis and its interpretation?
- What information will be gained from the results of the laboratory examination that could not be gained by other examinations or logically inferred without these examinations?
- What are the specific steps to be taken that depend upon the results of these examinations, or will the steps be taken regardless of the results?

This type of questioning of sampling for laboratory examination may limit it to situations where it is cost-effective.

Laboratory examination of samples taken in association with clinical examination is usually conducted to help establish the presence and severity of organ dysfunction – which generally cannot establish cause. The value and use of laboratory examinations in the assessment of organ function is discussed in the sections in this text that deal with system diseases. Similarly the nature and value of sampling to establish the etiological association of toxic or infectious agents with disease is discussed under specific disease headings.

Laboratory testing can also be conducted to determine risk and exposure factors. When used for this purpose the sampling strategy must be directed and should be conducted after the preliminary diagnosis has been made. It must be aimed at answering the specific questions above, otherwise it will be inordinately expensive. An example would be the examination of specific feeds that have been implicated as potential sources for a toxin following the epidemiological examination and risk factor analysis in a herd where a specific toxicity was established as the cause of mortality. Without this prior epidemiological examination a mass sampling of the herd and its environment for the presence of the toxin would be extremely expensive and of limited value.

At the time of the initial farm visit, it is advisable to collect samples that are pertinent to the problem and its differential diagnosis but are not of primary analytical significance in the initial definition of the problem. These can be stored and, depending upon the results of initial laboratory examinations, may be discarded or used to further define the problem. Duplicates of some samples with storage is often desirable so that second thoughts on tests can be accommodated. This is particularly important in serological work where the hindsight may be at a long time interval and a serum bank is most profitable when one is attempting a retrospective examination of prevalence.

In many outbreaks it is usually wise to collect samples from 'controls' that are established specifically to evaluate the problem under investigation. These may be clinically normal animals that have not experienced the suspect exposure factor, animals that are clinically normal but that have been exposed and are possibly in an incubation or subclinical stage, and from a third group of clinically affected animals. This system approximates the protocol for the Compton Metabolic Profile, which is described in detail in Chapter 28.

The other consideration is the number of animals to be included in each sampling group. The sample size required for the detection of an attribute varies with the confidence of detection that is desired, with the size of the population and the prevalence or frequency of the attribute in that population. Obviously there can be no set recommendation even for one disease. For example, the sample size required to confirm a diagnosis of copper deficiency in a group of animals with overt clinical deficiency disease will be much smaller than that which is required to establish a developing deficiency state or the risk for clinical disease in the face of deficient intakes on pasture. Unfortunately, cost severely limits the size of the sample that can be tested in most circumstances and the small size that is common can place severe restrictions on any meaningful interpretation. The commonly recommended 10 animals or 10% of the group would appear to have little validity in most examinations.

Numerical assessment of performance

Productivity indexes can be used as indicators of health; they can also be used to measure response to treatment or control measures. More and more they are being used as guides to husbandry and management questions to meet the present-day farmer's concerns with costs and returns. If recording systems are present on the farm they can be invaluable data sources in the investigation of herd problems with disease. Monitors of production efficiency are used extensively in performance or production management veterinary practice and are detailed in texts on that subject in the reference literature section.

Intervention strategies and response trials

As the result of a herd examination, a clinician formulates a hypothesis concerning the disease. This may include hypotheses on the population of animals at risk, the determinants of the disease, the source of the problem and its methods of transmission or propagation. There may be sufficient confidence in these hypotheses that they may result in **intervention strategies** to correct the problem without further analysis. In other outbreaks the hypotheses may be less secure and may require further examination of response trials.

Response trials are often used in an approach to herd disease problems and problems of production inefficiency. They have several purposes: they may be used to establish or confirm a diagnosis, and when used for this purpose it is usually because of the difficulty in confirming the diagnosis by other methods. This may result from the lack of a suitable laboratory test or because the result of the test is supportive for the diagnosis but not confirmatory. Response trials can also be used to determine the degree of intervention that is required and the efficacy of the level of intervention that has been used.

Example of reason for response trials

The finding of hypocupremia in a group of poorly growing calves would support a diagnosis of growth retardation due to copper deficiency but does not confirm it, as calves with normal growth can also be hypocupremic. The only way to confirm the association and the diagnosis is to conduct a response trial with copper treatment as the variable.

An example of monitoring efficacy of interventions

Response trials can be used to determine the degree of intervention that is required and the efficacy of the level of intervention that has been used. Copper deficiency in grazing calves may occur as a simple deficiency or as a conditioned deficiency. Simple copper deficiency can usually be prevented by a single subcutaneous treatment of copper glycinate and this may protect for several months. On the other hand, a conditioned copper deficiency may require treatment every 4–6 weeks.

Some prediction as to the required treatment frequency can be made by pasture element analysis but a response trial with 6-week-interval monitoring of blood copper concentrations and weight gain can monitor the efficacy of the treatment that has been decided upon and also allow a corrective intervention, if indicated. In the absence of a treatment response trial, a nonresponse due to an incorrect decision on treatment frequency could result in the discarding of the correct diagnosis.

There are many limitations to conducting response trials in clinical situations in private herds and their structure may not always meet the strict requirements of those conducted in research. It is not always possible to establish a controlled response trial in clinical practice but the efficacy of intervention strategies should still be monitored. The ultimate interest is in whether the disease or production problem is corrected; however, the efficacy of the individual strategies should be specifically monitored where possible. In the earlier example of calf mortality a decision might have been made to change the method of feeding colostrum and to improve the caloric intake of the calves. There can be various ways that either of these changes could be achieved. The overall efficacy of these changes will be

determined by improved survival of the calves. However, the efficacy of the colostrum management change in improving passive transfer should be determined specifically by measurements of serum immunoglobulin concentrations in the serum of a proportion of calves and the efficacy of caloric improvement by weight measurements. Should calf mortality drop, these latter measures are of limited value but if it does not, then there are measures of whether the failure was due to misdiagnosis of the problem or due to poor efficacy of the suggested corrective strategies in correcting their respective target areas.

A diagnosis made on the basis of a response trial is often presumptive and it has become customary to couch the diagnosis in terms of response to a treatment, for instance, 'selenium-responsive infertility' in sheep. This is not a diagnosis in terms of satisfying the original concepts of Koch's postulates, although it does satisfy the subsequent modifications of these postulates that are now generally accepted and have been based on a broader interpretation of disease causation. In populations of animals, diseases are largely the result of a number of interacting factors of different genres, including management, nutrition and environmental factors, interacting with traditional agent-causes of disease, including microbiological and toxic agents. The answer for the practical problem may be most economically derived by finding the cure rather than the cause. This is especially desirable if that course is cost-effective and finding the cause is more expensive than the wastage caused by the disease.

A simple example would be mortality in a group of cattle that followed a change of feed to a more concentrated ration. An epidemiological examination, including a temporal examination of cause or determinants, might closely link the mortality to the change in ration. This should be sufficient to indicate that the ration should be withdrawn or its method of feeding modified. The alternative approach would be to defer any decision for correction of the problem until the exact problem with the ration was established. This could involve a ration analysis and an examination for unknown toxic components. These examinations would take considerable time, would involve considerable costs, and could well give no additional information that would modify the immediate initial intervention strategy.

The role of the planned animal health and production program

Properly conducted herd health programs and planned animal health and production programs maintain accurate records on all matters of production and health. These are maintained against a background of epidemiological data, including number of animals in the herd, numbers of animals in the reproductive cycle segment group or age group that are therefore at risk. In many instances all the data required to effectively diagnose a disease or monitor its prevalence are already at hand in the records of these herds. It does put the veterinarian and the farmer in the position of almost being able to do a herd examination simply by consulting the records. This approach is detailed in texts on herd health and production medicine.

General systemic states

2

There are several general systemic states that contribute to the effects of many diseases. Because the systemic alterations are common to many diseases they are considered here as a group in order to avoid unnecessary repetition. Hyperthermia, fever, septicemia and toxemia are closely related in their effects on the body, and an appreciation of them is necessary if they are not to be overlooked in the efforts to eliminate the causative agent. Likewise, hypovolemic, hemorrhagic, maldistributive, obstructive and anaphylactic shock are best examined together. This chapter will also present the disturbances of free water, electrolytes and acid–base balance, and briefly introduce pain and stress as it relates to disease. Syndromes of poor performance, decreased appetite and sudden and unexpected death are also covered.

Hypothermia, hyperthermia, fever

Hypothermia, hyperthermia and fever – characterized by significant changes in body temperature – are presented here together, along with an introduction to thermoregulation mechanisms of the body.

BODY TEMPERATURE

Farm animals maintain a relatively constant body core temperature, **homeothermy**, during extreme ranges of thermal environments. This **homeothermic** state is achieved by physiological and behavioral mechanisms that modify either rates of heat loss from the body or the rate at which heat is produced by metabolism of feed or body energy reserves. For the body temperature to remain constant in changing thermal environments, the rate of heat loss must equal the rate of heat gain. The body temperature is a reflection of the balance between **heat gain** from the environment (radiation, conduction, convection) or due to metabolic activity (maintenance, exercise, growth, lactation, gestation, feeding) and **heat loss** to the environment (radiation, conduction, convection, evaporation) or due to metabolic activity (milk removal, fecal elimination, urinary elimination). Absorption of heat from the environment occurs when the external temperature rises above that of the body.

HEAT PRODUCTION

Heat production occurs as a result of metabolic activity and the digestion of feed, muscular movement and the maintenance of muscle tone. **Shivering thermogenesis** is a response to sudden exposure to cold and is a major contributor to enhanced heat production. **Nonshivering thermogenesis** is also induced by exposure to cold and is the mechanism in which heat is produced by the calorigenic effect of epinephrine and norepinephrine, which are released into the blood in increased amounts. In the neonate, heat is produced by the metabolism of brown adipose tissue. which is present in newborn farm animals and is a particularly important mechanism of heat production to prevent neonatal hypothermia.

HEAT LOSS

Heat is transferred to or from an animal by the four standard physical phenomena of **convection**, **conduction, radiation** and **evaporation**. Convection is a transfer of heat between two media at different temperatures, such as the coat surface and the air. As such, convective heat transfer depends on the temperature gradient between the coat surface and air, the surface area and the air speed over the surface. Conduction is the transfer of heat between two media that are in direct contact, such as the skin and water. Radiation is the absorption or emission of electromagnetic radiation at the body surface, and depends on the skin surface temperature and area. Evaporative heat transfer is a process whereby heat is lost by the evaporation of water, and is dependent on the water vapor pressure gradient between the epithelial surface and the environment and the air speed over the surface.

Evaporation occurs by sweating, salivation and respiration, with the relative

importance varying between species. Losses by evaporation of moisture vary between species depending upon the development of the sweat gland system and are less important in animals than in humans, beginning only at relatively high body temperatures. Horses sweat profusely, but in pigs, sheep and European cattle sweating cannot be considered to be an effective mechanism of evaporative heat loss. In Zebu cattle the increased density of cutaneous sweat glands suggests that sweating may be more important. Profuse salivation and exaggerated respiration, including mouth breathing, are important mechanisms in the dissipation of excess body heat in animals. The tidal volume is decreased and the respiratory rate is increased so that heat is lost but alkalemia due to respiratory alkalosis is avoided.

BALANCE BETWEEN HEAT LOSS AND GAIN

The balance between heat gain and heat loss is controlled by the heat-regulating functions of the hypothalamus. The afferent impulses derive from peripheral hot and cold receptors and the temperature of the blood flowing through the hypothalamus. The efferent impulses control respiratory center activity, the caliber of skin blood vessels, sweat gland activity and muscle tone. Heat storage occurs and the body temperature rises when there is a decrease in rate and depth of respiration, constriction of skin blood vessels, cessation of perspiration and increased muscle tone. Heat loss occurs when these functions are reversed. These physiological changes occur in, and are the basis of, the increment and decrement stages of fever.

BREED DIFFERENCES

Differences exist between breeds and races of cattle in coat and skin characters that affect heat absorption from solar radiation and heat loss by evaporative cooling; differences also exist in the metabolic rate, which influences the basic heat load. Interest in this subject has been aroused by the demands for classes of animal capable of high production in the developing countries of the tropical zone. Detailed information on the physiological effects of, and the mechanisms of adaptation to, high environmental temperatures are therefore available elsewhere.

These findings are of greater interest in more temperate climates where the demand for more economic animal husbandry methods has led to investigation of all avenues by which productivity might be increased. Such subjects as the provision of shelter in hot weather, the use of tranquilizers to reduce activity, and therefore heat increment, and the optimum temperature in enclosed pig houses are subjects of vital importance to the farming economy but are not dealt with in this book because they appear to have little relation to the production of clinical illness.

Hypothermia, caused by exposure to low environmental temperatures, and **hyperthermia** (**heat stroke** or **heat exhaustion**), caused by exposure to high environmental temperatures, are the major abnormalities of body temperature associated with extremes of environmental temperatures. **Anhidrosis**, occurring primarily in horses in hot humid climates and associated with the inability to sweat, is described in Chapter 35.

HYPOTHERMIA

Hypothermia is a lower than normal body temperature, which occurs when **excess heat is lost** or **insufficient is produced**. Neonatal hypothermia is a major cause of morbidity and mortality in newborn farm animals within the first few days of life. Cold injury and frostbite are presented under that heading in Chapter 30.

ETIOLOGY

Excessive loss of heat

Exposure to excessively cold air temperatures causes heat loss if increased metabolic activity, shivering and sustained muscular contraction and peripheral vasoconstriction are unable to compensate.

Insufficient heat production

Insufficient body reserves of energy and insufficient feed intake result in insufficient heat production.

Hypothermia also occurs secondary to many diseases in which there may be a decrease in the ability to shiver and skeletal muscle contraction associated with decreased cardiac output, decreased peripheral perfusion and shock. Examples include parturient paresis, acute ruminal acidosis (grain overload), and during anesthesia and sedation, and the reduction of metabolic activity that occurs in the terminal stages of many diseases. A sudden fall in body temperature in a previously febrile animal, the so-called premortal fall, is an unfavorable prognostic sign.

Combination of excessive heat loss and insufficient heat production

A combination of excessive heat loss and insufficient heat production is often the cause of hypothermia. Insufficient energy intake or starvation of newborn farm animals in a cold environment can be a major cause of hypothermia. This may not occur under the same environmental conditions if the animals receive an adequate energy intake. Fatal hypothermia may also occur in other circumstances, such as in certain breeds of pig (pot-bellied) following general anesthesia or sedation with higher doses of azaperone.[1] Mature pot-bellied pigs deprived of feed and kept outdoors during cooler months of the year may develop hypothermia, which would not normally occur in these conditions if the pigs were receiving adequate food.[2]

EPIDEMIOLOGY

Neonatal hypothermia

Newborn farm animals are prone to hypothermia in cool environments and hypothermia is a major cause of neonatal mortality. The neonates cannot maintain their rectal temperatures at normal values during the first few hours after birth under cold environmental conditions. Hypothermia and environmental thermoregulatory interactions are of particular importance in piglets and lambs because of their surface to volume ratio but are also relevant in calves and sick foals.

At birth, the neonatal ruminant moves from a very stable thermal environment, of similar temperature to its core body temperature, to a variable and unstable thermal environment that is 10–50°C colder than its core temperature. The coat is wet with placental fluids and energy loss is increased by evaporation and the low insulative value of a wet coat. The newborn calf becomes hypothermic in the first 6 hours after birth and only limited tissue substrates are available as energy sources. Neonates also are exposed to a variety of environmental pathogens against which they have little specific immunity. Thus the neonatal period is one of the most critical to the survival of an animal and during this period the morbidity and mortality can be high under adverse environmental conditions.

The continued emphasis in modern agriculture on the production of neonates throughout the year, including times of inclement weather and limited feed (late winter and early spring calving in beef herds in northern climates), the emphasis on short calving seasons, the use of high stocking densities, the production of animals with high muscle growth potential, which may be associated with an increased incidence of dystocia resulting in decreased vitality of newborn animals at birth, all appear to combine to increase the incidence of mortality due to hypothermia and related diseases of the neonate.

In lambs, more than 30% of deaths occur in the first few days of life and mortalities may be greater than 10%, with more than half of the losses due to hypothermia from either exposure or starvation. In calves, approximately 50% of deaths occur within 48 hours of birth

and most losses are either directly due to, or follow, dystocial parturitions where stillbirths and early postnatal mortality rates are about 20% compared with less than 5% in calves born without dystocia (eutocial).[3]

Thermoregulation in neonatal farm animals

Response to cold stress

Neonatal ruminants, compared with many **altricial** neonatal mammals, are **precocial** in their development, with well developed thermoregulatory mechanisms that allow them to maintain homeothermy in many environments.[3] Prolonged exposure to heat or cold induces hormonal and metabolic changes specific to each stress. This involves secretion of glucocorticoid hormones and increased activity of the sympathetic nervous system augmented by increased secretion of catecholamines. The principal metabolic effect of these increases is greater availability and utilization of substrates (fat, glycogen and protein) for catabolism, with increased production of heat.

Cold-induced thermogenesis

This is achieved by shivering thermogenesis in skeletal muscle tissue and nonshivering thermogenesis in brown adipose tissue. **Shivering thermogenesis** consists of involuntary, periodic contractions of skeletal muscle. Heat is produced during contraction of muscle bundles in skeletal muscle tissue that has increased in tone as well as in skeletal muscle contracting in overt tremors. Increased heat production in neonatal calves in the first several hours after birth can be significant when the animals first stand for 10 minutes; this effect is reproduced later when the calves are stronger and stand for longer periods. The principal site of cold-induced nonshivering thermogenesis in animals is brown adipose tissue, which is present in neonatal lambs, kids and calves but not in piglets. In neonatal lambs, approximately 40% of the thermogenic response during summit metabolism is attributed to **nonshivering thermogenesis**, with the balance of about 60% attributed to shivering thermogenesis.

Control of heat loss

The insulative nature of the external hair coat and cutaneous tissues to resist nonevaporative heat loss during cold exposure is critical in maintaining homeothermy. Total thermal insulation is the sum of tissue insulation and external insulation.

Tissue insulation. This is the resistance of cutaneous tissue to conductive heat loss from the body core to the skin surface. Tissue insulation is influenced by subcutaneous fat depth, which is minimal in neonates, and by vasoconstriction. Tissue insulation increases with age.

External insulation. This is the thermal resistance of the hair coat and air interface to radiative, convective and conductive heat losses from the skin surface to the environment. External insulation is a function of length and type of hair coat and the air interface. When exposed to dry, cold, still air environmental conditions, external insulation as a proportion of total thermal insulation in neonatal calves ranges from 65–75%. Moisture and mud in the coat decrease the value of external insulation; wind and rain can also decrease external insulation.

The neonate's total thermal resistance to heat loss is a function of the physical properties of the skin and hair coat and the ability to induce vasoconstriction of cutaneous blood vessels and piloerection of the hair coat. Neonatal calves are remarkably cold-tolerant in a dry, still air environment. The thermal demand of an outdoor cold environment is a function of **wind** and **precipitation** as well as **ambient temperature**.

Conductive heat loss is controlled by sympathetic regulation of blood vessels that supply cutaneous tissues, especially the ears and lower extremities. In response to cold, vessels constrict, peripheral blood flow diminishes and heat transfer is limited. Vasoconstriction of cutaneous vessels during cold exposure occurs first in the ears, followed by the lower extremities and then the skin surrounding the trunk. **Phasic vasodilation** in the skin of the ears and distal extremities at a point near freezing occurs by the sudden opening of arteriovenous anastomoses to permit **intermittent warming** (called the **hunting reaction**). Phasic vasodilation does not occur on the skin of the trunk.

Thermoregulating mechanisms

Heat exchange between any homeotherm and the environment is the result of:

- Heat production by metabolism
- Insensible heat loss by evaporation of moisture from the respiratory tract and skin
- Sensible heat transfer by conduction, convection and radiation.

There is a range in the effective thermal environment, called the **thermoneutral zone**, over which an animal maintains body temperature with minimal metabolic effort. Within this zone, body temperature is maintained primarily by varying blood flow to the body surface, piloerection of the hair coat, behavioral and postural changes. These responses adjust the physical processes of heat transfer to balance the body's heat production. The lower limit of the thermoneutral zone – the **lower critical temperature** – is the minimum temperature that an animal can tolerate without actually increasing its rate of metabolic heat production to maintain thermal balance.[4] The lower critical temperature of an animal is determined by the animal's ability to resist heat loss (thermal insulation) and the animal's resting, thermoneutral heat production through metabolism. An increase in thermal insulation or an increase in thermoneutral metabolic rate decreases the lower critical temperature, improving cold tolerance.

Estimates of lower critical temperatures of calves during the first day of life are not available but some estimates for older calves include 13°C for 2-day-old Ayrshire calves and 8–10°C for dairy and crossbred calves at 1–8 weeks of age. In lambs, estimates are 37°C and 32°C for light (2 kg) and heavy (5 kg) birth weights immediately after birth while still wet with amnionic fluid, and 31°C and 22°C when these lambs are more than 1 day old.[4]

Older cattle are much more cold tolerant, with lower critical temperatures of 0°C for 1-month-old calves and –36°C for finishing feedlot cattle. At the lower border of the cold zone is the **cold lethal limit** – the ambient temperature below which the calf is unable to generate sufficient heat to offset heat losses required to maintain thermal balance, and at which hypothermia begins. Prolonged periods of exposure below the cold lethal limit will result in death. The cold lethal limit also can be defined as the ambient temperature below which heat loss exceeds the animal's summit or maximal metabolism.

Because published values for lower critical temperatures assume **still air**, **dry clean coats**, **standard radiation** and a **standing animal given a maintenance level of feeding**, there are limitations to their use. Insulation of extremities decreases, and heat loss increases, at temperatures below freezing. Thus some lower critical temperatures for cattle are too low, which means that neonates may be affected by cold temperatures not normally considered harmful. External insulation can change because of changes in air velocity and long-wave radiation. Behavioral changes of animals may occur to minimize heat loss. For example, animals may orient towards the wind to decrease their profile, and they may seek shelter, huddle and change their posture. Solar radiation varies throughout the daylight hours depending on the quantity of cloud. In general, radiation balance is positive in the day, while at night, when the skies are clear, the radiation balance is usually negative. Heat production varies with the time of day, time since the last meal and physical activity. Rain will often depress intake of feed and illness and

hypothermia severely depress feed intake, whereas cold stimulates intake.

Heat production

Heat produced by metabolism varies directly with the level of feed intake. The more an animal eats, the greater the heat increment of feeding. Animals subjected to cold will increase their feed intake if given the opportunity. In adults, proportionate dry matter increases of up to 35% are typical. This increased feed intake is accompanied by decreased retention time in the intestine and a decrease in digestibility of approximately 2.5 g/kg per 8°C decrease in environmental temperature. Heat is also generated from physical activity. When newborn calves stand for the first time and are able to stand for 10 minutes, the energy expenditure is increased proportionately 30–100%. As calves become stronger and are able to stand for more than 30 minutes, heat production increases by 40%.

Cold thermogenesis

The major source of heat in cold thermogenesis, whether it is induced by either shivering thermogenesis or by nonshivering thermogenesis, is lipid. Glycogen is also important for maximum metabolic rates and for lipid metabolism. For the neonate, in the first 24 hours there is little digestion of colostral proteins and little catabolism of amino acids.

Shivering thermogenesis. This is the most obvious sign of increased heat production of cold thermogenesis.

Nonshivering thermogenesis. Functional brown adipose tissue is present in newborn calves, lambs and kids, and its primary function is to generate heat by nonshivering thermogenesis. The release of norepinephrine during cold exposure in neonatal ruminants stimulates increased blood flow to brown adipose tissue. Thyroid hormones also have an essential role in regulating cold thermogenesis. Glucocorticoids are essential for cold thermogenesis through the mobilization of lipid and glycogen to supply energy substrates. Large deposits of brown adipose tissue are present in the abdominal cavity (perirenal), around large blood vessels and in the inguinal and prescapular areas. In calves, 20 g/kg body weight (BW) may be present and in lambs from well-fed ewes, 6 g/kg BW. At parturition, marked changes occur in both the neonate's supply and demand for nutrients. In utero the fetal ruminant is provided with high levels of carbohydrate and low levels of fat, whereas after birth it is provided with colostrum high in fat and low in carbohydrate. Before colostrum is fed, the neonatal ruminant depends on mobilization of tissue glycogen and lipids to provide energy substrates for basal metabolism as well as thermogenesis in shivering muscle tissue and in brown adipose tissue. The major sources of energy substrates for thermogenesis in neonatal ruminants include glycogen and lipid in liver and muscle because protein catabolism is minimal during the early postnatal period.

Summit metabolism. This is the maximal rate of metabolism which occurs in response to cold without a decline in body temperature. The time for which summit metabolism can be maintained is usually short, e.g. a few minutes in neonatal lambs. It is approximately five times resting metabolic rate and is associated with increased sympathetic activity and development of metabolic acidosis and increased plasma concentrations of glucose, glycerol, free fatty acids and lactate. Prepartum hypoxia is likely associated with postpartum depression of sympathetic nervous activity and of thermogenic responses to cold.

Birth weight and summit metabolism. The principal factor which determines an animal's resting, thermoneutral metabolism is body size. In newborn animals, thermoneutral metabolic rates and summit metabolic rates are proportional to W^1 rather than $W^{0.75}$, which means that summit metabolism per unit of W is similar for all neonates regardless of size, but lightweight animals have more surface area per unit of W than heavyweight neonates. Therefore, lightweight neonates have a lower summit metabolic rate per unit of surface area and, as a consequence, lightweight neonates will be less cold-tolerant than heavyweight neonates. Summit metabolism can be 33% higher in a 55 kg newborn calf compared to a 32 kg calf. Thus lightweight neonates have a more difficult time maintaining thermal balance during cold stress because of a lower cold-induced thermogenic rate per unit of skin surface area than heavier animals. This, in part, explains the higher incidence of neonatal mortality in smaller piglets and lambs, and in smaller calves born to first-calf heifers, and even to mature cows.

Factors affecting cold thermogenesis

Several factors affect the ability of the newborn calf to avoid hypothermia. Prompt activation of thermogenic mechanisms must occur immediately after birth when the demand for heat production is usually highest. The development of functional brown adipose tissue must occur in fetal life in order to enable calves to have maximal nonshivering thermogenesis during the early postnatal period. Most of the functional brown adipose tissue is deposited in late gestation in lambs and calves.

Ambient temperature and nutrition during pregnancy can affect cold thermogenesis of lambs. Maternal cold exposure by winter shearing of sheep increases lamb birth weight independent of changes in prepartum feed intake. Lambs from cold-exposed (winter sheared) ewes were 15% heavier at birth, and had 21% more perirenal adipose tissue that was 40% more thermogenically active than lambs from unshorn ewes. Thus newborn lambs from cold-exposed ewes were more cold-tolerant. Acute cold exposure during late gestation increases glucose supply to the fetus, which stimulates insulin secretion which in turn promotes fetal growth; recruitment and proliferation of brown adipose tissue occurs to enhance cold tolerance of the newborn lamb. There is some evidence that prepartum exposure of pregnant cows to a cold environment may result in heavier calf weights.

Malnutrition of the dam during late gestation. This can adversely affect neonatal calf survival. Prepartum energy restriction beginning at day 90 of gestation of ewes can also reduce the proportional weight of perirenal adipose tissue and reduce the nonshivering ability of newborn lambs. The influence of prepartum nutritional restriction on cold thermogenesis in newborn calves is unknown but prepartum protein restriction during the last trimester reduced thermoneutral thermogenic rates by 12% without affecting birth weights, resulting in an estimated increase in the lower critical temperature. Maternal malnutrition also adversely affects the availability of energy substrates required by the neonate for cold thermogenesis. Nutritional restriction of pregnant ewes reduces total body lipid in fetal lambs but not muscle or liver glycogen. Thus, nutritional restriction of the fetus impairs cold tolerance of the neonate by reducing body substrate reserves available for cold thermogenesis and reduces nonshivering thermogenic capabilities.

European or British breeds of cattle are also more cold-tolerant and more adaptable to temperate climates, whereas Zebu cattle are more adaptable to subtropical climates because of greater heat tolerance.[4] The lack of cold tolerance of the newborn *Bos indicus* calf is associated with a higher mortality rate in purebred Brahman herds in the USA. These calves are less cold-tolerant and more susceptible to the weak calf syndrome.

Postnatal changes in cold thermogenesis

As calves and lambs grow during the early postnatal period, heat loss per unit of body weight declines because of improved thermal insulation and a decrease in the ratio of skin surface area to body weight. Nonshivering thermogenesis

decreases during the first month of age in lambs and calves, which is associated with a decrease in summit metabolism. This coincides with the conversion of brown adipose tissue to white adipose tissue by about 10 days after birth. Postnatal exposure to cold delays the disappearance of brown adipose tissue, which enhances cold tolerance of the lamb and calf by delaying the normal decline in nonshivering thermogenesis.

Risk factors for neonatal hypothermia

Calves

Beef calves born outdoors during cold weather are susceptible to hypothermia. Wind, rain and snow decrease the level of insulation and increase the lower critical temperature. Dairy calves born indoors are not usually exposed to cold environments that cause hypothermia. Hypothermia (<37°C) has been recognized in calves reared outdoors in cold climates and in some calves affected with enteritis.[3]

Dystocia can affect cold thermogenesis. During a normal delivery, fetal hypoxemia may occur, causing anaerobic glycolysis, the production of lactic acid and a mixed respiratory–metabolic acidosis that the calf can usually compensate for within hours after birth. In prolonged dystocia, a metabolic acidosis may occur, which will inhibit nonshivering thermogenesis and impair cold tolerance immediately after birth. Dystocia may result in a weak calf that has weak teat-seeking activity, a poor suck reflex and a poor appetite for colostrum, resulting in colostrum deprivation and hypogammaglobulinemia.

Colostrum supplies **passive immunity** to the calf and the **nutrients** to meet energy demands during the immediate postpartum period. In order for the calf to maintain thermal balance during cold exposure, it is critical that the calf ingests colostrum early to provide enough energy reserves to sustain cold thermogenesis. Thus it is important that newborn calves consume adequate colostrum to ensure adequate passive immunity and to aid in the maintenance of thermal stability during the early postnatal period when rates of heat loss are greatest. The limited availability of energy substrates from body reserves also requires that adequate quantities of colostrum are ingested during long periods of cold exposure, especially in neonatal calves at higher risk for developing hypothermia. The thermoneutral maintenance requirements of a 40 kg calf can be met with about 2.4 L of cow colostrum; an additional 125 mL of colostrum are required to supply the energy requirements for every 1°C decrease in effective environmental temperature below the lower critical temperature.[3]

Young calves to be reared for veal are usually transported for 1–2 days during the first 2 weeks of life. These calves are prone to cold stress because they are very young and are being fed at a low level directly after transport. Veal calves arriving in a veal calf unit are dependent on body reserves to meet their energy requirement because of limited feed allowances, and ambient temperatures should not be below 14°C immediately after arrival, to prevent extra mobilization of energy reserves.[5] The thermal requirements of these calves are higher during standing than during lying and the provision of bedding that stimulates lying will have a positive effect on thermal requirements.[6]

Survival of beef calves born in the USA can be influenced by ambient temperature.[7] Calving late in spring, compared with earlier calving during cold winter months, results in a decreased mortality, especially in calves born to 2-year-old dams.

Lambs

Cold exposure resulting in hypothermia is a primary cause of lamb mortality, as seen when large numbers of lambs die during or soon after periods of a few hours of low temperatures (<5°C) with wind and rain, or after prolonged rain. Deaths in 'bad' weather cannot necessarily be attributed with certainty to exposure as a primary cause, because lambs debilitated for other reasons, such as starvation, are highly susceptible to chilling and conditions such as low birth weight, birth injury and sparse hair coat all predispose lambs to cold exposure; under less harsh conditions such lambs may survive.

Colostrum intake is also critical in lambs. Under field conditions in the UK it is estimated that lambs require 180–210 mL colostrum per kg BW in the first 18 hours after birth to provide sufficient energy substrate for heat production.[3] This colostral requirement exceeds that for adequate transfer of colostral immunoglobulins. The thermoneutral and summit metabolic rates are much higher in lambs fed colostrum compared with unfed lambs at 4–5 hours of age. The increased metabolic rates are attributed to increased availability of energy substrates from colostrum: plasma concentrations of glucose and non-esterified free fatty acids are doubled from birth to 4 hours of age in colostrum-fed lambs but remain unchanged in colostrum-deprived lambs.

The heaviest losses in Australian sheep flocks, which occur in the form of 'outbreaks' when the weather is very bad, are due to hypothermia. The high mortality rates in newborn lambs due to the effects of cold exposure and starvation occur because many of these lambs are born during the late winter and early spring, when adverse conditions are most likely to occur. This is also true in the northern USA and Canada. The lambs are often born outdoors in unprotected pens designed to accommodate a large number of ewes. Under these circumstances, the lambs may be severely cold-stressed because the ambient air temperatures outside and within the lambing sheds are often 15°C or less, which is considerably lower than the critical temperatures described for heavy- (32°C) and lightweight (37°C) lambs. Cold-stressed lambs often become hypothermic because of excessive heat loss from exposure to inclement weather and because of heat production due to severe hypoxia at birth or to starvation.[8] Factors that further increase the susceptibility of lambs to hypothermia include:

- Lambs from ewes in poor condition
- Lambs from young or aged ewes
- Lambs from multiple births
- Lambs from dystocias
- Lambs with a low birth weight or born prematurely
- Breed differences in susceptibility to cold
- Length of the birthcoat
- Wetting of the birthcoat
- Exposure to wind.

The effects of experimental cold stress (0°C and –10°C) on pregnant ewes during the last weeks of gestation and their lambs of up to 3 days of age have been examined.[9] In general, ewes were unaffected by treatment. Cold-induced changes in lambs included physical weakness, depression and poor nursing response. Serum concentrations of glucose and insulin decreased and cortisol increased. The mortality rate was 40% in stressed lambs and 10% in lambs kept at the warmer temperatures.[9] Cold-exposed lambs had reduced amounts of adipose tissue in perirenal areas and extensive subcutaneous hemorrhages and edema in the distal portions of the thoracic and pelvic limbs.

Wetness of the fleece is a major factor in determining whether or not lambs become hypothermic. Wet lambs suffer a reduction in coat insulation, primarily as a result of reduced coat depths, but this effect is small compared with the increase in evaporative heat loss which occurs as a result of wetting. Lambs exposed to experimental air movement from a fan produce more body heat than those in still air, and differences in resistance to cold stress between single and twin lambs are largely caused by the corresponding differences in body weight and coat depth.

The relative importance of environmental and maternal factors is not easy to

determine. Inclement weather kills many lambs, probably more than would otherwise die, but principally those that are at risk because of reduced vigor – dependent upon poor preceding nutrition – or because of poor mothering – itself as dependent on poor nutrition of the ewe as on her inherited lack of mothering ability. The vigor of the lamb, principally manifested as 'sucking drive', is reduced by lack of reward, so that a vicious cycle is created if the ewe will not stand. Vigor is also greatly reduced by cold discomfort, giving inclement weather two points at which it influences lamb survival rates. The lamb dies of hypothermia and inanition.

Piglets

At birth, the newborn piglet experiences a sudden and dramatic 15–20°C decrease in its thermal environment. Because the newborn pig is poorly insulated, maintenance of homeothermia depends almost exclusively on its capacity to produce heat. Unlike most other mammals the newborn pig does not possess brown adipose tissue.[10] Consequently, neonatal pigs are assumed to rely essentially on muscular thermogenesis for thermoregulatory purposes. Newborn pigs shiver vigorously from birth because it is the main heat-producing mechanism and the thermogenic efficiency of shivering increases during the first 5 days of life.[10]

Thermoregulation in the newborn piglet is important in the first 2 days.[11] Metabolic heat production and rectal temperature increase and the development of adequate thermal insulation helps to withstand the effects of a cold environment. Body reserves are important for the piglet to survive in the first few hours and glycogen and fat reserves are utilized as major energy substrates for heat production within the first 12–24 hours. Thus ingestion of colostrum is crucial. Coldness impairs the development of thermostability and induces hypothermia, which diminishes the vigor of the piglet and reduces colostrum intake and immunoglobulins. Thus the need for a high ambient temperature for piglets in the first several days of life.

Foals

Newborn foals that are premature, dysmature or affected with neonatal maladjustment syndrome cannot maintain their rectal temperatures at normal values during the first few hours after birth under the environmental conditions usually encountered within foaling boxes in the UK.[12] Their overall mean metabolic rate is about 25% below the mean value for recumbent healthy foals.

This difference in resting metabolic rate affects the lower critical temperature – the air temperature below which heat loss exceeds resting heat production. The lower critical temperature for healthy foals is estimated to be about 10°C and for sick foals is about 24°C. When wet with amniotic fluid, the lower critical temperature probably will be much higher. Covering these foals with rugs and providing thermal radiation using radiant heaters would increase the lower critical temperature.

Premature foals are the most compromised compared to dysmature and those with neonatal maladjustment syndrome. They have small body masses, the lowest rates of metabolism and the lowest rectal temperature. Premature foals are also likely to be deficient in energy reserves and thermal insulation, in addition to immaturity of organ systems, which could limit further energy availability. **Colostrum intake** is also crucial to their survival.

Post-shearing hypothermia in sheep

Sudden unpredicted summer rainfall can cause high mortality due to hypothermia in newly shorn sheep.[13] A fall in body weight in the period immediately preceding shearing is another major risk factor. It is estimated that in Australia 0.8 million sheep die annually during the first 14 days after shearing and many of the deaths are associated with cold, wet, windy weather. Overall, crude mortality rates can range from 12–34% for sheep up to 28 days after shearing. In outbreaks in Australia in January the mean temperature can be 10°C, with a high rainfall and high wind velocity, accounting for a **wind chill factor** (a function of temperatures, rain and wind velocity). Other factors that increase heat loss include sunshine versus cloud, and the depth of the wool cover. The speed of the wind at the location of the animals varies greatly depending on the presence of protective windbreaks such as trees.

Cold environments and animal production

Farm animals maintain a relatively constant body core temperature during exposure to the extreme range of thermal environments experienced in countries such as Canada.[14] The severity of the winter is particularly challenging. Homeothermy is achieved by physiological and behavioral mechanisms that modify either rates of heat loss from the body or the rate at which heat is produced by metabolism of feed or body energy reserves. Despite the extremely cold temperatures that occur in most of the agricultural regions of Canada, the effective severity of extremely cold temperatures is reduced because of the dryness of the frozen environment and the effective external insulation of the animal's hair coat. The influence of wind can add to cold stress and the provision of shelter from wind by natural tree shelter belts or manmade structures such as porosity fences is required.

Prolonged exposure to cold results in subtle adaptation of hormonal and metabolic responses. Acclimatization to cold and winter conditions generally has little long-term effect on energy metabolism but increases thermal insulation and appetite. During prolonged exposure of cattle and sheep to cold environments down to –10 to –20°C there is a reduction in the apparent digestibility of the diet.[14] To offset the lowered digestibility, the animals would accordingly need to consume more feed to achieve a similar digestible energy intake when kept outdoors during winter than if they were kept in a heated barn.

PATHOGENESIS

Sudden exposure of neonatal animals at birth and during the first few days of life to cold ambient temperature results in subnormal body temperature, shivering and decreased cardiac output, heart rate and blood pressure. This results in muscular weakness and mental depression, respiratory failure, recumbency and a state of collapse and, eventually, coma and death. The entire body, especially the extremities, becomes cold and the rectal temperature is below 37°C and may drop to 30°C in neonates. Cold injury or frostbite of the extremities may occur in extremely cold conditions. Nonshivering induced thermogenesis may occur, resulting in depletion of brown adipose tissue deposits. The neurological signs of convulsions seen in some cases of hypothermia have not been adequately explained.[15] The nervous signs observed in piglets with an inadequate intake of milk and exposed to cold environmental temperature are probably due to a marked hypoglycemia.

In newborn lambs carbohydrate and lipid are the major energy substrates for heat production because protein catabolism is minimal during the first day after birth.[16] Liver glycogen concentrations increase markedly during the last few days before normal parturition. The amount of liver and skeletal muscle glycogen available in the newborn lamb at birth determines how long it can avoid hypoglycemia and hypothermia if not fed. The amount of lipid present in the newborn lamb can also affect the duration of the glycogen reserves. In growth-retarded lambs, lipid availability is decreased and glycogen exhaustion occurs earlier than normal. Such lambs are highly susceptible to hypothermia but this can be minimized by the early ingestion of colostrum, which

is rich in lipid and extends the availability of glycogen.

Deaths are the result of excessive body cooling due to low temperature, driving winds and starvation. Wetness may or may not be involved. The starvation results indirectly from poor mothering by the ewe, either because she is a poor mother, because the weather interferes with mothering or because the lamb is weak owing to poor antepartum nutrition. These lambs often walk after birth but at postmortem examination there is little to see. They may have sucked but there is little digestion and the intestine on the recumbent side is flaccid. There are also subcutaneous hemorrhages of the limbs and depletion of brown fat stores.

Hypothermia secondary to other diseases is due to failure of the thermoregulation mechanism and is usually accompanied by varying degrees of shock and the inability to invoke shivering thermogenesis.

CLINICAL FINDINGS

A decrease in body temperature to below 37°C represents hypothermia for most farm animal species. Weakness, decreased activity, cold extremities and varying degrees of shock are common. Bradycardia, weak arterial pulse and collapse of the major veins are characteristic. The mucous membranes of the oral cavity are cool and there is a lack of saliva.

Neonatal hypothermia

Body temperatures may be as low as 35°C in neonatal calves, piglets, lambs and foals exposed to a cold environment within hours after birth or following 12–24 hours of profuse diarrhea accompanied by marked dehydration and acidosis. However, acute dehydration in a thermoneutral environment is accompanied by a mild increase in rectal temperature. In the early stage of hypothermia, affected animals may be shivering and trembling and the skin of their extremities and ears feels cool to touch. Hypothermic piglets will attempt to huddle together, are lethargic, do not suck and eventually become recumbent and die. Hypothermic calves exposed to a cold environment will assume sternal recumbency, lie quietly, will have a weak suck reflex and will die in a few hours. In later stages, further weakness leading to coma is common. The mucous membranes of the oral cavity are cool and may be dry. The heart rate is commonly slower than normal and the intensity of the heart sounds decreased. Death is common when the body temperature falls below 35°C but field observations indicate that the temperature may fall below 30°C and animals still survive if treated intensively.

Shorn sheep hypothermia

Sheep with hypothermia associated with recent shearing and inclement weather have a range of body temperatures from 35–38°C. They huddle in tight groups and the animals that cannot maintain sufficient heat will become weak, recumbent and die within a few hours. They may be found in lateral or sternal recumbency, with their heads back over their shoulders. Palpebral reflexes are decreased, skin and extremities are cold, mucous membranes are pale to white and generalized weakness similar to circulatory collapse is common.

Hypothermia secondary to other diseases

The hypothermia secondary to other diseases is usually not marked and there are clinical findings related to the underlying illness. Hypothermia is common in diseases such as milk fever in cattle but returns to normal within a few hours after successful treatment with calcium salts. Successful treatment of the primary disease will usually return the temperature to within the normal range.

CLINICAL PATHOLOGY

Clinical pathological examinations are usually not done because the diagnosis is frequently obvious and the variability in biochemical changes make them of limited value in reaching a diagnosis of hypothermia. The serum concentrations of glucose, non-esterified fatty acids and immunoglobulins are commonly reduced, and hypoglycemia may be profound. However, the glucose concentration depends on the level of starvation that coexisted with the hypothermia. In starvation-induced depletion of body lipid and glycogen reserves, there is a depression in cold thermogenesis and subsequent hypothermia. In neonatal calves and lambs with hypothermia caused by excessive heat loss during short cold exposure, the serum concentrations of glucose, non-esterified fatty acids and immunoglobulins may be at adequate levels. Hemoconcentration, azotemia and metabolic acidosis may occur.

Necropsy findings

Lesions associated with hypothermia depend on the duration and severity of the hypothermia. Fatal hypothermia in lambs and calves is characterized by an absence of lesions. A relative absence of milk in the abomasum is common. Experimental cold stress may result in subcutaneous edema of the ventral body wall and subcutaneous edema and hemorrhages of the extremities. Marked reductions in the amount of perirenal adipose tissue may be obvious. However, intense cold exposure of short duration may cause death of calves with no significant changes in the visual appearance of perirenal, pericardial or cardial adipose tissue depots.

TREATMENT

Hypothermic newborn lambs

A system for the detection and treatment of hypothermia in newborn lambs can improve the survival rate.[17] Most lambs become hypothermic within 5 hours or at more than 12 hours after birth. Hypothermia in the first 5 hours of life is most commonly caused by a high rate of heat loss from the wet newborn lamb, whereas a depressed rate of heat production consequent to starvation is the most common cause in the older lamb. Twin and triplet lambs are more susceptible to hypothermia than singles because of lower body energy reserves; the ewe takes longer to lick dry two or three lambs, and the milk requirement of two or three lambs is higher than that of a single lamb and starvation is more likely.

Using an electronic thermometer, the body temperature of any weak or suspect lamb is taken.[18] Lambs of any age with mild hypothermia (37–39°C) are dried off if necessary to reduce heat loss, given ewe or cow colostrum by stomach tube and placed in a sheltered pen with the ewe. Lambs less than 5 hours of age with severe hypothermia (<37°C) are dried off and given an intraperitoneal injection of 20% glucose at a temperature of 39°C. A large lamb (>4.5 kg) is given 50 mL, a medium lamb (3.0–4.5 kg) 35 mL and a small lamb (<3.0 kg) 25 mL. Hypothermic lambs are then placed in warming pens, measuring 2 × 2 m and made of horizontally laid straw bales, two bales high. The pen is divided horizontally into two chambers by a sheet of weld mesh upon which the lambs lie. Warm air, at 38–40°C, is blown into the lower chamber from a domestic heater, and a sheet of polythene fitted over the entire pen retains the heat. When the lamb's temperature reaches 37°C, it is removed from the warmer and immediately fed ewe or cow colostrum by stomach tube at a rate of 50 mL/kg BW. Any lamb that is vigorous and able to suck is returned to its ewe in a sheltered pen and monitored over the next several hours. Colostrum can be hand milked from the ewe after administration of oxytocin.

The immersion of hypothermic lambs in water at 38°C can result in the recovery to an euthermic state in about 28 minutes at a reduced expense in metabolic effort by lambs. However, this requires extra labor and lambs must be quickly dried, otherwise the heat loss is exaggerated after removal from water because of the wet fleece.

Hypothermic newborn calves

Clinical management of hypothermic newborn calves is similar to that of lambs. Supplemental heat must be provided immediately. Rewarming can be done in small, enclosed boxes bedded with blankets and heat provided by infrared heat lamps. Colostrum or milk should be warmed to 40°C and intubated using an esophageal feeder. Fluids given intravenously must be warmed; one practical method requires submersion of the intravenous line in a sustained source of warm water. Intravenous dextrose (1 mL of 50% dextrose/kg BW) should be routinely administered to all hypothermic calves because most have moderate to severe hypoglycemia. This dosage rate of 50% dextrose will increase the serum glucose concentration of the calf by approximately 100 mg/dL, assuming that the extracellular fluid space is 50% of the calf's body weight. The rectal temperature should be taken every 30 minutes during treatment to assess progress.

A more aggressive rewarming technique involves the repeated administration of warm (40°C) 0.9% NaCl enemas via a flexible soft tube; a 20–30F Foley catheter works well in this regard when it is advanced through the anus and the bulb inflated to maintain the catheter in the rectum. Rectal fluid should be aspirated before infusing additional fluid volumes via the Foley catheter in order to maximize the warming ability of enema fluids. Use of enema fluids as part of the rewarming protocol makes it more difficult to monitor the increase in body temperature. Whether immersion of hypothermic calves in water at 38–40°C is beneficial has not been determined, but immersion presents practical difficulties.

Hypothermic newborn foals

The clinical management of sick foals that are prone to hypothermia is presented below under Control.

Hypothermic newborn piglets

Hypothermic piglets must be placed in a warming box with a heat lamp and treated with intraperitoneal administration of glucose for the hypoglycemia. The subject is presented in additional detail in Chapter 3.

CONTROL

Control and prevention of hypothermia is dependent on providing the necessary surveillance at the time of parturition in animals being born in cold environments. Early recognition and treatment of animals with diseases leading to hypothermia is also necessary.

Lambs and calves

Prevention of hypothermia in calves depends on the planning and implementation of effective management strategies that will limit the risk factors known to predispose newborn calves to hypothermia and starvation. Management strategies to prevent hypothermia from excessive heat loss are most important in the first 24 hours after birth. They include changing the calving season to a warmer time of the year to minimize exposure to severe weather. Measures to minimize excessive heat loss include providing a dry, draft-free environment for calving and lambing. Providing a protective shelter for beef cow/calf pairs for calving and during the first week after birth can reduce mortality from hypothermia. In extensive beef cow/calf herds, calf huts large enough for 8–10 calves provide excellent shelter from wind, rain and snow.

The provision of adequate surveillance and assistance at the time of lambing or calving is necessary to minimize the incidence of dystocia and its consequences for the neonate. The ingestion of adequate quantities of colostrum, beginning as soon after birth as possible, is important in order to provide immunoglobulins and energy sources for the neonate.

Piglets

The newborn piglet requires an adequate intake of colostrum within a few hours after birth, continued intake of milk after the colostral period, a warm external environment of 30–34°C for at least the first 3 days of life (with heat lamps) and protection from traumatic injuries such as crushing by the sow. Sows do not instinctively remove the amniotic fluid from the surface of piglets; it is removed by contact with other surfaces or by evaporation. Smaller than normal or weak piglets should be dried manually to minimize excessive heat loss. Cross-fostering is used when gilts or sows have large litters that they cannot nurse adequately.

Sick foals

Sick foals are prone to hypothermia but cold stress can be reduced by good management procedures, including the following:[12]

- The foal should be housed in an environment with minimal drafts, in which the air temperature is controlled at a steady value, set according to the foal's needs. Air temperature should be at, or a few degrees above, the lower critical temperature. This temperature may exceed 24°C for a sick, uncovered, recumbent foal. Radiant heaters are useful but should not be placed too close to the foal
- Excessive moisture should be removed from the foal's hair coat immediately after birth. A sick foal that cannot increase its metabolic rate is particularly susceptible to cold stress when wet with amniotic fluid[19]
- Additional insulation with foal rugs and leg bandages will reduce heat loss from the dry body surface. The dry sick foal needs an additional 10 mm of insulation for each 10°C decline in air temperature below 24°C. Because sick foals are recumbent, they should lie on a heated pad or on thick bedding material to minimize heat loss by conduction to the floor
- Energy intake should be sufficient to sustain resting metabolism and can be given by the oral or parenteral route
- Frequent monitoring of both rectal and air temperature, as well as energy intake, will assist in the diagnosis of thermal stress, so that appropriate action can be taken. A lack of shivering does not indicate an absence of cold stress.

HYPERTHERMIA (HEAT STROKE OR HEAT EXHAUSTION)

Hyperthermia is the elevation of body temperature due to excessive heat production or absorption, or to deficient heat loss, when the causes of these abnormalities are purely physical. Heat stroke (heat exhaustion) is the most commonly encountered clinical entity.

ETIOLOGY

The major causes of hyperthermia are the physical ones of high environmental temperature and prolonged, severe muscular exertion, especially when the humidity is high, the animals are fat, have a heavy hair coat or are confined with inadequate ventilation, such as on board ship or during road transportation. Fat cattle, especially British beef breeds, can be overcome by the heat in feedlots. Brahman cattle in the same pen may be unaffected. Angora goats are much more sensitive to high environmental temperatures than sheep, especially when they are young.[1] The original concept of sunstroke as being due to actinic irradiation of the medulla has now been discarded and all such cases are now classed as heat stroke.

High environmental temperature

The upper border of the thermoneutral zone – the **upper critical temperature** – is the effective ambient temperature above which an animal must increase heat loss to maintain thermal balance. The upper critical temperature in sheep with a light wool coat on board ship appears to be 35°C (95°F) at a humidity of 33–39 mmHg (4.4–5.2 kPa) vapor pressure. Differences between breeds of animal in their tolerance to environmental high temperatures, exposure to sunlight and exercise are important in animal management and production. Water buffalo have been shown to be less heat-tolerant than Shorthorn steers, which were less tolerant than Javanese Banteng and Brahman crossbreds – the last two appear to be equally tolerant. The differences appear to be at least partly due to capacity to increase cutaneous evaporation under heat stress.

There are similar differences in heat tolerance between lactating and nonlactating cows; lactating animals show significantly greater increases in rectal temperature and heart and respiratory rates when the environmental temperature is raised. This is primarily a result of the greater dry matter intake and heat of fermentation in dairy cattle that must be dissipated. Heat stress is therefore an important production-limiting disease when dairy cattle are kept in conditions of high heat and humidity.

Rested, hydrated horses are well able to maintain homeothermy in the hottest environmental conditions. Their most efficient mechanism in ensuring that body temperature is kept low is their capacity for heavy sweating.

Other causes of hyperthermia

- Neurogenic hyperthermia – damage to hypothalamus, e.g. spontaneous hemorrhage, may cause hyperthermia or poikilothermia
- Dehydration – due to insufficient tissue fluids to accommodate heat loss by evaporation
- Excessive muscular activity – e.g. strychnine poisoning
- Miscellaneous poisonings, including levamisole and dinitrophenols
- Malignant hyperthermia in the porcine stress syndrome
- Hyperkalemic periodic paresis in horses
- Fescue toxicity in ruminants and horses
- Cattle with hereditary bovine syndactyly
- Administration of tranquilizing drugs to sheep in hot weather
- Specific mycotoxins, e.g. *Claviceps purpurea, Acremonium coenophialum*, the causes of epidemic hyperthermia. Bovine idiopathic hyperthermia in cattle in Australia may be due to *Claviceps purpurea*[2]
- Iodism
- Sylade (possibly) poisoning.

PATHOGENESIS

The means by which hyperthermia is induced have already been described. The physiological effects of hyperthermia are important and are outlined briefly here.

Unless the body temperature reaches a critical point, a short period of hyperthermia is advantageous in an infectious disease because phagocytosis and immune body production are facilitated and the viability of most invading organisms is impaired. These changes provide justification for the use of artificial fever to control bacterial disease. However, the metabolic rate may be increased by as much as 40–50%, liver glycogen stores are rapidly depleted and extra energy is derived from increased endogenous metabolism of protein. If anorexia occurs because of respiratory embarrassment and dryness of the mouth, there will be considerable loss of body weight and lack of muscle strength accompanied by hypoglycemia and a rise in nonprotein nitrogen.

There is increased thirst due in part to dryness of the mouth. An increase in heart rate occurs due directly to the rise in blood temperature and indirectly to the fall in blood pressure resulting from peripheral vasodilatation. Respiration increases in rate and depth due directly to the effect of the high temperature on the respiratory center. An increased respiratory rate cools by increasing salivary secretion and the rate of air flow across respiratory epithelial surfaces, thereby increasing the rate of evaporative cooling. Urine secretion is decreased because of the reduced renal blood flow resulting from peripheral vasodilatation, and because of physicochemical changes in body cells that result in retention of water and chloride ions.

When the critical temperature is exceeded, there is depression of nervous system activity and depression of the respiratory center usually causes death by respiratory failure. Circulatory failure also occurs, due to myocardial weakness, the heart rate becoming fast and irregular. If the period of hyperthermia is unduly prolonged, rather than excessive in degree, the deleterious effects are those of increased endogenous metabolism and deficient food intake. There is often an extensive degenerative change in most body tissues but this is more likely to be due to metabolic changes than to the direct effects of elevation of the body temperature.

CLINICAL FINDINGS

An elevation of body temperature is the primary requisite for a diagnosis of hyperthermia and in most species the first observable clinical reaction to hyperthermia occurs when the rectal temperature exceeds 39.5°C (103°F). In most instances the temperature exceeds 42°C (107°F) and may reach 43.5°C (110°F). An increase in heart and respiratory rates, with a weak pulse of large amplitude, sweating and salivation occur initially, followed by a marked absence of sweating. The animal may be restless but soon becomes dull, stumbles while walking and tends to lie down.

In the early stages there is increased thirst and the animal seeks cool places, often lying in water or attempting to splash itself. When the body temperature reaches 41°C (106°F) respiration is labored and general distress is evident. Beyond this point the respirations become shallow and irregular, the pulse becomes very rapid and weak and these signs are usually accompanied by collapse, convulsions and terminal coma. Death occurs in most species when the core temperature exceeds the normal value by approximately 5°C (8°F). Abortion may occur if the period of hyperthermia is prolonged and a high incidence of embryonic mortality has been recorded in sheep that were 3–6 weeks pregnant. In cattle, breeding efficiency is adversely affected by prolonged heat stress and in intensively housed swine a syndrome known as

summer infertility, manifested by a decrease in conception rate and litter size and an increase in anestrus, occurs during and following the hot summer months in most countries. Sudden exposure of cattle that are acclimatized to cold temperatures (–20°C; –4°F) to warmer temperature (20°C; 68°F) results in heat stress. The respiratory rate may increase from 20 to 200 breaths/min within 1 hour, the heart rate will increase by 10–20 beats/min and the temperature will undergo an increase of 0.5–1.0°C (33–34°F). The respiratory rate is the most practical indicator of heat stress, and a respiratory rate above 70 breaths/min indicates that animals are suffering heat stress. It is not uncommon in hot humid climates to see cattle open-mouth breathing with respiratory rates exceeding 80 breaths/min during periods of heat stress. In summary, the progression of changes in cattle with heat stress is increased respiratory rate, rectal temperature and heart rate, followed by decreased urine concentration (due to increased water intake) and finally decreased appetite and milk production.

Affected horses are fatigued and have profound fluid and electrolyte losses, characterized by hypotonic dehydration due to excessive sweating. The resultant clinical signs include decreased performance, depression, weakness, increased heart and respiratory rates, and marked increases in rectal temperature (usually exceeding 42°C). Because of the hyponatremia, affected horses may lose the stimulus to drink, thereby exacerbating their dehydration. In advanced cases, the skin is dry and hot because sweating is impaired. Hyperthermic horses that have been participating in an endurance event may have synchronous diaphragmatic flutter as a result of hypocalcemia and metabolic alkalosis. Coma and death can occur in extreme cases of hyperthermia that are not identified and treated until the condition is advanced.

CLINICAL PATHOLOGY

No important clinicopathological change is observed in simple hyperthermia. However, horses with advanced hyperthermia typically have hyponatremic dehydration and azotemia. Horses with synchronous diaphragmatic flutter are typically hypocalcemic.

Necropsy findings

At necropsy there are only poorly defined gross changes. Peripheral vasodilatation may be evident, clotting of the blood is slow and incomplete, and rigor mortis and putrefaction occur early. There are no constant or specific histopathological changes.

TREATMENT

The presence of adequate drinking water is essential and together with shade and air movement is of considerable assistance when multiple animals are exposed to high air temperature.

If treatment of individual animals is necessary because of the severity or duration of the hyperthermia, affected animals should be immediately placed in the shade and hosed on the midline of the back with cold water so that their coats are saturated. Fans should be immediately placed in front of the animal to promote evaporative cooling, and cooled water, with and without added electrolytes, should be made available for the animal to drink. In severe cases of hyperthermia where large volumes of water are not available, very cold water (2–8°C) should be applied and immediately scraped off because the water becomes warm almost immediately. The application of very cold water does not induce a clinically relevant degree of peripheral vasoconstriction and has not been associated with clinically relevant side effects. Water applied by hose does not need to be scraped off because heat is conducted to the applied water stream. Placement of wet sheets or towels over the head or neck is not recommended as they provide unneeded insulation.

The rectal temperature should be monitored frequently during cooling, and water application should be stopped when the rectal temperature has returned to normal. Because affected animals may not be interested in or capable of drinking, the intravenous administration of fluids such as 0.9% NaCl is indicated in animals that are weak, recumbent or dehydrated. Horses often need 20–40 L of intravenous fluids over the first few hours of treatment. Horses with synchronous diaphragmatic flutter should be treated with intravenous calcium.

Fluids can also be administered orally to horses, but care should be taken to ensure that gastrointestinal motility is not impaired. A practical oral electrolyte solution is obtained by dissolving 20 g of table salt (NaCl) and 20 g of Litesalt (NaCl and KCl) in 5 L of water; this provides 107, 28, and 132 mmol/L of sodium, potassium and chloride, respectively. Five L of this fluid can be administered to an adult horse each hour by nasogastric tube.

CONTROL

Shade alone is a most important factor in maintaining the comfort of livestock and preventing heat stress. Shade reduces the heat gain from solar radiation and can be provided by trees or artificially by roofs or shades made from cloth or artificial material. Shades should be placed over feed and where the producer wants the animals to spend their time. The efficiency of metal shades can be increased by painting metal shades white on the topside and black on the underside. A north–south orientation will permit drying under the shades as the shaded area moves throughout the day; this may be helpful in decreasing the incidence of coliform mastitis if sprinklers are used under the shades and cattle prefer to lie under the shades than in freestalls.

In dairy and feedlot cattle, the following measures should be taken to manage heat stress:

- Provide cool clean water and plenty of trough space for drinking
- Use shades and intermittent sprinkler systems (wet time of 1–2 min with an adequate dry off time of 20–30 min); continuous application of water increases the local humidity and decreases the effectiveness of evaporative cooling
- Enhance airflow by fans or by providing mounds for cattle to stand on
- Adjust rations and feed a larger percentage of the ration in the evening when it is cooler
- Minimize handling during periods of greatest heat stress
- Select cattle based on breed and coat characteristics, and house the most susceptible cattle (heavy, black) on east-sloping lots with the most shade.

In exercising horses, periodic rests in the shade with fans and water sprinklers and maintaining a normal hydration status can be very helpful in preventing heat stress. Monitoring the heart rate is a useful and practical method of assessing the degree of heat stress in horses, in that heart rates remain elevated for a longer period of time in horses undergoing heat stress.

If animals have to be confined under conditions of high temperatures and humidity, the use of tranquilizing drugs has been recommended to reduce unnecessary activity. However, care is needed because blood pressure falls and the animals may have difficulty losing heat if the environment is very hot, and in some cases may gain heat. Chlorpromazine, for example, has been shown to increase significantly the survival rate of pigs exposed to heat and humidity stress.

FEVER (PYREXIA)

Fever is an elevation of core body temperature above that normally maintained by an animal and is independent to the effects of ambient conditions on body temperature. It is important to realize that fever is a combination of hyperthermia and infection or inflammation that results from an elevated set-point for temperature regulation.

ETIOLOGY

Fevers may be septic, the more common type, or aseptic, depending on whether or not infection is present.

Septic fevers

These include infection with bacteria, viruses, protozoa or fungi as:

- Localized infection such as abscess, cellulitis, empyema
- Intermittently systemic, as in bacteremia, endocarditis
- Consistently systemic, as in septicemia.

Aseptic fevers

- Chemical fevers, caused by injection of foreign protein, intake of dinitrophenols
- Surgical fever, due to breakdown of tissue and blood
- Fever from tissue necrosis, e.g. breakdown of muscle after injection of necrotizing material
- Severe hemolytic crises (hemoglobinemia)
- Extensive infarction
- Extensive necrosis in rapidly growing neoplasms such as multicentric lymphosarcoma in cattle
- Immune reactions – anaphylaxis, angioneurotic edema.

PATHOGENESIS

Most fevers are mediated through the action of endogenous pyrogens produced by granulocytes, monocytes and macrophages. The most important and best known **endogenous pyrogen** is interleukin-1, produced by monocytes and macrophages. The febrile response is initiated by the introduction of an **exogenous pyrogen** to the body. Exogenous pyrogens include pathogens such as bacteria, viruses, bacterial endotoxins, antigen–antibody complexes, hemoglobinemia in a hemolytic crisis, and many inorganic substances. In hypersensitivity states, soluble antigen–antibody complexes may act as mediators. One of the most potent exogenous pyrogens is the lipopolysaccharide of Gram-negative bacteria.

Endogenous pyrogens

Endogenous pyrogens are proteins released from monocytes and, to a lesser extent, lymphocytes. These proteins were originally designated as **monokines** and **lymphokines** respectively, but are now more commonly referred to under the more general term of **cytokines**. One of the pyrogenic cytokines is interleukin-1, formerly known as lymphocyte activating factor. **Interleukin-1** stimulates T-lymphocyte proliferation in the presence of antigen and thereby enhances the immune response. The mediators between endogenous pyrogen and the hypothalamus appear to be prostaglandins and the level of calcium in the hypothalamus appears to regulate its activity.

Interleukin-1 initiates fever by inducing an abrupt increase in the synthesis of **prostaglandins**, particularly prostaglandin E_2, in the anterior hypothalamus. The elevated prostaglandin levels in the hypothalamus raise the thermostatic set point and induce the mechanisms of heat conservation (vasoconstriction) and heat production (shivering thermogenesis) until the blood and core temperature are elevated to match the hypothalamic set point.

Prostaglandin precursors are believed to be the chemical mediators of fever according to the following sequence:

1. Endogenous pyrogens cause the release of arachidonic acid, with subsequent synthesis of prostaglandins
2. Arachidonic acid breakdown products modulate the hypothalamic thermoregulatory mechanism, resulting in an increase in the set point value
3. Prostaglandin synthetase-inhibitor antipyretics lower fever by blocking the synthesis of prostaglandins or prostaglandin precursors from arachidonic acid.

A cytokine known as **tumor necrosis factor (TNF)-α** reproduces many of the physiological derangements observed in septic shock and mediates many of the deleterious effects of Gram-negative bacterial infection, including fever.

In addition to their pyrogenic activity, cytokines mediate the **acute phase response**, which is a term now being used to describe the reaction of animals to pathogen invasion, tissue injury, immunological reactions and inflammatory processes. During the acute phase response, the liver increases the synthesis of certain proteins, whereas albumin synthesis is reduced. Haptoglobins, fibrinogen, ceruloplasmin and proteinase inhibitors have been examined in cattle with the acute phase response.[1] In this response, the serum iron concentration decreases during fever, which inhibits the growth of certain bacteria that require iron. Blood concentrations of zinc also decrease, with a simultaneous increase in serum copper concentrations.[2] Measurement of acute phase proteins may provide a basis for monitoring the severity of some infections and act as an aid in making a diagnosis. The concentration of fibrinogen can be a useful addition to routine hematological determination in animals.[3]

The physiological mechanisms involved in the production of fever after stimulation by pyrogens must be matured or sensitized by previous exposure to pyrogen. Injection of pyrogens into newborn lambs does not cause fever but subsequent injections do.

Effect of pyrogens on the hypothalamus

The effect of bacterial and tissue pyrogens is exerted on the thermoregulatory center of the hypothalamus so that the thermostatic level of the body is raised. The immediate response on the part of organs involved in heat regulation is the prevention of heat loss and the increased production of heat. This is the period of **increment**, or chill, which is manifested by cutaneous vasoconstriction, resulting coldness and dryness of the skin and an absence of sweating. Respiration is reduced and muscular shivering occurs, while urine formation is minimal. The extremities are cold to the touch and the rectal temperature is elevated and the pulse rate increased. When the period of heat increment has raised the body temperature to a new thermostatic level the second period of fever, the **fastigium**, or period of constant temperature, follows. In this stage the mechanisms of heat dissipation and production return to normal. Cutaneous vasodilatation causes flushing of the skin and mucosae, sweating occurs and may be severe, and diuresis develops. During this period there is decreased forestomach motility in ruminants, metabolism is increased considerably to maintain the body temperature, and tissue wasting may occur. There is also an inability to maintain a constant temperature when environmental temperatures vary.

When the effect of the pyrogenic substances is removed, the stage of **decrement**, or fever defervescence, appears and the excess stored heat is dissipated. Vasodilatation, sweating and muscle flaccidity are marked and the body temperature falls. The fall in body temperature after the initial rise is accompanied by a decline in plasma zinc and plasma total iron concentrations. If the toxemia

accompanying the hyperthermia is sufficiently severe, the ability of tissues to respond to heat production or conservation needs may be lost and as death approaches there is a precipitate fall in body temperature.

Febrile response

The febrile response, and the altered behavior that accompanies it, are thought to be part of a total mechanism generated to conserve the resources of energy and tissue being wasted by the causative infection. The febrile response has major effects on immune mechanisms. Endogenous pyrogens stimulate T-cell proliferation. The increased body temperature causes increases in leukocyte mobility, leukocyte bactericidal and phagocytic activities, lymphocyte transformation, and also enhances the effects of interferon and interleukin-1.

Some possible adverse effects of fever include anorexia, which can lead to excessive catabolism if prolonged. Rarely, extremely high fevers can result in disseminated intravascular coagulation and effects on the central nervous system that may lead to convulsions.

CLINICAL FINDINGS

The effects of fever are the combined effects of hyperthermia and infection or inflammation. There is elevation of body temperature, an increase in heart rate with a diminution of amplitude and strength of the arterial pulse, hyperpnea, wasting, oliguria often with albuminuria, increased thirst, anorexia, scant feces, depression and muscle weakness. The temperature elevation is always moderate and rarely goes above 42°C (107°F).

The **form of the fever may vary.** Thus the temperature rise may be:

- Transient
- Sustained, without significant diurnal variation
- Remittent, when the diurnal variation is exaggerated
- Intermittent, when fever peaks last for 2–3 days and are interspersed with normal periods
- Atypical, when temperature variations are irregular.

A biphasic fever, consisting of an initial rise, a fall to normal and a secondary rise, occurs in some diseases, e.g. in strangles in the horse and in erysipelas in swine. The outstanding example of intermittent fever in animal disease is equine infectious anemia.

In farm animal practice the most common cause of a fever is the presence of an inflammatory process such as pneumonia, peritonitis, mastitis, encephalitis, septicemia, viremia and the like. The clinical abnormalities that are typical of the particular disease must be detected and differentiated in the process of making a diagnosis. In the absence of physical causes of hyperthermia, the presence of a fever indicates the presence of inflammation, which is not always readily apparent. A **fever of unknown origin** occurs commonly in farm animals and requires repeated clinical and laboratory examinations to elucidate the location and nature of the lesion.

In **horses**, a **fever of unknown origin** is characterized by prolonged, unexplained fever associated with nonspecific findings such as lethargy, inappetence and weight loss. In a series of horses with fever of unknown origin, the cause was found to be infection in 43%, neoplasia in 22%, immune-mediated in 7% and miscellaneous diseases in 19%. The cause remained undetermined in 10%.[4]

The **magnitude of the fever** will vary with the disease process present and it is often difficult to decide at what point the elevated temperature is significant and represents the presence of a lesion that requires specific treatment. This is especially true when examining groups of animals with nonspecific clinical findings including an elevated temperature. The typical example is a group of feedlot cattle affected with depression, inappetence, dyspnea and fever ranging from 39.5–40.5°C. The suspected disease may be pneumonic pasteurellosis but it may be impossible to make that diagnosis based on auscultation of the lungs of all the affected animals. Some of the animals may have a fever of unknown origin from which they will recover in a few days and specific therapy is not required. Under these circumstances and based on clinical experience, the tendency is to make a diagnosis of '**acute undifferentiated bovine respiratory disease**' or '**undifferentiated fever**' in animals with a temperature ≥ 40.5°C for 2 days in succession. This emphasizes the need to select an upper threshold value that indicates a clinically and physiologically significant fever.

CLINICAL PATHOLOGY

There are no clinicopathological findings that are specific for fever. The hemogram will reflect the changes associated with the cause of the fever. Inflammation is characterized by marked changes in the total and differential leukocyte count characteristic for each disease. A wide variety of tests can be performed to identify the location and nature of the lesion causing the fever. The most commonly used include:

- Microbiologic testing of blood samples
- Analysis of serous fluids from body cavities
- Cerebrospinal fluid analysis
- Milk sample analysis
- Reproductive tract secretion analysis
- Joint fluid analysis
- Biopsies
- Exploratory laparotomy.

Medical imaging may be necessary to detect deep abscesses.

Necropsy findings

The necropsy findings will be characteristic of the individual disease process and are commonly characterized by varying degrees of peracute, acute and chronic inflammation depending on the severity of the disease, the length of illness and whether or not treatment had been given. In the case of longstanding fevers the above findings are still characteristic but they may fluctuate in severity daily or over longer periods.

Fever must be differentiated from hyperthermia due to a physical cause such as **heat stroke** or **exhaustion** or **malignant hyperthermia**. In **fever of unknown origin**, the history, physical examination, laboratory findings and epidemiological setting should be reviewed. Localizing clinical findings may provide a clue to the body system or organ involved. Common inflammatory processes include:

- **Abscesses of the peritoneum, pleura and lungs**
- **Septic metritis**
- **Endocarditis**
- **Polyarthritis**
- **Pyelonephritis**.

Many animals are placed in the category of fever of unknown origin because the veterinarian overlooks, disregards or rejects an obvious clue. No algorithms or computer-assisted diagnostic programs are likely to solve the diagnostic challenge. In order to improve the diagnostic accuracy, veterinarians will have to work harder. This requires obtaining a detailed history, repeated physical examinations, reconsideration of the epidemiological characteristics of the affected animal, requesting consultations from colleagues, and the investment of time to consider the diagnosis and the circumstances.

TREATMENT

Antimicrobial agents

The most important aspects of the clinical management of fever should be directed at its cause. The main objective is to identify and treat the primary disease. Antimicrobial agents are indicated for the treatment of bacterial infections. The selection of antimicrobial, the route of administration and the duration of treatment depend on the cause of the infection, its severity and the accessibility

of the lesion to the drug. The use of antimicrobial agents to prevent secondary bacterial infections in animals with viral diseases (e.g. viral interstitial pneumonia) is controversial and of doubtful benefit.

In animals with a **fever of unknown origin**, broad-spectrum antimicrobial agents seem rational. However, blind therapy is not recommended because it may lead to drug toxicity, superinfection due to resistant bacteria, and interference with subsequent accurate diagnosis by cultural methods. In addition, the fall of the temperature following treatment may be interpreted as a response to therapy, with the conclusion that an infectious disease is present. If such a trial is begun the response should be monitored daily to determine effectiveness and continued efforts should be made to determine the cause of the fever. In some cases it may be necessary to surgically remove by drainage techniques the source of the infection located in abscesses or body cavities such as the pleural cavity.

Antipyretics

Since fever ordinarily does little harm and usually benefits the animal's defense mechanism, antipyretic agents are rarely essential and may actually obscure the effect of a specific therapeutic agent or of the natural course of the disease. If the fever is high enough to cause discomfort or inappetence, or is so high that death due to hyperthermia is possible, then nonsteroidal anti-inflammatory drugs (NSAIDs) should be administered. Most NSAIDs, such as flunixin meglumine, are inhibitors of prostaglandin synthesis and act centrally to lower the thermoregulatory set point. Rectal temperatures start to decline within 30 min of parenteral NSAID administration but usually do not completely return to within the normal physiological range.

Septicemia/viremia

Septicemia is the acute invasion of the systemic circulation by pathogenic bacteria accompanied by sepsis or septic shock with possible bacterial localization in various body systems or organs if the animal survives. Septicemia is a common cause of morbidity and mortality in newborn farm animals which have not received a sufficient quantity of colostrum in the first 24 hours after birth. **Bacteremia** is different from septicemia in that bacteremia is not accompanied by sepsis or septic shock. The difference between septicemia and bacteremia is one of degree. In bacteremia, bacteria are present in the bloodstream for only transitory periods and do not produce clinical signs; for example, a clinically unimportant bacteremia probably occurs frequently after rectal examination or other manipulations in which mucosa is disturbed. In septicemia, the pathogen is present throughout the course of the disease and is directly responsible for initiation of the disease process.

Viremia is the invasion of the systemic circulation by pathogenic viruses with localization in various body tissues and in which the lesions produced are characteristic of the specific virus. Many infections associated with rickettsias, protozoa and fungi are also spread hematogenously throughout the body but do not initiate a systemic inflammatory response syndrome.

ETIOLOGY

Many different infectious agents can result in septicemia or viremia. Some of the notable examples of septicemias and viremias are outlined below.

All species

Anthrax, pasteurellosis and salmonellosis are found in all species of food animal.

Neonatal septicemias

Neonatal septicemias are caused most commonly by Gram-negative bacteria.

Calves

Bacteremia and septicemia are often associated with *Escherichia coli* and *Salmonella* spp. *E. coli* is most frequently isolated from the blood of calves[1] but Gram-positive infections may be found in 10% of septicemic calves and polymicrobial infections in 28%.[2] Calf septicemia is infrequently caused by an *Actinobacillus-suis*-like bacteria.[3] Thirty percent of severely ill calves with or without diarrhea are bacteremic, with the risk of bacteremia being higher in calves with failure of transfer of colostral immunoglobulins.[1,4,5]

Piglets

Septicemia due to *E. coli* is possible, also septicemia with localization in the joints, endocardium and meninges associated with *Streptococcus suis* type 1.

Foals

Septicemia with localization associated with *E. coli*, *Actinobacillus equuli*, *Klebsiella pneumoniae*, α-hemolytic *Streptococcus*, and *Salmonella* spp. are seen.

Lambs

Septicemia associated with *E. coli* occurs most frequently.

Cattle

Histophilus somni, *Pasteurella multocida*, *Mannheimia haemolytica*, *Pasteurella (Yersinia) pseudotuberculosis*, acute and chronic infections with bovine virus diarrhea virus and bovine malignant catarrh are encountered.

Sheep (young lambs)

Histophilus somni is the main pathogen.

Pigs

Hog cholera and African swine fever viruses and *Erysipelothrix insidiosa* are encountered.

Horses, donkeys, mules

African horse sickness and *M. haemolytica* infection are implicated.

Secondary septicemias

The principal cause of death in subacute radiation injury is septicemia resulting from loss of leukocyte production because of injury to bone marrow. Septicemia may also result when there is a congenital defect in the immune system or when immunosuppression occurs in older animals as a result of corticosteroid therapy or toxin such as bracken.

EPIDEMIOLOGY

Systemic infections associated with bacteria, viruses, rickettsia, protozoa and other pathogens occur in animals of all ages and under many different circumstances. The epidemiological characteristics for each entity are presented under each disease described in this book. The risk factors for each infectious disease are categorized according to:

- **Animal risk factors**
- **Environmental risk factors**
- **Pathogen risk factors.**

For example, colostrum-deprived newborn animals are highly susceptible to septicemia.[6] Failure of transfer of passive immunity in foals is defined by serum IgG_1 levels of ≤ 400 mg/dL; partial failure of transfer of passive immunity between 400 and 800 mg/dL. Serum IgG concentrations of ≥ 800 mg/dL are less frequently associated with sepsis in foals and this is considered the threshold concentration for prophylaxis in foals.

PATHOGENESIS

Two mechanisms operate in septicemia: the **exotoxins** or **endotoxins** produced by the infectious agents initiate a profound toxemia and high fever because of their initiation of the release of host mediators and because of the rapidity

with which the agents multiply and spread to all body tissues (see also Toxemia and Shock. The clinical manifestations are the result of the effect of the pathogens on monocytes and lymphocytes, which initiate the **systemic inflammatory response syndrome**. TNF-α is associated with clinical septicemia in newborn foals[7] and calves,[8] with plasma TNF-α concentration being associated with the severity of clinical signs.

Localization of certain pathogens occurs in many organs and may produce severe lesions in animals that survive the toxemia. Direct endothelial damage and hemorrhages may also be caused. The same general principles apply to a viremia, except that toxins are not produced by viruses. It is more likely that the clinical manifestations are the result of direct injury of the cells invaded by the virus. **Transplacental infection** can occur, resulting in fetal **mummification**, **abortion**, or **infection of the fetus that may be carried to term**.

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) is common in severe septicemic disease, especially that which terminates fatally. It is initiated by vascular injury with partial disruption of the intima, caused by the circulation of foreign materials such as bacterial cell walls, antigen–antibody complexes and endotoxin, with subsequent platelet adherence and the formation of platelet thrombi. Once coagulation proceeds, the initial hypercoagulable state changes to hypocoagulation, as clotting factors and platelets are consumed. The activation of the fibrinolysis system can be a major cause of the hemorrhagic diathesis present in this syndrome.

CLINICAL FINDINGS

The major clinical findings in septicemia are **fever**, **cardiovascular dysfunction and shock**, and **submucosal and subepidermal hemorrhages** that are usually petechial and occasionally ecchymotic. The hemorrhages are best seen under the conjunctiva and in the mucosae of the mouth and vulva. Tachycardia, tachypnea and shock-induced organ dysfunction with cardiovascular hypotension, myocardial asthenia and respiratory distress may occur in severe cases if the pathogen initiates the release of the host mediators, causing the **systemic inflammatory response syndrome (SIRS)**. These features are described under Toxemia and Shock.

Specific signs may occur as the result of localization of the infection in joints, heart valves, meninges, eyes or other organs. The clinical findings characteristic of each disease in which septicemia and viremia occur are presented under each disease heading in this book.

Neonatal septicemia

Neonatal septicemia is common in all farm animal species from a few hours up to several days of age. The following features are common:

- Recumbency
- Depression
- Absence or marked depression of the suck reflex
- Dehydration
- Fever
- Diarrhea
- Injected or congested mucous membranes
- Weakness
- Rapid death.

Colostrum-deprived foals are commonly very ill and become comatose and die within several hours. Localized infections in the joints and lungs are frequent in foals that survive for several days. Septic polyarthritis is common and is characterized by heat, pain, synovial distension and lameness. Pneumonia is often observed and is characterized by dyspnea and abnormal lung sounds. The survival rate of foals with confirmed septicemia in one series was 70%.[9]

In calves under 30 days of age with septicemia clinical findings can include evidence of shock with cold extremities, dehydration, weak pulse, prolonged capillary refill time, weakness and recumbency.[2] Findings indicative of localization include ophthalmitis, neurological abnormalities, omphalophlebitis and polyarthritis.

Clinical sepsis score

A **clinical sepsis score** for the early diagnosis of septicemia in newborn foals has been evaluated and validated.[10] It should be recognized that application of such scoring systems is statistically flawed, as it assigns equal weights to predictors and equal weights to change in severity within a given predictor. Nevertheless, such sepsis scores have been adopted by some and do have the value of facilitating the identification of neonates at risk for being septicemic. A score for predicting bacteremia in neonatal dairy calves from 1–14 days of age has also been suggested to predict clinically whether a sick calf has bacteremia.[11] The calves are scored according to degrees of **hydration status**, **fecal appearance**, **general attitude**, **appearance of scleral vessels** and **umbilical abnormality**. However, the sensitivity, specificity and positive predictive value are too low to be of diagnostic value.[5]

CLINICAL PATHOLOGY

Blood culture

Isolation of the causative bacteria from the bloodstream should be attempted by culture. Ideally, blood cultures should be obtained just before the onset of fever and from a major vein or any artery. The standard is three blood cultures or animal inoculation at the height of the fever. A minimum of 10 mL of blood (preferably 30 mL) should be collected anaerobically after aseptic preparation of the venipuncture site by clipping and scrubbing with povidone iodine scrub. Blood samples should be inoculated into a broth medium with the ratio of blood to broth being 1:10 to 1:20,[12] and the culture bottles should be examined for growth daily for up to a week.[13] Growth is manifest as turbidity and possibly by the presence of hemolysis.

Hemogram

The presence of **leukopenia** or **leukocytosis** is an aid in diagnosis and the type and degree of leukocytic response may be of prognostic significance.

Plasma fibrinogen concentrations may be increased.[2] Consumption coagulopathy is detected by falling platelet counts, prothrombin and fibrinogen values, and also by the presence of fibrin degradation products.

Immunoglobulin status

Low levels of serum protein and immunoglobulins are associated with failure of transfer of colostral immunoglobulins in newborn farm animals with consequent septicemia due, most commonly, to Gram-negative bacteria.

Serology

Serological tests are available for most infectious diseases described in this book.

Necropsy findings

The lesions will reflect the specific disease causing the septicemia. Subserous and submucosal hemorrhages may be present, together with embolic foci of infection in various organs accompanied by the lesions typical of the specific pathogen.

TREATMENT

The principles of treatment are similar to those described for the treatment of toxemia, fever and shock, and treatment should focus on broad-spectrum antimicrobial agents and general supportive measures. For neonatal septicemia the provision of a source of immunoglobulins by plasma or blood transfusion is necessary when there is failure of transfer of passive immunity. Whether such treatment alters the mortality rate is uncertain. Intensive care of the newborn with septicemia is described in Chapter 3. The frequency of bacteremia (approximately 30%) is sufficiently high in calves

with diarrhea that are severely ill (as manifest by reduced suckle reflex, > 6% dehydration, weakness, inability to stand, or clinical depression) that affected calves should be routinely treated for bacteremia, with emphasis on treating potential *E. coli* bacteremia.[1,4,5] Strict hygienic precautions to avoid spread of infection are also necessary.

Toxemia and endotoxemia

Toxemia is a clinical systemic state caused by widespread activation of host defense mechanisms to the presence of toxins produced by bacteria or injury to tissue cells. Toxemia does not include the diseases caused by toxic substances produced by plants or insects or ingested organic or inorganic poisons. Theoretically, a diagnosis of toxemia can be made only if toxins are demonstrable in the bloodstream. Practically, toxemia is often diagnosed when the syndrome described below is present. In most cases there is contributory evidence of a probable source of toxins, which in many cases are virtually impossible to isolate or identify.

The most common form of toxemia in large animals is **endotoxemia**, caused by the presence of lipopolysaccharide cell-wall components of Gram-negative bacteria in the blood, and characterized clinically by abnormalities of many body systems. Because of the overwhelming importance of endotoxemia in large animals with Gram-negative bacterial infections, the focus of this discussion will be on endotoxemia. The abnormalities of endotoxemia include:

- Marked alterations in cardiopulmonary function
- Abnormalities in the leukon (neutropenia and lymphopenia) and thrombocytopenia that may lead to coagulopathies
- Increased vascular permeability
- Decreased organ blood flow and metabolism, leading to heart and renal failure
- Decreased gastrointestinal motility
- Decreased perfusion of peripheral tissues, leading to shock
- The need for intensive and complex therapy
- A high case fatality rate.

Current therapeutic regimens are only moderately successful.

Gram-negative bacteria such as *E. coli*, *Salmonella* spp., *Pasteurella* spp. and *Histophilus somni*, as examples, cause many diseases of ruminants in which endotoxemia is common.[1] Varying degrees of severity of toxemia occur in diseases such as mastitis, peritonitis, pneumonia and pleuritis, pericarditis, septic metritis, septicemia of neonates, myositis, meningoencephalitis and some enteritides. Endotoxemia is also one of the commonest causes of death in horses affected with gastrointestinal disease due to a physical obstruction causing strangulation and ischemic necrosis.

ETIOLOGY OF TOXEMIA AND ENDOTOXEMIA

Toxins can be classified as antigenic or metabolic.

Antigenic toxins

These are produced by bacteria and to a lesser extent by helminths. Both groups of pathogens act as antigens and stimulate the development of antibodies. Antigenic toxins are divided into exotoxins and endotoxins.

Exotoxins

These are protein substances produced by bacteria that diffuse into the surrounding medium. They are specific in their pharmacological effects and in the antibodies that they induce. The important bacterial exotoxins are those produced by *Clostridium* spp., for which commercial antitoxins are available. They may be ingested preformed, as in botulism, or produced in large quantities by heavy growth in the intestines, such as in enterotoxemia, or from growth in tissue, as in blackleg and black disease.

Enterotoxins

These are exotoxins that exert their effect principally on the mucosa of the intestine, causing disturbances of fluid and electrolyte balance. The most typical example is the enterotoxin released by enterotoxigenic *E. coli*, which causes a hypersecretory diarrhea in neonatal farm animals.

Endotoxins

The endotoxins of several species of Gram-negative bacteria are a major cause of morbidity and mortality in farm animals. The endotoxins are lipopolysaccharides found in the outer wall of the bacteria. Endotoxins are released into the immediate surroundings when the bacteria undergo rapid proliferation with production of unused sections of bacterial cell wall or, most commonly, when the bacterial cell wall breaks. Endotoxin gains access to the blood when there is a severe localized infection, such as a coliform mastitis in dairy cattle, or a disseminated infection, such as coliform septicemia in newborn calves.

Gram-negative bacteria are present in the intestinal tract as part of the normal microflora and endotoxins are also present. The endotoxins are not ordinarily absorbed through the intestinal mucosa unless it is injured, as in enteritis or more particularly in acute intestinal obstruction. Ordinarily, small amounts of endotoxin that are absorbed into the circulation are detoxified in the liver but, if hepatic efficiency is reduced or the amounts of toxin are large, a state of endotoxemia is produced. Endotoxins may also be absorbed in large amounts from sites other than intestine including the mammary gland, peritoneum, abscesses and other septic foci, or from large areas of injured or traumatized tissue. The best known endotoxins are those of *E. coli*, which have been used extensively as models for experimental endotoxemia, and *Salmonella* spp.

The most common causes of endotoxemia in horses are associated with diseases of the gastrointestinal tract including colitis, intestinal strangulation or obstruction and ileus.[2] Complications associated with foaling and grain overload are also common causes.

Metabolic toxins

These may accumulate as a result of incomplete elimination of toxic materials normally produced by body metabolism, or by abnormal metabolism. Normally, toxic products produced in the alimentary tract or tissues are excreted in the urine and feces or detoxified in the plasma and liver. When these normal mechanisms are disrupted, particularly in hepatic dysfunction, the toxins may accumulate beyond a critical point and the syndrome of toxemia appears. In obstruction of the lower alimentary tract there may be increased absorption of toxic phenols, cresols and amines that are normally excreted with the feces, resulting in the development of the syndrome of autointoxication. In ordinary circumstances in monogastric animals these products of protein putrefaction are not absorbed by the mucosa of the large intestine but when regurgitation into the small intestine occurs there may be rapid absorption, apparently because of the absence of a protective barrier in the wall of the small intestine.

In liver diseases, many of the normal detoxification mechanisms, including

oxidation, reduction, acetylation and conjugation with such substances as glycine, glucuronic acid, sulfuric acid and cysteine, are lost and substances which are normally present in insufficient quantity to cause injury accumulate to the point where illness occurs. The production of toxins by abnormal metabolism is taken to include the production of histamine and histamine-like substances in damaged tissues. Ketonemia due to a disproportionate fat metabolism, and lactic acidemia caused by acute ruminal acidosis (grain overload), are two common examples of toxemia caused by abnormal metabolism.

PATHOGENESIS OF ENDOTOXEMIA

The specific effects of the particular bacterial exotoxins and metabolic toxins are presented in the relevant sections of specific diseases in the Special Medicine section of this book. The principles of the effects of bacterial endotoxemia will be presented here.

The total toxic moiety of the lipopolysaccharide molecule is generally similar regardless of the bacterial source. Endotoxemia results in an extraordinary array of pathophysiological effects, involving essentially all body systems. Of the endotoxins produced by bacteria most is known of those produced by *E. coli*.

Endotoxins are normally present in the intestine and although the intestinal mucosa provides a highly efficient barrier, limiting transmural movement of endotoxins, small quantities are absorbed into the portal blood. These endotoxins are removed by the liver and do not reach the peripheral blood. In hepatic failure the level of endotoxins in plasma is increased. Significantly greater quantities of endotoxins escape the intestine when the mucosal barrier is disrupted by intestinal ischemia, trauma, ionizing radiation, bacterial overgrowth, reduced luminal pH or inflammatory intestinal disease.[3] These conditions not only temporarily overwhelm the capacity of the liver to remove endotoxin from the portal circulation but also allow transmural movement of endotoxins into the peritoneal cavity from which they reach the peripheral blood.

Endotoxemia may also occur when Gram-negative bacteria gain access to tissues and/or blood. Most of these organisms liberate endotoxin during rapid growth and gain access to the blood from primary foci of systemic or superficial tissue infections. An example is coliform septicemia in newborn farm animals. Once the endotoxins gain access to the blood, they are removed from the circulation by the mononuclear phagocyte system, and the response of these phagocytes to the lipopolysaccharides determines the severity of the clinical illness.

Biochemical mediators

Endotoxins do not cause their effects via direct toxic effect on host cells but rather induce the production of soluble and cell-bound mediators from a broad range of host cells, including endothelial and smooth muscle cells, polymorphonuclear granulocytes, platelets, thrombocytes and cells of the monocyte/macrophage lineage. These cells release a series of phlogistic biochemical mediators, which include cytokines, platelet-activating factor, thromboxane A_2, prostaglandins, leukotrienes, proteinases, toxic oxygen metabolites and vasoactive amines. Macrophages become highly activated for enhanced secretory, phagocytic and cidal functions by the lipopolysaccharide. The cytokines derived from the macrophages are responsible for many of the pathophysiological consequences of endotoxemia. Pulmonary intravascular macrophages are the most important producers of cytokines in large animals.

Animals have evolved to recognize and respond to the lipopolysaccharide of Gram-negative bacteria. Although lipopolysaccharide may directly injure the host tissue, many of its effects are indirectly mediated through inappropriate activation of host defense mechanisms, culminating in multiple-organ dysfunction and failure. Importantly, the response to endotoxin can be attenuated with certain substances. Experimentally, the use of detergents, such as a nonionic surfactant, can attenuate the response of the horse given endotoxin.[4] The literature on the pathophysiological effects of endotoxemia and Gram-negative bacteremia in swine has been reviewed.[5]

There is a large individual variability in the response to endotoxin administration, with much of the variability still being unexplained. Circulating lipopolysaccharide forms complexes in plasma with high density lipoproteins or a unique plasma protein termed **lipopolysaccharide-binding protein** (LBP) and bound lipopolysaccharide is cleared from plasma within a few minutes by fixed and circulating macrophages in the bovine lung and liver that recognize the lipopolysaccharide–LBP complex. The lipopolysaccharide–LBP complex binds to a membrane-bound receptor (mCD14) on mononuclear cells via a secreted linking protein called MD-2 and then attaches to a **toll-like receptor 4** (TLR4) on the mononuclear cell membrane; the lipopolysaccharide–LBP–mCD14–MD-2 complex is then internalized and lipopolysaccharide is thought to be destroyed in the process. Internalization of lipopolysaccharide activates the intracellular signaling pathway via nuclear factor kappa B (**NF-κB**), which translocates to the nucleus and causes the transcription of many cytokine genes and release of proinflammatory cytokines, of which **TNF-α**, **interleukin-1** and **interleukin-6** are the most important. Some of the genes activated include those that code for cyclooxygenase 2 (**COX-2**, the inducible form of cyclooxygenase), inducible nitric oxide (**iNOS**), **endothelial adhesion molecules**, which promote the adhesion of neutrophils to endothelial surfaces, and chemokines.

The plasma concentrations of the **arachidonic acid metabolites**, **thromboxane A_2** and **prostacyclin**, increase in several species during endotoxemia, and these eicosanoids are probably responsible for the hemodynamic abnormalities caused by endotoxin. Endotoxin initiates cellular events that activate a cell-membrane enzyme known as phospholipase A_2. Activation of this enzyme leads to the hydrolysis of membrane-bound phospholipids; arachidonic acid is released from the phospholipid portion of damaged mammalian cell membranes.[6] The enzyme cyclooxygenase converts arachidonic acid into intermediate endoperoxides, which are substrates for the formation of prostaglandins, thromboxane and prostacyclin, by specific synthetases. Platelets are the principal source of thromboxane, which acts as a potent vasoconstrictor and induces platelet aggregation. Most prostacyclins are synthesized in vascular endothelial cells and cause vasodilation and inhibit platelet aggregation. The generalized endotoxin-induced production of cyclooxygenase products may contribute to the multisystemic organ dysfunction, shock and disseminated coagulopathy that culminates in death.

TNF-α is released by macrophages early in the course of endotoxemia and circulating TNF-α activity correlates with the severity and outcome of disease. Infusion of TNF induces an endotoxemic-shock-like syndrome and TNF-α blockade confers marked protection against the effects of Gram-negative sepsis and lipopolysaccharide administration. Experimentally, pretreatment of horses with monoclonal antibody to TNF-α can reduce the hematological and clinical effects of endotoxin-induced TNF activity[7] and interleukin-6 activity can be reduced by neutralization of TNF-α.[8] Interleukin-1 release is proinflammatory and leads to pyrexia and the hepatic acute phase response. Interleukin-6 contributes to the hepatic acute phase response and promotes B-lymphocyte proliferation. Interleukin-6 may have value as a prognostic indicator, as its plasma concentration appears to be a better predictor of mortality in humans than TNF-α or interleukin-1.

The systemic effects of endotoxemia can be demonstrated experimentally by parenteral injection of purified endotoxin, TNF-α or interleukin-1. In naturally occurring disease, however, the total effect includes those of bacterial toxins plus those of mediators produced by tissues in response to the toxins, and the counterbalancing effects of anti-inflammatory molecules that are also secreted during sepsis, such as interleukin-4, interleukin-10, interleukin-11, interleukin-13, and soluble CD14 receptors. The pathophysiological effects of endotoxemia associated with Gram-negative bacteria are summarized here according to their effects on various body systems or functions.

Cardiopulmonary function

The hemodynamic effects of endotoxemia are manifested in two phases.[9] In the early stages, heart rate and cardiac output commonly increase, although systemic blood pressure remains near or slightly less than normal. This is known as the **hyperdynamic phase** of endotoxemia. Oxygen demands of peripheral tissues are increased during the hyperdynamic phase, resulting in compensatory mechanisms that increase blood flow in an attempt to meet the increased metabolic demands. However, despite the absolute increase in cardiac output and oxygen delivery during this hyperdynamic phase, blood flow still may be inadequate to meet the needs of tissues in a hypermetabolic state. During the hyperdynamic state, affected animals hyperventilate and have decreased capillary refill time and red, congested mucous membranes. Microcirculatory shunting of blood continues in organs such as the gastrointestinal tract and kidney. Ischemia of intestinal mucosa is manifested clinically by ileus and diarrhea may occur. Decreased renal perfusion will result in decreased urine output.

With uncontrolled endotoxemia, the hyperdynamic phase progresses to the **hypodynamic phase** of shock. Changes include decreased cardiac output, systemic hypotension, increased peripheral resistance and decreased central venous return. Hypothermia, rapid irregular pulses, prolonged capillary refill time, pale to cyanotic mucous membranes, acidemia and hypoxemia provide clinical evidence of this advanced stage of endotoxemia. The skin and extremities are cool. Severe pulmonary edema and increasing pulmonary hypertension occur. In horses, administration of endotoxin at high dosages can induce circulatory shock with increased heart rate, decreased cardiac output and stroke volume, and concomitant increases in peripheral vascular resistance. The slow intravenous infusion of low dosages of endotoxin into conscious horses results in pulmonary hypertension without causing hypotensive, hypovolemic shock.[10] Intestinal vasoconstriction occurs as part of the compensatory response to endotoxemia following slow infusion of low dosages of endotoxin.

Infusion of endotoxin into swine induces widespread changes including intense pulmonary vasoconstriction and hypertension, bronchoconstriction, increased vascular permeability, hypovolemia, systemic hypotension, pulmonary edema, hypoxemia, granulocytopenia and thrombocytopenia.[5] The vascular changes in endotoxemia include increased vascular permeability, changes in vascular tone and microvascular obstruction. Increased capillary permeability promotes transmural movement of albumin and other colloids, which carry water to the interstitial space. The result is hypoalbuminemia, hypoproteinemia, interstitial edema, pulmonary edema, relative hypovolemia, decreased return to the heart and further decreases in cardiac output. Arterial and arteriolar vasoconstriction develops in the systemic and pulmonary circulations. Prolonged infusion of endotoxin into sheep causes systemic hypotension, pulmonary hypertension and acute lung injury with progressive respiratory failure.[11]

Endotoxemia causes an acute and severe neutropenia, which precedes neutrophilia and hemoconcentration. Neutropenia is due mainly to leukocyte margination and sequestration; persistence of severe neutropenia is a poor prognostic indicator. Hemoconcentration is due to movement of fluid from the vascular to extravascular spaces. Endotoxin administration causes an immediate accumulation, margination and activation of leukocytes in the microcirculation, particularly in the alveolar capillaries. This is followed by degranulation and leukocyte migration into the interstitium and endothelial cell damage. Pulmonary sequestration of neutrophils is preceded by endotoxin uptake by pulmonary intravascular macrophages, indicating that the pulmonary macrophage response is pivotal to the subsequent inflammatory response. Leukopenia appears to be an immediate response to endotoxin administration, and is observed as early as 5 min after infusion. The rebound leukocytosis is caused by humoral effects on the bone marrow; a neutrophil-releasing factor that promotes release of neutrophils from bone marrow, and macrophage-colony-stimulating factor, which stimulates granulopoiesis. Colostrum-fed calves have a greater neutrophilia in response to endotoxin than colostrum-deprived calves, possibly because of absorption of a granulopoietic factor from colostrum. Endotoxemia also induces a lymphopenia that is secondary to the release of endogenous corticosteroids and redistribution of lymphocytes from peripheral blood and the spleen to lymphatic tissue.

Thrombocytopenia is consistently observed after endotoxin administration, but occurs later than neutropenia, although it is sustained for a longer period of time. Endotoxin affects platelet function by a number of different mechanisms.

Hemostatic system

Endotoxins cause endothelial injury directly or indirectly, and thereby expose subendothelial collagen and tissue thromboplastin, initiating the intrinsic and extrinsic coagulation cascades, respectively.[3] Endotoxin can initiate the coagulation cascade directly by activation of factor XII or by inducing platelet release of thromboxane and other procoagulant substances. Endotoxin may induce coagulopathy indirectly by endothelial damage with secondary factor XII activation, or through the effects of complement activation. Macrophages and leukocytes have been shown to release a procoagulant substance in response to endotoxin, which functions similarly to factor VII and may also have a role in perpetuating coagulopathy in endotoxemia via the extrinsic pathway.

Disseminated coagulopathy is the cause of diffuse microvascular thrombosis and eventual organ failure subsequent to endotoxemia. The experimental injection of endotoxin can cause diffuse microthrombosis in multiple or organ systems. The principal clinical finding of DIC in horses is petechial and/or ecchymotic hemorrhages on mucous membranes and sclerae with a tendency to bleed from venepuncture sites. Spontaneous epistaxis or prolonged hemorrhage after nasogastric intubation may also occur. The result of exaggerated thrombin formation during DIC is widespread fibrin deposition in the microcirculation causing circulatory obstruction and organ hypoperfusion that may lead to ischemic necrosis and failure. The ultimate consequences are multiple organ failure and death.

Thermoregulation

Bacterial endotoxins are potent stimulators of macrophage interleukins, which belong to a family of polypeptides functioning as key mediators of various infectious, inflammatory and immunological challenges to the host. Interleukin-1 induces fever, an increase in the number and immaturity of circulating neutrophils, muscle proteolysis through increased prostaglandin E_2 production, hepatic acute phase protein production, and

reduced albumin synthesis. Interleukin-1 participates in the acute phase response, which is characterized by fever, hepatic production of acute phase proteins, neutrophilia and procoagulant activity.[9]

Endotoxins commonly cause a fever followed by hypothermia. Serum interleukin-6 concentrations are lower in endotoxin-induced colostrum-deprived foals and take longer to reach peak levels compared to colostrum-fed foals.[12] The higher and more rapid concentrations in colostrum-fed foals may be part of a resistance factor in equine neonates. Interleukin-6 plays a key role in host defense, regulating antigen-specific immune responses, hematopoiesis, cellular differentiation and the acute phase reaction subsequent to an inflammatory insult. Serum TNF-α responds in a similar pattern in colostrum-deprived and colostrum-fed foals given endotoxin and the mean rectal temperature in colostrum-deprived foals is significantly less than in colostrum-fed foals.[12]

Gastrointestinal function

Endotoxemia can cause a profound inhibition of gastrointestinal motility, including the stomach, small and large intestine. Postoperative ileus is a frequent and serious complication of equine colic surgery and there is a good correlation between the incidence of ileus and the presence of ischemic intestine. Low doses of endotoxin infused into ponies produced profound disruption of normal fasting intestinal motility patterns, with an inhibition of gastric contraction amplitude and rate, left dorsal colon contraction product and small-colon spike rate.[13] In the small intestine, there is an increase in abnormally arranged regular activity and a decrease in irregular activity. Experimental endotoxemia in the horse causes cecal and proximal colonic hypomotility (ileus) by a mechanism involving α-adrenergic receptors, which is reversible by yohimbine.[14] Numerous mediators may interact with the sympathetic nervous system to induce this effect.

The administration of endotoxin to adult dairy cows can reduce the frequency of reticulorumen contractions; this is caused by endotoxin-induced mediators[15] and the effect can be abolished by flunixin meglumine. Endotoxemia also decreases the abomasal emptying rate in cattle and is suspected to play a role in the development of left displaced abomasum.

Carbohydrate metabolism

The effects on carbohydrate metabolism include a fall in plasma glucose concentration, the rate and degree varying with the severity of endotoxemia, a disappearance of liver glycogen and a decreased glucose tolerance of tissues so that administered glucose is not used rapidly. Endotoxic shock can result in lactic acidemia and both hyper- and hypoglycemic responses. **Hyperglycemia** occurs early and transiently in endotoxic shock, is accompanied by increased rates of glucose production and is dependent on mobilization of hepatic glycogen. **Hypoglycemia** is very common in prolonged or severe endotoxemia. Experimental infusion of endotoxin into sheep results in transient hyperglycemia associated with increased hepatic glucose production followed by hypoglycemia 3–8 hours later, when hepatic glucose production decreases. Sympathetic activation occurs early in endotoxemia and is probably responsible for the initial hyperglycemia and glycogenolysis. Blood pyruvate and lactate concentrations increase as a result of poor tissue perfusion and the anaerobic nature of tissue metabolism. By extrapolation from the known pathogenesis of endotoxic shock in horses, it is likely that the resulting accumulation of lactate has significant effects in causing mental depression and poor survival.

Protein metabolism

There is an increase in tissue breakdown (catabolism) and a concomitant increase in serum urea nitrogen concentration. The changes observed include alterations in individual plasma amino acid concentrations, increased urinary nitrogen excretion and increased whole-body protein turnover. The time-course changes in the concentrations of plasma amino acids and other metabolites during and after acute endotoxin-induced fever in mature sheep have been described. Rapid and extensive changes occur in the patterns of tissue protein metabolism in the ruminant in response to endotoxin administration, and these changes may contribute to economic losses incurred during infectious disease outbreaks. There is also an alteration in the aminogram (the relative proportions of the amino acids present in blood) and the electrophoretic pattern of plasma proteins. The globulins are increased and albumin decreased as part of the acute phase reaction.

Mineral metabolism

Negative mineral balances occur. These include hypoferremia and hypozincemia as part of the acute phase reaction as the animal attempts to sequester these microminerals from invading bacteria, but blood copper concentrations are commonly increased concurrently with an increase in blood ceruloplasmin levels.

Reproduction and lactogenesis

Endotoxemia can cause pregnancy failure in domestic animals, particularly when pregnancy is corpus-luteum-dependent. In horses and cattle, experimentally induced endotoxemia causes an immediate and pronounced release of prostaglandin $F_{2\alpha}$. The intravenous administration of endotoxin may influence luteal function by the activation of the arachidonic acid cascade, by a direct effect of prostaglandin $F_{2\alpha}$ on the corpus luteum. The administration of endotoxin to mares pregnant 21–35 days results in a decrease in progesterone and fetal death, which can be prevented by daily treatment with a progesterone compound.[16] Similar results have been produced in pregnant dairy cows during the first 150 days of lactation, and coliform mastitis in the first 5 months of lactation is becoming an increasingly important cause of early embryonic death and return to estrus. The uterus of the early postpartum cow is capable of absorbing endotoxin, which may provoke changes in the serum concentrations of prostanoids[17] and is thought to contribute substantially to the systemic signs of toxic metritis in cows. Endotoxin has a negative effect on the genital functions of the ram; the changes in luteinizing hormone (LH) and testosterone are similar to those seen after heat-induced stress.

In recently farrowed swine with the mastitis–metritis–agalactia syndrome, it is suggested that the endotoxin from the mammary glands affected with mastitis may be important in the pathogenesis of the agalactia.

Combined effects on body systems

The combined effects of the hypoglycemia, hyper L-lactatemia and acidemia interfere with tissue enzyme activity and reduce the functional activity of most tissues. Of these factors, acidemia is probably the most important in adult animals; in neonates glucose levels are probably as important as acidemia because profound hypoglycemia is more commonly encountered in neonatal animals. Experimental endotoxemia in calves at 24–36 hours of age causes severe hypoglycemia, lactic acidemia and hypotension commonly associated with moderate to severe sepsis.[18] The myocardium is weakened, the stroke volume decreases and the response to cardiac stimulants is diminished. There is dilatation and in some cases damage to capillary walls, so that the effective circulating blood volume is decreased; this decrease, in combination with diminished cardiac output, leads to a fall in blood pressure and the development of circulatory failure. The resulting decline in the perfusion of tissues and oxygen consumption contributes greatly to the animal's decline and to the clinical signs, such as the dark red coloration of the oral

mucosa. Respiration is little affected except in so far as it responds to the failing circulation.

There is decreased liver function, and the damage to renal tubules and glomeruli causes a rise in blood nonprotein nitrogen and the appearance of albuminuria. The functional tone and motility of the alimentary tract is reduced and the appetite fails; digestion is impaired, with constipation usually following. A similar loss of tone occurs in skeletal muscle and is manifested by weakness and terminally by prostration.

Apart from the effects of specific toxins on the nervous system, such as those of *Clostridium tetani* and *Clostridium botulinum*, there is a general depression of function attended by dullness, depression and finally coma. Because of the suspected role of *E. coli* in the etiology of edema disease of swine, it is noteworthy that some of the characteristic nervous system lesions of that disease are missing from experimentally induced porcine colitoxicosis. Changes in the hemopoietic system include depression of hemopoiesis and an increase in the number of leukocytes – the type of cell that increases often varying with the type and severity of the toxemia. Leukopenia may occur but is usually associated with aplasia of the leukopoietic tissue associated with viruses or specific exogenous substances such as radioactive materials. Most of these pathophysiological effects of endotoxicosis have been produced experimentally, and it is apparent that very small amounts of endotoxin can contribute greatly to the serious effects of intestinal disease, especially in the horse.

Endotoxin tolerance

The repeated administration of lipopolysaccharide results in attenuation of the host response, known as endotoxin tolerance. This refractoriness to endotoxin-mediated effects comprises two phases. Early phase tolerance is transient, occurs within hours or days and is not associated with anti-endotoxin antibody production. Late phase tolerance requires several days to develop and is long lasting, antigen specific and the result of antibody production. By this mechanism it is possible for individual animals to survive a dose of endotoxin lethal to the nontolerant individual. Experimentally, horses develop endotoxin tolerance following sequential sublethal infusions of endotoxin.[19]

Hypersensitivity

A secondary effect produced by some toxins is the creation of a state of hypersensitivity at the first infection so that a second infection, or administration of the same antigen, causes anaphylaxis or an allergic phenomenon such as purpura hemorrhagica. Also, a generalized Schwartzmann reaction can be induced in pigs by an injection of *E. coli* endotoxin, especially if there are two injections properly spaced (in time). Pigs on a vitamin-E-deficient diet are much more severely affected than pigs on a normal diet. Vitamin E is protective; selenium is not.

Other infectious toxins

In mycoplasmosis (*Mycoplasma mycoides* var. *mycoides*), at least part of the toxic effect is attributable to galactans contained in the toxins. These have a noticeably local effect in causing hemorrhages in alveolar ducts and pulmonary vessel walls so that pulmonary arterial blood pressure rises as systemic blood pressure falls. Later lesions are pulmonary edema and capillary thrombosis, which are characteristic of the natural disease of pleuropneumonia. Disseminated intravascular coagulation is also a characteristic of the lesions associated with the toxin of *Pseudomonas* spp.

CLINICAL FINDINGS OF TOXEMIA AND ENDOTOXEMIA

Acute toxemia

The clinical findings of acute toxemia in most nonspecific toxemias are similar. The syndrome varies with the speed and severity of the toxic process but the variations are largely of degree. **Depression**, **anorexia** and **muscular weakness** are common in acute endotoxemia. **Calves do not suck voluntarily** and may not have a suck reflex. Scant feces are common but a low-volume diarrhea may also occur. The heart rate is increased and initially the intensity of the heart sounds is increased, but later as the toxemia worsens the intensity may decrease. The pulse is weak and rapid but regular. A **fever** is common in the early stages of endotoxemia but later the temperature may be normal or subnormal. In neonatal calves, foals and lambs a fever may not occur because of failure of thermoregulation or deprivation of colostrum. Terminally, there is muscular weakness to the point of collapse and death occurs in a coma or with convulsions.

Endotoxemia

When toxin formation or liberation into the circulation is rapid and the toxicity of the toxin high enough, the onset of cardiovascular collapse is rapid enough to cause a state of 'toxic' or 'septic' shock. The remarkable clinical findings are:

- Severe **peripheral vasodilatation** with a consequent fall in blood pressure
- **Pallor of mucosa**
- **Hypothermia**
- **Tachycardia**
- **Pulse of small amplitude**
- **Muscle weakness**.

The syndrome is discussed also in the section on Shock. Endotoxemia is most commonly associated with bacteremia or septicemia due to infection with Gram-negative organisms, especially *E. coli*.

The clinical findings of severe endotoxemia include:

- Depression
- Hyperthermia followed by hypothermia
- Tachycardia followed by decreased cardiac output
- Decreased systemic blood pressure
- Cool skin and extremities
- Diarrhea
- Congested mucosae with an increased capillary refill time
- Muscular weakness, leading to recumbency.

Renal failure is common and is characterized by anuria. If DIC develops, it is characterized by petechial and ecchymotic hemorrhages on mucous membranes and sclerae with a tendency to bleed from venepuncture sites.

Chronic toxemia

Lethargy, separation from the group, inappetence, failure to grow or produce and emaciation are characteristic signs of chronic toxemia.

Localized infection

With localized infections there are, in addition to the general signs of toxemia, the clinical effects of the space occupation by the lesion. These are presented under Localized infections.

CLINICAL PATHOLOGY OF ENDOTOXEMIA

Hematology

Changes in total and differential leukocyte numbers occur in endotoxemia. Leukocytosis and neutrophilia occur with mild endotoxemia and leukopenia, neutropenia and lymphopenia increase in severity and duration with increasing severity of endotoxemia. Endotoxin-induced rebound neutrophilia may occur and is attributed to an accelerated release of neutrophils from the bone marrow reserve into the circulation through generation of the neutrophil releasing factor.

In experimental sublethal endotoxemia in foals 3–5 days of age, there is leukopenia followed by leukocytosis, hypoglycemia, increased prothrombin time and partial thromboplastin time, and mild hypoxemia.[20]

Serum biochemistry

A low plasma glucose concentration, high serum urea concentration (nonprotein

nitrogen), and a low serum albumin and total protein concentration are usually present in acute endotoxemia. Decreased albumin and total protein concentrations are in response to increased capillary permeability, whereas the azotemia reflects a decreased glomerular filtration rate. Adult herbivores have a mild hypocalcemia, hypomagnesemia and hypokalemia, and hypophosphatemia,[21] which most likely reflects inappetence and decreased gastrointestinal tract motility.

In more chronic toxemic states, a high serum total protein concentration, with globulins noticeably increased on electrophoretic examination, is more common.

Endotoxin

Endotoxin can be detected in the whole blood of horses using a whole blood hemagglutination inhibition assay.[22] However, sensitivity, specificity and predictive values are not high enough to be of routine use.

NECROPSY FINDINGS OF TOXEMIA AND ENDOTOXEMIA

Gross findings at necropsy are limited to those of the lesion that produces the toxin. Microscopically, there is degeneration of the parenchyma of the liver, the glomeruli and tubules of the kidney and of the myocardium. There may also be degeneration or necrosis in the adrenal glands.

TREATMENT OF ENDOTOXEMIA

The principles of treatment of endotoxemia or septic shock include: 1) removal of the foci of infection; 2) administration of antimicrobial agents with a Gram-negative spectrum; 3) aggressive fluid and electrolyte therapy to combat the relative hypovolemia, hypoglycemia, and electrolyte and acid–base disturbances; and 4) NSAIDs or glucocorticoids for the inhibition of products of the cyclooxygenase pathway. These four treatments are routinely applied. Other treatments that may be applied in selected cases include the administration of inotropic agents or vasopressors, intravenous or intramammary administration of polymyxin B, and hyperimmune plasma containing antibodies directed against core lipopolysaccharide antigens. Potential therapeutic agents under investigation (such as pentoxifylline, dimethyl sulfoxide, tyloxapol and insulin) cannot be currently recommended for treating endotoxemic animals.

Endotoxemic or septic shock occurs when the animal is overwhelmed by an infection or endotoxemia. This is a complex disease that requires a rapid and comprehensive treatment plan, including the following.

Removal of foci of infection

Removal of endotoxin before it can be absorbed is an important cornerstone of treatment in foals and calves with omphalophlebitis, horses with ischemic or necrotic bowel and lactating dairy cattle with coliform mastitis.

Antimicrobial agents

Bactericidal Gram-negative antimicrobial agents are always indicated whenever there is evidence of septicemia or a localized infection causing endotoxemia. The choice and route of administration will depend on the pathogens suspected of causing the infection and endotoxemia and the site of infection. The speed of kill of Gram-negative bacteria may be an important clinical issue, as antimicrobial agents with a rapid kill (such as moxalactam) can produce a bolus release of endotoxin into the blood stream by punching multiple holes in the bacteria, causing a rapid explosion of the bacteria due to osmotic fluid shifts and bolus release of endotoxin. Antimicrobial agents that alter the cell wall of Gram-negative bacteria can theoretically produce a bolus release of endotoxin when administered to animals with Gram-negative septicemia. On this basis, β-lactam antibiotics effective against Gram-negative bacteria should theoretically be avoided, however, clinical experience has not indicated deleterious effects following administration of β-lactam antibiotics. Moreover, coadministration of aminoglycosides blocks the potential bolus release of endotoxin by β-lactam antibiotics.[23] However, it is clinically prudent to ensure that whenever antimicrobial treatment is initiated in endotoxemic animals, that NSAIDs are administered concurrently.

Aggressive fluid therapy

The intravenous infusion of large quantities of fluids and electrolytes is a high priority in the management of endotoxemia.[24] Maintenance of peripheral perfusion is essential to any therapeutic regimen for treatment of endotoxic shock. Large volumes of isotonic fluids have been standard practice. Lactated Ringer's solution or other balanced electrolyte solution must be given by intravenous infusion over several hours. A beneficial response is noted by the following:

- Correction of peripheral vasoconstriction
- Restoration of an acceptable pulse quality
- Return of urine output
- Increase in the central venous pressure
- Restoration of arterial blood pressure
- Restoration of cardiac output
- Restoration of oxygen delivery to acceptable levels.[24]

It may be necessary to deliver fluids in amounts equivalent to 0.5–1.0 times the estimated blood volume of the animal over a period of several hours. Glucose should always be included in the infusion fluids because hypoglycemia, increased glucose utilization and inappetence are usually present.

Hypertonic solutions

The use of hypertonic saline, 7.5% NaCl, may enhance tissue perfusion and decrease the volume of subsequent fluids required for a beneficial response.[25] Experimentally, the use of hypertonic saline in sublethal *E. coli* endotoxemia in mature horses was associated with a more effective cardiovascular response than was an equal volume of isotonic saline solution. Cardiac output is increased and peripheral vascular resistance is decreased compared to results for isotonic saline controls. Hypertonic saline rapidly expands the plasma volume and increases preload by acting as an effective osmotic agent in the extravascular compartment, causing a translocation of fluid from the intracellular space and gastrointestinal tract.

Hypertonic sodium bicarbonate is widely used for the initial treatment of metabolic acidosis in endotoxemic adult horses. However, in horses with experimental endotoxemia, hypertonic sodium bicarbonate did not normalize blood pH, and it increased blood L-lactate concentrations and caused hypokalemia, hypernatremia and hyperosmolality.[26]

Nonsteroidal anti-inflammatory drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been in general use for the treatment of endotoxemia because of their analgesic, anti-inflammatory and antipyretic properties. NSAIDs suppress production of thromboxane and prostaglandins and reduce the acute hemodynamic response to endotoxemia. Although NSAIDs are routinely administered to endotoxemic animals, a large-scale study in humans with severe sepsis failed to demonstrate an effect of ibuprofen on mortality, despite improvement in a number of clinical indices and decreased production of arachidonic acid metabolites.[27]

Flunixin meglumine is the NSAID most commonly used in the treatment of endotoxemia in horses and cattle[28] and remains the NSAID of choice for treating this condition. Flunixin meglumine is a potent inhibitor of cyclooxygenase and its action on this enzyme to inhibit the synthesis of eicosanoids such as prostaglandin E_2 may explain the anti-

inflammatory action of the drug. Flunixin meglumine also modulates the acute hemodynamic changes and hyper L-lactatemia commonly seen during endotoxemia, which may increase survival rate. Endotoxin-stimulated production of thromboxane B_2 (a metabolite of thromboxane) and prostaglandin $F_{1\alpha}$ are blocked by flunixin meglumine at 0.25 and 0.10 mg/kg respectively,[29] which resulted in a widespread clinical use of an 'anti-endotoxemic' dose of 0.25 mg/kg. However, the term 'anti-endotoxemic effect' should be discouraged as it is misleading, and a dose rate of 1.1 mg/kg BW every 12 hours is recommended in horses. Care should be taken to ensure adequate hydration in endotoxemic animals receiving multiple doses of flunixin meglumine. Flunixin meglumine is usually given intravenously or intramuscularly in cattle at 1.1–2.2 mg/kg BW every 24 hours.[30] The oral administration of flunixin meglumine at 2.2 mg/kg BW prior to experimentally induced endotoxemia in cattle exerted an effect equal to that after intravenous administration by minimizing the fever and prostaglandin $F_{2\alpha}$ metabolite concentration induced by the endotoxin administration. However, flunixin meglumine did not prevent the decrease in peripheral mononuclear cells and polymorphonuclear leukocytes seen after endotoxin administration. The bioavailability of flunixin meglumine in cattle ranges from 53–60% in cattle and 80–86% in horses.[30]

Flunixin meglumine was superior to prednisolone and dimethylsulfoxide in providing protection and mitigating the effects of experimental endotoxemia in calves but was only partially protective against the hypotension and hyper L-lactatemia and failed to alter the hypoglycemic effect.[31] Although flunixin meglumine is the most widely used NSAID in endotoxemia, there is little experimental evidence demonstrating its efficacy over other NSAIDs. Ketoprofen, flunixin meglumine, ketorolac and phenylbutazone have been compared for treating experimental endotoxemia in calves.[32] Each drug modified the response to endotoxin but none was clearly superior to the others in modulating the clinical signs. Phenylbutazone given to calves at 5 mg/kg BW/day intravenously for 5 days suppressed the clinical response to experimental endotoxin in neonatal calves with progressively increasing amounts of endotoxin until large amounts were given.[32] There were no significant differences between ketoprofen and flunixin meglumine in in vitro studies of the effects of the drugs on equine peripheral blood monocytes.[33] An interesting finding in adult dairy cows with experimentally induced endotoxemia was that flunixin meglumine and phenylbutazone delayed the plasma clearance of endotoxin by 2–3 and 6–12 times respectively,[34] suggesting that both NSAIDs may prolong the clinical signs of endotoxemia in cattle, possibly by interfering with hepatic metabolism. The clinical significance of this finding is unknown.

Glucocorticoids

Glucocorticoids (corticosteroids) have been used extensively in the past for the treatment of endotoxemia and shock. The rationale for the use of glucocorticoids includes:

- Organelle and cell-membrane stabilization
- Improved cellular metabolism and gluconeogenesis
- Improved microcirculation
- Decreased production of endogenous toxins such as myocardial depressant factor
- Decreased leukocyte activation and degranulation
- Minimal reticuloendothelial depression and histologic organ damage.[24]

The corticosteroids most commonly used in endotoxic shock were hydrocortisone, prednisolone, methylprednisolone and **dexamethasone**. However, these corticosteroids have been most beneficial therapeutically when given as a pretreatment in experimental situations. Published evidence, based on controlled clinical trials, that corticosteroids are efficacious in naturally occurring cases of endotoxemic shock in farm animals appears to be lacking.

Glucocorticoids improve capillary endothelial integrity and tissue perfusion, decrease activation of complement and the clotting cascade, decrease neutrophil aggregation, stabilize lysosomal membranes, protect against hepatic injury and improve survival rate. However, there are concerns about their use in septicemic animals because they may cause immunosuppression. Large doses are required, which are cost-prohibitive in farm animals where they are used most commonly in acute cases and in doses such as 1 mg/kg BW of dexamethasone intravenously every 24 hours. It is currently believed that glucocorticoids, if they are to be clinically effective, **must be given as early as possible** to endotoxemic animals. Glucocorticoids are less frequently administered to endotoxemic animals as a result of a number of studies supporting the use of NSAIDs.

Inotropic agents and vasopressors

Critically ill neonates and adults may require the administration of positive inotropic agents and vasopressor agents. Inotropic agents increase cardiac contractility, thereby increasing cardiac output and oxygen delivery. Vasopressor agents increase systemic arterial blood pressure. Inotropic and vasopressive agents are usually administered for short periods of time during anesthesia or recovery from anesthesia.

Dobutamine (0.5–1.0 µg/kg BW/min in adults and 1–3 µg/kg BW/min in neonates) is the inotropic agent of choice.[35] Dobutamine should be diluted in 0.9% NaCl, 5% dextrose or lactated Ringer's solution and the dose carefully titrated by monitoring heart rate and rhythm and blood pressure. **Norepinephrine** (0.01–1 µg/kg BW/min) is the vasopressor agent of choice in hypotensive animals that have not responded to intravenous fluid loading or dobutamine.[35] Norepinephrine should be diluted in 5% dextrose and the dose titrated as there is marked individual variability in the response to norepinephrine administration.

Polymyxin B

Polymyxin B is a cationic antibiotic that has an appropriate charge distribution to stoichiometrically bind to the lipid A moiety of lipopolysaccharide. Parenteral administration of antimicrobial doses of polymyxin can lead to nephrotoxicity, neurotoxicity and ototoxicity but lower, non-nephrotoxic doses are effective in ameliorating the effects of endotoxin in horses. Specific endotoxin binding agents such as intravenous polymyxin B are therefore theoretically of benefit and have shown efficacy in endotoxemic horses when administered at a recommended dose of 5000 U/kg administered at 8–12-hour intervals[36,37] but definitive efficacy studies have not been completed in endotoxemic calves or horses with naturally acquired endotoxemia. In particular, because the efficacy of polymyxin B is focused against circulating lipopolysaccharide before it is bound to lipopolysaccharide binding protein, it is currently believed that polymyxin B, like glucocorticoids, must be given as early as possible to endotoxemic animals if they are to be clinically effective. Attractive features of polymyxin B are its shelf life and ease of storage, ease of administration (intravenous bolus) cost and 8–12-hour duration of effect.[37]

Antiserum

Hyperimmune serum is commercially available for the treatment of endotoxemia in the horse. The rationale is that anti-lipid A antibodies bind circulating lipopolysaccharide, thereby preventing the subsequent inflammatory cascade. However, on theoretical grounds it is difficult for an antibody to competitively

inhibit the strong binding affinity and high specificity between lipopolysaccharide and lipopolysaccharide binding protein. There are also difficulties with spatial hindrance between immunoglobulin (Ig)G and the R-core subfraction of lipopolysaccharide that contains lipid A. It is therefore difficult to believe that antiserum against core lipopolysaccharide antigens will ever be therapeutically successful in animals with naturally acquired endotoxemia, and large-scale studies in septic humans have failed to observe a decrease in mortality following the administration of hyperimmune core-lipopolysaccharide plasma. However, the administration of antiserum has many theoretical advantages separate from those of endotoxin neutralization, and it may be that plasma transfusion alone is beneficial.

The use of antiserum to the rough mutant of *E. coli* 0111:B4(J–5) as a treatment of experimental or naturally acquired endotoxemia has been demonstrated in some, but not all, studies in adult horses[38,39] but not in foals and calves.[40] One study in foals indicated that administration of hyperimmune serum resulted in a worsening of the clinical signs and augmented release of TNF-α and interleukin-6.[41] Antiserum does not appear as rational a treatment for neutralizing circulating lipopolysaccharide as polymyxin B and, for this reason, the administration of hyperimmune serum should probably be reserved for animals that fail to improve after polymyxin B administration.

Anticoagulants

Disseminated intravascular coagulation (hypercoagulative states) can be treated with heparin in an attempt to impair intravascular coagulation. Much of the knowledge regarding DIC in endotoxemia has been extrapolated from species other than large animals, and there is little objective information available to guide the clinical use of anticoagulants in endotoxemic large animals. Instead, the focus of treatment should be aggressive intravenous fluid administration in order to maximize microcirculation.

CONTROL OF ENDOTOXEMIA

The hallmarks of a control program are to decrease the risk or prevent neonatal septicemia, institute early and aggressive treatment of Gram-negative bacterial infections and ensure prompt surgical removal of ischemic and damaged intestine. Vaccines based on core lipopolysaccharide antigens are widely used in North America to decrease the incidence and severity of Gram-negative mastitis in lactating dairy cows (see Ch. 15) and Gram-negative infections in pigs, but similar vaccination protocols have not been developed for horses, small ruminants and New World camelids, which are also at risk of endotoxemia.

Toxemia in the recently calved cow

A special occurrence of toxemia of major importance in food-animal practice is that caused by several diseases in the period immediately after calving in the dairy cow. The syndrome is characterized clinically by lack of appetite, marked reduction in milk yield, reduced ruminal and intestinal activity, dullness, lethargy and a fever. The term 'parturition syndrome' is often used but is not recommended because its general adoption could dissuade clinicians from seeking more accurate identification of the component disease.

The diseases commonly included in the broad category of periparturient toxemia are:

- Acetonemia
- The fat cow syndrome and pregnancy toxemia
- Mastitis
- Peritonitis
- Septic metritis.

A brief account of septic metritis in cattle is provided here because of the common occurrence of septic metritis and the profound nature of the systemic signs of illness in affected cattle. All the other diseases are described under their respective headings in this book.

POSTPARTUM SEPTIC METRITIS IN CATTLE

Postpartum septic metritis occurs primarily in dairy cows within 2–10 days of parturition and is characterized clinically by severe toxemia and a copious, foul-smelling uterine discharge, with or without retention of the fetal membranes.

ETIOLOGY

The etiology is multifactorial. It is assumed that a combination of impaired neutrophil function, abnormal postpartum uterine involution, often with retained fetal membranes, and infection of the uterus precipitates the disease. A mixed bacterial flora is common, which includes organisms such as *Arcanobacterium (Actinomyces or Corynebacterium) pyogenes*, *Bacteroides* spp., *Fusobacterium necrophorum*; these commonly predominate as a mixed flora in cows with retained placenta and postpartum metritis,[1,2] particularly after 5–7 days post partum. Other observations found that *E. coli* predominates in cows with retained placenta,[3] particularly in the first 5–7 days post partum. *Staphylococcus* spp., *Streptococcus* spp., *Pseudomonas aeruginosa*, *Proteus* spp. and occasionally *Clostridium* spp. are also present; the last can occasionally result in tetanus if *C. tetani* proliferates.

EPIDEMIOLOGY

The disease occurs in cows of all ages but is most common in mature dairy cows within 2–4 days of parturition. Factors strongly associated with an increased incidence of metritis include:

- Large herds
- Dystocias
- Retained fetal membranes
- Overconditioning or underconditioning of cows.[4]

Septic metritis is most common in cows with fetal membranes retained for more than 24 hours following parturition. Several cause and effect relationships have been implicated for retained placenta in cattle,[5] with impaired neutrophil function being the most likely underlying cause.

Retention of fetal membranes is associated most commonly with abortion, dystocia and multiple births. The most commonly used definition is the presence of fetal membranes 12 hours or more following parturition but retention for more than 6–8 hours is the time limit set, particularly in older cows.[5] Approximately 10% of dairy cows have retained fetal membranes for longer than 6 hours after parturition.[6] The incidence between herds ranges from 3 to 27%. In single calvings the incidence is about 10%; in twin calvings 46%. Metritis occurs in about 50% of cows with retained placenta, and metritis is 25 times more likely to occur with retained placenta than without. Other less common risk factors for retained placenta include:

- Old age
- Increased gestation length
- Hormone-induced parturition
- Fetal anasarca
- Uterine prolapse
- Fetotomy.

The factors that are associated with retention of the placenta are indirectly associated with the development of postpartum metritis. The forceful removal of retained placenta, particularly in the first 4 days post partum, is also considered to be a major predisposing factor to septic metritis. Recent work indicates that the fundamental cause of retained placenta is impaired neutrophil function, whereby the ability of the maternal immune system to recognize the placenta as 'foreign' tissue is impaired.[7] In other words, retained placenta is an indication of an impaired immune system.

Uncomplicated cases of retained fetal membranes in cattle have no significant effect on subsequent fertility and the calving-to-conception interval. However, the calving-to-conception interval is significantly increased in cows that develop clinical metritis as a sequel to retained fetal membranes. Vitamin E and selenium deficiency, placentitis and vitamin A deficiency have also been suggested as factors.

PATHOGENESIS

Failure of normal uterine involution combined with retention of the fetal membranes and infection of the uterus with a mixed bacterial flora results in acute metritis and a severe toxemia. There is diffuse necrosis and edema of the mucosa and wall of the uterus. There is marked accumulation of foul-smelling fluid in the uterus and enlargement of the uterus. Absorption of toxins results in severe toxemia, particularly in fat cows, which may develop irreversible fatty degeneration of the liver.

CLINICAL FINDINGS

Affected cows become acutely anorexic and toxemic within 2–10 days after parturition. There is a marked drop in milk production. The temperature is usually elevated, in the range 39.5–41.0°C, but may be normal in the presence of severe toxemia. The heart rate is usually elevated and may range from 96–120 beats/min. The respiratory rate is commonly increased to 60–72 breaths/min and the breath sounds may be louder than normal. Rumen contractions may be markedly depressed or absent. A foul-smelling fluid diarrhea may occur. Mild to moderate dehydration is common because affected cows do not drink normally.

Retention of the fetal membranes is common, and manual examination of the vagina reveals the presence of copious quantities of foul-smelling, dark brown to red fluid containing small pieces of placenta pooled in the vagina. When the fetal membranes are retained and protruding through the cervix, the hand can usually be inserted through the cervix and into the uterus. Manual exploration of the uterine cavity will usually reveal the state of adherence of the fetal membranes. Often the fetal cotyledons are firmly attached to the maternal caruncles, but occasionally they have separated from the caruncles and the placenta can be removed by simple traction.

Rectal examination usually reveals that the uterus is large, flaccid and lacks the longitudinal ridges that indicate involution. In large cows the enlarged, flaccid uterus may be situated over the pelvic brim extending into the ventral part of the abdomen and thus may not be easily palpable and examined. This is an important finding because the fetal membranes may be fully retained in the uterus and no evidence of their presence may be detectable on examination of the vagina and the cervix, which may be almost closed, making examination of the uterus impossible.

The presence of viscid, nonodorous mucus in the cervix and anterior part of the vagina usually, but not always, indicates that the fetal membranes have been expelled. When evidence of a retained placenta and septic metritis cannot be found on examination of the reproductive tract, either by rectal palpation or vaginal examination, and if the history indicates some uncertainty about the disposition of the placenta, a retained placenta and septic metritis should be considered until proven otherwise. Persistent toxemia, tachycardia (100–120 beats/min), anorexia and rumen stasis that cannot be explained by any other disease should arouse suspicion of septic metritis until proved otherwise.

Tenesmus occurs most commonly when the fetal membranes are retained and this causes irritation in the vagina. Manual examination of the vagina may also stimulate tenesmus.

The course of the disease varies from 2–10 days. Those cases with retained fetal membranes may be toxemic and not return to normal appetite until the membranes are fully expelled, which may take up to 10 days. Necrotic pieces of placenta may be passed for 10–14 days after treatment is begun.

CLINICAL PATHOLOGY

Hematology

A leukopenia, neutropenia and degenerative left shift occur in acute cases and the degree of change parallels the severity of the disease and reflects the absorption of endotoxin from the uterine lumen.

Vaginal/uterine fluid

Samples of fluid from the vagina and uterus reveal a mixed bacterial flora including *E. coli*, *Proteus* spp., *A. pyogenes*, *Staphylococcus* spp. and *Streptococcus* spp., with the predominant bacteria varying mainly with time since parturition. In general, *E. coli* predominates in the first 5 days after parturition, whereas *A. pyogenes* and *F. necrophorum* predominate after the first 5 days in cattle with retained placenta.[8,9] Uterine lochia of cattle with retained placenta had a much higher endotoxin concentration in the first 2 days post partum than did lochia of healthy cattle or cattle that had undergone a dystocia but did not have retained placenta. Endotoxin was not detected in the plasma of cattle with high lochial endotoxin concentrations, indicating effective systemic clearance.[8]

Other samples and tests

Ketonuria may occur in animals that are overconditioned and mobilize excessive quantities of depot fat, resulting in ketosis. **Liver function tests** reveal a

decrease in liver function, which may be irreversible in excessively fat cows.

NECROPSY FINDINGS

The uterus is enlarged, flaccid and may contain several liters of dark brown, foul-smelling fluid with decomposed fetal membranes. The uterine mucosa is necrotic and hemorrhagic and the wall of the uterus is thickened and edematous. In severe cases, fibrin may be present on the serosal surface of the uterus. The liver may be enlarged and fatty and there is usually mild degeneration of the myocardium and kidneys.

The fat cow syndrome

This is characterized by excessive body condition, anorexia to inappetence, ketonuria, a marked loss in milk production, decreased rumen movements and delayed involution of the uterus. The temperature is usually normal but the heart and respiratory rates may be increased. The prognosis is poor in cows that are totally anorexic; those that are inappetent will usually recover after 5–7 days of supportive therapy.

Acute diffuse peritonitis

This may occur in cows within a few days postpartum and is characterized by anorexia, toxemia, a spontaneous grunt or one that can be elicited by deep palpation, rumen stasis, fever and the presence of an inflammatory exudate in the peritoneal fluid.

Peracute and acute mastitis

This occurs in cows within a few days after parturition and is characterized by severe toxemia, swelling of the affected quarters and abnormal milk.

TREATMENT

Conservative therapy

Uncomplicated cases of retained fetal membranes without any evidence of clinical toxemia usually do not require parenteral or intrauterine treatment. The placenta will usually be expelled within 4–6 days. Cows with retained fetal membranes and tenesmus should be examined vaginally to ensure that there is no evidence of injury to the vagina or cervix. In cows with tenesmus, if the placenta is detached and loose it should be removed by careful traction. Forceful removal of the placenta should be avoided.

Antimicrobial agents

Cows with retained fetal membranes but **without systemic illness** should be monitored but treatment with antimicrobial agents is not indicated. Antibiotic treatment with oxytetracycline (10 mg/kg BW, daily) before placental shedding delays detachment of the placenta; this finding is consistent with the concept that intrauterine bacterial infection facilitates placental detachment.[9]

Cows with retained fetal membranes **complicated by septic metritis and toxemia** should be treated with antimicrobial agents daily for several days or until recovery occurs. Death can occur in untreated animals. Because of the mixed bacterial flora in the postpartum uterus with a retained placenta, broad-spectrum antimicrobials are recommended. Intramuscular procaine penicillin (22 000 U/kg BW every 24 h), subcutaneous ceftiofur (2.2 mg/kg BW every 24 h), intramuscular ampicillin (10 mg/kg BW) and intravenous oxytetracycline (11 mg/kg BW every 24 h) are commonly administered for several days until recovery is apparent.[10,11] Ceftiofur increases the cure rate and milk yield, and decreases rectal temperature, when administered to dairy cows with fever and vaginal discharge or dystocia.[12] Subcutaneous administration of ceftiofur (1 mg/kg BW) achieved concentrations of ceftiofur derivatives in uterine tissue and lochial fluid that exceeded the reported minimal inhibitory concentrations for common metritis pathogens.[13] Ampicillin increased the pregnancy rate and decreased the cure rate, compared to ceftiofur, in cattle that were also treated with intrauterine ampicillin and cloxacillin.[14] In general, oxytetracycline use should be confined to the first 5–7 days post partum when *E. coli* predominates, as it is likely to be ineffective against *A. pyogenes* in the endometrium. Oxytetracycline at 30 mg/kg BW intravenously as a single dose in cows with retained fetal membranes resulted in concentrations of the antimicrobial in uterine secretions, placenta and cotyledon for 32–36 hours.[15] Two intramuscular injections of oxytetracycline at 25 mg/kg BW resulted in lower peak concentrations, but these were maintained for 144 hours. Parenteral oxytetracycline appears to decrease endotoxin production, as indicated by the severity of leukopenia in cattle with retained placenta.[9]

In **severely affected cases**, large amounts of balanced isotonic crystalloid fluids, electrolytes and glucose by continuous intravenous infusion may be necessary and often result in a marked beneficial response within 24–48 hours. The uterus should always be examined by palpation per rectum and vaginally to determine the degree of uterine involution, the thickness of the uterine wall, the volume of the uterus, the nature of the luminal contents and the degree of attachment of the placenta to the cotyledons. This can be done daily to assess progress. Uterine fluids should be drained by creating a siphon, if sufficiently liquid in nature, although care must be taken to ensure that the tube does not penetrate a friable uterine wall. If parenteral antimicrobial and supportive therapy is provided the placenta will invariably be expelled within 6–8 days and usually within 4–6 days. The use of antimicrobial agents must be accompanied by appropriate withdrawal periods for the milk produced by treated animals.[16]

Intrauterine medication

The necessity for intrauterine medication is controversial. There is limited evidence, if any, that the intrauterine infusion of antimicrobial agents with or without lytic enzymes and estrogens has any beneficial effect in the treatment of postpartum septic metritis. Nevertheless, a wide variety of antimicrobial agents have been used for intrauterine medication for retained placenta and metritis in cows, although in general, β-lactam-resistant antibiotics should be administered because the uterine lumen can contain β-lactamase-producing bacteria. Intrauterine infusion of 0.5 g of the first-generation cephalosporin cephapirin improved the reproductive performance, but only when administered after 26 days in milk.[17,18] Intrauterine infusion of 1 g of the third-generation cephalosporin ceftiofur in 20 mL of sterile water once between 14 and 20 days of lactation had no effect on reproductive performance but decreased the risk of culling and increased the time to culling.[19] Tetracycline products (5–6 g) are commonly used but should be administered as a powder dissolved in an appropriate volume of 0.9% NaCl, as vehicles such as propylene glycol can irritate the endometrium. Infusion of oxytetracycline decreases lochial odor and the incidence of fever in cattle with retained placenta.[20] In cattle with retained placenta, intrauterine administration of a povidone-based oxytetracycline solution (5 g daily until expulsion) combined with fenprostalene (1 mg subcutaneously) did not alter the time to detachment of the placenta but increased the frequency of pyometra;[21] this finding was consistent with the concept that intrauterine bacterial infection facilitates placental detachment.[9] Milk from cows treated by intrauterine infusion of antimicrobial agents should be discarded for an appropriate period of time in order to avoid illegal residues.[16]

Intrauterine administration of antiseptics (povidone iodine, chlorhexidine, hypertonic saline) has been done but studies demonstrating efficacy are lacking.

Ancillary treatment and control

Portions of retained placenta protruding from the vagina should be wrapped in a plastic rectal sleeve to minimize wicking of fecal bacteria after defecation, although this supposition has not been verified. Alternatively, protruding remnants of

placenta can be excised, although this may prolong to the time to expulsion because the decreased weight may interfere with traction on the remaining placenta in the uterine lumen. Complete manual removal is often requested by the producer but is not recommended because studies have not demonstrated its efficacy.

The infusion of collagenase solution (200 000 U dissolved in 1 L of 0.9% NaCl containing 40 mg calcium chloride and sodium bicarbonate) into the umbilical arteries within 12 hours of parturition is an effective treatment for retained placenta. Collagenase injection therefore provides an effective method for preventing septic metritis in cattle with retained placenta. However, the collagenase solution is expensive, not widely available and the technique is difficult in some animals because of difficulty in identifying intact umbilical arteries for injection. As a result, collagenase injection is rarely performed in clinical veterinary practice. The efficacy of umbilical artery infusion with antimicrobial agents has not been adequately evaluated.

Ecbolic drugs have been proposed for the prevention and treatment of retained placenta in cattle. These include prostaglandins, ergot derivatives, oxytocin and β_2-adrenoceptor antagonists.[22] The rationale for their use is that they stimulate uterine contractions and physically aid in the expulsion of the fetal membranes. In general, the consensus is that they are ineffective after the diagnosis of a retained placenta is recognized. However, their use may be effective if used immediately after calving. In particular, the frequent intramuscular administration of oxytocin appears to provide the most effective means of preventing metritis, with a recommended protocol of 20 IU every 3 hours for postpartum days 0–3, 30 IU every 2 hours for postpartum days 4–6 and 40 IU every 2 hours for postpartum days 7–10.[23] A large study found that intramuscular injection of oxytocin (30 IU) immediately after parturition and 2–4 hours later decreased the incidence of retained placenta and the calving-to-conception interval.[24] Fenprostalene at 1 mg subcutaneously, 25 mg dinoprost tromethamine intramuscularly, or 20 IU oxytocin given to a large number of dairy cows in five commercial dairy herds did not reduce the incidence of retained fetal membranes or improve reproductive performance.[6] A detailed review failed to identify any evidence supporting the use of estrogen or prostaglandins in the first 7–10 days post partum.[23]

The finding that retained placenta can be caused by neutrophil dysfunction at calving[7] provides the basis for epidemiological evidence that deficiency of trace minerals or vitamins (such as selenium and vitamin E) is associated with an increased incidence of retained placenta. In regions deficient in seleni m, supplementation of the diet up to 0.3 ppm can decrease the incidence of retained placenta in herds that are fed a total mixed ration. Selenium can also be administered by intraruminal boluses or parenteral administration of vitamin E/selenium preparations during the dry period.

IDENTIFICATION OF AFFECTED COWS

Cows affected with retained placenta and metritis should be identified and recorded in the records system and examined 30–40 days after parturition for evidence of further complications such as pyometra.

Hypovolemic, hemorrhagic, maldistributive and obstructive shock

Synopsis

Etiology Shock due to a reduction in venous return (circuit failure) secondary to hypovolemia, hemorrhage, maldistribution of blood or obstruction to venous return

Clinical findings Depression and weakness, subnormal temperature, elevated heart rate with weak thready pulse, cold skin and extremities, prolonged capillary refill time. Progressive development without aggressive fluid therapy and collapse and death from irreversible shock

Clinical pathology Increased blood or plasma L-lactate concentration, decreased venous oxygen tension, evidence of multiple organ dysfunction. Decreased central venous pressure, low mean arterial blood pressure terminally. Changes in heart rate, activity level and blood or plasma L-lactate concentration indicate the efficacy of treatment

Necropsy findings None specific for hypovolemic or maldistributive shock; the source of hemorrhage may be apparent in hemorrhagic shock

Diagnostic confirmation Clinical signs, blood or plasma L-lactate concentrations, venous oxygen tension

Treatment Aggressive fluid therapy based on intravenous isotonic crystalloid solutions and possibly colloid solutions. Blood transfusion or stroma-free hemoglobin administration for hemorrhagic shock. Initial treatment by rapid infusion with small-volume hypertonic saline solutions gives rapid but transient resuscitative affect. Antimicrobial agents and non-steroidal anti-inflammatory drugs in maldistributive shock due to endotoxemia

ETIOLOGY

The circulatory system consists of a pump (the heart) and a circuit (the vasculature). Circulatory shock can result from abnormal functioning of the pump or circuit, or both. It is clinically very important to differentiate **pump failure** (cardiogenic shock due to acute or chronic heart failure) from **circuit failure**, because the diagnosis and treatment of cardiogenic shock is vastly different to that of circuit shock. Cardiogenic shock is covered in detail in Chapter 8, whereas circuit failure is addressed in the following section.

Circuit failure occurs whenever the cardiac output is reduced below a critical point because of inadequate venous return to the heart. There are four main ways that circuit failure occurs:

- **Hypovolemic shock** occurs when there is a reduction in circulating blood volume due to plasma or free water loss
- **Hemorrhagic shock** occurs when there is a reduction in circulating blood volume due to rapid blood loss
- **Maldistributive shock** occurs when there is a reduction in circulating blood volume due to increased capillary permeability, pooling of blood in capacitance

vessels (such as the veins in the splanchnic circulation), or pooling of plasma is a large third space such as the thoracic or abdominal cavities
- **Obstructive shock** occurs when there is an acute reduction in venous return due to a mechanical obstruction, such as pericardial tamponade or pulmonary artery thrombosis. Obstructive shock is extremely rare in large animals.

Regardless of the initiating cause for circuit failure and inadequate venous return, tissue hypoperfusion results, leading to impaired oxygen uptake and anaerobic metabolism. The end result of inadequate tissue perfusion is the development of multiple organ failure, L-lactate acidemia, and strong ion (metabolic) acidosis, manifest as the **hypodynamic stage** of shock. Hypovolemia and poor tissue perfusion results in cold extremities, elevated heart rate, a weak thready pulse, decreased capillary refill times and altered mental status. Cardiac arrhythmias may occur because of myocardial ischemia and electrolyte and acid–base disturbance. There is anorexia and gastrointestinal stasis. Signs of renal failure include anuria or oliguria and azotemia.

Common causes of circuit failure in large animals are as follows.

Hypovolemic shock
- Fluid loss and dehydration, such as in neonatal calf diarrhea and burn injury, especially when fluid loss is severe and rapid
- Fluid loss into the gastrointestinal tract due to acute intestinal obstruction.

Hemorrhagic shock
Acute hemorrhage with loss of 35% or more of total blood volume, equivalent to an acute blood loss of 2.8% of body weight (assuming blood volume is 8% of body weight) will lead to clinical signs of severe hemorrhagic shock. In contrast, acute hemorrhage with loss of less than 10% of total blood volume (equivalent to an acute blood loss of less than 0.8% of body weight) produces minimal detectable clinical changes.

Traumatic injury or spontaneous rupture of large blood vessels are the common reasons for acute hemorrhage. Any sort of minor surgical wound, e.g. castration, dehorning, may lead to excess hemorrhage where there is a hemorrhagic tendency due to defects of clotting. Some of the more common causes of hemorrhagic shock areas follow.

Cattle and sheep
- Spontaneous pulmonary hemorrhage associated with caudal vena caval syndrome
- Abomasal ulcer, sometimes originating from a bovine viral leukosis lesion (cattle)
- Enzootic hematuria with bleeding from a bladder lesion (cattle)
- Pyelonephritis with bleeding from a renal lesion (cattle)
- Intra-abdominal hemorrhage as a result of arterial aneurysm, possibly associated with copper deficiency (cattle)
- Laceration of arteries in the wall of the vagina as a result of dystocia
- Ruptured middle uterine artery during prolapse or torsion of uterus
- Cardiac tamponade due to rupture of coronary artery or ventricular chamber, rupture of aorta (see Chapter 1)
- Rupture of liver associated with dystocia in lambs, and in older lambs possibly associated with vitamin E deficiency.

Horses
- Ethmoidal hematoma[1]
- Exercise-induced pulmonary hemorrhage[2]
- Rupture of the middle uterine, uteroovarian (especially right side) or iliac artery associated with parturition, more commonly in aged mares[3]
- Nasal bleeding from hemorrhage into the guttural pouch, from carotid or maxillary arteries with guttural pouch mycosis or associated with rupture of the longus capitis muscle following trauma[4]
- Rupture of mesenteric arteries secondary to strongyle larval migration
- Splenic hematoma[5] or rupture following blunt trauma
- Rupture of liver with hyperlipemia
- Hemangioma, hemangiosarcoma and other neoplasia
- Persistent bleeding from the vulva in association with ulcerated varicose veins on the dorsal wall of the vagina[6]
- Congenital venous aneurysm (rare).[7]

Pigs
- Esophagogastric ulceration
- Proliferative hemorrhagic enteropathy
- Rupture of liver in hepatosis dietetica
- Congenital neonatal bleeding, e.g. umbilical hemorrhage.

Maldistributive shock
- Endotoxemia in neonatal septicemia, salmonellosis, coliform mastitis in lactating dairy cattle, toxic metritis in cattle
- Septic shock due to Gram-positive bacterial septicemia[8–10]
- Too sudden reduction of pressure in a body cavity, e.g. by rapid withdrawal of ascitic fluid.

Obstructive shock
- Pericardial tamponade.

PATHOGENESIS
Hypovolemic shock
When cardiac output falls as a result of decreased venous return, the carotid and aortic baroreceptors stimulate the sympathetic nerves and adrenal medulla to release catecholamines resulting in vasoconstriction in vessels with alpha-adrenergic receptors.[8,11] Vasoconstriction leads to **decreased renal perfusion**, which activates the renin–angiotensin–aldosterone system, thereby inducing sodium and water retention. The decrease in renal perfusion can result in renal ischemia and nephrosis if the ischemia is sufficiently severe and prolonged (see Chapter 11). Hypovolemia also stimulates the release of antidiuretic hormone (vasopressin). There is contraction of the spleen and venous capacitance vessels, an increased peripheral vascular resistance and an increase in heart rate in an attempt to maintain cardiac output and blood perfusion through the coronary and cerebral blood vessels.

Water shifts from the interstitial space to the vascular space in response to the contraction of precapillary arterioles. In the initial stages of hypovolemic failure the primary signs are those of interstitial fluid depletion and dehydration, with dry mucous membranes, sunken eyes and decreased skin turgor. Peripheral vasoconstriction in the face of continued hypovolemia and falling cardiac output results in the opening of arteriovenous shunts and decreased perfusion of organ systems, with resultant damage from hypoxia and tissue acidosis and the development of clinical signs of peripheral vascular failure and shock. Arterial blood pressure falls terminally, and a decrease in mean arterial pressure indicates a complete lack of cardiovascular reserve. The rate at which hypovolemia develops profoundly affects the outcome because compensatory mechanisms are more readily overcome by acute than chronic changes.

Hemorrhagic shock
The major effects of hemorrhage are loss of blood volume (hypovolemic shock), loss of plasma protein (decreased plasma oncotic pressure), and loss of erythrocytes (decreased oxygen-carrying capacity).

With acute and severe hemorrhage, the rapid loss of blood volume results in hypovolemic shock and the loss of erythrocytes in anemic anoxia. The combination of these two factors is

termed hemorrhagic shock and is often fatal. With less severe hemorrhage, the normal compensatory mechanisms, including release of blood stored in the spleen and liver and the withdrawal of fluid from the tissue spaces, may maintain a sufficient circulating blood volume, but the anemia is not relieved and the oncotic pressure of the blood is reduced by dilution of residual plasma protein. The resulting anemia and edema are repaired with time provided the blood loss is halted.

Maldistributive shock

In normal animals the healthy intestinal mucosa is an effective barrier to the absorption of endotoxin that is present in the gut and the small amounts of endotoxin that are absorbed into the portal blood are cleared by the liver and do not reach the systemic circulation. When the integrity of the intestine is compromised by factors such as ischemia, trauma or inflammation, sufficient endotoxin can be absorbed to overwhelm the clearance mechanisms of the liver, and endotoxin may also leak to the peritoneal cavity and thereby gain access to the systemic circulation. Endotoxin can also be absorbed from sites of local infection, as with diffuse peritonitis, coliform mastitis and toxic metritis, or released from Gram-negative bacteria in the blood stream. Intestinal mucosal integrity is lost in the terminal stages of circulatory shock due to tissue hypoxia, and endotoxin translocation from the intestinal tract is markedly increased in the terminal stages of shock, independent of the initiating cause.

Endotoxin and other bacterial toxins cause direct endothelial damage.[11] Endotoxin also activates macrophages and neutrophils provoking the release of a multitude of **inflammatory mediators**, including TNF, interleukin-1, interleukin-6 and platelet activating factor, which lead to endothelial damage, leaky vessels, hypotension and vasculitis and eventually decreased intravascular volume.[12] Inadequate perfusion of tissue with appropriately oxygenated blood impedes oxidative cellular metabolism and leads to the release of arachidonic acid, which is metabolized by the cyclooxygenase pathway to yield prostaglandins and thromboxane A_2 or by the lipoxygenase pathway to yield leukotrienes.[13,14] These **eicosanoids** are potent vasoactive compounds. They can act locally or be carried in the circulation to act at distant sites to further adversely affect vascular reactivity and vascular permeability.[11] Endotoxin itself also provokes increased synthesis and release of eicosanoids[13] and many of the early effects of endotoxin are mediated by these metabolites of arachidonic acid.[15]

A further consequence to tissue hypoxia is damage to endothelium with exposure of collagen; tissue thromboplastin can initiate the intrinsic and extrinsic coagulation cascades, leading to damage to other organ systems and further complications from the development of DIC,[11] which may be central to the development of irreversible shock.

In the early **hyperdynamic stage** of endotoxemia and sepsis there is an increased oxygen demand by peripheral tissue and an increase in heart rate and cardiac output with pulmonary and systemic vasoconstriction.[16] Pulmonary hypertension increases transvascular fluid filtration in the lung and pulmonary edema can develop when hypertension is accompanied by increased vascular permeability.[17] There is hypoxemia and, despite the increase in cardiac output, blood flow may be inadequate to meet the needs of tissue in a hypermetabolic state.[11] The **late hypodynamic** stage of endotoxemia and sepsis is characterized by decreased venous return, cardiac contractility, cardiac output and mean arterial pressure.

Obstructive shock

In severe pericardial tamponade, the rapid increase in pericardial fluid volume impedes diastolic filling of the heart and therefore results in decreased cardiac output. A similar response occurs in advanced traumatic reticulopericarditis in cattle that have ingested a wire; however, in the latter condition the obstruction is slow to develop.

CLINICAL FINDINGS

Depression, weakness and listlessness are accompanied by a fall in temperature to below normal. The skin is cold and skin turgor is decreased. The mucosae are pale gray to white and dry, and capillary refill time is extended beyond 3–4 s.

There is an increase in heart rate to 120–140 beats/min in horses and cattle, with abnormalities of the pulse including small and weak pressure amplitudes (a 'thready' pulse). Cardiac arrhythmias are present terminally. Venous blood pressure is greatly reduced in hypovolemic and hemorrhagic shock and the veins are difficult to raise. Arterial blood pressure, measured either directly by arterial puncture or by indirect oscillometric methods, is decreased terminally and fails to provide an early indicator of the severity of the circulatory failure.

Anorexia is usual but thirst may be evident and there is anuria or oliguria. Nervous signs include depression, listlessness and obtusion, and coma in the terminal stages.

During the early hyperdynamic stage of maldistributive shock the temperature is normal or elevated, mucous membranes are injected and brick-red in color, there is tachycardia but normal capillary refill time, and the extremities (particularly ears) are cool to the touch. Whereas these signs are not specific for shock, the recognition of this stage in animals that are at risk for maldistributive shock, such as the neonate or animals with early signs of acute intestinal accident, can allow the early institution of therapy, which will frequently result in a better outcome than therapy instituted when the later stages of shock are manifest.

Therapeutic reversal of maldistributive shock in its later stages is difficult. In contrast, circulatory failure that is a result of hypovolemic or hemorrhagic shock is relatively easily treated and can be successfully reversed even at stages of profound depression.

CLINICAL PATHOLOGY

The use of clinical pathology is directed at determining the cause and severity of shock and at monitoring the effectiveness of therapy. Volume expansion and restoration of tissue perfusion will usually correct acid–base and strong ion (metabolic) acidosis in the majority of animals with shock and abnormalities are addressed once fluid balance is established.[18]

Examination of the blood for hematocrit and plasma protein concentration are valuable in indicating the magnitude of the blood loss in hemorrhagic shock and provide a clinically useful index to the progress of the disease. However, there can be a **delay in the fall** of the hematocrit following hemorrhage for up to 4–6 hours because splenic contraction temporarily augments circulating red cell numbers. The hematocrit and plasma protein concentrations usually fall to their lowest levels 12–24 hours following hemorrhage, and determination at this time provides a clinically useful index of the amount of blood lost. Signs of a regenerative response (increased hematocrit, presence of reticulocytes, increased red blood cell volume) should be seen within 4 days of an acute hemorrhage in ruminants and pigs but cannot be used as a guide in the horse. In general, the hematocrit increases by 1% per day following acute hemorrhage in ruminants.

Abdominocentesis, **thoracocentesis** and **ultrasound** are used to identify sites of internal bleeding. **Thrombocyte** and **clotting factor** examinations are indicated in cases in which unexplained spontaneous hemorrhages occur.

Monitoring in shock

Clinical parameters of heart rate, pulse character, mucous membrane color,

temperature of the extremities (particularly the ears) and activity level provide extremely useful guides to the efficacy of treatment when performed serially over time. The single most valuable index is the **heart rate**, although, in animals housed in a stable ambient temperature, **peripheral skin temperature** is also a useful clinical guide but not during rapid intravenous fluid administration because a thermal lag of at least 30 minutes before increased blood and heat flow to the periphery is manifest as an increase in skin surface temperature.[19] Blood or plasma **L-lactate concentration** and **venous oxygen tension** provide the most useful measures of the adequacy of oxygen delivery and tissue perfusion, and therefore the efficacy of treatment. These two laboratory parameters are much more informative than measurement of **central venous pressure** or **mean arterial blood pressure**, and blood pressure measurement is discussed mainly for historical interest.

Blood or plasma L-lactate concentration, preferably measured in arterial blood or blood from a large vein such as the jugular vein, provides an indication of prognosis and an even more valuable serial measure of the efficacy of treatment. In general terms, plasma L-lactate concentrations are normally less than 1.5 mmol/L and fluctuate slightly depending on diet and time since feeding. Plasma L-lactate concentrations of more than 4 mmol/L indicate the presence of widespread anaerobic metabolism and the need for aggressive therapy, and plasma L-lactate concentrations above 10 mmol/L are associated with a high mortality in humans, pigs and horses.[20] Blood L-lactate concentrations are increased in cows with abomasal volvulus (3.8 mmol/L;[21] 7.3 mmol/L;[22] 4.8 mmol/L[23]); however, blood lactate concentration did not provide an accurate prognostic indicator for survival. In general, it is the **change in plasma L-lactate concentration after initiation of therapy** that provides the most useful guide to treatment. In particular, failure to decrease the plasma L-lactate concentration despite aggressive and appropriate therapy is a poor prognostic sign.

Venous blood oxygen tension (P_{O_2}), preferably measured in a large vein such as the jugular vein, provides an indication of the adequacy of oxygen delivery and is a useful guide to the efficacy of treatment. In general terms, venous P_{O_2} is normally 35–45 mmHg, arterial P_{O_2} is normally 90 mmHg and the difference between the venous and arterial P_{O_2} depends on the amount of oxygen extracted by tissues. Whenever tissues receive inadequate blood flow and therefore oxygen delivery, their oxygen extraction ratio increases, resulting in a greater difference between arterial P_{O_2} and venous P_{O_2} and a lower value for venous P_{O_2}. **Venous P_{O_2} below 30 mmHg** indicates inadequate oxygen delivery and the need for aggressive therapy; hemoglobin in erythrocytes or stroma free solution in hemorrhagic shock, plasma volume expansion in hypovolemic and maldistributive shock. A venous P_{O_2} below 25 mmHg indicates severe abnormalities in oxygen delivery, and venous P_{O_2} below 20 mmHg indicates impending death. Aggressive resuscitation should always increase venous P_{O_2} to more than 40 mmHg, and failure to substantially increase venous P_{O_2} despite aggressive and appropriate therapy is a poor prognostic sign.

Central venous pressure (CVP) is another measure of hypovolemia but individual measurements can be misleading and serial measurements should be used. By definition, central venous pressure can only be measured by a catheter placed in a blood vessel within the thorax (typically the cranial vena cava), as this permits measurement of negative values for central venous pressure. 'Central venous pressure' is frequently measured in the jugular vein through a short intravenous catheter; this pressure is more correctly termed jugular venous pressure and, because it cannot be negative, is of much less clinical value than measuring CVP in shocked animals. The normal CVP of the standing horse referenced to the point of the shoulder (scapulohumeral joint) is 12 ± 6 cmH_2O (1.2 ± 0.6 kPa) and is markedly influenced by factors such as head position and excitement.[24] In contrast, the normal CVP of a standing calf is 0.6 ± 0.8 cmH_2O (0.06 ± 0.08 kPa), with only a small decrease in CVP to −1.9 ± 1.0 cmH_2O (0.19 ± 0.10 kPa) being present in hypovolemic calves that were severely dehydrated (14% body weight).[25] A general rule of thumb in horses is to administer fluids as long as the CVP remains below 2 cmH_2O (0.2 kPa), and to immediately discontinue fluid administration whenever CVP exceeds 15 cmH_2O (1.5 kPa). The main clinical utility of CVP measurement is ensuring that volume overload is not occurring.

Mean arterial blood pressure is an insensitive but specific method for determining the severity of shock and the efficacy of therapy, in that mean arterial blood pressure only decreases in the terminal stages of shock, indicating a complete lack of cardiovascular reserve.

NECROPSY FINDINGS

In **hemorrhagic shock** there is extreme **pallor** of all tissues and a thin **watery appearance of the blood** may be accompanied by large extravasations of blood if the hemorrhage has been internal. Where the hemorrhage has been **chronic**, anemia and edema are characteristic findings. In obstructive shock there is a large increase in pericardial fluid (usually blood), or the presence of a large thrombus in the cranial or caudal vena cava or pulmonary circulation, or evidence of severe abdominal distension (such as in ruminal tympany). There are **no specific findings** in hypovolemic or maldistributive shock, although in maldistributive shock the capillaries and small vessels of the splanchnic area may be congested and there may be evidence of pulmonary edema. With death from septic shock the major findings relate to the changes associated with the infectious disease. Dehydration is evident in animals dying from hypovolemic shock.

DIFFERENTIAL DIAGNOSIS

Circulatory failure due to a circuit abnormality can be diagnosed when there is no detectable primary cardiac abnormality, and when a primary cause such as hemorrhage, dehydration, or endotoxemia is known to be present. Ideally, endotoxemic or septic shock should be diagnosed in its early hyperdynamic stage and aggressively treated at this stage. This requires a knowledge of the risks for shock with various conditions in each of the animal species. Hypovolemic, hemorrhagic, or maldistributive shock should be anticipated:

- In septicemic disease, especially of the neonate
- In acute localized infections
- With intestinal disease, but especially with those in the horse that have acute intestinal accident as part of the differential diagnosis
- When severe trauma occurs
- Where there is severe fluid loss for any reason
- Where decompression of an area is to be practiced (i.e. removal of fluid from a body cavity)
- When there is to be a significant surgical procedure.

TREATMENT

Identification of cause

The identification and, if possible, the immediate elimination of the precipitating cause of the shock is important in cases where circulatory failure is initiated by conditions that are amenable to surgical correction. Prompt surgical intervention coupled with aggressive fluid therapy may save an animal, whereas delaying surgery until shock is advanced is almost always followed by fatality. This requires a full clinical examination and often ancillary laboratory examination to accurately identify the cause.

The identification of cause will also give some indication of the likelihood of success in treatment. In general there is greater success in the treatment and management of hypovolemic and hemorrhagic shock, especially if treatment is instituted early in the clinical course. Effective treatment and management of maldistributive shock is less successful unless the sepsis can be controlled and the source of the endotoxemia eliminated.

Hypovolemic and maldistributive shock

The rapid administration of intravenous fluids is the single most important therapy in animals with hypovolemic or maldistributive shock. The goal is to increase venous return and thereby restore circulatory function and tissue perfusion. Crystalloid solutions (fluids that contain electrolytes) and colloid solutions (fluids that increase the plasma oncotic pressure and expand plasma volume) can be used. The general principles and practice of fluid therapy are extensively discussed in the section on disturbances of free water, electrolytes and acid–base balance.

Isotonic crystalloid solutions

These are the least expensive and most commonly used treatment for hypovolemic and maldistributive shock in large animals. Balanced electrolyte solutions, such as lactated Ringer's solution, are preferable to 0.9% NaCl solutions.[26] Fluids for the restoration of the extracellular fluid volume must contain sodium but glucose solutions (fluids that provide free water when the glucose is metabolized) are not indicated in the treatment of shock. **Large volumes** of isotonic crystalloid fluids are required. There is no set dose and each case needs to be assessed individually; an initial administration of 100 mL/kg by rapid intravenous infusion is not unusual and 50 mL/kg is probably the minimum. Isotonic crystalloid solutions expand the interstitial fluid volume and promote urine flow; however, beneficial responses are absent shortly after the cessation of fluid administration unless the syndrome is resolved.[17,27]

More fluids are administered as required on the basis of clinical response and the monitoring measures discussed above; in general this involves continuous intravenous infusion during the clinical course. In calves, ruminants and horses the re-establishment of adequate tissue perfusion by intravenous fluid therapy can often be sustained by oral administration of large volumes of electrolyte solutions.[28]

The disadvantages of the use of isotonic crystalloid solutions are the large volume required for treatment, the requirement for repeated treatment, and a sustained increase in pulmonary artery pressure with the risk for production of pulmonary edema in animals with maldistributive shock due to endotoxemia.[29] Moreover, the delivery of large volumes of isotonic fluid to large animals takes time and is difficult to accomplish in the field. This has led to the widespread use of **small-volume hypertonic saline solutions** for the initial resuscitation of shocked animals. The intravenous administration of small volumes of hypertonic salt solutions results in a transcompartmental and transcellular shift of fluid into the vascular compartment, with an increase in the circulating volume, cardiac contractility and stroke volume and an increase in blood pressure with a reduction in peripheral and pulmonary vascular resistance.[17,26,27,29,30] However, there is little improvement in renal function, the improvement in hemodynamic function is very **short-lived** and their use must be followed by intravenous isotonic crystalloid fluids.

Hypertonic saline solution

This has been used successfully in fluid therapy of hypovolemic, maldistributive and hemorrhagic shock and is of value for the rapid resuscitative effect and the lower risk for induction of pulmonary edema in animals with endotoxemia[27,29–31] Small volumes (4–5 mL/kg) of hypertonic saline (7.2%, 2400 mosmol/L) are infused intravenously over 4–5 min. Too rapid an infusion will result in vasodilation and death and too slow an infusion will diminish the resuscitative effect. There is a risk of phlebitis if there is perivascular deposition of hypertonic fluid.

Colloids

The intravenous administration of colloid solutions (dextran, gelatin polymers, hexastarch) induces a more sustained increase in plasma volume than crystalloid solutions and smaller volumes are required for therapy, but colloid solutions are expensive and are rarely used in cattle and occasionally used in horses, with the exception of blood transfusion. Colloid solutions also have a risk for the induction of pulmonary edema[28] and may also increase risk for coagulopathy.[11] For horses, equine plasma is available commercially but is expensive. The use of hypertonic saline in combination with colloids or infusions containing albumin gives a more sustained response and hypertonic saline–dextran solution (2400 mosmol/L sodium chloride with 6% Dextran-70) at a dose of 5 mL/kg is more effective than hypertonic saline alone.[17,31]

Hemorrhagic shock

The source of the hemorrhage should be determined and the cause corrected. The other immediate concern is to replenish the blood volume and a decision must be made if this will be with fluids, whole blood or stroma-free hemoglobin solutions. Blood transfusion replaces all elements of the blood and in cases of severe hemorrhage blood transfusion is the most satisfactory treatment. However, a **decision for blood transfusion** should not be made lightly as the procedure is time-consuming, costly and carries some risk.[32] The collection of blood for transfusion and its administration is covered in detail in Chapter 9. The decision to use whole blood in addition to fluids for treatment is based on the need to replace erythrocytes. The hematocrit can be a guide, in combination with clinical assessment, if the hemorrhage started at least 4 hours previously. With acute hemorrhage (< 4 h), transfusion is indicated solely on the basis of the severity of clinical signs.

In the period immediately following hemorrhage a hematocrit of 20% is indicative of a significant loss of erythrocytes and the hematocrit should be monitored over the next 24–48 hours. If there is a fall to less than 12%, a transfusion of blood is indicated, but a stable packed cell volume (PCV) between 12% and 20% is not usually an indication for transfusion.[33]

Blood should be administered intravenously with an in-dwelling catheter through an in-line filter. Administration of the blood at too rapid a rate may cause overloading of the circulation and acute heart failure, particularly in animals with both circuit and pump failure. A gallon (4.5 L) of blood usually requires an hour to administer to a cow and comparable rates in the smaller species are advisable; and an infusion rate of 10–20 mL/kg/h is recommended for the horse,[32] with faster rates (40 mL/kg/h) for foals.[33]

Hypertonic saline solution is recommended in the initial treatment of hemorrhagic shock and has been shown to be effective in the treatment of experimental hemorrhagic shock in large animals.[17,18,24] Hypertonic saline can be of particular value to the ambulatory clinician, as this therapy can be used in emergency situations for the initial resuscitation of cases of hemorrhagic shock pending transfusion.[17,18] A further advantage to the ambulatory clinician is the ease of portability of this fluid. The use of hypertonic saline is contraindicated where the hemorrhage has not been controlled, as its use in these cases will result in more protracted bleeding.

Drugs to assist coagulation and arrest hemorrhage are used in some cases but there is limited information on their efficacy. Aminocaproic acid (10 g in 1 L of saline for an adult horse, administered

intravenously) has been recommended[34] for the management of hemoperitoneum in the horse. Formalin has traditionally been used to control hemorrhage and 10–30 mL of buffered neutral formalin in 500 mL of saline administered rapidly intravenously through an intravenous catheter has been recommended for the control of postparturient hemorrhage in mares.[35] Ergonovine maleate, 1–3 mg intramuscularly at 3-hour intervals has also been used to control hemorrhage in the postparturient mare.[36]

Animals should be kept quiet and in a dark stall to minimize excitement and the risk of further hemorrhage. Analgesic drugs should be given with hemorrhagic disease where there is pain, such as rupture and hemorrhage of the broad ligament of the uterus.

Obstructive shock

The source for the obstruction should be identified and specific remedies applied. This is a rare cause of shock in large animals.

Ancillary treatment

A large number of drugs have been shown to influence various components of the inflammatory response in septic shock but none has been shown to alter the eventual outcome and the interference of one aspect of the inflammatory cascade triggered by endotoxin should not be expected to improve overall survival.[11] The specific treatment of maldistributive shock has been discussed earlier.

Corticosteroids

There is considerable controversy over the use of corticosteroids in shock. Experimental studies have shown that they may have value in the prevention of maldistributive shock but for this to occur corticosteroids must be given prior to the bacterial or endotoxin challenge. There is little evidence that they are of value in the treatment of hypovolemic, hemorrhagic or maldistributive shock in animals once clinical signs have developed.[11,26,37,38] Despite this, corticosteroids are frequently used in the treatment of shock in animals.[26] The dose that is used is considerably higher than that used for other indications, for example a dose of 1–2 mg/kg BW of dexamethasone intravenously.

Cyclooxygenase inhibitors

The use of cyclooxygenase inhibitors such as flunixin meglumine (0.25 mg/kg BW) and ketoprofen (0.5–2.2 mg/kg BW) has attractions in that they inhibit the production of the vasoactive prostaglandins and thromboxane A_2. This may not be entirely advantageous as the alternate path of metabolism of arachidonic acid is to leukotrienes, which are also potent mediators of inflammation. Treatment of horses with endotoxemia with cyclooxygenase inhibitors does result in a better maintenance of blood pressure and tissue perfusion but does not influence the eventual mortality.[11] Tirilazad mesylate suppresses eicosanoid production and TNF activity and has been shown to be of benefit in the treatment of experimental endotoxemia in calves.[39]

Antibiotic therapy

With maldistributive shock the appropriate antibiotic therapy should be immediately instituted. Antibiotic therapy will not counteract the immediate effects of endotoxin and may theoretically increase the release of endotoxin in the short term but this should not be a contraindication to antibacterial therapy. Pending the result of bacterial culture and susceptibility testing a broad-spectrum bactericidal antibiotic, or a combination of antibiotics to achieve a broad spectrum, should be used. Gram-negative septicemia in calves or foals, or acute–diffuse peritonitis, must be treated with antibiotics as well as by aggressive fluid therapy if there is to be any chance of survival.

Vasoconstrictors and vasodilators

The administration of vasoconstrictors and vasodilators in cases of shock remains problematic unless the patient's cardiovascular status is accurately known and can be continuously monitored. In general, their use is not currently recommended. The administration of a vasoconstrictor substance in a case of low-pressure distributive shock might seem rational because blood pressure would be elevated but it could reduce tissue perfusion still further. α-Adrenergic blockers improve tissue perfusion and cardiac function once the circulating blood volume has been restored but if hypotension is already present it will be further exacerbated.[40] Dopaminergic agonists may be useful in the early stages of maldistributive shock as long as monitoring is adequate.[26] This is seldom possible in large animal ambulatory practice and their use in large animals is confined to referral hospitals.

Immunotherapy

Immunotherapy with antibody directed against the **core lipopolysaccharide antigens** of Gram-negative bacteria may be of value in the therapy or prevention of shock produced by endotoxin in some diseases but not in others. Immunotherapy has shown some promise in the treatment of shock associated with experimental endotoxemia in horses but none for the control of maldistributive shock associated with Gram-negative sepsis in the neonate.[41–43] Hyperimmune serum is available commercially and may be indicated in those cases where endotoxemia is a risk, in which case it is given before the onset of severe signs.[44] Vaccination with these antigens has proved of value in the reduction of clinical disease produced by endotoxemia and in a reduction of the occurrence of endotoxin-induced shock associated with Gram-negative mastitis in cows, although it does not reduce the occurrence of infection of the udder.[45,46]

Allergy and anaphylaxis

When exposure of an animal to an antigen produces a state of increased reactivity of the animal's tissues to that antigen, a state of specific immune responsiveness is achieved. In most animals these responses are defensive and beneficial but, on occasion, they can be detrimental to the host. In these cases a state of hypersensitivity is said to exist, which is clinically recognizable as allergy. When the reaction is sudden and clinically severe it is called anaphylaxis and if sufficiently severe it may result in anaphylactic shock.

There are a number of immune reactions that can be harmful to tissues but in large animals the immediate hypersensitivity reactions, especially those that result in severe anaphylaxis, pulmonary (potentially recurrent airway obstruction (RAO) horses) and dermatological diseases (such as Queensland itch) are most important. There are other immediate hypersensitivity reactions that should be noted. They include isoimmune erythrolysis of foals – a specific cytotoxic hypersensitivity – and the more generalized formation of circulating immune complexes, which cause vasculitis, thrombosis, hemorrhage and consequent tissue damage. Purpura hemorrhagica is probably the best example.

There are four major mechanisms for the induction of a hypersensitivity response. They are classified as types I– IV based on the immune mechanism that elicits the disease state.[1] Types I–III are antibody-mediated responses to antigen and include such conditions as systemic anaphylactic shock (type I), autoimmune hemolytic anemia (type II) and the local Arthus reaction (type III). Type IV hypersensitivity is caused by the induction of sensitized T lymphocytes and thus has a cell-mediated mechanism.[1]

TYPE I

In **immediate hypersensitivity reactions** the antigen, or allergen, reacts with antibody, which may be either circulating or cell-bound, to set in train a series of complex biochemical and pharmacological reactions that culminate in the release of pharmacologically active mediators. There are a number of recognized mediators and the importance of any one varies with the host species and possibly the nature of the hypersensitivity reaction. In general they act to contract smooth muscle and increase capillary permeability. These agents may act immediately at the site of antigen–antibody reaction or they may be carried in the blood to produce effects in susceptible tissues at sites remote from the primary focus. The difference in manifestation of acute, immediate-type hypersensitivity reactions between species appears to depend largely on differences in the tissue site of antibody binding and the distribution of susceptible smooth muscle, as well as differences in the major pharmacological mediators of the reaction. The high incidence of atopic hypersensitivity with familial predisposition seen in humans and dogs does not occur in large animals.

The literature on immunoglobulin-E-mediated hypersensitivity in food-producing animals has been reviewed and the details are available.[1]

Immunological injury in the absence of significant release of pharmacological mediators also occurs but it is rarely approached from the clinical standpoint as a primary allergy and is generally considered in the disease complex in which it is occurring. The anemia and glomerulitis that accompany equine infectious anemia is an example. Serum sickness is rare in large animals.

TYPE II

Autoimmune reactions are uncommon in farm animals. They contribute to the formation of spermatic granulomas. Isoimmune hemolytic anemia and thrombocytopenic purpura could be considered as examples and are dealt with elsewhere under those headings.

TYPE III

Arthus-type reaction or the **Arthus phenomenon** is the development of an inflammatory lesion, with induration, erythema, edema, hemorrhage and necrosis, a few hours after intradermal injection of antigen into a previously sensitized animal producing precipitating antibody; it is classed as a type III hypersensitivity reaction in the Gell and Coombs classification of immune responses. The lesion results from the precipitation of antigen–antibody complexes, which causes complement activation and the release of complement fragments that are chemotactic for neutrophils; large numbers of neutrophils infiltrate the site and cause tissue destruction by release of lysosomal enzymes.

TYPE IV

Cell-mediated or **delayed hypersensitivity** is of importance in the tuberculin and other long-term skin sensitivity tests, but similar delayed reactions to topically applied antigens are not common in farm animals. Queensland and sweet itch are probably examples. Delayed hypersensitivity reactions may contribute to the pathology of many diseases such as mycoplasmal pneumonia in swine, but those are considered clinically under their initiating etiology.

TREATMENT

The **treatment of allergic states** is by the use of functional antagonists which have opposing effects to those of the allergic mediators, and the specific pharmacological antagonists, especially antihistamines and corticosteroids. The functional antagonists include the sympathomimetic drugs, those related to epinephrine and, to a less extent, the anticholinergic drugs. Of the sympathomimetic drugs there is a choice between those with an alpha-response (vasoconstriction and maintaining vascular permeability) and those with a beta-response (bronchodilatory and cardiac-stimulatory). Of the pharmacological antagonists, antihistamines have very limited usefulness, being effective only when the allergic mediator is histamine, the corticosteroids have very wide applicability, and the NSAIDs, including acetylsalicylic acid, phenylbutazone and meclofenamic acid, all inhibit prostaglandin synthesis and thus reduce inflammation.

ANAPHYLAXIS AND ANAPHYLACTIC SHOCK

Anaphylaxis is an acute disease caused by antigen–antibody reaction. If severe it may result in anaphylactic shock.

ETIOLOGY

Most commonly, severe anaphylactic reactions are seen in farm animals following the parenteral administration of a drug or biological product.[1] Other routes of entry of the allergen, such as via the respiratory or gastrointestinal tract, may also result in anaphylactic reactions. The reaction may occur at the site of exposure or in other areas.

In general the reaction is due to sensitization to a protein substance entering the bloodstream and a second exposure to the same substance. In veterinary practice such incidents are not uncommon, although the sensitizing substance cannot always be isolated.

Although severe anaphylactic reactions occur usually after a second exposure to a

sensitizing agent, reactions of similar severity can occur with no known prior exposure. In large-animal practice this is most likely to occur after the injection of sera and bacterins, particularly heterologous sera and bacterins in which heterologous serum has been used in the culture medium.

Hypersensitivity reactions are sometimes observed at a higher incidence than normal in certain families and herds of cattle.

Anaphylactic reactions can occur in the following circumstances:

- Repeated intravenous injection of biological preparations such as glandular extracts
- Repeated blood transfusions from the same donor
- Repeated injections of vaccines, e.g. those against foot-and-mouth disease and rabies
- Rarely, after a first injection of a conventional drug such as penicillin, usually procaine or benzathine penicillin, or a test agent such as bromsulfalein. The reaction is reminiscent of 'serum sickness' in humans because there has been no known previous exposure to the product, but occurs much earlier. It may in fact be immediate and is usually within a few hours after injection
- Similar rare occurrences after the injection of lyophilized *Brucella abortus* strain 19 vaccine and *Salmonella* vaccine. These, like the preceding group, are really anaphylactoid reactions because there has been no apparent previous exposure to the sensitizing antigen
- Assumed anaphylactic reaction to ingested protein occurs in animals at pasture or in the feedlot
- Cows, especially Channel Island cattle, may develop anaphylaxis when milking is stopped because the cows are being dried off – severe urticaria and respiratory distress occur 18–24 hours later
- A systemic reaction after *Hypoderma* spp. larvae are killed in their subcutaneous sites may be anaphylactic, but is more likely to be a toxic effect from breakdown products of the larvae
- Anaphylactic like reactions can be produced experimentally in calves by injecting the endotoxin-like extract of ruminal contents. Acute toxemia develops about 30 minutes later, but an anaphylactic reaction occurs when the same extract is injected 15 days later. This response is more correctly termed endotoxemic shock.

PATHOGENESIS

Anaphylactic reactions occur as the result of antigen reacting with circulating or cell-bound antibody. In humans and dogs a specific class of reaginic antibody, IgE, has been identified and has particular affinity for fixed tissue mast cells.[1] The tissue distribution of mast cells in part accounts for the involvement of certain target organs in anaphylactic reactions in these species. Homocytotropic antibody has been detected in farm animals but the classes of antibody involved in anaphylactic reactions have not been fully identified and are likely to be diverse. Anaphylactic antibodies may be transferred via colostrum.

Antigen–antibody reactions occurring in contact with, or in close proximity to fixed tissue mast cells, basophils and neutrophil leukocytes result in the activation of these cells to release pharmacologically active substances that mediate the subsequent anaphylactic reaction. These substances include biogenic amines such as histamine, serotonin and catecholamines; vasoactive polypeptides such as kinins, cationic proteins and anaphylatoxins; vasoactive lipids such as prostaglandins and slow reacting substance of anaphylaxis (SRS-A); and others. Knowledge of the type and relative importance of pharmacological mediators of anaphylaxis in farm animals rests with studies of severe anaphylactic reactions that have been induced experimentally, but it is likely that these mediators are also of significance in less severe reactions. From these studies it appears that histamine is of less importance as a mediator in farm animals than in other species and that prostaglandins and SRS-A are of greater importance. Bradykinin and 5-hydroxytryptamine (5-HT) are also known to act as mediators in cattle but the reactions in all species are complex and involve a sequence of mediator effects.

In the horse, there are four phases in the development of the anaphylactic response. The **first is acute hypotension** combined with pulmonary arterial hypertension 2–3 minutes after the injection of the triggering agent; it coincides with histamine release. In the **second phase, blood plasma 5-HT levels rise, and central venous blood pressure rises** sharply at about 3 minutes and onward. The **third phase** commences at about 8–12 minutes, and is largely reflex and **manifested by a sharp rise in blood pressure**, and alternating apnea and dyspnea. Finally, there is a second and more protracted systemic hypotension due to prostaglandin and SRS-A influence which persists until the return to normality.

In cattle, there is a similar diphasic systemic hypotension with marked pulmonary venous constriction and pulmonary artery hypertension. An increase in mesenteric venous pressure and mesenteric vascular resistance causes considerable pooling of blood on the venous side of the mesenteric vessels. In both cattle and horses these reactions are accompanied by severe hemoconcentration, leukopenia, thrombocytopenia and hyperkalemia.

Sheep and pigs also show a largely pulmonary reaction.

In horses and cattle the marked changes in vascular tone coupled with increased capillary permeability, increased secretion of mucous glands and bronchospasm are the primary reactions leading to the development of severe pulmonary congestion, edema and emphysema and edema of the gut wall. Death is due to anoxia.

Less severe reactions are also dependent upon the effect of mediators on capillary permeability, vascular tone and mucous gland secretion. The major manifestation depends on the distribution of antibody-sensitized cells and of susceptible smooth muscle in the various organs. In cattle, reactions are generally referable to the respiratory tract but the alimentary tract and skin are also target organs. Sheep and pigs show largely a pulmonary reaction and horses manifest changes in the lungs, skin and feet.

Sensitization of a patient requires about 10 days after first exposure to the antigen, and persists for a very long time: months or years.

CLINICAL FINDINGS

Cattle

In cattle, initially there is a sudden onset of severe dyspnea, muscle shivering and anxiety. In some cases there is profuse salivation, in others moderate bloat and yet others diarrhea. After an incompatible blood transfusion, the first sign is often hiccough. Additional signs are urticaria, angioneurotic edema and rhinitis. Muscle tremor may be severe and a rise in temperature to 40.5°C (105°F) may be observed. On auscultation of the chest there may be increased breath sounds, crackles if edema is present, and emphysema in the later stages if dyspnea has been severe. In most surviving cases the signs have usually subsided within 24 hours, although dyspnea may persist if emphysema has occurred.

In natural cases the time delay after injection of the reagin intravenously is about 15–20 min but in experimentally induced cases a severe reaction may be evident within 2 min and death within 7–10 min of the injection. Clinical signs

include collapse, dyspnea, wild paddling, nystagmus, cyanosis, cough and the discharge of a creamy, frothy fluid from the nostrils. Recovery, if it occurs, is complete in about 2 hours.

Sheep and pigs

In sheep and pigs, **acute dyspnea is common.** Laminitis also occurs rarely in ruminants.

Horses

In the horse, naturally occurring anaphylactic shock is manifested by severe dyspnea, distress, recumbency and convulsions. Death may occur within less than 5 min but it usually requires about an hour. Laminitis and angioneurotic edema are also common signs in the horse. Experimentally induced anaphylaxis may be fatal but not in such a short time. Within 30 min of injecting the reagin the horse is showing anxiety, tachycardia, cyanosis and dyspnea. These signs are followed by congestion of conjunctival vessels, increased peristalsis, fluid diarrhea, generalized sweating and erection of the hair. If recovery occurs it is about 2 hours after the incident began. Death, if it occurs, takes place about 24 hours after the injection.

Pigs

In pigs, experimentally produced anaphylactic shock can be fatal within a few minutes, with systemic shock being severe within 2 min and death occurring in 5–10 min. The disease appears to occur in only one phase, in contrast to the four fairly distinct states in horses. Labored respiration, severe cyanosis, vomiting and edema of the larynx, stomach and gallbladder are the usual outcome.[9]

CLINICAL PATHOLOGY

Blood histamine levels may or may not be increased and few data are available on blood eosinophil counts. Tests for sensitivity to determine the specific sensitizing substance are rarely carried out for diagnostic purposes but their use as an investigation tool is warranted. Serological tests to determine the presence of antibodies to plant proteins in the diet have been used in this way.

Some significant changes occur during immediate anaphylaxis in cattle and horses but whether they have diagnostic importance is uncertain. There is a marked increase in packed cell volume, a high plasma potassium concentration and a neutropenia.

NECROPSY FINDINGS

In acute anaphylaxis in young cattle and sheep the necropsy findings are confined to the lungs and are in the form of severe pulmonary edema and vascular engorgement. In adult cattle there is edema and emphysema without engorgement. In protracted anaphylaxis produced experimentally in young calves, the most prominent lesions are hyperemia and edema of the abomasum and small intestines. In pigs and sheep pulmonary emphysema is evident and vascular engorgement of the lungs is pronounced in the latter. Pulmonary emphysema and widespread petechiation in the horse may be accompanied by massive edema and extravasations of blood in the wall of the large bowel. There may also be subcutaneous edema and lesions of laminitis.

DIFFERENTIAL DIAGNOSIS

- A diagnosis of anaphylaxis can be made with confidence if a foreign protein substance has been injected within the preceding hour, but should be made with reservation if the substance appears to have been ingested.
- Characteristic signs as described above should arouse suspicion and the response to treatment may be used as a test of the hypothesis.
- Acute pneumonia may be confused with anaphylaxis, but there is usually more toxemia and the lung changes are more marked in the ventral aspects; in anaphylaxis there is general involvement of the lung.

TREATMENT

Treatment should be administered immediately; a few minutes' delay may result in the death of the animal. Epinephrine is the most effective treatment for anaphylaxis and anaphylactic shock. Epinephrine administered intramuscularly (or one-fifth of the dose given intravenously) is often immediately effective, the signs abating while the injection is being made. Corticosteroids potentiate the effect of epinephrine and may be given immediately following the epinephrine. Antihistamines are in common use but provide variable results due to the presence of mediators other than histamine. Atropine is of little value.

The identification of mediators other than histamine in anaphylactic reactions in farm animals has led to studies of the effectiveness of drugs more active against these mediators than antihistamines. Acetylsalicylic acid, sodium meclofenamate and diethylcarbamazine have all shown ability to protect against experimentally induced anaphylaxis in cattle and horses and warrant trial in anaphylactic reactions in these species. One of the important clinical decisions, especially in horse practice, is to decide whether an animal is sufficiently hypersensitive to be at risk when being treated. An acute anaphylactic reaction, and even death, can occur soon after intravenous injection of penicillin into a horse. In suspect cases it is customary to conduct an intradermal or a conjunctival test for hypersensitivity with a response time of about 20 minutes, but these tests have their limitations. The types of sensitivity are not necessarily related and there is no sure relationship between anaphylactic sensitivity and either skin (or conjunctival) sensitivity or circulating antibody, and the test often gives false negatives. The reason why some animals develop systemic hypersensitivity and some develop cutaneous hypersensitivity does not appear to be related to the nature of the reagin but may be related to the size of the sensitizing dose.

OTHER HYPERSENSITIVITY REACTIONS

These reactions include anaphylaxis of a less severe degree than anaphylactic shock and cases of cell-mediated delayed hypersensitivity. The resulting clinical signs vary depending on the tissues involved, but are usually localized and mild.

ETIOLOGY

Exposure to any of the etiological agents described under anaphylaxis may result in this milder form of hypersensitivity. Exposure may occur by injection, by ingestion, by inhalation or by contact with the skin.

PATHOGENESIS

In anaphylactic reactions the clinical signs may depend on the portal of entry. Thus ingestion may lead to gastrointestinal signs of diarrhea, inhalation to conjunctivitis, rhinitis, and laryngeal and bronchial edema. Cutaneous lesions can result from introduction of the reagin via any portal. They are usually manifested by angioedema, urticaria or a maculopapular reaction. All the lesions result from the liberation of histamine, serotonin (5-HT) and plasma kinins as in anaphylactic shock.

CLINICAL FINDINGS

In ruminants inhalation of a sensitizing antigen may cause the development of allergic rhinitis. On ingestion of the sensitizing agent there may be a sharp attack of diarrhea and the appearance of urticaria or angioneurotic edema; in ruminants mild bloat may occur. Contact allergy is usually manifested by eczema. In farm animals the eczematous lesion is commonly restricted to the skin of the lower limbs, particularly behind the pastern, and at the bulbs of the heels, or to the midline of the back if the allergy is due to insect bites. In many cases of allergic disease the signs are very transient

and often disappear spontaneously within a few hours. Cases vary in severity from mild signs in a single system to a systemic illness resembling anaphylactic shock. On the other hand, cases of anaphylaxis may be accompanied by local allergic lesions.

DIFFERENTIAL DIAGNOSIS

The transitory nature of allergic manifestations is often a good guide, as are the types of lesion and sign encountered. The response to antihistamine drugs is also a useful indicator. Skin test programs as applied to humans should be utilized when recurrent herd problems exist. The differential diagnosis of allergy is discussed under the specific diseases listed above.

TREATMENT

A combination of epinephrine, antihistamines and corticosteroids is usually highly effective. Skin lesions other than edema may require frequent local applications of lotions containing antihistamine substances. Continued exposure to the allergen may result in recurrence or persistence of the signs. Keeping the animals indoors for a week often avoids this, probably because the allergen occurs only transiently in the environment. Hyposensitization therapy, as it is practiced in human allergy sufferers, may have a place in small animal practice but is unlikely to be practicable with farm animals.

Edema

Synopsis

Etiology Increased hydrostatic pressure (chronic (congestive) heart failure or obstruction to venous return), decreased plasma oncotic pressure (hypoalbuminemia), increased capillary permeability (endotoxemia) or decreased lymphatic drainage (obstruction to lymph flow) result in accumulation of fluid in the interstitial space

Clinical findings Pitting, cool, usually dependent, subcutaneous swelling and fluid accumulation in peritoneal and pleural cavities. Distribution of edema varies with animal species

Clinical pathology Hypoalbuminemia except with obstruction to venous return or lymph flow. Examinations aimed at establishing the organ principally responsible for edema formation (commonly heart, kidney, gastrointestinal tract, and liver) and at the cause of the organ failure

Necropsy findings Fluid accumulation in tissues and body spaces. Specific changes with cause

Diagnostic confirmation Clinical findings coupled with clinical pathology

Treatment Diuretics (furosemide) and colloid replacement fluid therapy using blood, plasma, or plasma volume expanders. Correction of specific cause

ETIOLOGY

Edema results from four causes: **increased hydrostatic pressure** in capillaries and veins due to chronic (congestive) heart failure or obstruction to venous return; **decreased plasma oncotic pressure**; **increased capillary permeability** in endotoxemia, part of the allergic response, vasculitis and damage to the vascular endothelium; or **obstruction to lymphatic flow**.

Increased hydrostatic pressure

- Symmetric ventral edema in chronic (congestive) heart failure, symmetric pulmonary edema in acute heart failure
- Generalized edema in enzootic calcinosis of cattle
- Local symmetric ventral edema in udder edema in late pregnancy from compression of veins and lymphatics by the developing mammary gland (and possibly the enlarging fetus and uterus), causing mammary or ventral edema in cows (particularly heifers), mares and occasionally ewes.[1] Sodium and potassium intakes and cation–anion differences in the diet contribute to the severity of udder edema.[2] Edema resolves 5–10 days following parturition
- Local edema by compressive lesions on veins (as in thymic lymphosarcoma with compression of the cranial vena cava)[3] draining other anatomic locations
- Local edema in portal hypertension due to hepatic fibrosis causing ascites (rare in large animals).

Decreased plasma oncotic pressure

Decreased total protein concentration in plasma, and particularly decreased plasma albumin concentration, will result in symmetric ventral edema. Hypoalbuminemia is more important than hypoglobulinemia in inducing edema formation because albumin provides the largest contribution to plasma oncotic pressure. Hypoalbuminemia can result from **increased loss** (due to blood-sucking parasites or across the gastrointestinal tract, kidneys or into a large third space such as the pleural or peritoneal cavities), **decreased production** (as in chronic hepatic failure) or **decreased intake**:

- Chronic blood loss, especially in heavy infestations with blood-sucking parasites such as *Strongylus* sp. in the horse, *Fasciola* sp. in ruminants, *Haemonchus* sp. in ruminants of all ages, especially goats, and *Bunostomum* sp. in calves
- Protein-losing gastroenteropathies as in Johne's disease and amyloidosis in adult cattle, right dorsal colitis in horses; heavy infestation with nematode parasites in ruminants, particularly *Ostertagia* sp. in young cattle and cyathostomiasis in horses
- Glomerulonephropathies, such as amyloidosis in adult cattle, inherited glomerulonephritis in Finnish Landrace lambs
- Chronic liver damage causing failure of plasma protein synthesis (rare and terminal in large animals)
- Terminally in prolonged malnutrition with low dietary protein intakes, e.g. ruminants at range in drought time.

Increased capillary permeability

- Increased capillary permeability due to endotoxemia
- Allergic edema as in urticaria and angioneurotic edema caused by local liberation of vasodilators
- Toxic damage to vascular endothelium or vasculitis – in anthrax, gas gangrene and malignant edema in ruminants, edema disease of pigs, mulberry heart disease in pigs, equine viral arteritis, equine infectious anemia, purpura hemorrhagica in horses, and heartwater (cowdriosis) in ruminants.

Obstruction to lymphatic flow

- Part of the edema caused by tumors or inflammatory swellings is lymphatic obstruction. Extensive fluid loss also originates from granulomatous lesions on serous surfaces. Ascites or hydrothorax may result
- Congenital in inherited lymphatic obstruction edema of Ayrshire and Hereford calves
- Sporadic lymphangitis (bigleg) of horses
- Edema of the lower limbs of horses immobilized because of injury or illness.

PATHOGENESIS

Edema is the excessive accumulation of fluid in the interstitial space of tissue caused by a disturbance in the mechanism of fluid interchange between capillaries, the interstitial space and the lymphatic vessels. At the arteriolar end of the

capillaries the hydrostatic pressure of the blood is sufficient to overcome its oncotic pressure and fluid tends to pass into the interstitial space. At the venous end of the capillaries the position is reversed and fluid tends to return to the vascular system. The pressure differences are not great, but there is a large area for exchange, and a small increase in hydrostatic pressure or a small decrease in oncotic pressure leads to failure of the fluid to return to the capillaries.

Increased fluid passage into the interstitial space can also occur where there is increased vascular permeability due to vascular damage. Under these circumstances, fluid accumulates in the interstitial space when the fluid flux across the endothelium is greater than the ability of the lymphatic system to drain it. Alternatively, capillary hydrostatic pressure, oncotic pressure and vascular permeability might be normal, but fluid and vascular permeability can accumulate in the interstitial space when lymphatic drainage is occluded.

Edema of the lower limbs of immobilized horses ('filling') is usually ascribed to poor lymphatic or venous return due to inactivity of the 'foot pump'. Lower limb edema in horses may also be related to changes in the hematocrit and plasma protein concentration in the distal limb vasculature as a result of inactivity.

CLINICAL FINDINGS

Accumulation of edematous transudate in subcutaneous tissues is referred to as **anasarca**, in the peritoneal cavity as **ascites**, in the pleural cavities as **hydrothorax** and in the pericardial sac as **hydropericardium**. Anasarca in large animals is usually confined to the ventral wall of the abdomen and thorax, the brisket and, if the animal is grazing, the intermandibular space because of the large hydrostatic pressure gradient between the submandibular space and heart. Intermandibular edema may be less evident in animals housed such that they do not have to lower their heads to feed. Edema of the limbs is uncommon in cattle, sheep and pigs but occurs in horses quite commonly when the venous return is obstructed or there is a lack of muscular movement. Hydrothorax is not common with generalized edema and is usually an indication of an obstructive intrathoracic lesion. Local edema of the head in the horse is a common lesion in African horse sickness and purpura hemorrhagica.

Edematous swellings are **soft**, **painless** and **cool to the touch**, and **pit on pressure**. In ascites there is distension of the abdomen and the fluid can be detected by a fluid thrill on tactile percussion, fluid sounds on succussion and by paracentesis. A level top line of fluid may be detectable by any of these means. In the pleural cavities and pericardial sac the clinical signs produced by the fluid accumulation include restriction of cardiac movements, embarrassment of respiration and collapse of the ventral parts of the lungs. The heart sounds and respiratory sounds are muffled, and the presence of fluid may be ascertained by percussion and thoracocentesis or pericardiocentesis.

More localized edemas cause more localized signs: pulmonary edema is accompanied by respiratory distress and in some cases by an outpouring of froth from the nose; cerebral edema is manifested by severe nervous signs of altered mentation. A not uncommon entity is a large edematous plaque around the umbilicus in yearling horses. The plaque develops rapidly, causes no apparent illness and subsides spontaneously after about 7 days. Thrombophlebitis is a common cause of localized edema, particularly of the head in horses and cattle with thrombophlebitis of both jugular veins. Head edema usually occurs in affected animals only when there is rapid and complete occlusion of both jugular veins by thrombophlebitis; a slower rate of jugular vein occlusion permits development of collateral veins for venous drainage of the head.

CLINICAL PATHOLOGY

Cytological examination of a sample of fluid reveals an absence of inflammatory cells where edema is the result of increased hydrostatic pressure, decreased plasma oncotic pressure (hypoalbuminemia), increased vascular permeability or obstruction to lymphatic flow. Thoracocentesis or abdominocentesis is useful to differentiate the causes of fluid accumulation, in conjunction with measurement of serum albumin concentration and central venous pressures.

Examinations should always be directed towards determining the mechanism for hypoalbuminemia; in particular, the renal and gastrointestinal systems and liver are examined for evidence of disease and altered function. In general, the serum albumin concentration is usually less than 15 g/L in animals with generalized edema due to decreased plasma oncotic pressure. Generalized edema should always be expected whenever serum albumin concentration is less than 10 g/L.

NECROPSY FINDINGS

The nature of the accumulation of fluid in most cases is obvious on gross postmortem examination but the determination of the cause of the disease that has resulted in hypoalbuminemia may require further histological and cultural examination. Necropsy findings for the specific diseases where edema is a feature are given in the individual disease sections.

DIFFERENTIAL DIAGNOSIS

- Rupture of urethra or bladder for differentiation of ascites
- Peritonitis or pleuritis for accumulation of fluid in abdominal or pleural cavities
- Cellulitis for local edema

TREATMENT

The treatment of edema should be aimed at correcting the cause, whether it is increased hydrostatic pressure, decreased plasma oncotic pressure, increased endothelial permeability, or obstruction to lymphatic drainage. Chronic (congestive) heart failure may need to be treated with digoxin and thrombophlebitis of the jugular veins may need specific treatment (see Ch. 8). Hypoalbuminemia may require the administration of plasma or plasma substitutes, although this is only a short-term measure and is expensive. Parasitic gastroenteritis requires administration of the appropriate anthelmintic, obstructive edema requires removal of the physical cause, and increased permeability edema requires resolution of the cause of endothelial damage.

Ancillary nonspecific measures include restriction of the amount of salt in the diet and the use of diuretics. Diuretics may relieve the effects of pressure temporarily but the primary cause needs to be addressed for a satisfactory outcome. Aspiration of edema fluid is rarely successful and is not routinely recommended. Aspiration usually provides temporary relief because the fluid rapidly accumulates.

Disturbances of free water, electrolytes and acid–base balance

There are many diseases of farm animals in which there are disturbances of body fluids (free water), electrolytes and acid–base balance. A disturbance of body water balance in which more fluid is lost from the body than is absorbed results in reduction in circulating blood volume and in **dehydration** of the tissues. In contrast, the rapid ingestion of large quantities of water can lead to overhydration (**water intoxication**).

Electrolyte imbalances occur commonly as a result of loss of electrolytes,

shifts of certain electrolytes or relative changes in concentrations due to loss of water. Common electrolyte imbalances include hyponatremia, hypokalemia, hypocalcemia and hypochloremia.

Acid–base imbalances, either **acidemia** or **alkalemia**, occur as a result of the addition of acid and depletion of alkali reserve, or the loss of acid with a relative increase in alkali reserve.

Under most conditions, the above disturbances of fluid and electrolyte balance will occur simultaneously, in varying degrees, depending on the initial cause. Each major abnormality will be described separately here with emphasis on etiology, pathogenesis, clinical pathology and treatment. However, it is important to remember that actual disease states in animals in which treatments with fluids and electrolytes are contemplated are rarely caused by single abnormalities. In most cases it is a combination of dehydration together with an electrolyte deficit, and often without a disturbance of the acid–base balance, that necessitates treatment.

DEHYDRATION

ETIOLOGY

There are two major causes of dehydration:

- Inadequate water intake
- Excessive fluid loss.

Deprivation of water, a lack of thirst due to toxemia, and the inability to drink water as in esophageal obstruction, are examples of dehydration due to inadequate water intake. The most common cause of dehydration is when excessive fluid is lost. Diarrhea is the most common reason for excessive fluid loss, although vomiting, polyuria and loss of fluid from extensive skin wounds or by copious sweating may be important in sporadic cases. Severe dehydration also occurs in acute carbohydrate engorgement in ruminants, acute intestinal obstruction and diffuse peritonitis in all species, and in dilatation and volvulus of the abomasum. In most forms of dehydration, deprivation of drinking water being an exception, the serious loss, and the one that needs correction, is not the fluid but the electrolytes (Fig. 2.1).

The ability to survive for long periods without water in hot climates represents a form of animal adaptation that is of some importance. This adaptation has been examined in camels and in Merino sheep. In the latter, the ability to survive in dry, arid conditions depends on a number of factors, including insulation, the ability to carry water reserves in the rumen and extracellular fluid space, the ability to adjust electrolyte concentrations in several fluid locations, the ability of the kidney to conserve water and the ability to maintain the circulation with a lower plasma volume. Dehydrated mammals in hot environments can save water by reducing the rate of panting and sweating and regulating body temperature above hydrated levels. Sweating is a significant avenue of evaporative heat loss in goats when they are hydrated and exposed to high ambient temperatures above 40°C.

Observations of drinking behavior of cattle transported to the abattoir indicate that those animals that had been sold in livestock markets prior to arrival at the abattoir are more thirsty and more tired than cattle sent directly from farms.[1] This indicates inadequate water intake and dehydration.

PATHOGENESIS

Two factors are involved in the pathogenesis of dehydration:

- Depression of tissue water content with resulting interference in tissue metabolism
- Reduction in the free water content of blood.

The initial response to negative water balance is the withdrawal of fluid from the tissues and the maintenance of normal blood volume. The fluid is drained primarily from the intracellular and interstitial fluid spaces. Essential organs including the central nervous system,

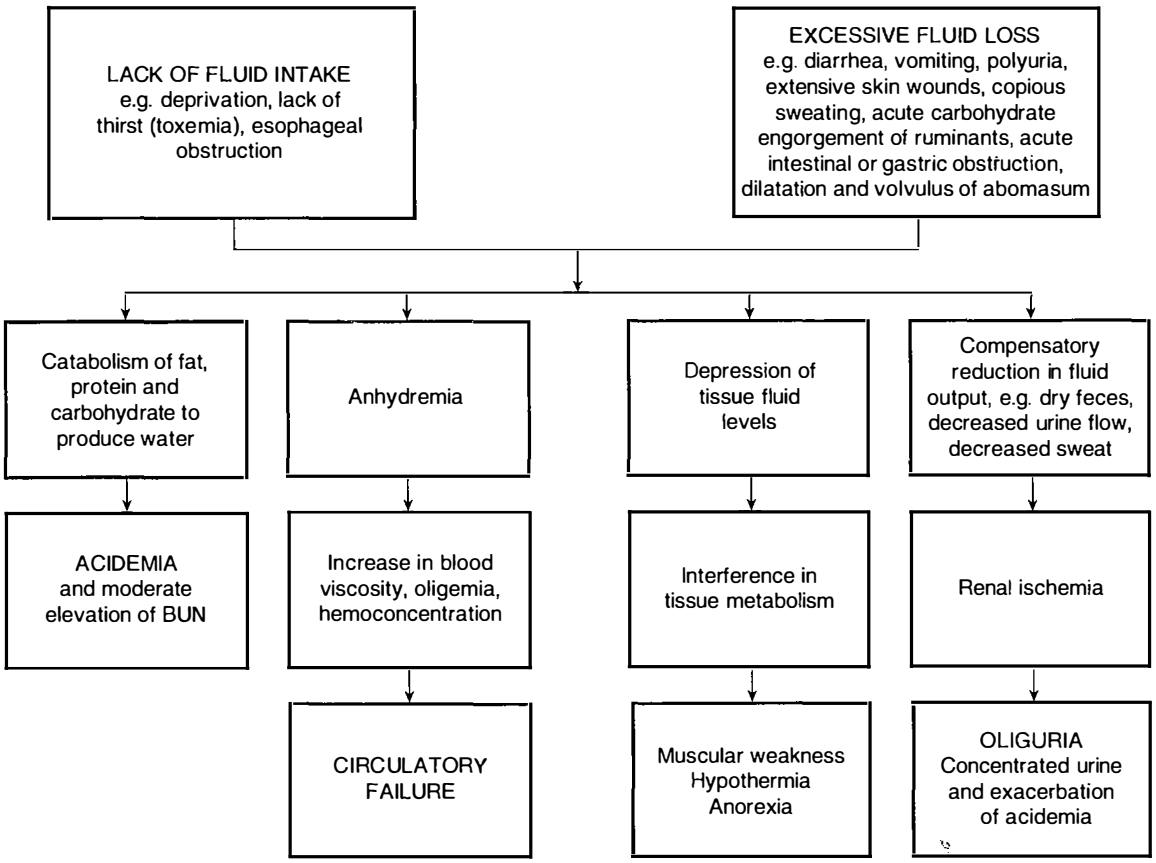

Fig. 2.1 Etiology and pathogenesis of dehydration.

heart and skeleton contribute little and the major loss occurs from connective tissue, muscle and skin. The loss of fluid from the interstitial and intracellular spaces results in loss of skin elasticity, dryness of the skin and mucosa, and a reduction and retraction of the eyeball (enophthalmia) due to reduction in the volume of the postorbital fat deposits. In the goat, total body water may be reduced as much as 44% before death occurs.

The secondary response to continued negative water balance is a reduction in the fluid content of the blood causing a reduction in circulating blood volume (**volume depletion**) and an increase in the concentration of the blood (**hemoconcentration**). Because of the hemoconcentration, there is an increase in the viscosity of the blood, which impedes blood flow and may exacerbate peripheral circulatory failure. The loss in circulating blood volume also contributes to the mental depression of dehydrated animals, which is also due to varying degrees of acidemia and toxemia depending on the cause of the dehydration. In deprivation of water and electrolytes or in deprivation of water alone or inability to consume water in an otherwise normal animal (e.g. esophageal obstruction), the dehydration is minimal because the kidney compensates effectively by decreasing urine output and increasing urine osmolality. In addition, water is preserved by reduced fecal output and increased absorption, which results in dehydration of the contents of the rumen and large intestine, which in turn results in dry, scant feces.

In calves with acute diarrhea there is increased fecal output of water compared to normal calves but the total water losses are not much greater than in normal calves. In the diarrheic calf the kidney compensates very effectively for fecal water loss, and the plasma volume can be maintained if there is an adequate oral fluid intake. Urine excretion decreases, the urine becomes progressively more concentrated and the renal insufficiency may accentuate pre-existing acidemia and electrolyte imbalance, hence the importance of restoring renal function. The newborn calf is able to concentrate urine at almost the same level as the adult. This illustrates the importance of oral fluid and electrolyte intake during diarrhea to compensate for continuous losses. However, it is possible for metabolic acidosis to occur in diarrheic calves and goat kids that are not dehydrated.[2,3]

Goats are more sensitive to water deprivation during pregnancy and lactation than during anestrus. Water deprivation for 30 hours causes a marked increase in the plasma osmolality and plasma sodium concentration in pregnant and lactating goats. Pregnant and lactating goats drink more than goats in anestrus.

The dehydration in horses used for endurance rides is hypotonic, in which both sodium and water are lost through sweating. This may account for the lack of thirst in some dehydrated horses with the exhaustion syndrome. Weight losses of 10–15 kg/h may occur in horses exercising in high environmental temperatures exceeding 32°C (89°F) and a horse weighing 450 kg can lose 45 L of fluid in a 3-hour ride.

Dehydration exerts important effects on tissue metabolism. There is an increase in breakdown of fat, then carbohydrate and finally protein, to produce water of metabolism. The increased endogenous metabolism under relatively anaerobic conditions results in the formation of acid metabolites and the development of metabolic acidosis. Urine formation decreases because of the restriction of renal blood flow and this, together with the increased endogenous metabolism, causes a moderate increase in blood levels of nonprotein nitrogen.[4] The body temperature may increase slightly initially – dehydration hyperthermia – because of insufficient fluid to maintain the loss of heat by evaporation. The onset of sweating in steers after exposure to high environmental temperatures has been shown to be delayed by dehydration.

Dehydration may cause death, especially in acute intestinal obstruction, vomiting and diarrhea, but it is chiefly a contributory cause of death when combined with other systemic states, such as acidosis, electrolyte imbalances, toxemia and septicemia.

CLINICAL FINDINGS

The first and most important clinical finding in dehydration is **dryness** and **wrinkling of the skin**, giving the body and face a shrunken appearance. The eyes recede into the sockets and the skin subsides slowly after being picked up into a fold. The dehydration is usually much more marked if water and electrolyte losses have been occurring over a period of several days. Peracute and acute losses may not be obvious clinically because major loss will have occurred from the intravascular compartment and only minor shifts have occurred from the interstitial spaces. Sunken eyes and inelastic skin are not remarkable clinical findings of dehydration in the horse.

The best indicator of hydration status in calves has been demonstrated to be the **degree of recession of the eye into the orbit**. Hydration status is assessed by gently rolling the lower eyelid out to its normal position and estimating the distance of eye recession in millimeters. This distance is multiplied by 1.7 to provide an estimate of the degree of dehydration as a percentage of euhydrated body weight.[5] The second best indicator of hydration status in calves is the elasticity of the skin of the neck and lateral thorax, which are assessed by pinching the skin between the fingers, rotating the skin fold 90° and noting the time required after release of the skin fold for the skin fold to disappear (normally < 2 s). The elasticity of the skin fold on the upper or lower eyelid is a poor indicator of hydration status in calves and is not recommended. The best methods for assessing hydration status in adult cattle and other large animals has not been determined but it is likely that eye recession and skin tent duration in the neck region provide the most accurate and sensitive methods for estimating hydration status.

In diarrheic calves, the severity of dehydration, hypothermia and metabolic acidosis are associated with the degree of mental depression.[6] The combined effects of acidemia and dehydration also contribute to hypothermia.

Loss of body weight occurs rapidly in dehydration and muscular weakness and inappetence or anorexia are common. In horses deprived of water for 72 hours there is a mean body weight loss of about 15%, and 95% of the animals have a urine specific gravity of 1.042, a urine osmolality of 1310 mosmol/kg and a urine osmolality/serum osmolality ratio of 4:14. Prerenal azotemia also develops.

The degree of thirst present will depend on the presence or absence of other diseases causing an inflammatory response or endotoxemia. In primary water deprivation, dehydrated animals are very thirsty when offered water. In dehydration secondary to enteritis associated with severe inflammation, acidemia and electrolyte imbalance, there may be no desire to drink. Horses that become dehydrated in endurance rides may refuse to drink and the administration of water by oral intubation and enemas may be necessary. In cattle on pasture and deprived of water for up to 9 days and then given access to water, there will be staggering, falling, convulsions and some death – signs similar to salt poisoning in pigs. Experimental restriction of the water intake in lactating dairy cattle for up to 4 days may reduce milk yield by 75% and decrease body weight by 14%. A 10% reduction in water intake causes a drop in milk production that may be difficult to detect. Behavioral changes are obvious: cows spend considerable time licking the water bowls. In cold climates, cattle are often forced to eat snow as a source of

water. The snow must be soft enough so that it can be scooped up by the cattle and 3–5 days are necessary for the animals to adjust to the absence of water and become dependent on snow. During this time there is some loss of body weight. Lactating ewes relying on snow as a source of free water reduce their total water turnover by approximately 35%.

CLINICAL PATHOLOGY

Dehydration is characterized by an increase in the packed cell volume and total serum protein concentration, although the latter response may be modified by the presence of severe enteritis, peritonitis, or proteinuria.

ACUTE OVERHYDRATION (WATER INTOXICATION)

Synopsis

Etiology Rapid ingestion of large quantities of water
Epidemiology Access to water by thirsty calves, or calves that have been marginally deprived of water for some time
Clinical findings Dark red urine, weakness and depression
Clinical pathology Hemoglobinuria, hemoglobinemia, hypo-osmolality, hyponatremia, hypochloremia
Necropsy findings Hemoglobinuria and renal cortical necrosis
Diagnostic confirmation Epidemiological, presence of hyponatremia and hypochloremia; rule out other causes of intravascular hemolysis
Treatment Time, possibly intravenous hypertonic saline but usually too late to be effective

The rapid ingestion of large amounts of water by young calves with normal serum sodium concentrations may result in intravascular hemolysis, hemoglobinemia and hemoglobinuria. In contrast, water ingestion in hypernatremic animals may result in cerebral edema but does not produce hemoglobinuria. The cerebral edema syndrome is described in sodium chloride poisoning. Water intoxication (acute overhydration) is described here.

ETIOLOGY

The ingestion of excessive quantities of water when animals are very thirsty may result in overhydration, which is also called water intoxication. The primary cause of acute overhydration is a rapid decrease in the osmolality of the small intestinal contents, which are normally isotonic to plasma. Such a rapid decrease in luminal osmolality occurs within 5 minutes of water ingestion[2] because thirsty calves close their esophageal groove when drinking. This results in a large volume of water in the abomasum, which is subsequently emptied into the duodenum. Free water rapidly moves from the small intestinal lumen into the intravascular compartment because of the large surface area for absorption in the small intestine and development of an osmotic gradient between the small intestinal lumen and intestinal capillary bed. The end result is a rapid decrease in plasma osmolality and expansion and rupture of erythrocytes, leading to intravascular hemolysis, hemoglobinemia, hemoglobinuria, hyponatremia, hypochloremia and a decrease in plasma protein concentration from preingestion values.

EPIDEMIOLOGY

The syndrome has been reported from several countries but is uncommon. Calves 2–4 months of age are most commonly affected but the disease is also recorded in adult cattle,[1] sheep[3] and pygmy goats.[4] Water intoxication occurs in calves in normal husbandry systems when animals that have had limited access to water are suddenly given free access. Commonly water intoxication occurs when calves previously fed a milk replacer diet but no other fluid, or weaned calves that have been on a starter diet but limited water, are turned out to pasture or to yards where water is freely available. Calves that are not fed supplementary salt or that have lost salt as a result of severe exercise or high environmental temperatures may be at higher risk[5] but the syndrome also occurs where salt has not been restricted. The majority of calves show clinical signs within minutes to hours of access to water.

The condition has been reproduced in calves by gavage with water at 12% of body weight.[6]

CLINICAL FINDINGS

Hemoglobinuria as a result of intravascular hemolysis is prominent and there may be a moderate to severe hemolytic anemia. Dark red urine is passed shortly following access to water. Additional signs include tachycardia and hypothermia if the temperature of the water ingested is below body temperature. Affected animals are usually depressed and weak.

CLINICAL PATHOLOGY

Hemoglobinuria and hemoglobinemia are evident and there is hypo-osmolality, hyponatremia and hypochloremia.[5] Serum total protein and albumin concentration may be decreased but are usually within the normal range because animals are usually mildly dehydrated and thirsty before ingesting large volumes of water.

Postmortem findings

There is marked pallor of the carcass and renal cortical necrosis due to hemoglobinemic nephrosis may be evident histologically.[7]

DIFFERENTIAL DIAGNOSIS

Other causes of intravascular hemolysis and hemoglobinuria.

TREATMENT

Treatment of affected animals is usually not attempted as the hypo-osmotic lysis has already occurred when clinical signs are manifest and serum osmolality is usually gradually increasing as the distal convoluted tubules eliminate excessive free water. Hypertonic saline (7.2% NaCl, 5 mL/kg BW over 5 min intravenously) is usually administered to correct the hyponatremia and hypochloremia but treatment is not necessary in mild cases. Case fatality is low and hemoglobinuria persists for only a few hours.

CONTROL

Water intoxication does not occur commonly and can be avoided by preventing thirsty animals from having unlimited access to water. Calves should have free access to water by the end of the first week of life.

ELECTROLYTE IMBALANCES

Most electrolyte imbalances are due to a net loss of electrolytes associated with diseases of the alimentary tract. Sweating, exudation from burns, excessive salivation and vomiting also result in electrolyte losses, but are of minor importance in farm animals, with the exception of sweating in the horse and dysphagia in ruminants. The electrolytes of major concern are sodium, chloride, potassium,

calcium and phosphorus. Losses of bicarbonate are presented under acid– balance imbalance.

HYPONATREMIA

Sodium is the most abundant ion in the extracellular fluid and is chiefly responsible for the maintenance of osmotic pressure of the extracellular fluid. The most common cause of hyponatremia is increased loss of sodium through the intestinal tract in enteropathies (Fig. 2.2). This is particularly marked in the horse with acute diarrhea and to a moderate extent in calves with acute diarrhea. The sodium is lost at the expense of the extracellular fluid. In calves with acute diarrhea due to enterotoxigenic *E. coli* the sodium concentration of the intestinal fluid secreted in response to the enterotoxin is similar to that of plasma, and hyponatremia usually occurs (**hypotonic dehydration**). Animals affected with diarrhea of several days' duration continue to lose large quantities of sodium and the hyponatremia may become severe. Hyponatremia can become severe when sodium-free water or 5% dextrose are used as the only fluid therapy in animals already hyponatremic. Hyponatremia can also occur in animals with proximal tubular dysfunction.

Hyponatremia causes an increase in the renal excretion of water in an attempt to maintain normal osmotic pressure, which results in a decrease in the extracellular fluid space, leading to a decreased circulating blood volume, hypotension, peripheral circulatory failure and ultimately renal failure. Muscular weakness, hypothermia and marked dehydration are common findings.

Isotonic dehydration occurs when there is a parallel loss of sodium and water. **Hypertonic dehydration**, which is uncommon, occurs when there is a loss or deprivation of water with minor losses or deprivation of sodium. Hypertonic dehydration can occur in animals that are unable to consume water because of an esophageal obstruction. The dehydration in isotonic and hypertonic dehydration is mild compared to the marked clinical dehydration that can occur in hypotonic dehydration accompanied by marked loss of water and concentration of the extracellular space (Fig. 2.3).

There are no clinical signs that are characteristic of hyponatremia. There is usually dehydration, muscular weakness and mental depression, which occur with other disturbances of both water and electrolytes and with acid–base imbalance. Similarly, there are no clinical signs characteristic of hypochloremia. However, hyponatremia affects the osmotic pressure of the extracellular fluid, and hypochloremia promotes the reabsorption of bicarbonate and further development of alkalosis. Polyuria and polydipsia occur in cattle with dietary sodium chloride deficiency.

HYPOCHLOREMIA

Hypochloremia occurs as a result of an increase in the net loss of the electrolyte in the intestinal tract in acute intestinal obstruction, dilatation and impaction and volvulus of the abomasum and in enteritis (Fig. 2.4). Normally a large amount of chloride is secreted in the abomasum by the mucosal cells in exchange for bicarbonate, which moves into the plasma. The hydrogen, chloride and potassium ions secreted in gastric juice are normally absorbed by the small intestine. Failure of abomasal emptying and obstruction of the proximal part of the small intestine will result in the sequestration of large quantities of chloride, hydrogen and potassium ions which leads to a **hypochloremic, hypokalemic metabolic alkalosis**. A severe hypochloremia can be experimentally produced in calves by feeding them a low chloride diet and daily removal of abomasal contents. Clinical findings include anorexia, weight loss, lethargy, mild polydipsia and polyuria. A marked metabolic alkalosis occurs, with hypokalemia, hyponatremia, azotemia and death.

HYPOKALEMIA

Hypokalemia may occur as a result of decreased dietary intake, increased renal excretion, abomasal stasis, intestinal obstruction and enteritis, and repeated administration of corticosteroids with

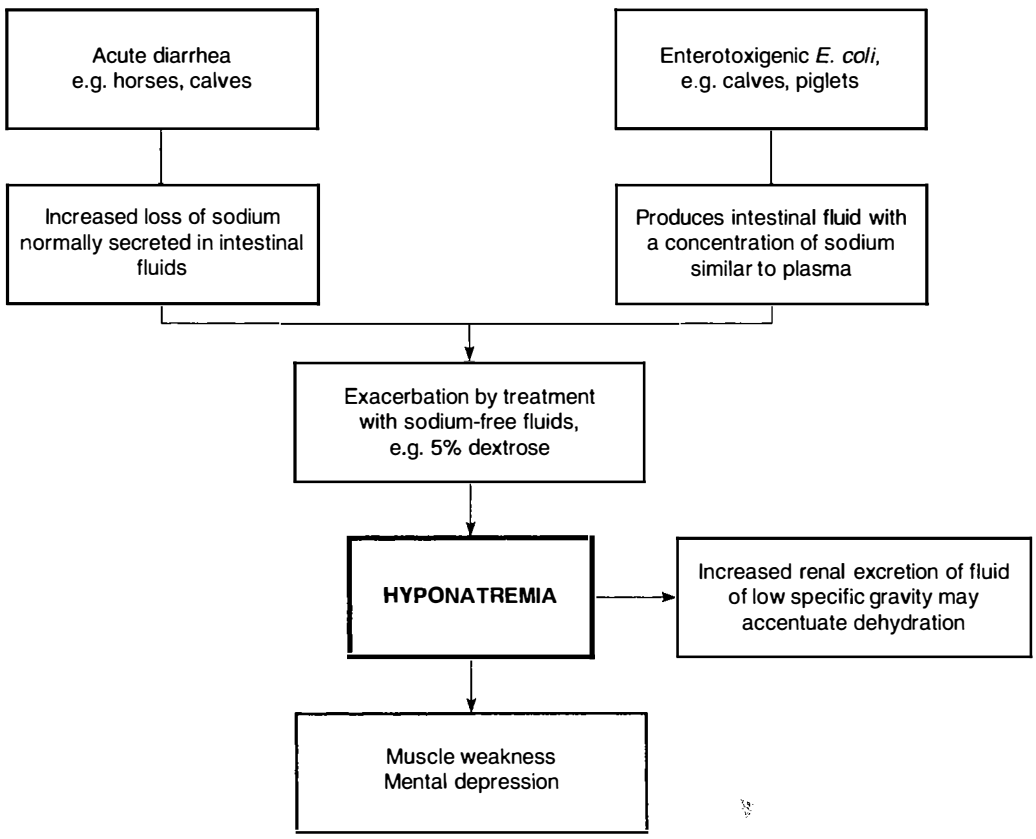

Fig. 2.2 Etiology and pathogenesis of hyponatremia.

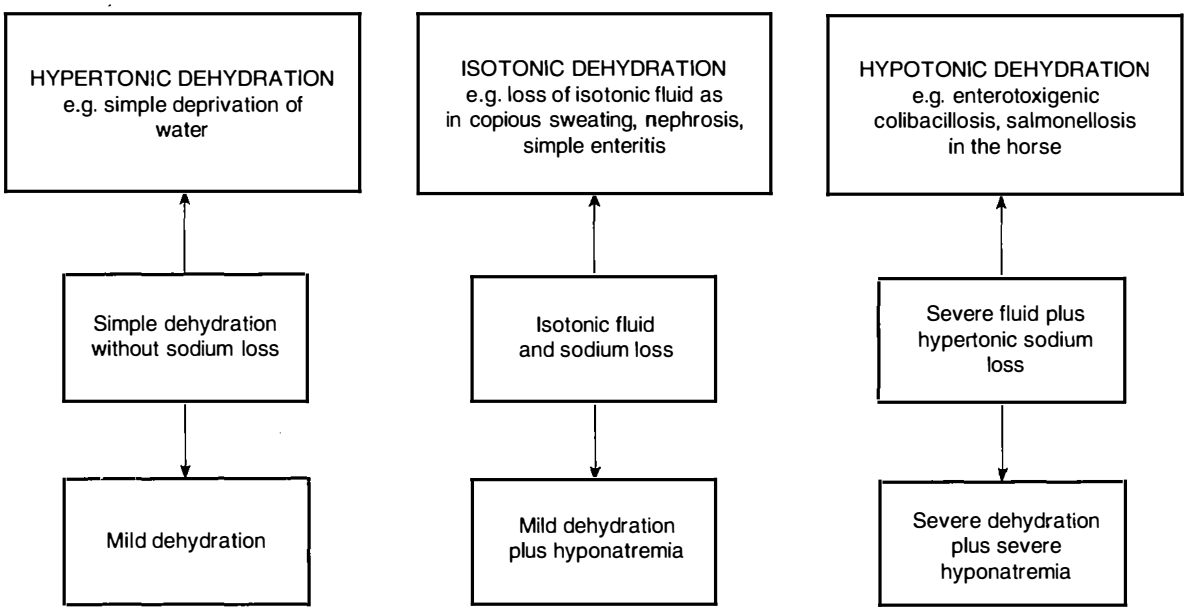

Fig. 2.3 Types of dehydration.

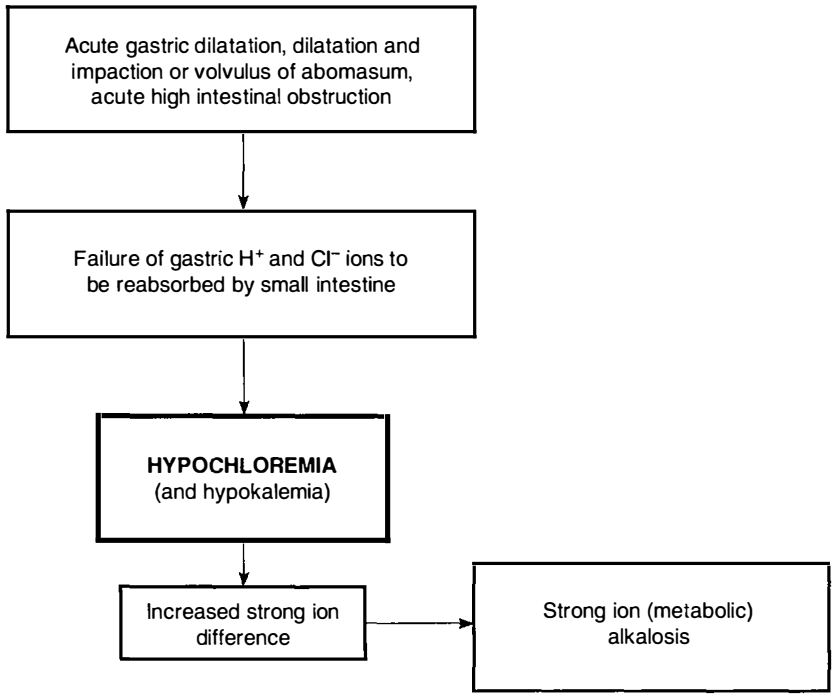

Fig. 2.4 Etiology and pathogenesis of hypochloremia.

mineralocorticoid activity (Fig. 2.5). The prolonged use of potassium-free solutions in fluid therapy for diarrheic animals may result in excessive renal excretion of potassium and hypokalemia. Alkalosis may result in an exchange of potassium ions for hydrogen ions in the renal tubular fluid, resulting in hypokalemia. Hypokalemia can cause muscle weakness, prolonged unexplained recumbency, inability to hold up the head, anorexia, muscular tremors and, if severe enough, coma. The treatment of ketosis in lactating dairy cows with multiple dosages of isoflupredone, a glucocorticoid with some mineralocorticoid activity, can cause hypokalemia and recumbency, with a high case fatality rate.[1]

The most common occurrence of hypokalemia in ruminants is in diseases of the abomasum that cause stasis and the accumulation of fluid in the abomasum. Potassium becomes sequestered in the abomasum along with hydrogen and chloride, resulting in **hypokalemia, hypochloremia** and **metabolic alkalosis**.

Metabolic alkalosis and hypokalemia in cattle are often accompanied by muscular weakness and paradoxic aciduria. Hypokalemia causes muscle weakness by lowering the resting potential of membranes, resulting in decreased excitability of neuromuscular tissue. Thus, the differential diagnosis of the animal with muscle weakness should always include hypokalemia.

Hypokalemia and alkalosis also are often directly related because of the renal response to either. Hypokalemia from true body deficits of potassium will cause decreased intracellular concentration of this ion. The intracellular deficit of potassium and excess of hydrogen will cause hydrogen secretion into the urine when distal sodium reabsorption is required. This situation exists in metabolic alkalosis, where sodium bicarbonate

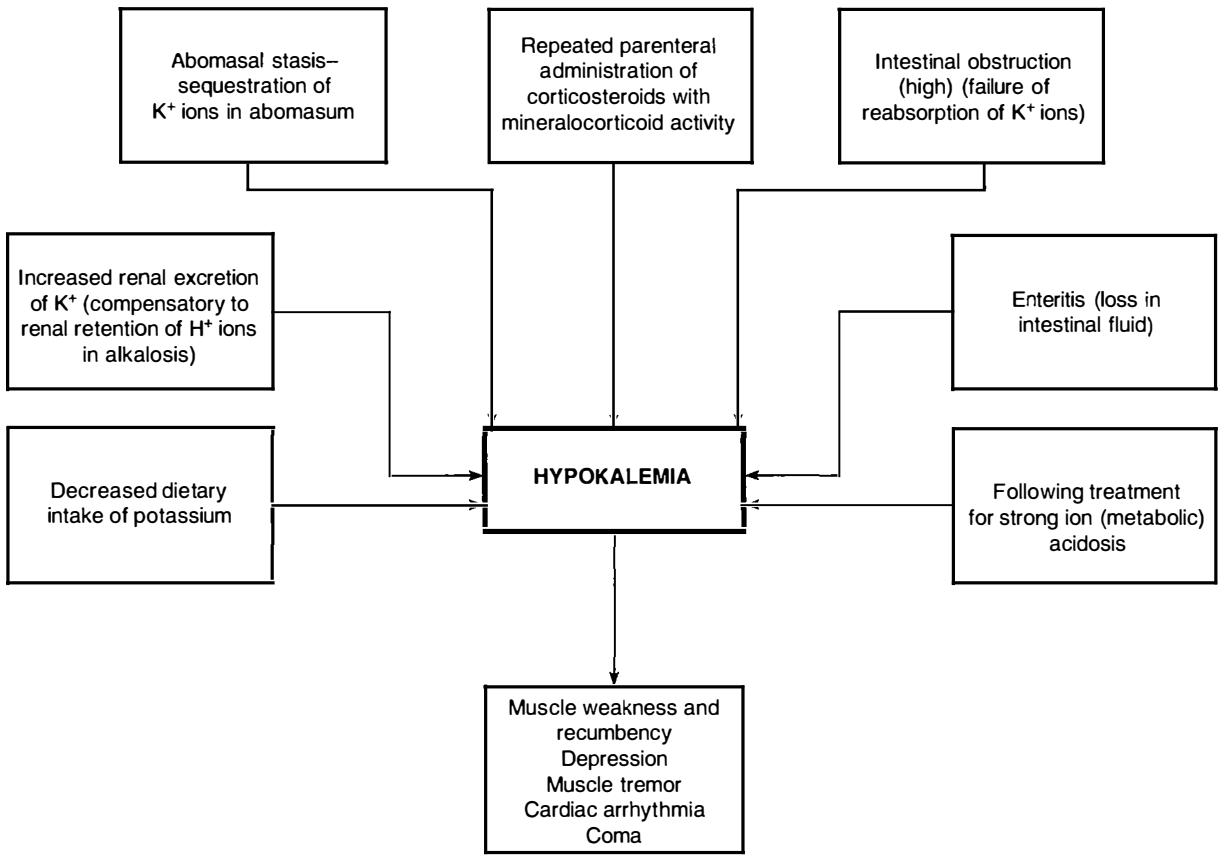

Fig. 2.5 Etiology and pathogenesis of hypokalemia.

reabsorption in the proximal nephron is decreased because of the excess of plasma bicarbonate. Distal nephron avidity for sodium is increased to protect extracellular fluid volume, and the increased distal sodium reabsorption is at the expense of hydrogen secretion, although it is contrary to the need of acid retention in the presence of alkalosis. In other words, the kidney prioritizes maintenance of plasma volume above that of acid–base balance, presumably because respiratory compensation can usually keep blood pH within the normal physiological range. Because electroneutrality of extracellular fluid must be maintained by reabsorbing an equivalent charge of cations and anions, the reabsorption of chloride and of bicarbonate in the kidneys are inversely proportional to each other. Thus, with excess trapping of chloride in the abomasum, the kidneys will compensate for the resulting hypochloremia by increasing bicarbonate reabsorption, which may proceed until metabolic alkalosis develops.

The **treatment of hypochloremic, hypokalemic alkalosis** requires correction of extracellular fluid volume and sodium and chloride deficits with 0.9% NaCl infusions and oral KCl. Providing adequate chloride ion allows sodium to be reabsorbed without bicarbonate. Increased proximal reabsorption of sodium will decrease distal acid secretion because less sodium is presented to the distal nephron. As less bicarbonate is reabsorbed and less acid secreted, the metabolic alkalosis is resolved. Specially formulated solutions containing potassium are necessary in cases of severe hypokalemia and small-intestinal obstruction.

Hypokalemia also occurs following treatment of the horse affected with metabolic acidosis and hyponatremia, and probably reflects whole-body potassium depletion. Horses used for endurance rides may be affected by hypokalemia, hypocalcemia and alkalosis due to loss of electrolytes during the competition. Synchronous diaphragmatic flutter also occurs, which may be the result of the electrolyte imbalance (particularly hypocalcemia) causing hyperirritability of the phrenic nerve.

Since potassium is the major intracellular cation, the measurement of plasma or serum potassium is not a reliable indication of whole-body potassium status. Extremely low levels or high levels are usually indicative of a potassium imbalance, often associated with other electrolyte and acid–base imbalances. In severe alkalosis, for example, potassium leaves the extracellular space and becomes concentrated in the cells. This may result in low serum potassium levels when, in fact, there might not be potassium depletion of the body. Conversely, in severe metabolic acidosis of calves with acute diarrhea, the potassium leaves the cells and moves into the extracellular fluid. This results in hyperkalemia in some cases where the body potassium is normal or even decreased. When changes occur in the concentration of intracellular and extracellular potassium, the ratio of intracellular to extracellular potassium may decrease by as much as 30–50%, which results in a decrease in the resting membrane potential. This is thought to be the explanation for the effects of hypokalemia and hyperkalemia on muscle function.

The potassium concentration of red blood cells may be a more accurate indicator of whole-body potassium deficit in diarrheic horses and provides a basis for a calculated oral dose of potassium chloride in horses with diarrhea, which is a safe therapeutic procedure.

Potassium should be administered intravenously or orally. The intravenous route is used only for the initial treatment of recumbent ruminants with severe hypokalemia and rumen atony, as it is much more dangerous and expensive than oral treatment. The most aggressive **intravenous treatment** protocol is an isotonic solution of KCl (1.15% KCl), which should be administered at less than 3.2 mL/kg per hour, equivalent to a maximal delivery rate of 0.5 mEq of K^+/kg BW per hour. Higher rates of potassium

administration run the risk of inducing hemodynamically important arrhythmias, including ventricular premature complexes that can lead to ventricular fibrillation and death. A less aggressive intravenous treatment is an isotonic equimolar mixture of NaCl (0.45% NaCl) and KCl (0.58% KCl), and the least aggressive intravenous treatment is the addition of 10 mmol of KCl/L of Ringer's solution, which will increase the solution osmolarity to 329 mosmol/L. Clinical experience with oral administration of KCl has markedly decreased the number of adult ruminants treated with intravenous KCl.

Oral administration of potassium is the method of choice for treating hypokalemia. Inappetent adult cattle should be treated with 30–60 g of feed grade KCl twice with a 12-hour interval, with the KCl placed in gelatin boluses. Adult cattle with severe hypokalemia (< 2.5 mEq/L) should initially be treated with 120 g of KCl, followed by two 60 g KCl treatment at 8-hour intervals, for a total 24-hour treatment of 240 g KCl. Higher doses have been administered to dairy cows but these are accompanied by diarrhea, and oral administration of 0.58 g KCl/kg BW was toxic in 6-month-old Holstein calves, manifest by excessive salivation, muscular tremors of the legs and excitability, and a peak plasma [K^+] of 9.0 mEq/L. Extrapolating this toxic dose in normokalemic calves to hypokalemic 600 kg cows suggests that a daily dose of 240 g KCl approaches the upper limit of safety. The recommended doses are empirical but are effective in rapidly increasing serum [K^+] and [Cl^-]. Inappetent horses often have whole-body potassium depletion and would benefit from supplementary dietary potassium (25–50 g/d KCl).

HYPERKALEMIA

Hyperkalemia is not as common in farm animals as hypokalemia, occurring most commonly in severe metabolic acidosis. The classic description for the development of hyperkalemia in metabolic acidosis involves a purported redistribution of potassium from the intracellular space to the extracellular space because a large proportion of the excess hydrogen ions are buffered intracellularly. Thus potassium is supposedly exchanged with hydrogen ions across the cell membrane in order to maintain electroneutrality. A more likely mechanism is that metabolic acidosis is accompanied by acidemia and a decreased intracellular pH; during intracellular acidosis the function of all enzyme systems is decreased. As a direct result of the intracellular acidosis, the Na–K-ATPase activity is decreased, with potassium leaving the cell down its concentration gradient.

Hyperkalemia is potentially more life-threatening than hypokalemia. Hyperkalemia (when over 7–8 mmol/L) has a profound effect on cardiac function. There is usually marked bradycardia and arrhythmia and sudden cardiac arrest may occur. The electrocardiogram (ECG) changes in experimentally induced hyperkalemia in the horse have been described. The changes include four successive stages as hyperkalemia increased. There was a widening and lowering of amplitude followed by inversion and disappearance of the P wave, an increase in the amplitude of the T wave, an increase in the QRS interval, with some irregularity in the ventricular rate, and periods of cardiac arrest that became terminal or were followed by ventricular fibrillation. The minimum plasma potassium concentration required to induce ECG changes was 6–7 mmol/L and severe cardiotoxic effects occurred at levels between 8–11 mmol/L. The effects of hyperkalemia on the ECG are exacerbated by the presence of hyponatremia.

Hyperkalemia has traditionally been treated by intravenous administration of sodium bicarbonate, glucose, insulin and sometimes calcium. Hypertonic saline is just as effective as is hypertonic sodium bicarbonate in decreasing hyperkalemia and hyperkalemia-associated brady-arrhythmias, as a result of sodium-induced intracellular movement of potassium, extracellular volume expansion and the strong ion effect of increasing the serum concentration of a strong cation. The long-held myth regarding the need to administer glucose and insulin to 'drive' potassium into the cells during hyperkalemia needs to be re-evaluated. Calcium counteracts the effect of hyperkalemia on the resting membrane potential by increasing the threshold potential to a higher value, thereby returning an appropriate difference between resting and threshold potentials. Calcium can be administered intravenously at 0.2–0.4 mL of a 23% calcium gluconate solution/kg BW. The focus of treatment in hyperkalemia should be correction of acidemia, plasma volume expansion and increasing the serum sodium concentration. Glucose and insulin are not routinely needed to correct hyperkalemia.

Hyperkalemic periodic paralysis occurs in heavily muscled Quarterhorse. Affected horses become weak, may stand base-wide and are reluctant to move. Sweating commonly occurs and generalized muscle fasciculations are apparent. Affected horses remain bright and alert but may yawn and do not eat or drink. Some horses become recumbent and may appear to be in a state of flaccidity. Attacks may occur in a rest period following exercise or at random. During the episode the serum potassium concentration is elevated by up to twofold and returns to normal values when the animal recovers. Treatment consists of sodium bicarbonate, hypertonic saline or 5% dextrose given intravenously, possibly with insulin.

HYPOCALCEMIA

Hypocalcemia or milk fever may occur in recently calved mature dairy cows that have been inappetent or anorexic for a few days. Hypocalcemia can be due to a reduction in dry matter intake because of illness or it may be the earliest stages of hypocalcemic parturient paresis. The clinical findings include anorexia, mild tachycardia with a reduction in the intensity of the heart sounds and occasionally an arrhythmia, a decrease in the frequency and amplitude of rumen contractions or complete ruminal stasis, and a decrease or complete absence of feces, which may last from 6–36 hours if untreated.

Hypocalcemia cases often mimic intestinal obstruction and create problems in the differential diagnosis. Affected cattle may not exhibit any evidence of muscular weakness and the detection of the hypocalcemic state can be elusive. The total serum calcium concentrations range from 1.5–2.0 mmol/L and the response to intravenous therapy is usually good, although recovery may require several hours before the appetite returns to normal and feces are passed.

Calcium should be administered by the intravenous, subcutaneous, or oral route. **Calcium gluconate** and **calcium borogluconate** are the preferred forms for intravenous and subcutaneous administration because $CaCl_2$ causes extensive necrosis and sloughs of tissue when administered perivascularly. Compared to calcium gluconate, calcium borogluconate has improved solubility and shelf life. Plasma ionized calcium concentrations are increased to a greater extent following $CaCl_2$ treatment when high equimolar solutions of $CaCl_2$ and calcium gluconate are administered, leading to more cardiac arrhythmias during $CaCl_2$ administration. A typical treatment to an adult lactating dairy cow with periparturient hypocalcemia is 500 mL of 23% calcium borogluconate by slow intravenous injection with cardiac auscultation, this provides 10.7 g of calcium. Although the calculated calcium deficit in a recumbent periparturient dairy cow is 4 g calcium, additional calcium should be provided to overcome the continued loss of calcium in milk. A field study comparing the effectiveness of different doses of calcium for treating periparturient milk fever determined that

9 g of calcium was superior to 6 g. A good rule of thumb for administering 23% calcium borogluconate solutions (2.14 g calcium/100 mL) to cows with periparturent hypocalcemia is therefore to administer 1 mL/kg BW. There do not appear to be any clinically important advantages to slow administration of the solution over 6 h, when compared to 15 min.[2]

The normal cardiac response to **intravenous calcium administration** is an increase in the strength of cardiac contraction and a slowing of the heart rate. Intravenous administration is continued until the first arrhythmia is detected (a bradyarrhythmia such as a prolonged pause); the rate of intravenous administration is then slowed until a second arrhythmia is detected, at which time intravenous administration is discontinued and the remainder of the solution is placed subcutaneously over the lateral thorax. This treatment method titrates the calcium dose required for each animal. Auscultation of the heart is an absolute requirement during treatment: visual monitoring of the jugular pulse at the base of the neck does not allow the early detection of bradyarrhythmias, making it more likely that the cow will receive a toxic and possibly lethal dose of calcium. The maximum safe rate of calcium administration in cattle is 0.07 mEq of Ca^{2+}/kg BW/min, which is equivalent to 0.065 mL 23% calcium borogluconate/kg BW/min. For a 500 kg normocalcemic dairy cow, this corresponds to a maximum safe rate of administration of 33 mL/min. Typical rates of administration through a 14-gauge needle are 50 mL/min; this rate of administration is safe for cows with hypocalcemia, provided that cardiac auscultation is performed during administration.

Subcutaneous administration of calcium solutions has been practiced for many years. To facilitate absorption, it is preferable to administer no more than 125 mL at a site. A 14-gauge needle is placed subcutaneously over the lateral thorax, 125 mL is administered, the needle is redirected and another 125 mL is administered. The process is then repeated on the other side of the cow. Although the effectiveness of subcutaneous administration of calcium has been documented in healthy normal cows, there do not appear to be any reports documenting the rapidity by which subcutaneous calcium is absorbed by cows with periparturient hypocalcemia. Subcutaneous administration of calcium gluconate is not recommended in recumbent cows because poor peripheral blood flow is suspected to lead to slow absorption from the subcutaneous site. Calcium chloride is not recommended for subcutaneous administration because of extensive tissue damage; the addition of dextrose to the administered calcium is also not recommended because it increases the tonicity of the solution and propensity for bacterial infection and abscessation. Rectal calcium administration is not recommended because it causes severe mucosal injury and tenesmus but does not increase plasma concentrations of calcium.

Oral administration of calcium has also been practiced for many years, usually by ororuminal intubation of calcium borogluconate solutions designed for parenteral administration. Over the past decade there has been increased interest in improving the efficacy of oral calcium formulations. The results of a number of studies indicate that oral calcium salts are effective at increasing plasma calcium concentration; orally administered calcium is absorbed by a dose-dependent passive diffusion process across ruminal epithelium and a dose-independent calcium-binding protein mechanism in the small intestine that is modulated by vitamin D. Rapid correction of hypocalcemia by oral calcium administration is predominantly by passive ruminal diffusion, as small intestinal absorption is too slow to be of clinical value.

Two calcium formulations are currently recommended for oral administration to ruminants; $CaCl_2$ and calcium propionate, but most commercially available products contain 50 g of $CaCl_2$. Calcium chloride has the advantage of low cost and low volume (because of its high solubility), but $CaCl_2$ can severely damage the pharynx and esophagus in ruminants with reduced swallowing ability, can lead to necrosis of the forestomach and abomasum when administered in high doses, and can lead to aspiration pneumonia when administered as a drench. Calcium propionate has the advantage that it is less irritating while providing a gluconeogenic substrate (propionate), but the disadvantages of higher volumes and cost. Oral calcium solutions should only be administered to cattle that have normal swallowing ability, precluding their administration to animals with advanced clinical signs of hypocalcemia. Higher plasma calcium concentrations are obtained more quickly when calcium solutions are drenched after administration of vasopressin to induce esophageal groove closure, or when the calcium solution is administered as a drench instead of ororuminal intubation. Calcium solutions are suspected to have a higher likelihood of aspiration pneumonia than calcium gels (with a consistency similar to toothpaste), although this supposition does not appear to have been verified. Commercially available formulations of calcium gels contain 50 g of $CaCl_2$ and increase plasma calcium concentrations within 30–60 minutes and for at least 6 hours. Retreatment at 12-hour intervals (if needed) therefore appears indicated and provide 100 g of $CaCl_2$ and 37 g of calcium over 24 hours, but more aggressive treatment protocols are not recommended.

HYPOPHOSPHATEMIA

Hypophosphatemia also occurs in cattle under conditions similar to those of hypocalcemia. A decrease in feed intake or alimentary tract stasis will result in a decrease in serum inorganic phosphate. Acute recumbency in lactating dairy cattle may be associated with marginal phosphorus deficiency,[3] although a cause and effect relationship between hypophosphatemia and recumbency has not been established.[4] However, many inappetent and weak cows have marginal hypophosphatemia and clinically appear to benefit from normalization of their plasma concentration of phosphate. As such, it is currently recommended that ruminants with marked hypophosphatemia and signs of illness should be treated with phosphorus-containing solutions.

Almost all commercially available intravenous solutions for treating hypophosphatemia use **phosphite** (PO_2^{2-}) or **hypophosphite** (PO_3^{3-}) salts as the source of phosphorus because these salts are very soluble, even in the presence of calcium and magnesium. However, the phosphorus in phosphite and hypophosphite is unavailable to mammals, meaning that the vast majority of 'phosphate'-containing solutions have no efficacy in treating hypophosphatemia. Instead, the **monobasic monophosphate form of sodium phosphate (NaH_2PO_4)** should be administered. The pH of the solution should be mildly acidic (pH 5.8) to maintain phosphate solubility in cold weather but is not needed in warm ambient temperatures. A recommended treatment to an adult lactating dairy cow with severe hypophosphatemia is 300 mL of 10% NaH_2PO_4 (monohydrate) solution by slow intravenous injection; this provides 7 g of phosphate and increases plasma phosphate concentrations for at least 6 hours. Human enema formulations that contain a mixture of monobasic sodium phosphate monohydrate and dibasic sodium phosphate heptahydrate in a buffered solution have also been administered to cattle with hypophosphatemia but are not recommended. This human enema solution is extremely hypertonic and must therefore be diluted before administration. A major drawback with intravenous administration of

phosphate solutions is that they should not be administered within 2 hours of intravenous calcium administration, because of concerns that calcium-phosphate precipitates may be formed in the plasma of cattle with treatment-induced hypercalcemia and hyperphosphatemia. This has traditionally been evaluated by calculating the calcium–phosphorus product, whereby metastatic calcification may occur if the product of serum calcium concentration and serum phosphate concentration (both in mg/dL) exceeds 70.

Hypophosphatemia is more safely treated by administration of **oral monosodium phosphate**, and this is the preferred method of administration in ruminants with rumen motility. Oral administration also results in a more prolonged increase in plasma phosphorus concentration. Recommended dose is 200 g of feed grade monosodium phosphate (contains 50 g of phosphate) administered in gelatin boluses, drench, or by ororuminal intubation. Phosphorus in other feed grade minerals (such as bone meal or dicalcium phosphate) is poorly available and is not recommended for the treatment of hypophosphatemia.

HYPOMAGNESEMIA

Magnesium is usually administered parenterally only when a ruminant exhibits clinical signs of hypomagnesemia. Treatment of hypomagnesemia is more dangerous (to the animal and clinician) and less satisfying than treatment of periparturient hypocalcemia; the response to treatment is much slower in hypomagnesemia presumably because magnesium concentrations must be normalized in cerebrospinal fluid, which turns over at approximately 1% per minute.

Treatment of hypomagnesemia has historically used 25% Epsom salts solution (magnesium sulfate heptahydrate; $MgSO_4.6H_2O$); this solution concentration was selected because it provided approximately 1 mmol of magnesium per liter. It should be noted that 25% Epsom salts solution is markedly hypertonic (2028 mosmol/L). A typical treatment for an adult cow has been slow intravenous administration (over at least 5 min) of 100 mL of the 25% Epsom salts solution, this provides 2.5 g of magnesium (25 mg of magnesium/mL of solution). More recently, hypomagnesemia has been treated using commercially available combined calcium and magnesium solutions; 500 mL of these solutions typically contain 1.6–2.7 g of magnesium in the form of a borogluconate, chloride or hypophosphite salt. Although the calculated extracellular deficit in a cow with hypomagnesemia is 2 g of magnesium, we should provide additional magnesium to correct presumed intracellular deficiencies and to overcome the anticipated urinary loss of magnesium. Combined calcium and magnesium solutions are preferred for intravenous administration to 25% Epsom salts solution because ruminants with hypomagnesemia frequently have hypocalcemia, and hypercalcemia provides some protection against the toxic effects of hypermagnesemia. Moreover, administration of solutions containing magnesium as the only cation increases the risk of developing cardiac and respiratory failure during treatment. The maximum safe rate of administration of magnesium in cattle is 0.08 mEq Mg^{2+}/kg BW per minute, which is equivalent to 0.04 mL 25% Epsom salts/kg BW per minute. For a 500 kg beef cow with hypomagnesemia, this corresponds to a maximum safe rate of administration of 20 mL/min.

Magnesium-containing solutions (such as 25% Epsom salts solution) can also be administered subcutaneously, although this frequently leads to necrosis of the skin, particularly when 50% Epsom salts solution is administered. Only combined calcium and magnesium solutions should therefore be administered subcutaneously.

The oral bioavailability of magnesium is low and much lower than that of calcium. Accordingly, oral administration of magnesium is not recommended for the treatment of hypomagnesemia, but is essential for the prevention of hypomagnesemia. Magnesium absorption from the rumen is facilitated by volatile fatty acids but decreased by potassium and the ammonium ion.

Rectal administration may be the only practical and safe method for treating a convulsing hypomagnesemic beef cow. After evacuating the rectal contents, an enema containing 60 g of Epsom salts (magnesium sulfate heptahydrate) or magnesium chloride in 200 mL of water can be placed in the descending colon (and not the rectum) and the tail held down for 5 minutes; this increases plasma magnesium concentrations within 10 minutes. However, enema solutions can be prematurely evacuated, eliminating the chance for therapeutic success, and some degree of colonic mucosal injury is expected because of the high osmolarity of 30% solutions (approximately 2400 mosmol/L). The safety of this treatment protocol does not appear to have been evaluated, although a 50 mL enema of a 30% $MgCl_2.6H_2O$ solution rapidly and effectively increased serum magnesium concentration in 7–10-week-old calves and relieved clinical signs of hypomagnesemia.

Oral administration of magnesium hydroxide and magnesium oxide excessively alkalinizes the rumen and can create a severe metabolic alkalosis (strong ion alkalosis), as absorption of magnesium leads to hypermagnesemia and increased plasma strong ion difference. Because oral administration of sodium bicarbonate causes expansion of the plasma volume and creates a metabolic alkalosis (strong ion alkalosis) without hypermagnesemia, it is likely that oral sodium bicarbonate is a more effective treatment for grain overload in ruminants.

ACID–BASE IMBALANCE

The pH of mammalian blood is maintained within the normal range of 7.35–7.45 by its buffer systems, of which hemoglobin is the most important, because it has the greatest buffering capacity. However, because the blood hemoglobin concentration is regulated on the basis of oxygen delivery instead of acid–base balance, and because rapid changes in hemoglobin concentration occur only with marked changes in hydration status or splenic contraction associated with exercise, the **bicarbonate system** has traditionally been considered to be the most important buffer. Other buffers in blood are plasma proteins and phosphate. The addition of relatively large amounts of acid or alkali to the blood is necessary before its buffering capacity is exhausted and its pH changed. Changes from normal acid–base balance towards alkalemia or acidemia occur commonly in sick animals and make a significant contribution to the observed clinical signs.

The traditional approach for assessing acid–base balance focuses on how plasma carbon dioxide tension (P_{CO_2}), plasma bicarbonate concentration ($[HCO_3^-]$), the negative logarithm of the apparent dissociation constant (pK_1') for plasma carbonic acid (H_2CO_3), and the plasma solubility of CO_2 (S) interact to determine plasma pH. This relationship is most commonly expressed as the

Henderson–Hasselbalch equation: $pH = pK_1' + \log([HCO_3^-]/S \times P_{CO_2})$. The evaluation of acid–base balance using the Henderson–Hasselbalch equation has historically used pH as an overall measure of acid–base status, P_{CO_2} as an independent measure of the respiratory component of acid–base balance, and extracellular base excess, actual HCO_3^- concentration or standard HCO_3^- as a measure of the nonrespiratory (also called metabolic) component of acid–base balance.

When using the traditional Henderson–Hasselbalch approach, **four primary** acid–base **disturbances** can be distinguished: **respiratory acidosis** (increased P_{CO_2}), **respiratory alkalosis** (decreased P_{CO_2}), **metabolic acidosis** (decreased extracellular base excess or actual HCO_3^- concentration) and **metabolic alkalosis** (increased extracellular base excess or actual HCO_3^- concentration). The anion gap is easily calculated from the results of serum biochemical analysis and is used to determine whether unmeasured anions are present. The Henderson–Hasselbalch equation has a long history of use and remains widely and routinely used in the clinical management of acid–base disorders. These advantages should not be overlooked. The principal disadvantage of the Henderson–Hasselbalch equation is that it is more descriptive than mechanistic, decreasing the value of the approach in explaining the cause of acid–base changes during disease. This is because the Henderson–Hasselbalch equation fails to distinguish between the effects of independent and dependent variables on plasma pH.

Actual plasma HCO_3^- concentration in units of mmol/L is not measured but calculated using the Henderson–Hasselbalch equation and measured values for pH and P_{CO_2}, whereby:

$$[HCO_3^-] = S \times P_{CO_2} \times 10^{(pH - pK1')}.$$

The values for pK_1' and S at 37°C are 6.12 and 0.0307/mmHg respectively for normal mammalian plasma. The equation at 37°C is therefore:

$$[HCO_3^-] = 0.0307 \times P_{CO_2} \times 10^{(pH-6.12)}.$$

Because actual HCO_3^- concentration is calculated from pH and P_{CO_2}, it can never provide an independent measure of the nonrespiratory component of an acid–base disturbance. A primary decrease in P_{CO_2} (respiratory alkalosis) at normal pH always is accompanied by a decrease in plasma HCO_3^- concentration (which would be interpreted as a metabolic acidosis). Likewise, a primary increase in P_{CO_2} (respiratory acidosis) at normal pH always produces an increase in plasma HCO_3^- concentration (which would be interpreted as a metabolic alkalosis). In both cases, the actual HCO_3^- concentration is dependent upon the pH and P_{CO_2}, thereby providing no additional information as to the cause of the acid–base imbalance than that obtained by knowledge of the pH and P_{CO_2}. It is therefore illogical to use actual HCO_3^- concentration to define the nonrespiratory (metabolic) component of an acid–base disturbance.

The current use of actual HCO_3^- concentration in the evaluation of acid–base status results from Van Slyke's work in 1924, where pH and total CO_2 (which is highly correlated with actual $[HCO_3^-]$) could be measured more accurately than P_{CO_2}. This led to the graphical depiction of the curvilinear HCO_3–pH relationship, the so-called Davenport diagram, to represent acid–base disturbances. With the later development of accurate and practical laboratory methods in the 1950s to measure P_{CO_2}, acid–base derangements were graphically depicted as approximately linear $\log(P_{CO_2})$–pH relationships. This development led directly to the **base excess** concept.

The normal range of plasma bicarbonate in large animals is 24–30 mmol/L (this should be compared to the normal range in humans, which is 22–24 mmol/L). In mild metabolic acidosis the bicarbonate concentration is in the range of 20–24 mmol/L, moderate metabolic acidosis is 14–18 mmol/L, and in severe cases the values are below 10 mmol/L and carry a grave prognosis. The levels of P_{CO_2}, P_{O_2}, plasma bicarbonate and blood pH can be used to determine the degree of compensation, if any, which has taken place. In metabolic acidosis there may be a compensatory decrease in P_{CO_2} due to hyperventilation; in metabolic alkalosis there may be an increase in P_{CO_2} due to hypoventilation. In respiratory acidosis due to severe pneumonia the arterial P_{O_2} will be markedly decreased.

The **base excess** value directly expresses the amount (usually expressed in units of mEq/L) of strong base (or acid) added per liter of blood or plasma, when the normal mean base excess value is arbitrarily fixed at zero. As such, the base excess is defined as the amount of strong acid (such as HCl) needed to titrate the pH of 100% oxygenated human blood to 7.40 at 37°C and at a P_{CO_2} of 40 mmHg. By definition, the normal base excess value for humans is 0 mEq/L (range is –2 to +2 mEq/L), and a base excess of more than +2 mEq/L indicates metabolic alkalosis, whereas a value of less than –2 mEq/L (negative base excess value or base deficit) reflects metabolic acidosis. The **normal range of base excess** in large animals is 0–6 mmol/L.

Mathematical formulas and nomograms are available to calculate base excess from measured pH, P_{CO_2} and blood hemoglobin concentration. Base excess is usually expressed as BE_{ECF} (also called **standard base excess** or **in vivo base excess**). Extracellular base excess is the preferred measurement as this formulation provides the best clinical estimate of the required mmol/L of HCO_3^- required to correct metabolic acidosis, as it assumes a fixed hemoglobin concentration of 5 g/dL. Clearly, the BE_{ECF} value will be incorrect when applied to animals with anemia or polycythemia; however, the error introduced by this approximation is small and usually clinically insignificant.

Most blood gas analyzers calculate base excess in units of mEq/L using Siggaard-Andersen's empirical equation derived from his nomogram with hemoglobin concentration [Hb] and actual HCO_3^- concentrations in mmol/L:

$$BE_{blood} = (1 - 0.023 \times [Hb]) \times ([HCO_3^-] - 24.4 + (7.7 + 2.3 \times [Hb]) \times (pH - 7.40)),$$

which is equivalent to the following expression when [Hb] = 3.1 mmol/L = 5 g/dL:

$$BE_{ECF} = 0.93 \times ([actual\ HCO_3^-] - 24.4 + 14.83 \times (pH - 7.40)).$$

The calculated BE_{ECF} value assumes normal serum protein concentration (7.2 g/dL) and therefore provides an inaccurate estimate of the magnitude of a metabolic acidosis or alkalosis in domestic animals with hypoproteinemia or hyperproteinemia. The ability of **extracellular base excess** (BE_{ECF}) and actual HCO_3^- concentration to accurately characterize the metabolic component of acid–base status has been controversial for many years, although BE_{ECF} has advantages compared to actual HCO_3^- concentration. The major advantages of the base excess approach are that BE_{ECF} is theoretically related to strong ion difference and is independent of respiratory activity. On this basis, when using the traditional Henderson–Hasselbalch approach to acid–base balance, the recommended approach is to use pH as an overall index of acid–base status, P_{CO_2} as an index of the respiratory component and standard (in vivo) base excess as an index of the nonrespiratory (metabolic) component.

The **strong ion approach** to acid–base balance provides a revolutionary method to assess acid–base balance that is becoming more widely adopted. This strong ion approach differs in three important areas from the traditional bicarbonatecentric application of the Henderson–Hasselbalch equation:

1) acid–base balance is examined using a systems approach; 2) a clear conceptual distinction is made between dependent variables (such as pH and $[HCO_3^-]$) and the independent variables; and 3) the effects of protein concentration on acid–base balance are considered.

The strong ion approach reduces the chemical reactions in plasma to that of simple ions in solution. This assumption can be made because the quantitatively important plasma cations (Na^+, K^+, Ca^{2+}, Mg^{2+}) and anions (Cl^-, HCO_3^-, protein, lactate, sulfate, ketoacids) bind each other in a salt-like manner. Plasma ions (such as Cu^{2+}, Fe^{2+}, Fe^{3+}, Zn^{2+}, Co^{2+} and Mn^{2+}) that enter into oxidation–reduction reactions, complex ion interactions and precipitation reactions are not categorized as simple ions but are assumed to be quantitatively unimportant in determining plasma pH, primarily because their plasma concentrations are low.

Simple ions in plasma can be differentiated into two main types, nonbuffer ions (strong ions or strong electrolytes) and buffer ions. Strong ions are fully dissociated at physiological pH and therefore exert no buffering effect. Strong ions do, however, exert an electrical effect because the sum of completely dissociated cations does not equal the sum of completely dissociated anions. Stewart termed this difference the **strong ion difference** (SID). Because strong ions do not participate in chemical reactions in plasma at physiological pH, they act as a collective positive unit of charge.

In contrast to strong ions, **buffer ions** are derived from plasma weak acids and bases that are not fully dissociated at physiological pH. The conventional dissociation reaction for a weak acid (HA), conjugate base (A^-) pair is:

$$HA \rightleftharpoons H^+ + A^-$$

and, at equilibrium, an apparent weak acid dissociation constant (K_a) can be calculated adopting the accepted convention regarding hydrated solutes as $K_a = [H^+][A^-]/[HA]$. For a weak acid to act as an effective buffer, its pK_a (defined as the negative logarithm of the weak acid dissociation constant K_a) lies within the range of pH ± 1.5.

Conceptually, the buffer ions can be subdivided into volatile buffer ions (HCO_3^-) and nonvolatile buffer ions (non-HCO_3^-). Bicarbonate is considered separately because this buffer system is an open system in arterial plasma; rapid changes in carbon dioxide tension and hence arterial plasma HCO_3^- concentration can be readily induced through alterations in respiratory activity. In contrast, the non-HCO_3^- buffer system is a closed system containing a fixed quantity of buffer. Another important physiological distinction between these two buffer systems is that an open buffer system such as HCO_3^- can be effective beyond the limits of pH = pKa ± 1.5. Finally, it should be appreciated that HCO_3^- is a homogeneous buffer ion while the nonvolatile buffer ion (A^-) represents a diverse and heterogeneous group of plasma buffers (albumin, globulin and phosphate) that is being modeled as a single buffer. Another assumption in Stewart's strong ion model is that HA and A^- do not take part in plasma reactions that result in the net destruction or creation of HA or A^-. This is because when HA dissociates, it ceases to be HA (therefore decreasing plasma [HA]) and becomes A^- (therefore increasing plasma $[A^-]$). The sum of [HA] and $[A^-]$ (called A_{TOT}) therefore remains constant through conservation of mass, whereby: $[A_{TOT}] = [HA] + [A^-]$.

In summary, the strong ion approach assumes that plasma ions act as either strong ions, volatile buffer ions (HCO_3^-) or nonvolatile buffer ions (A^-). Plasma therefore contains three types of charged entity: SID, HCO_3^- and A^-. The requirement for electroneutrality dictates that at all times the SID equals the sum of bicarbonate buffer ion activity (HCO_3^-) and nonvolatile buffer ion activity (A^-), such that: $SID - HCO_3 - A^- = 0$. This equation obviously assumes that all ionized entities in plasma can be classified as either a strong ion (SID), a volatile buffer ion (HCO_3^-) or a nonvolatile buffer ion (A^-).

An equation **relating plasma pH to three independent variables (P_{CO_2}, SID, A_{TOT})** and three constants (K_a, K_1, S) has been developed based on these assumptions. The most important factors that determine plasma pH are P_{CO_2}, SID and the concentrations of individual nonvolatile plasma buffers (albumin, globulins, phosphate). A change in any one of these variables will produce a direct and predictable change in plasma pH. Using the strong ion approach, six **primary acid–base disturbances can be distinguished**, instead of the four primary acid–base disturbances (respiratory acidosis, respiratory alkalosis, metabolic acidosis, metabolic alkalosis) differentiated when using the traditional Henderson–Hasselbalch approach. The strong ion approach indicates that acidemia results from an increase in P_{CO_2} and nonvolatile buffer concentration, or from a decrease in SID. Alkalemia results from a decrease in P_{CO_2} and nonvolatile buffer concentration, or from an increase in SID. The unmeasured strong anion concentration is quantified by calculating the strong ion gap (SIG).

ACIDEMIA

ETIOLOGY

The traditional Henderson–Hasselbalch approach to acid–base balance indicates that general causes of nonrespiratory **(metabolic) acidosis** can be divided into three categories on the basis of pathogenesis (Fig. 2.6):

- Excessive loss of base (bicarbonate)
- Accumulation of endogenous or exogenous acid
- Combination of both of the above processes.

For comparison, the strong ion approach indicates that general causes of nonrespiratory (metabolic) acidosis can be divided into **two categories**: **strong ion acidosis** due to a decrease in strong cation concentration (hyponatremia) or increase in strong anion concentration (hyperchloremia, hyper L-lactatemia, hyper D-lactatemia, ketoacidosis), and **nonvolatile buffer ion acidosis** due to an increase in albumin, globulin and phosphate concentration.

Some common specific causes include acute diarrhea in newborn animals, acute enteritis in adult cattle and horses and carbohydrate engorgement in ruminants and horses. Metabolic acidosis without dehydration, which is probably due to hyper D-lactatemia, has been described in neonatal goat kids[1] and neonatal calves.[2] Respiratory acidosis also occurs where there is retention of carbon dioxide in the blood as a result of interference with normal respiratory exchange. Thus pneumonia, severe pulmonary emphysema, depression of the respiratory center and left-sided heart failure may all be accompanied by respiratory acidosis. Metabolic acidosis occurs in the newborn at the time of parturition if this is prolonged and difficult. It is also common in shock with peripheral circulatory failure and anaerobic oxidation. A decrease in renal excretion of acid in renal insufficiency or renal failure also contributes to a metabolic acidosis. The administration of excessive quantities of acidifying solutions for the treatment of metabolic alkalosis also may cause acidosis. Acute intestinal obstruction in the horse is commonly accompanied by metabolic acidosis, whereas in other species alkalosis occurs, at least initially.

PATHOGENESIS

The traditional Henderson–Hasselbalch approach indicates that metabolic acidosis is characterized by a low arterial blood pH and a reduced plasma bicarbonate concentration, following the loss of bicarbonate or the addition of hydrogen ions. Extra- and intracellular buffering and respiratory compensation minimize the change in

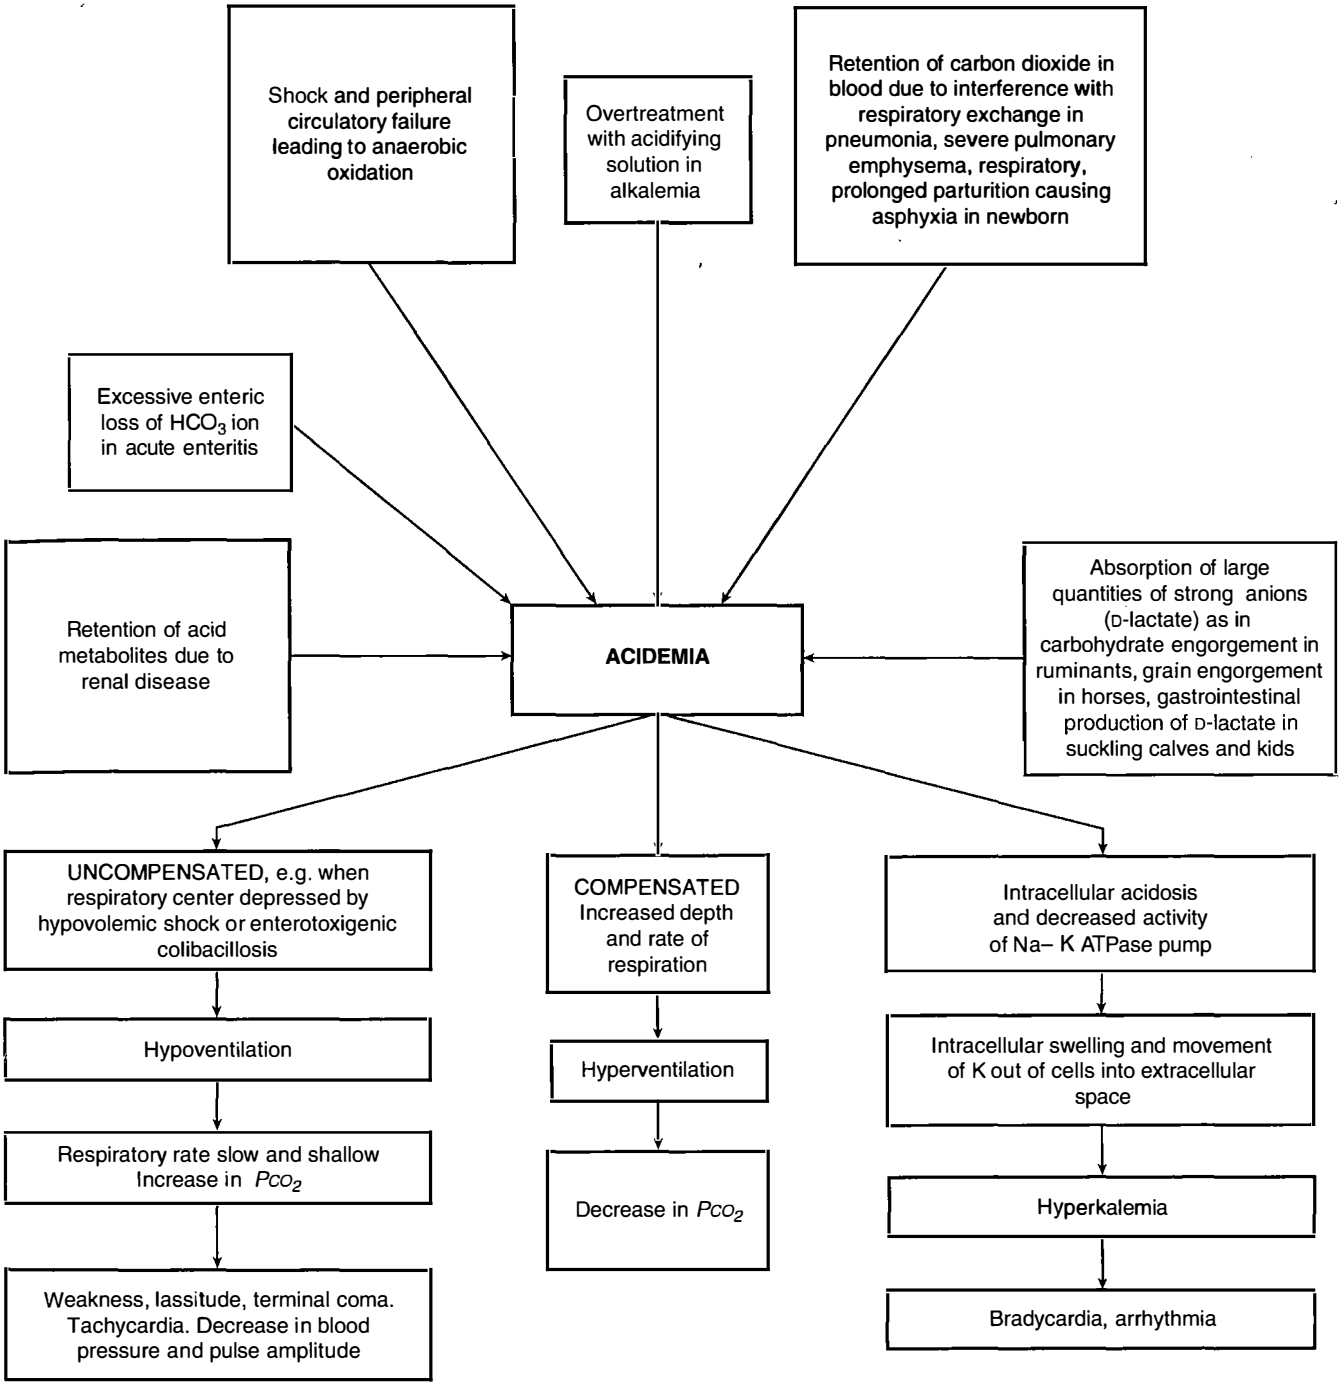

Fig. 2.6 Etiology and pathogenesis of acidema.

pH until the kidney can excrete sufficient hydrogen ions to correct the acid–base imbalance.[3] In general, the body will tolerate a pH range of 7.0–7.6, although survival has been reported at pH values beyond these limits for short periods, particularly in neonatal animals with diarrhea.

Acidemia generally depresses cardiac contractility and cardiac output in the denervated heart. In the intact animal, however, activation of the sympathetic nervous system in response to acidemia causes increased cardiac contractility, increased heart rate and increased cardiac output. In acidemia, the myocardial response to catecholamines is not depressed until the blood pH is decreased to below 7.0–7.1.[4] The increased carbon dioxide tension of the blood and depletion of bicarbonate causes an increase in the depth and then the rate of respiration by stimulation of the respiratory center (Kussmaul breathing). However, when hypovolemic shock is severe enough, there is often depressed respiratory function, resulting in the additional accumulation of hydrogen ions, and so the acidemia is accentuated.

Acidemia causes varying degrees of depression of the central nervous system and muscular weakness.[1,5] Central nervous abnormalities may develop in neonatal foals that develop severe respiratory compromise, resulting in hypoxemia and hypercapnia, because of the reduced ability of the cerebrospinal fluid to buffer acid–base changes.[6] Carbon dioxide concentration within the central nervous system (CNS) may have an effect on respiratory rate, neurotransmitter activity, CNS activity, cerebral blood flow and cerebral extracellular fluid volume. If the blood–CSF and brain–CSF interfaces in the neonate are immature and unable to adequately compensate for vascular changes in CO_2, the hypercapnia may contribute to the CNS abnormalities that

are often seen in sick newborn foals. The increased cerebral blood flow may be associated with cerebral edema, resulting in the depression of cerebral activity observed in these sick foals.

The increased urinary excretion of acids in acidosis also causes polyuria, which may be sufficiently severe to cause dehydration or accentuate concomitant dehydration.

CLINICAL FINDINGS

The major clinical manifestation of metabolic acidosis is mental depression and varying degrees of muscular weakness. Newborn calves and goat kids with metabolic acidosis are depressed, weak and reluctant to suck.[5] In severe acidemia, affected animals may be in lateral recumbency and appear to be in a state of coma. The depth and rate of respirations may be increased because of the increased PCO_2. Respiratory compensation is normally evident when the bicarbonate level is diminished to 50% of normal. Calves affected with severe acidemia and dehydration due to acute diarrhea may be unable to compensate because of depressed respiratory function. Their respiratory rate will be much slower and the depth of respiration much more shallow than normal. There is usually tachycardia, which becomes worse as the acidosis becomes more severe, and the amplitude of the pulse and blood pressure both decrease. A concomitant hyperkalemia will cause bradycardia, heart block, sudden collapse and rapid death. This is particularly evident when animals with acidosis and hyperkalemia are transported and handled for treatment. The increased muscular activity appears to accentuate the abnormalities and sudden death is not uncommon. Weakness, lassitude and terminal coma are frequent observations.

A syndrome of metabolic acidosis with minimal signs of dehydration or diarrhea has been described in calves from 1–4 weeks of age.[2,7] Affected calves are depressed, weak and ataxic, and the suck and menace reflexes may be weak or absent. Some calves appear comatose. On succussion of the abdomen fluid-splashing may be audible, which suggests that the syndrome may be related to diarrhea, which most of the calves may have had but from which they appeared to recover. The same abnormality has also occurred in goat kids with no apparent history of previous diarrhea.[1] The abnormal laboratory findings include a reduced venous blood pH, PCO_2 and bicarbonate ion concentration, marked hyper D-lactatemia, elevated blood urea nitrogen, increased anion gap and a neutrophilic leukocytosis with a left shift. Many of the clinical signs appear to be primarily the consequence of hyper D-lactatemia.[2] The intravenous administration of 2.5–4.5 L of isotonic (1.3%) sodium bicarbonate solution, the amount depending on the severity of the condition,[7] is necessary.

ALKALEMIA

ETIOLOGY AND PATHOGENESIS

Alkalemia is caused by an increased absorption of alkali, excessive loss of acid or a deficit of carbon dioxide (Fig. 2.7). Abomasal atony due to dilatation, impaction or torsion of the abomasum is one of the commonest causes of alkalemia in cattle. There is continuous secretion of

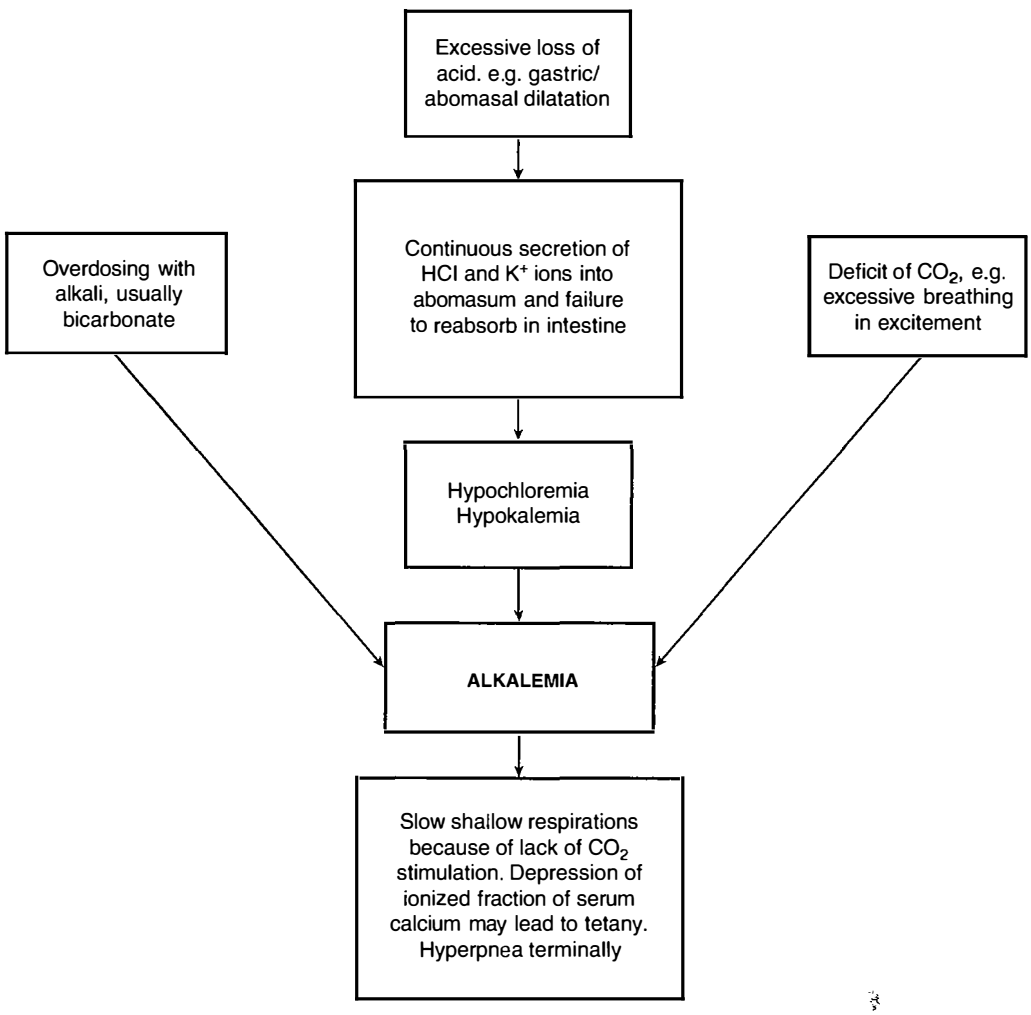

Fig. 2.7 Etiology and pathogenesis of alkalemia.

hydrochloric acid and potassium into the abomasum, with failure of evacuation of the abomasal contents into the duodenum for absorption. Sequestration of hydrochloric acid and potassium occurs in the abomasum, along with reflux into the rumen, all of which results in a hypochloremic, hypokalemic alkalosis. In metabolic alkalosis, potassium will shift from the extracellular to the intracellular space, resulting in a hypokalemia when in fact there may not be depletion of total body potassium. In cattle with metabolic alkalosis there is a paradoxical aciduria, which is not well understood but may be due to severe electrolyte depletion placing limits on the kidney to regulate acid–base balance. Paradoxic aciduria must be differentiated from postparturient aciduria, which has been reported to occur in dairy cows.

Metabolic alkalosis has been recorded in cows with severe coliform mastitis but the pathogenesis is unknown.[8]

CLINICAL FINDINGS

The clinical findings of alkalosis are not characteristic enough to be recognized reliably. Alkalosis results in slow, shallow respirations in an attempt to preserve carbon dioxide. Muscular tremors and tetany with tonic and clonic convulsions may occur because of depression of the ionized fraction of serum calcium. Hyperpnea and dyspnea may also occur in the terminal stages.

NATURALLY OCCURRING COMBINED ABNORMALITIES OF FREE WATER, ELECTROLYTE AND ACID–BASE BALANCE

These abnormalities are seldom primary and usually secondary to a serious disease state such as abomasal volvulus, rumen overload or acute intestinal obstruction – diseases that are in themselves life-threatening. Fluid and electrolyte abnormalities are also life-threatening and simple correction of the primary abnormality, for example removal of a large section of a horse's small intestine, is valueless unless the dehydration, hyponatremia and acidosis are also corrected. The variation that can occur in these naturally occurring errors of fluid, electrolyte and acid–base balance is what makes their diagnosis and treatment so difficult. If it were possible to have instant clinicopathological advice on what the abnormalities were, and how they were progressing as determined by constant laboratory monitoring, there would be little challenge in it. However, under normal clinical circumstances these services are not readily available and it is necessary to have an understanding of the basic physiology and pathology of these diseases to be able to predict by clinical examination and examination of the history, the likely deficiencies and imbalances and their degrees of severity.

In the preceding paragraphs the individual abnormalities of fluid and electrolyte homeostasis were described. In most naturally occurring diseases, the abnormalities are complex. In example, the probable events in a case of acute diarrhea are set out diagrammatically in Figure 2.8. It is important to remember that the variation in fluid and electrolyte imbalance is **dynamic** as a result of the compensatory changes occurring in various organs, especially the respiratory and circulatory systems and the kidneys. It is this volatility which makes clinical pathological monitoring so important. Some generalizations on the dynamics of fluid and electrolyte status are as follows:

- The body water and electrolytes are maintained at a homeostatic level by the buffering system of the blood, the lungs and the kidney
- In disturbances of body water and electrolytes, the changes that occur are also dynamic, and there is constant reaction by the homeostatic mechanism to restore the water and electrolyte relationship to normal
- With some exceptions, it is unusual to find an uncompensated alkalemia or acidemia. A partial compensation in the opposite direction of the primary acid–base imbalance is usually in progress and it is important to determine the nature of the primary disturbance for the selection of rational therapy
- Often, the nature of the primary disturbance can be determined from a consideration of the history and the clinical findings
- The dehydration caused by deprivation of water and electrolytes (lack of water or inability to drink) is mild and animals may appear only mildly dehydrated even after several days of water deprivation. The feces are hard and dry, the rumen contents are firm and dry and urine volume is considerably decreased
- With the exception of clinical dehydration, the clinical findings of electrolyte and acid–base imbalances are not characteristic
- Without laboratory evaluation, the nature and degree of electrolyte and acid–base imbalance must be assumed and estimated based on the history of the affected animal and the changes that are most likely to have occurred.

NATURE OF THE DISEASE AND HISTORY

The **history of the case**, the **length of time** the animal has been affected and the **tentative diagnosis** will provide a clinical assessment of the possible nature and degree of electrolyte and acid–base imbalance. Animals affected with acute diarrhea due to infectious enteritis are likely to be in a state of metabolic acidosis and hyponatremia. In intestinal obstruction of the horse, there are varying degrees of dehydration and metabolic acidosis. Obstruction of the upper intestinal tract, or abomasal stasis, is characterized by varying degrees of dehydration, and metabolic alkalosis with hypochloremia and hypokalemia. A combination of the clinical assessment and the available laboratory evaluation will allow the clinician to make the most rational approach to treatment.

The information on the duration of illness must be accurate or it will be misleading. The sequence of clinical findings in the history may indicate the trend in severity. Animals that have had a profuse watery diarrhea for 18–24 hours may be severely acidemic. Acute intestinal obstruction in cattle is not as severe as in the horse. Acute gastric or intestinal rupture in the horse or in cattle is usually rapidly fatal. Acidosis in grain overload in cattle may be fatal in 24–48 hours; acidosis in the horse with grain overload may be much more rapidly fatal as electrolyte disturbances are more severe in the horse.

CLINICAL FINDINGS

Dehydration is usually obvious clinically and determination of the PCV and total serum solids will improve the assessment.

A normal **temperature** is not a good prognostic guide but a subnormal temperature suggests a worsening situation.

A gradually progressive **tachycardia** indicates that the patient is deteriorating. In general, in the horse, a heart rate up to 60 beats/min suggests a minor lesion (but not always), a heart rate between

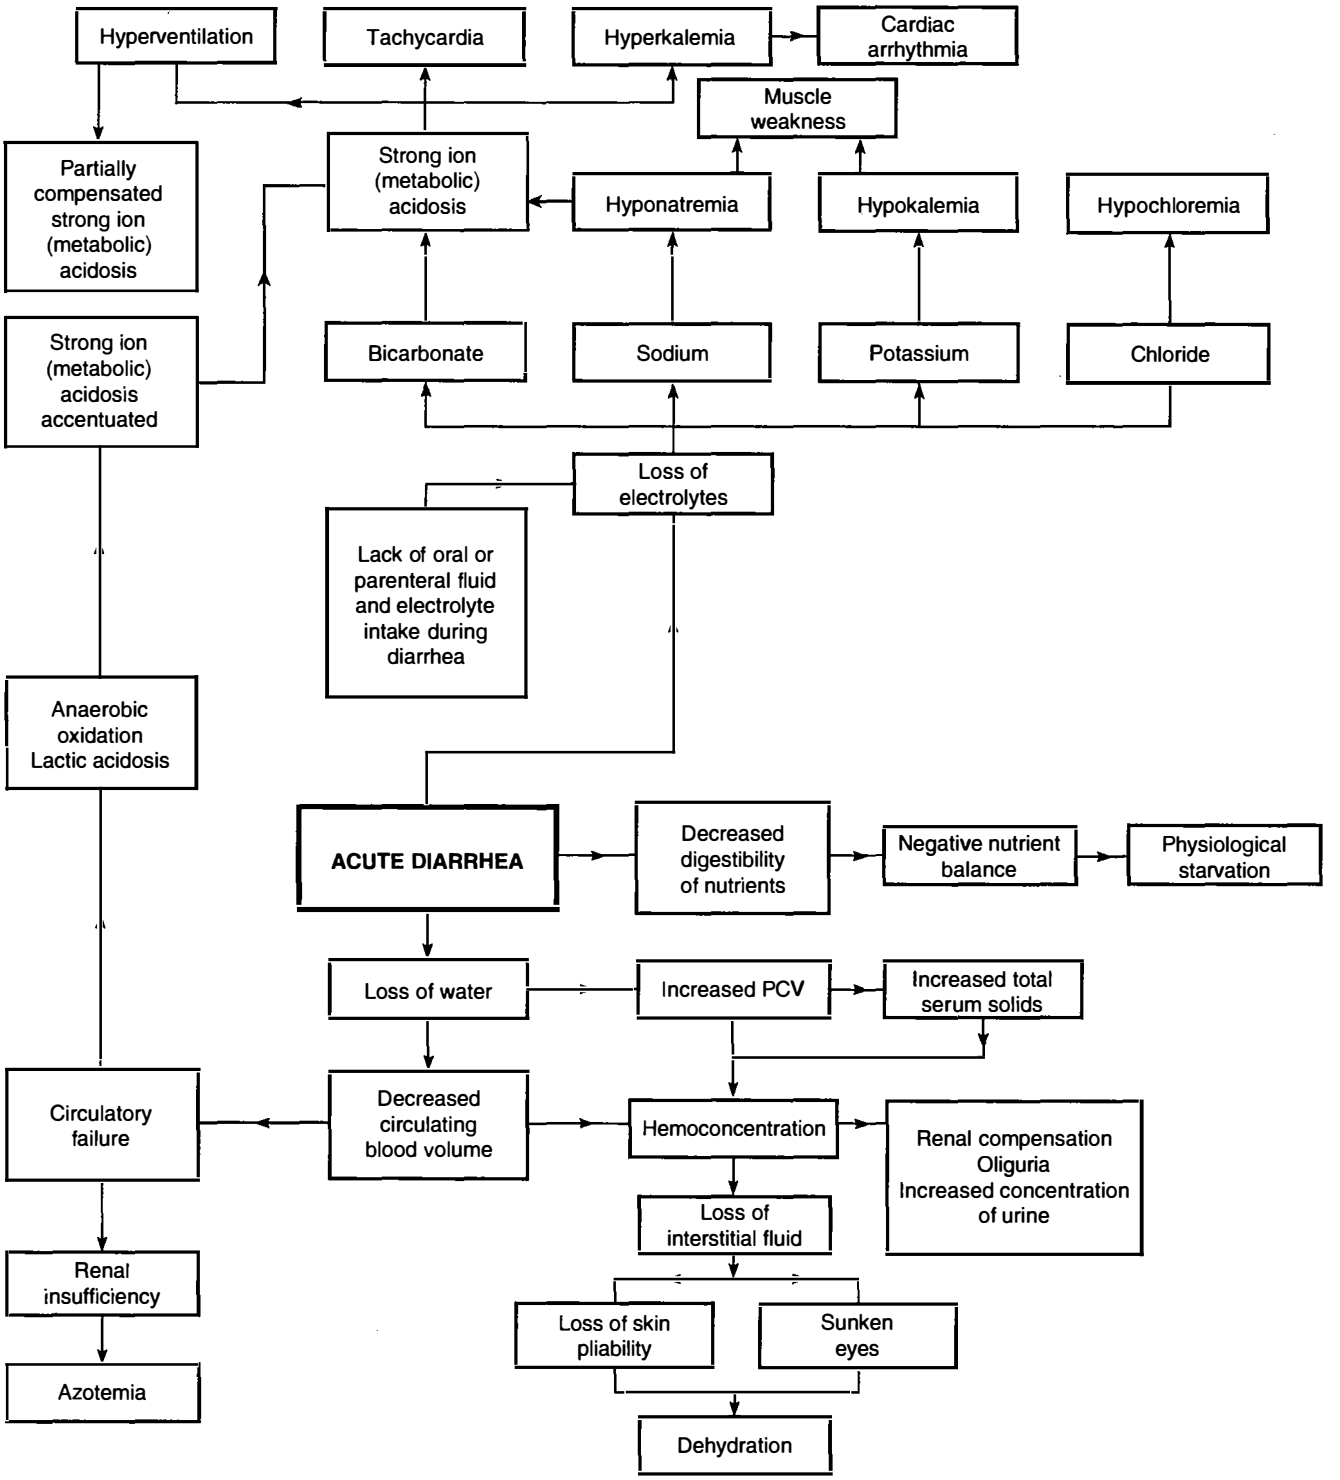

Fig. 2.8 The interrelationships between the changes in body water, electrolytes and acid–base balance that can occur in diarrhea.

60–80 beats/min is in the danger area, 80–100 beats/min is serious; more than 100 beats/min is commonly premortal (except in intestinal tympany that may be relieved).

A **cold clammy skin** that remains tented for more than 30 seconds suggests severe dehydration. **Cyanosis of the oral mucous membranes and a capillary refill time of more than 4 s** suggests a poor prognosis, as does rapid respiration (three to four times normal) with intermittent hyperpnea and apnea.

Muscular tremors and leg buckling are grave signs in the horse and are commonly followed by collapse and death. The inability of any dehydrated animal to stand (other reasons being eliminated) is ominous. **Severe depression** and dullness are commonly observed in acute conditions, and coma is usually terminal.

Metabolic acidosis is characterized by varying degrees of mental depression, weakness and ataxia. Some of the depression and weakness will be due to dehydration. In newborn animals with metabolic acidosis associated with diarrhea, a failure to suck and the lack of a suck reflex are common.

CLINICAL PATHOLOGY

Some representative laboratory values in examples of body water and electrolyte disturbances are given in Table 2.1.

Packed cell volume and total serum solids

The PCV and the **total serum proteins** or **total serum solids** will indicate the

Table 2.1 Representative laboratory values (mean ± SD) in body water and electrolyte disturbances

Clinical pathology	Acute diarrhea in horse	Acute diarrhea in calf	Metabolic alkalosis due to abomasal dilatation impaction/volvulus in cattle	Acute intestinal obstruction in horse	Acute carbohydrate engorgement in ruminants
Packed cell volume (%)	60 ± 7	45.3 ± 7.0	42 ± 6	64 ± 5	45 ± 6
Total serum solids (g/dL)	10 ± 2	8.6 ± 1.5	8.2 ± 1.5	11.5 ± 1.5	8.5 ± 1.8
Blood pH (venous)	7.10 ± 0.15	7.08 ± 0.12	7.49 ± 0.15	7.15 ± 0.04	7.10 ± 0.05
Plasma bicarbonate (mmol/L)	12 ± 3	13.7 ± 4.2	35.4 ± 5.7	18 ± 6	12.5 ± 3.5
Partial pressure of carbon dioxide (mmHg)	45 ± 8	46.8 ± 6.4	46.4 ± 7.5	48 ± 6	40 ± 6
Serum sodium (mmol/L)	126 ± 3	138 ± 9.4	138.5 ± 5.4	135 ± 5	132 ± 4
Serum chloride (mmol/L)	99 ± 3	101.4 ± 7.5	88.6 ± 12.8	98 ± 4	93 ± 3
Serum potassium (mmol/L)	3.0 ± 1.2	7.4 ± 1.6	3.4 ± 0.6	3.8 ± 0.6	5.0 ± 2.5
Blood urea nitrogen (mg/dL)	60 ± 30	50.1 ± 30.5	40 ± 15	65 ± 35	55 ± 25

severity of water loss. Anemic animals and those affected with diseases causing hypoproteinemia may provide misleading values.

The normal range depends on the age and species of animal, previous excitement and the presence of anemia or hypoproteinemia. A packed cell volume of 30–40% is considered normal; between 40% and 50%, fluid therapy may or may not be necessary; between 50% and 60%, fluids are necessary for recovery and above 60% intensive fluid therapy is necessary and the prognosis is unfavorable. A total serum solids of 6.0–7.5 g/dL is usually considered normal; at 8–10 g/dL fluids are needed and the prognosis is favorable and above 12 g/dL the prognosis is unfavorable.

Blood pH and blood gases

Sample collection and analysis

A useful screening test for acid–base status in animals without evidence of respiratory disease is the total CO_2. Total CO_2 is defined as the amount of total carbon dioxide in plasma that can be liberated with a strong acid, and can be calculated from the results of routine blood gas analysis as: total CO_2 = $[HCO_3^-]$ + dissolved CO_2 + $[H_2CO_3]$. The $[HCO_3^-]$ is calculated using the Henderson–Hasselbalch equation, the dissolved CO_2 is equal to $S \times PCO_2$, whereas $[H_2CO_3]$ is negligible.

Many automatic serum biochemical analyzers directly measure total CO_2 (instead of calculating its value from the results of blood gas analysis) but for total CO_2 measurement it is important that blood collection tubes are completely filled before serum is harvested: failure to completely fill the blood tubes promotes escape of CO_2 from serum into the partial vacuum above, thus resulting in measured total CO_2 values that underestimate true serum total CO_2.[1] Because changes in total CO_2 reflect changes in actual $[HCO_3^-]$, total CO_2 can never provide an independent measure of the nonrespiratory component of an acid–base disturbance. Total CO_2 does, however, provide a useful screening test for the presence of acid–base disturbances in domestic animals without clinical evidence of respiratory disease. In the absence of respiratory disease, a decrease in total CO_2 indicates a metabolic acidosis, whereas an increase in total CO_2 indicates metabolic alkalosis. Total CO_2 has historically been measured using the Harleco apparatus,[2] although this methodology is no longer used due to the availability of point-of-care analyzers.

If the primary clinical interest is acid–base assessment, then a jugular venous blood sample should be anaerobically obtained in a 3 mL plastic syringe that has been previously coated internally with sodium heparin (by drawing sodium heparin into the syringe barrel and then expelling all heparin from the syringe into the barrel before blood collection). Three mL of air should then be drawn into the syringe and forcibly expelled; this process is repeated three times. Evacuating the syringe in this manner ensures that minimal heparin is retained to dilute the blood sample but a sufficient quantity is still present to prevent coagulation.[3] After blood collection, the air bubbles should be removed from the blood in the syringe, the end should be corked to prevent loss of CO_2 and addition of O_2 to the blood sample and the syringe should be placed on ice (4°C) until analysis. This will minimize any time-related changes in pH, PCO_2 and base excess that occur when blood is held at room temperature (20°C), particularly in blood samples with high white blood cell concentrations. The change in pH, PCO_2 and base excess per hour at 22–24°C are –0.024, +2.5 and –0.5 respectively.[3] A portable blood gas analyzer for equine venous blood is available and provides reproducible and acceptable analysis.[4]

If the primary interest is evaluation of the respiratory system, an arterial blood sample should be obtained in the same manner but the sample should be kept at body temperature (preferable) or room temperature before blood gas analysis, which should be performed as soon as possible. This is because keeping 3 mL plastic syringes on ice (4°C) facilitates oxygen diffusion through the plastic syringe barrel, causing an increased PO_2.[5]

Use of point-of-care clinical analyzing systems has greatly facilitated routine evaluation of acid–base status in domestic animals. Thorough assessment of acid–base status requires blood gas analysis and serum biochemical analysis, with blood samples being obtained from a major vein or any artery. If serum total protein, albumin and phosphate concentrations are approximately normal, then acid–base status should be evaluated using blood pH, PCO_2 and extracellular base excess concentration. This is the traditional Henderson–Hasselbalch approach. The presence of unidentified anions should be investigated by calculating the anion gap. If serum total protein, albumin, and phosphate concentrations are markedly abnormal, then acid–base status should be evaluated using blood pH, PCO_2, measured $[SID^+]$ and $[A_{TOT}]$. This is the simplified strong ion approach. The presence of unidentified strong ions should be investigated by calculating the SIG.

Blood pH and acid–base interpretation

Normal blood pH varies from 7.35 to 7.45 (venous blood). The degree of acidemia encountered includes moderate acidemia (pH 7.30–7.25), severe acidemia (pH 7.25–7.20), grave (and commonly fatal except in neonates) acidemia (pH 7.10–7.00). Horses with volvulus or strangulation of the intestines generally have blood lactate levels over 75 mg/dL (8.2 mmol/L) whereas cases of impaction have levels of 5–9 mg/dL (0.55–1.0 mmol/L). The normal value is 6.0 mg/dL (0.78 mmol/L) with a range of 4–12 mg/dL (0.44–1.33 mmol/L). The survival rate in a series fell from 85% to 0% as the lactate concentration increased from 75 to 155 mg/dL (8.3 to 17.2 mmol/L).

Serum electrolytes

Serum electrolyte concentrations indicate the severity of the electrolyte losses

and the necessity for replacement with either balanced electrolyte solution or specific electrolyte solution. Serum concentrations of **sodium, chloride and potassium** are usually determined. The total deficit for each electrolyte can be estimated using the standard formula presented under calculation of electrolyte requirements.

Serum electrolyte concentrations depend on the initial cause and the severity of the disease. For example, in most cases of acute diarrhea there is hyponatremia and metabolic acidosis, which are usually marked in the horse with acute diarrhea. The serum levels of chloride may be normal or subnormal in acute diarrhea. The serum levels of potassium will be below normal initially but as acidosis develops and becomes severe, **hyperkalemia** may occur. In diseases causing **abomasal atony** there will be **hypochloremic, hypokalemic and metabolic alkalosis.**

Water and electrolyte abnormalities are classified into three types based on the measurement of electrolytes and osmolality:

- **Hypertonic dehydration** (true dehydration/desiccation): osmolality greater than 300 mosmol/kg (300 mmol/kg), associated with water deprivation, some acute gastrointestinal problems and some types of diarrhea
- **Hypotonic dehydration** (acute desalting water loss): osmolality less than 260 mosmol/kg (260 mmol/kg), associated with acute diarrhea, particularly secretory diarrheas, such as salmonellosis
- **Isotonic dehydration:** normal electrolyte and osmolality levels, as in horses losing electrolytes and water in almost equal proportions.

Urea nitrogen and creatinine

Plasma urea nitrogen and **plasma creatinine** are metabolic breakdown constituents that can be used to assess the degree of dehydration and to distinguish between prerenal, renal and postrenal uremia. The plasma urea nitrogen and creatinine concentration will be elevated, depending on the severity of the dehydration and decrease in circulating blood volume. Following treatment with fluids and electrolytes in prerenal uremia, the levels of plasma urea and creatinine will decline.

Total leukocyte and differential counts

A marked leukopenia and neutropenia with a degenerative left shift carries an unfavorable prognosis. A regenerative left shift with a neutrophilia is a favorable prognosis. A marked lymphopenia indicates severe stress and the prognosis may be unfavorable.

Blood glucose

Blood glucose concentration can be determined using conventional laboratory techniques, which require the submission of heparinized blood samples as soon as possible to avoid erroneous results due to hemolysis or erythrocyte glycolysis. A quantitative, rapid method of determining blood glucose concentrations in mature cattle and calves is available and the results correlate with the conventional, laboratory-based method.[6] The laboratory-based plasma glucose levels were 10–15% higher than the blood glucose levels determined by the rapid field method. The field method is based on the glucose oxidase reaction and uses impregnated test strips and a pocket-sized, digital readout reflectance meter to measure colorimetric change.

Anion, strong ion and osmolal gaps

Acid–base balance has traditionally been evaluated by using the Henderson–Hasselbalch equation to characterize four primary acid–base disturbances (i.e. respiratory acidosis and alkalosis, metabolic acidosis and alkalosis) and by calculating the **anion gap** to estimate the unmeasured anion concentration. Evaluation of the anion gap has become routine in many medical institutions. The calculation takes little time, is essentially without cost and is valuable in assessing a variety of clinical conditions in which electrolyte imbalances occur.

The anion gap (AG) represents the difference between the concentration of unmeasured anions [UA] and unmeasured cations [UC] in serum, which can be expressed in the equation:[7]

$$[Na^+] + [K^+] + [UC] = [Cl^-] + [HCO_3^-] + [UA],$$

which can be rearranged to:

$$[UA] - [UC] = AG = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-]).$$

A change in [UA] or [UC] will cause a change in the AG. Under normal circumstances, approximately two-thirds of the AG originates from the net negative charge of serum proteins, and the remainder represents the serum concentration of phosphate and strong anions, such as lactate, sulfate, β-OH butyrate, acetoacetate and anions associated with uremia.[7] The normal range for AG depends on the age and species. The normal range for 2–3-week-old foals is 9–22 mEq/L which is higher than that for 2-year-old horses (range 8–13 mEq/L). The range of AG (mean ± 2 SD) for adult animals varies for different species: 8–13 mEq/L (horse), 14–20 mEq/L (cow) and 17–29 mEq/L (sheep). AG values greater than 30 mEq/L have been seen in critically ill cattle, with the increase being attributed to an increase in blood lactate and ketoacid concentration as well as to anions associated with uremia.

A potentially valuable clinical use for the AG is in estimating the plasma L-lactate concentration, which provides information about the adequacy of oxygen delivery to the tissues, thereby providing a means for assessing the severity of cardiovascular or pulmonary dysfunction, monitoring the response to treatment and formulating a prognosis for survival. The normal plasma L-lactate concentration is generally considered to be less than 1.5 mmol/L. Increases in plasma L-lactate concentration have been categorized as mild (2.5–4.9 mmol/L), moderate (5.0–9.9 mmol/L) and severe (≥ 10 mmol/L), with L-lactate concentrations greater than 10 mmol/L being associated with a high mortality in humans, pigs and horses.[7]

Because lactate determinations may not be available in some laboratories, calculation of the AG can be considered a 'poor man's plasma lactate'. The correlation between AG and L-lactate concentrations is excellent in horses with intestinal disease. The AG of neonatal calves with experimental diarrhea was 28.6 ± 5.6 mEq/L, and the blood lactate concentration ranged from 1.1–2.9 mmol/L; the AG was significantly correlated with serum phosphate and creatinine concentration. The AG of adult cattle with abomasal volvulus was 20.5 ± 7.8 mEq/L and the blood L-lactate concentration ranged from 0.6–15.0 mmol/L. The AG in adult cattle is only moderately correlated with L-lactate concentrations and is similarly correlated with serum phosphate and creatinine concentrations in neonatal calves and adult cattle, as well as with serum albumin and total protein concentrations in adult cattle. Anion gap determination is of limited usefulness in predicting blood L-lactate concentration in sick cattle, whereas the correlation between AG and serum concentration in sick cattle suggests that an increased AG should suggest the potential presence of uremic anions.[7]

In summary, the determinants and utility of the anion gap in predicting hyperlactatemia are as follows.[7]

- The AG in critically ill cattle is influenced by at least three factors: blood L-lactate concentration and the serum concentrations of phosphate and creatinine
- There is a substantial quantity of unmeasured anions in sick cattle

(approximately 7 mEq/L), which implies that either unidentified cations or anions other than chloride, bicarbonate, L-lactate, pyruvate, β-OH butyrate or phosphate are present in critically ill cattle or that the formula used to assign protein charge was inaccurate
- The correlation coefficient between AG and blood L-lactate concentration is similar to that observed in human patients and less than that seen in sick horses
- The AG appears to predict blood L-lactate concentration more accurately in neonatal calves with experimental diarrhea than that in adult cattle with spontaneously occurring abomasal volvulus.

Strong ion gap

The **strong ion gap** represents the concentration of unmeasured strong ions in plasma and is more specific in detecting the presence of unmeasured strong ions in plasma than the anion gap. The SIG concept is a logical extension of the AG concept and was developed using the strong ion difference approach in order to express SIG in terms of other factors: $SIG = A_{TOT}/(1 + 10^{(pK_a - pH)}) - AG$, where SIG represents the difference between unmeasured strong cation concentration and unmeasured strong anion concentration in plasma or serum.[8] Calculation of the SIG requires species-specific values for the total plasma concentration of nonvolatile weak acids (A_{TOT}; i.e. the total concentration of plasma nonvolatile buffers; albumin, globulin and phosphate) and the negative logarithm to the base 10 (pK_a) of the effective dissociation constant (K_a) for plasma nonvolatile buffers. Values for A_{TOT} and pK_a have been determined for the plasma of horses (A_{TOT}, 15.0 mmol/L = 0.22 mmol/g of total protein or 0.47 mmol/g of albumin; pK_a, 6.66) and calves (A_{TOT}, 23.1 mmol/L = 0.41 mmol/g of total protein or 0.75 mmol/g of albumin; pK_a, 7.08).[8,10]

The normal SIG value is –5 to +5 mEq/L. An increase in SIG to above 5 mEq/L (a rare occurrence) therefore reflects an increase in unmeasured strong cations or a decrease in unmeasured strong anions. A decrease in SIG to below –5 mEq/L (a common occurrence) reflects a decrease in unmeasured strong cations or, more likely, an increase in unmeasured strong anions.

The SIG offers a more accurate approach to identifying unmeasured strong ions in plasma than does the AG. The critical difference between the AG and SIG is that the SIG provides an estimate of the difference between unmeasured strong cations and strong anions, whereas AG provides an estimate of the difference between unmeasured cations and anions (including strong ions and nonvolatile buffer ions such as albumin, globulins, and phosphate). A change in SIG therefore provides a more specific method for detecting a change in unmeasured strong ions (such as lactate) than a change in AG.

Osmolal gap

Evaluation of the osmolal gap is a means of detecting an increased amount of abnormal osmotically active solute in the blood. The osmolal gap is the difference between the measured plasma osmolality and the osmolality calculated from the plasma concentration of normally measured solutes. Sodium and potassium and their associated anions, along with glucose and urea, constitute the majority of normal osmotically active solutes. The following formula is recommended, although many clinicians disregard the contribution of serum urea nitrogen (SUN) because it is an ineffective osmole that easily crosses cell membranes:

$$1.86 \times ([Na^+] + [K^+]) + (glucose/18) + (SUN/2.8) + 8.6.$$

Examination of the triad of **calculated osmolality**, **measured osmolality** and the **osmolal gap** is beneficial in the diagnosis and prognosis of a number of diseases.

The effects of acidemia on the anion gap and electrolytes can vary depending on the cause of the acidosis and the species involved. Experimentally in horses, the infusion of L-lactic acid and D- and L-lactic acid results in acidosis with a high anion gap.[11] An infusion of hydrochloric acid causes metabolic acidosis with a decreased anion gap. Saline infusions cause mild acidosis with no significant change in anion gap. The plasma potassium was decreased by the infusions of the organic acids but not by hydrochloric acid. Hypophosphatemia occurred with the saline and hydrochloric acid infusions but not with the organic acids. These results indicate that large changes in plasma potassium and serum inorganic phosphate can occur in acidosis in the horse and are probably not the direct result of acidemia. High-intensity exercise in the horse results in a progressive rise in plasma potassium and lactate.[12]

Arterial blood pressure

Arterial blood pressure and central venous pressure are not measured routinely but are occasionally measured in referral centers where the technical assistance and instrumentation are readily available. Mean arterial blood pressure provides a rough guide for the presence and severity of terminal shock but not for the severity or extent of the initiating lesion.

Jugular or central venous pressure

This is more useful as a monitor during fluid replacement. Normal pressure is 2–10 cmH_2O (0.3–1.0 kPa), referenced to the point of the shoulder (scapulohumeral joint). Below 2 cmH_2O (0.3 kPa) requires fluid therapy; above 15 cmH_2O (1.5 kPa) indicates cardiac failure and volume overload.

Total body water

Total body water can be measured in horses before and after exercise using orally administered deuterium oxide followed by a series of blood samples taken for analysis.[13] Mean total body water content is about 62%. It is not determined clinically.

PRINCIPLES OF FLUID AND ELECTROLYTE THERAPY

The most important principle is to prevent or minimize dehydration and electrolyte loss whenever possible. This means the provision of an adequate water supply, adequate drinking space and a continuous supply of salt and the necessary minerals. The next most important principle is to treat potential losses of fluid and electrolytes as quickly as possible to minimize the degree of dehydration and acid–base imbalance that may occur in animals with diseases in which losses are occurring.

The **major therapeutic objectives** are to **correct the abnormalities** that already exist and to monitor and **provide maintenance therapy** until the animal has recovered. Correction of the abnormalities may require 4–6 hours and maintenance therapy may be necessary for 2–4 days, depending on the cause of the disease. There are at least four possible abnormalities that could exist at the same time and must be corrected:

- **Fluid volume deficit**
- **Plasma osmolar deficits**
- **Specific electrolyte imbalances**
- **Acid–base imbalance.**

The two major problems are to determine the nature and degree of the abnormalities present and to decide which fluid and electrolyte replacement solution should be used.

The ideal situation would be to make both a clinical and laboratory evaluation of the animal as described above. The history and the diagnosis will suggest the possibility of acidemia or alkalemia and the electrolyte imbalances that are likely to be present. The degree of dehydration can usually be recognized clinically. Severe dehydration and acidemia should be treated as quickly as possible. A summary of the disturbances of fluid and electrolyte balance that occur in some common diseases of cattle and horses,

and the suggested fluid therapy, is presented in Table 2.2.

Calculation of electrolyte requirements

The electrolyte deficits can be estimated using the serum electrolyte values of the affected animal. The total deficit of the electrolyte in milliequivalents (mEq) is the product of the deficit of the electrolyte in mEq per liter (ΔmEq/L) and the distribution space for the electrolyte. For sodium, chloride and bicarbonate, the distribution space is the extracellular fluid volume, which approximates 30% of BW in normally hydrated adults and 50% in normally hydrated neonates. In other words, for sodium, chloride and bicarbonate, the total milliequivalent deficit = (ΔmEq/L) × (estimated euhydrated body weight in kg) × (0.3 or 0.5).

There is less certainty about the size of the potassium space because potassium is mainly an intracellular ion.

Types of intravenous fluid

Fluids are categorized on the basis of their physical nature (**crystalloid** or **colloid**) and osmolarity (**hypotonic**, **isotonic** or **hypertonic**). Isotonic or slightly hypotonic crystalloid solutions are most commonly administered parenterally, although under specific circumstances hypertonic crystalloid solutions or isotonic colloid solutions are preferred.

Crystalloid solutions

A crystalloid is a substance that forms a true solution and is capable of being crystallized. Examples of crystalloid solutions are Ringer's solution, lactated Ringer's solution, acetated Ringer's solution, 0.9% NaCl, 7.2% NaCl (hypertonic saline), 1.3% $NaHCO_3$, 8% $NaHCO_3$, calcium gluconate and 50% dextrose. Sodium chloride is the classic crystalloid solution, as table salt (NaCl) exists as a crystal but dissolves completely when placed in water. Because crystalloids dissolve completely in water, crystalloid solutions containing sodium distribute throughout the entire extracellular fluid space and are therefore not confined to the intravascular space. Sodium-containing crystalloid solutions are always indicated in hypovolemia (circuit problem) but are contraindicated in congestive heart failure (pump problem) because they provide an additional sodium load, and animals with heart failure have already retained too much sodium. Sodium-containing crystalloid solutions are also contraindicated in the presence of severe hypoalbuminemia because sodium-containing crystalloids will further decrease plasma albumin concentration and oncotic pressure, resulting in movement of fluid into the interstitial spaces and exacerbating tissue edema.

Crystalloid solutions are characterized in terms of the number of molecules (numerator) per volume of solution (denominator). The number of molecules is expressed in moles (abbreviated as mol), where 1 mol of compound is equivalent to the molecular weight of the compound in grams (formula weights for NaCl, $NaHCO_3$ and KCl are 58.5 g, 85 g and 74 g respectively). Because body fluids are dilute, we express moles as millimoles (mmol = mol/1000) to facilitate readability.

Crystalloid solutions are commonly expressed in terms of the number of charged components (numerator) per volume of solution (denominator). The number of charged components is expressed in equivalents (abbreviated as Eq), where 1 Eq is the number of each charged component that combines with or replaces 1 mol of hydrogen ion (this means that Eq is always a positive number). Because body fluids are dilute, equivalents are expressed as milliequivalents (mEq = Eq/1000). To calculate the number of mEq from mmol, we simply multiply the number of millimoles by the valence (charge), whereby: mEq/L = (mmol/L) × valence. For instance, 1 mmol of NaCl in solution provides 2 mEq: 1 mEq of Na^+ (1 × 1) and 1 mEq of Cl^- (1 × 1), assuming that NaCl acts as a strong electrolyte in water (i.e. it completely dissociates into Na^+ and Cl^- in water). In comparison, 1 mmol of $CaCl_2$ in solution provides 4 mEq: 2 mEq of Ca^{2+}

Table 2.2 Summary of disturbances of body water, electrolytes and acid–base balance in some common diseases of cattle and horses, and suggested fluid therapy

Disease	Major abnormalities and deficits	Fluid and electrolyte requirements
Neonatal calf diarrhea (including piglets and lambs)	Metabolic acidosis, low plasma bicarbonate, severe dehydration, loss of sodium, hyperkalemia when acidosis severe	Equal mixtures of isotonic saline and isotonic sodium bicarbonate with 5% dextrose. Balanced electrolytes too, IV and PO. See Colibacillosis, Ch. 18, for details
D-lactic acidosis (carbohydrate engorgement of ruminants)	Metabolic acidosis, low plasma bicarbonate, severe dehydration	Sodium bicarbonate initially followed by balanced electrolytes, IV. See Acute carbohydrate engorgement of ruminants, Ch. 6, for details
Acute diffuse peritonitis	Dehydration. Slight metabolic alkalosis due to paralytic ileus	Balanced electrolyte solutions in large quantities IV for hydration and maintenance
Right-side dilatation/abomasal volvulus of cattle, abomasal impaction (dietary or vagal nerve injury)	Metabolic alkalosis, marked hypochloremia, hypokalemia, severe dehydration	Balanced electrolyte solutions or high-potassium and chloride-acidifying solution, IV. May give acidifying solutions orally. See Right-side displacement of abomasum Ch. 6, for details; can also use mixture of 2 L of isotonic saline (0.9%), 1 L isotonic potassium chloride (1.1%) and 1 L isotonic dextrose (5%)
Peracute coliform mastitis	Severe dehydration, mild electrolyte deficits including mild hypocalcemia. Metabolic acidosis if diarrhea present	Balanced electrolyte solutions IV in large quantities for hydration and maintenance for 24–48 hours (100–150 mL/kg B W/24 h)
Acute diarrhea in the horses (enteric salmonellosis	Severe dehydration, marked hyponatremia, metabolic acidosis. Hypokalemia occurs following bicarbonate therapy	Hypertonic sodium bicarbonate (5%) 3–5 L 500 kg BW followed by high-sodium, high-potassium alkalinizing solution to correct hypokalemia following bicarbonate therapy. All by the IV route
Acute grain engorgement in the horse	Metabolic acidosis, dehydration and shock	Hypertonic sodium bicarbonate (5%) 3–5 L/500 kg BW followed by balanced electrolytes IV
Water and electrolyte deprivation. Esophageal obstruction in horses	Moderate dehydration	Balanced electrolytes IV. When obstruction relieved, provide electrolyte solution orally
Acute intestinal obstruction	Metabolic acidosis or alkalosis dependent on level of obstruction. Severe dehydration in horse, moderate in cow	Isotonic sodium bicarbonate initially, 3–5 L/500 kg BW followed by balanced electrolytes IV. Horses may develop hypokalemia following bicarbonate therapy and must be given potassium chloride

(1 × 2) and 2 mEq of Cl^- (2 × 1), and 1 mmol of dextrose provides 0 mEq, because dextrose does not dissociate into charged components in water.

The principal reason we define constituents of plasma in terms of mEq instead of mmol is because electroneutrality must be preserved at all times; the difference between the charge assigned to all strong cations (Na^+, K^+, Ca^{2+}, Mg^{2+}) and strong anions (Cl^-, lactate, sulfate, ketoacids, non-esterified fatty acids, etc.) in plasma is called the **strong ion difference** and this factor independently and directly alters blood pH and therefore acid–base status. The normal SID of plasma is approximately 40 mEq/L, although there are species differences in the actual value. Electrolyte solutions with an effective SID of more than 40 mEq/L are therefore alkalinizing because they create a strong ion alkalosis. Electrolyte solutions with an effective SID = 0 are acidifying because they create a strong ion acidosis. Electrolyte solutions of intermediate SID may be alkalinizing or acidifying, depending upon the change in plasma SID relative to the decrease in plasma protein concentration (which is alkalinizing) (Table 2.3).

Table 2.3 Summary of effective strong ion difference (SID) and osmolarity of parenterally administered crystalloid solutions

Solution	Effective SID (mEq/L)	Osmolarity (mosmol/L)
Hypertonic solutions (>312 mosmol/L)		
Alkalinizing		
8.4% $NaHCO_3$	1000	2000
5.0% $NaHCO_3$	595	1190
10% NaH_2PO_4	145	1150
Acidifying		
50% dextrose	0	2500
7.2% NaCl	0	2460
25% magnesium sulfate	0	2028
23% calcium borogluconate	0	1069
Isotonic solutions (300 to 312 mosmol/L)		
Alkalinizing		
Tromethamine	210	300
1.3% $NaHCO_3$	155	310
Carbicarb	75	300
McSherry's solution	54	312
Darrow's solution	53	312
Acidifying		
Ringer's solution	0	309
0.9% NaCl	0	308
1.15% KCl	0	308
Hypotonic solutions (<300 mosmol/L)		
Alkalinizing		
Acetated Ringer's	27	294
Lactated Ringer's	<14	275
Acidifying		
5% dextrose	0	250

The effective SID is the difference between the strong cation and strong anion concentration after metabolizable anions (such as lactate or acetate) have been completely metabolized to produce bicarbonate. Electrolyte solutions with an effective SID of more than 27 mEq/L are alkalinizing because they create a strong ion alkalosis. Electrolyte solutions with an effective SID = 0 are acidifying because they create a strong ion acidosis.

Isotonic, hypertonic, and hypotonic crystalloid solutions

The tonicity of the solution is an important clinical issue. Complete understanding of the tonicity concept requires differentiation of two terms, **osmolality** and **osmolarity**. Osmolality is the number of dissolved particles per kilogram of solution and is expressed as mosmol/kg of solution. The normal plasma osmolality in large animals is approximately 285 mosmol/kg, and plasma osmolality is aggressively defended by increasing water intake (osmolality > 285 mosmol/kg) or promoting free water excretion (osmolality < 285 mosmol/kg). The correct term in plasma and extracellular fluid is osmolality, because this factor is measured in the laboratory; however, frequently the term osmolarity is used because 1 kg of plasma approximates 1 L of plasma and because osmolarity can be easily calculated from the concentration of electrolytes in the fluid solution. Osmolarity is the number of particles per liter of solution and is expressed as mosmol/L of solution.

One kg (1 L) of plasma from an adult large animal has two components, 70 g of protein and 930 g of plasma water. Accordingly, the osmolality of normal plasma (285 mosmol/kg) is equivalent to a plasma water osmolarity of 306 mosmol/L ((285 mosmol/kg)/(0.93 L/kg)). Ringer's solution, 0.9% NaCl and 1.3% $NaHCO_3$ are therefore considered isotonic solutions because they distribute in plasma water and have calculated osmolarities of 309 mosmol/L, 308 mosmol/L and 310 mosmol/L respectively.

The normal plasma osmolarity for large animals is 306 mosmol/L; solutions are defined as isotonic (300–312 mosmol/L), hypertonic (> 312 mosmol/L) or hypotonic (< 300 mosmol/L). Using this categorization, it is readily apparent that some routinely used crystalloid solutions are hypotonic; in particular, lactated Ringer's solution (275 mosmol/L) is mildly hypotonic and 5% dextrose (250 mosmol/L) is moderately hypotonic, although, as glucose is metabolized, 5% dextrose becomes an increasingly hypotonic solution. Erythrocytes are resistant to increases in plasma osmolarity, whereas they are susceptible to mild decreases in osmolarity; this is the basis of the red blood cell fragility test whereby red blood cell suspensions are placed in solutions of decreasing osmolarity. Because of hypotonic-induced hemolysis, parenterally administered fluids should be isotonic or hypertonic.

Hypotonic crystalloid solutions

Lactated Ringer's solution is a balanced, polyionic, alkalinizing, hypotonic (275 mosmol/L), crystalloid solution containing physiological concentrations of Na^+, K^+, Ca^{2+}, Cl^- and lactate ($CH_3CH(OH)COO^-$). Lactated Ringer's solution alkalinizes because lactate is predominantly metabolized to the bicarbonate ion, whereby:

$$CH_3CH(OH)COO^- + 3O_2 \rightarrow 2CO_2 + 2H_2O + HCO_3^-.$$

The lactate in lactated Ringer's is a racemic equimolar mixture of L-lactate and D-lactate; in healthy animals L-lactate is rapidly metabolized; however, animals have negligible D-lactate dehydrogenase activity, leading to slow clearance of D-lactate, which is primarily through the urinary system. DL-lactate solutions such as lactated Ringer's therefore have approximately half the alkalinizing ability of L-lactate solutions. The effective SID of lactated Ringer's solution is less than 14 mEq/L because L-lactate can also be used in gluconeogenesis instead of bicarbonate production. Lactated Ringer's solution is the standard intravenous fluid for neonates and adult horses because these animals tend to get acidemic when inappetent. However, lactated Ringer's solution is theoretically inferior to acetated Ringer's solution, because critically ill animals may have increased blood lactate concentrations and it is incongruous to add lactate in this situation.

Acetated Ringer's solution is a balanced, polyionic, alkalinizing, hypotonic (294 mosmol/L), crystalloid solution. Commercially available formulations of acetated Ringer's solution contain physiological concentrations of Na^+, K^+, Mg^{2+}, Cl^-, acetate (CH_3COO^-) and gluconate ($CH_2(OH)\{CH(OH)\}_4COO^-$); the gluconate is problematic because calves (and presumably all large animals) slowly metabolize gluconate.[14] Acetated Ringer's solution alkalinizes because acetate is metabolized to the bicarbonate ion, whereby:

$$CH_3COO^- + 2O_2 \rightarrow CO_2 + H_2O + HCO_3^-.$$

The strong ion approach to acid–base balance states that acetated Ringer's solution is alkalinizing because it contains a metabolizable strong anion (acetate) that, when metabolized, increases the SID.

Five percent dextrose is 250 mosmol/L as administered, but plasma osmolarity decreases as the glucose is metabolized, leaving free water. Because 5% dextrose has no sodium to expand the extracellular volume and has much less energy content than 50% dextrose on a volume basis, the only application of 5% dextrose is to provide free water or as a vehicle for pharmacological agents.

Isotonic crystalloid solutions

Ringer's solution is a balanced, polyionic, nonalkalinizing, isotonic, crystalloid solution that contains physiological concentrations of Na^+, K^+, Ca^{2+}, and Cl^-. This solution is mildly acidifying because its effective SID = 0 mEq/L. Addition of a fluid with a SID of 0 mEq/L to plasma (normal SID ≈ 40 mEq/L) will decrease plasma SID and therefore directly and independently decrease plasma pH because a 1 mEq/L decrease in SID decreases plasma pH by approximately 0.016. Ringer's solution is the standard intravenous fluid for adult ruminants because these ruminants tend to get alkalemic when inappetant.[15]

Isotonic saline (0.9% NaCl solution) is an isotonic crystalloid solution that has little merit in the routine treatment of sick ruminants, principally because ruminants usually develop hypocalcemia and hypokalemia when inappetent. Accordingly, the use of 0.9% NaCl should be confined to horses, the irrigation of surgical sites and wounds, or as a vehicle for adding other electrolytes and dextrose. Like Ringer's solution, 0.9% NaCl is mildly acidifying because effective SID = 0 mEq/L.

Isotonic sodium bicarbonate (1.3% $NaHCO_3$ solution) is an alkalinizing isotonic crystalloid solution that is used to treat severe acidemia (indicated whenever blood pH < 7.20 as a result of metabolic acidosis). This solution is alkalinizing because it buffers hydrogen ion: $HCO_3^- + H^+ \rightleftharpoons CO_2 + H_2O$, and because it increases SID (effective SID = 155 mEq/L). Sodium bicarbonate is superior to sodium L-lactate and sodium acetate for the treatment of metabolic acidosis because it provides an immediate source of bicarbonate. On theoretical grounds, sodium bicarbonate ($NaHCO_3$) should not be used to treat severe respiratory acidosis because additional CO_2 generated may worsen the respiratory acidosis.

Tromethamine (Tham, tris-hydroxymethyl aminomethane, 300 mmol/L) is an isotonic solution of an organic amine that is a safe and effective buffer.[16] After administration, 70% of the neutral compound $(CH_2OH)_3C\text{-}NH_2$ in tromethamine is immediately protonated to the strong cation $(CH_2OH)_3C\text{-}NH_3^+$ in plasma, with the net equation being:

$$(CH_2OH)_3C\text{-}NH_2 + H^+ \rightleftharpoons (CH_2OH)_3C\text{-}NH_3^+.$$

The remaining 30% of the administered tromethamine remains unprotonated and can therefore cross cell membranes and potentially buffer the intracellular compartment. Tromethamine therefore provides an alternative alkalinizing agent to sodium bicarbonate; however, tromethamine does not currently appear to offer any important clinical advantages over sodium bicarbonate in spontaneously breathing animals.

Isotonic formulations are available for intravenous administration with or without electrolytes; administration of tromethamine without electrolytes leads to hyponatremia and it would appear preferable to administer tromethamine in conjunction with electrolytes.

Carbicarb is an isotonic buffer (300 mosmol/L) made from equimolar disodium carbonate (Na_2CO_3) and sodium bicarbonate; carbonate avoids generation of CO_2 when buffering acidemic blood:[17]

$$CO_3^{2-} + H^+ \rightleftharpoons HCO_3^-.$$

Carbicarb was suspected to decrease the incidence and magnitude of hypercapnia when rapid alkalinization was needed in animals with mixed metabolic and respiratory acidosis. Despite numerous studies comparing Carbicarb to sodium bicarbonate, the potential clinical advantages of Carbicarb have only been demonstrated in animals being ventilated or with extremely limited ventilatory ability. Carbicarb has been administered intravenously to diarrheic calves; however, these studies have failed to identify a clinically important advantage over conventional isotonic sodium bicarbonate administration.[18] Accordingly, there does not appear to be a compelling reason to prefer Carbicarb to isotonic sodium bicarbonate when rapid alkalinization of conscious animals is required.

Darrow's solution is an isotonic polyionic solution formulated by Darrow in 1946 for use in human infants; the solution has been administered to calves.[19,20] Compared to other isoosmotic polyionic solutions, Darrow's solution is hyponatremic, hyperkalemic and hyperlactatemic and does not contain calcium or magnesium. As such, Darrow's solution is not recommended for administration to large animals.

McSherry's balanced electrolyte solution is an isotonic polyionic solution formulated by McSherry and Grinyer in 1954 for intravenous and intraperitoneal administration to dehydrated diarrheic calves.[21] On theoretical grounds, this is an excellent parenteral fluid for resuscitating dehydrated diarrheic calves that deserves more frequent use. Unfortunately, commercial formulations are currently unavailable.

Hypertonic crystalloid solutions

Fifty percent dextrose is 2500 mosmol/L (approximately eight times normal osmolarity). Fifty percent dextrose solutions are commonly administered to ruminants with ketosis or hypoglycemia and produce a transient increase in cardiac contractility.[22] Some commercially available formulations in Europe contain an equimolar mix of dextrose and fructose, although the addition of fructose does not appear to produce a more sustained increase in plasma glucose concentration than that produced by glucose alone.[23]

The necessity for glucose in fluid therapy has been controversial. Hypoglycemia occurs commonly in septicemic neonates and calves with diarrhea but is uncommon in most other common diseases in which there is an acute fluid and electrolyte disturbance. Dextrose will promote the movement of extracellular potassium into the cell, will provide metabolic water and is a source of carbohydrate. If glucose is indicated, large quantities of parenteral glucose are necessary to meet the maintenance energy requirements and every effort must be made to restore the animal's appetite and to provide the necessary requirements through dietary intake. The energy requirements for maintenance are calculated on the basis of metabolic body size, $kg^{0.73}$, which is a measure of the fasting metabolism in an animal not eating and not doing any muscular work. If 1 g of dextrose given intravenously will provide 5 kcal (2.1 kJ) of energy, the

Table 2.4 Estimated daily energy requirements of fasting cattle.

Body weight (kg)	Metabolic body size (kg $W^{0.73}$)	Metabolizable energy requirements (kcal)	Glucose 0% (L/day)
45 (1-month-old calf)	16	1760	7
90	27	2970	1.2
180	45	4950	2.0
360	74	8140	3.3
454	67	9510	3.8
544	100	12100	4.8

approximate amounts of dextrose solution needed to meet the energy needs for maintenance in cattle are shown in Table 2.4. Table 2.4 comprises a rough estimate of the requirements and should be used as a general guideline only. Every effort should be made to supply the energy needs through oral intake of energy-containing foods.

NaCl 7.2% (Hypertonic saline) is 2460 mosmol/L (approximately eight times normal osmolarity) and is used for the rapid resuscitation of animals with hypovolemia. Hypertonic saline should be administered at 4–5 mL/kg BW intravenously over 4–5 min (1 (ml/kg BW)/min). Faster rates of administration lead to hemodynamic collapse due to vasodilation and decreased cardiac contractility, whereas slower rates of administration provide no advantages over isotonic crystalloid solutions. Like high-volume 0.9% NaCl, small-volume hypertonic saline consistently induces a mild strong ion acidosis as its effective SID = 0 mEq/L. In general, the decrease in pH following hypertonic saline administration is less than 0.08 pH units and rapidly dissipates with time.[23] The effect of hypertonic saline on acid–base balance is therefore clinically inconsequential.

The use of small volumes (4–5 mL/kg BW) of hypertonic saline solution, ranging in concentration from 7.0% to 7.5%, has been extensively evaluated for the treatment of various forms of hemorrhagic, septic and endotoxic shock.[24] Plasma volume is increased by the movement of free water from the intracellular space, thereby increasing cardiac output, mean arterial blood pressure, systemic oxygen delivery and glomerular filtration rate. Total peripheral vascular resistance and pulmonary vascular resistance decrease, and mean circulatory filling pressure increases. Urine output is restored and acid–base equilibrium returns towards normal in conjunction with improved tissue perfusion.

Hypertonic saline solution is widely used for the treatment of dairy cattle with endotoxic shock and endotoxemia associated with coliform mastitis. Affected cows are given 2 L of hypertonic saline (4–5 mL/kg BW) intravenously, followed by immediate access to drinking water and other supportive therapy. The small volume of hypertonic saline followed by the oral water load increases circulatory volume rapidly, induces slight metabolic acidosis, increases renal perfusion and glomerular filtration rate, and induces homeostatic changes in serum calcium and phosphorus.[25] In experimental endotoxin-induced mastitis of cattle, small volumes of hypertonic saline given intravenously (7.5%, 5 mL/kg BW) resulted in expanded plasma volume and increased the cows' voluntary water intake by about 12 times compared to cows treated with isotonic saline.[26] The rapid intravenous administration of hypertonic saline can successfully, but only transiently, resuscitate calves in experimental endotoxic shock.[27] Hypertonic saline (7.2% NaCl, 2400 mosmol/L), 4 mL/kg BW intravenously over 4 min can be safely administered to endotoxic calves.[28] On a comparative basis, the rapid infusion of large-volume isotonic saline is superior to small-volume hypertonic saline for initial resuscitation of experimentally induced acutely endotoxemic calves.[27]

Hypertonic saline has been associated with greater and more prolonged improvement in cardiopulmonary function and survival in horses with experimentally induced hemorrhagic and endotoxemic shock and in halothane-induced hypotension in horses.[29] When given intravenously to normal conscious horses at 5 mL/kg BW, there are increases in plasma osmolality and serum sodium and chloride but clinically normal horses rapidly regulate variable sodium loads.[30]

Sodium bicarbonate 8.4% is 2000 mosmol/L (approximately seven times normal osmolarity). This solution is used for rapid alkalinization, particularly in the presence of severe acidemia (pH < 7.20). The solution osmolarity was selected because it provides 1 mEq of HCO_3^-/mL of solution, which facilitates calculation of the volume to be administered. The speed of intravenous administration of 8.4% sodium bicarbonate should not exceed 1 (ml/kg BW)/min. There is one report of the intravenous administration of 8.4% sodium bicarbonate to normovolumic calves with experimentally induced mixed respiratory and metabolic acidosis; the study found that rapid administration of $NaHCO_3$ (5 mL/kg intravenously over 5 min) rapidly corrected the metabolic acidosis, increased blood pH and improved cardiovascular status without inducing paradoxical cerebrospinal fluid acidosis,[31] suggesting that this treatment may be of value in treating dehydrated diarrheic calves. Efficacy studies in calves with naturally acquired diarrhea appear indicated. Hypertonic solutions of sodium bicarbonate are highly effective for the initial treatment of acidosis associated with D-lactic acidosis in calves, acute diarrhea in calves[31] and strong ion (metabolic) acidosis in newborn calves.[32]

Sodium bicarbonate 5% is 1190 mosmol/L (approximately four times normal osmolarity). This solution is also used for rapid alkalinization in the presence of severe acidemia (pH < 7.20). The speed of intravenous administration of 5.0% sodium bicarbonate should not exceed 2 (ml/kg)/min. Three to five L of 5% sodium bicarbonate may be necessary as initial therapy to correct the severe hyponatremia and strong ion (metabolic) acidosis that occurs in the horse with acute diarrhea. Following this initial treatment, hypokalemia characterized by muscular weakness commonly occurs, which can be treated using a high sodium, high potassium, alkalinizing solution.

Calcium gluconate 23% or calcium borogluconate are 1069 mosmol/L (approximately three and a half times normal osmolarity). Calcium borogluconate is the standard treatment for milk fever (hypocalcemia) in cattle. D-gluconate is an aldose sugar produced by oxidation of D-glucose and is the preferred salt for calcium-containing parenteral solutions because it does not cause tissue necrosis as severe as does $CaCl_2$. Calcium gluconate should not be added to sodium bicarbonate solutions because a white precipitate ($CaCO_3$) forms immediately that interferes with normal fluid administration. Likewise, calcium gluconate should not be administered with tetracycline antibiotics because a yellow precipitate forms.

Colloid solutions

A colloid is a substance that is too large to pass through a semipermeable membrane. Examples of colloid solutions administered to ruminants are whole blood, stroma-free hemoglobin, plasma, dextrans, hydroxyethyl starches and

gelatins. As a group, colloid solutions are excellent for sustained expansion of plasma volume, which is in marked contrast to the effect of crystalloid solutions. Colloid solutions are contraindicated in congestive heart failure because these animals have increased plasma volume. Colloid solutions are also contraindicated in the presence of oliguric or anuric renal failure because the sustained volume overload may lead to pulmonary edema.

Whole blood is the perfect balanced colloid/crystalloid solution, with great O_2-carrying capacity. It has a short shelf life (< 24 h at 4°C) and is expensive to obtain. Whole blood administration runs the risk of disease transmission and allergic reactions; the latter are extremely rare in ruminants with the first blood transfusion but common enough in horses for blood typing or cross-matching to be required. Excellent descriptions for collecting, storing and administering blood are available elsewhere (Chapter 9).[33]

Stroma-free hemoglobin is a blood substitute containing a purified hemoglobin glutamer-200 solution (13 g hemoglobin/dL) derived from cattle blood. A commercially available solution has a 2-year shelf life at 20°C, an osmolarity of 300 mosmol/L and an oncotic pressure of 43 mmHg; the solution is therefore isotonic but hyperoncotic. Stroma-free hemoglobin solutions are excellent at increasing oxygen delivery and carrying capacity, while providing similar plasma volume expansion to dextrans and hydroxyethyl starches. The major theoretical concerns regarding administration of stroma-free hemoglobin solutions are potent vasoconstriction[34] and hemoglobinuric nephrosis. Some of the original experimental studies examining the effects of stroma-free hemoglobin administration were completed in sheep[35,36] and there are occasional reports of its successful administration to critically ill horses in a clinical situation. It is likely that the high cost of this product will minimize its administration to large animals.

Plasma (fresh or frozen) is an excellent balanced colloid/crystalloid solution. Compared with blood, plasma has a much longer shelf life (at least 1 year at –20°C) but is more expensive to obtain. Details for collection, harvesting, storing and administering plasma are available elsewhere,[33] and bovine, equine and New World camelid plasma is commercially available. Like blood, administration of plasma runs the risk of disease transmission and allergic reactions, although these risks are less than with blood transfusion.

Plasma is routinely administered to foals with inadequate transfer of passive immunity. Hyperimmune plasma is occasionally administered to neonatal foals and adult horses with Gram-negative septicemia and endotoxemia. There appears to be only one report documenting the efficacy of plasma administered to neonatal calves with diarrhea, and these calves were probably colostrum-deprived. The 14-day survival rate in diarrheic calves that received 600–800 mL of bovine plasma (5 g protein/dL) and electrolytes intravenously was 93% (37/40), which was significantly greater than the survival rate of calves receiving intravenous electrolytes alone (54%, 7/13).[37] Another study failed to identify a beneficial effect of blood transfusion in treating diarrheic calves.[38] Because blood is cheaper to obtain than plasma, whole blood transfusions are usually administered when a neonatal ruminant needs plasma.

Dextran preparations (such as Dextran-70) are high-molecular-weight glucose polymers obtained by bacterial fermentation of sucrose; the fermentation metabolites then undergo acid hydrolysis and fractionation. The molecular weight of dextran can therefore be 'selected', and two dextran products, Dextran-70 (mean molecular weight 70 000) and Dextran-40 (mean molecular weight 40 000) are commercially available. Because the molecular weight of Dextran-70 is similar to albumin (molecular weight 65 000), there is limited diffusion of dextran into the interstitial space and Dextran-70 therefore acts clinically as a plasma volume expander; this is in contrast to isotonic crystalloid solutions, which act as extracellular fluid volume expanders. Dextran-70 has been the most widely used dextran formulation in large animals and is therefore the recommended product for administration. Dextran-70 is supplied as a 6% concentration in 0.9% NaCl; this provides a hyperoncotic but isotonic solution. Reported administration rates of Dextran-70 are 5–40 (mL/kg)/h, but it is safer to administer Dextran-70 at less than 20 (mL/kg)/h. One mL of Dextran-70 expands the plasma volume by 0.8–1.2 mL, but 50% of the administered dose is gone by 24 hours. Dextran administration runs the risk of exacerbating pre-existing coagulopathies, although the clinical significance of dextran-induced prolongation of activated partial thromboplastin time (APTT) by decreasing factor VIII:C is probably minimal. The risk of coagulopathy is dependent upon the administration rate, total dose administered (20 mL/kg is maximum 24 h dose in humans) and the molecular weight of dextran. The deleterious effects of dextrans are usually associated with large doses or prolonged administration.

The use of **hypertonic saline–dextran solution** (4 mL/kg, 2400 mosmol/L sodium chloride in 6% Dextran-70 administered intravenously once over 4 min) combined with an isotonic oral alkalinizing solution containing sodium chloride (3.22 g/L), potassium chloride (1.12 g/L), sodium acetate trihydrate (4.76 g/L) and glucose anhydrous (16.22 g/L), providing 300 mosmol/kg of water and administered at 55 mL/kg BW, was superior to either solution alone for the treatment of experimentally induced hypovolemic diarrhea in calves.[39] The combined treatment resulted in immediate and sustained increases in plasma volume, cardiac output and stroke volume, thereby improving tissue perfusion. Rapid and sustained rehydration after the combined treatment was indicated by improvement in hydration and clinical depression scores and decreases in hematocrit, blood lactate concentration and serum creatinine, albumin and phosphate concentrations. Resuscitation with oral electrolyte solution alone was slower but was complete within 24 hours. Resuscitation with the hypertonic saline–dextran solution alone resulted in only transient benefit.

The administration of hypertonic saline–dextran solution (7.2% NaCl solution with 6% dextran at the rate of 4 mL/kg BW, intravenously during a 4 min period, combined with oral administration of isotonic electrolyte solution at the rate of 50–60 mL/kg BW) provided a rapid and effective method for resuscitating severely dehydrated calves with experimentally induced diarrhea[40] or with naturally acquired diarrhea.[41]

Hydroxyethyl starch preparations (hetastarch, pentastarch) Two hydroxyethyl starch preparations are currently commercially available; hetastarch and pentastarch. Hetastarch is a high-molecular-weight glucose polymer (mean molecular weight 450 000) that is chemically synthesized from amylopectin, producing a highly branched glucose polymer with a structure similar to that of glycogen. Because the molecular weight of hetastarch is much greater than that of albumin, hetastarch decreases endothelial permeability by sealing separations of endothelial cells. Hetastarch is hydrolyzed in blood by α-amylase, and the addition of hydroxyethyl groups slows hydrolysis and therefore prolongs the duration of plasma volume expansion. Hetastarch is supplied as a 6% concentration in 0.9% NaCl; this provides a hyperoncotic but approximately isotonic solution. Reported administration rates are 5–40 (mL/kg BW)/h but, like Dextran-70, it is safer to administer hetastarch at less than 20 (mL/kg BW)/h. Like Dextran-70, hetastarch administration also runs

the risk of exacerbating pre-existing coagulopathies. The risk of coagulopathy is dependent upon the administration rate and total dose administered (20 mL/kg BW is the maximum 24 h dose in humans).

Pentastarch has a mean molecular weight of 280 000 and is available as a 10% solution. Pentastarch has two important advantages over hetastarch: it has less exacerbating effect on pre-existing coagulopathies and the rate of elimination is faster. Pentastarch has rarely been administered to large animals.

Gelatins (modified bovine collagens) are available for veterinary use. The formulation uses gelatin with a mean molecular weight of 30 000 and is a 5.6% suspension in NaCl. Compared to dextrans and hydroxyethyl starches, gelatins have a shorter plasma half-life but appear to have less effect on coagulation. In general, gelatins have not been evaluated as completely as dextrans and hydroxyethyl starches and, on this basis, are not currently preferred.

Practical administration of electrolyte solutions

Under ideal conditions, with laboratory evaluation of the animal, the deficits can be accurately assessed and fluids containing the deficient electrolytes can be formulated. However, under most practice conditions this is not possible and **polyionic crystalloid solutions** are in general use. These usually contain sodium, potassium, chloride and calcium or magnesium at a concentration similar to the electrolyte composition of extracellular fluid; the solutions may also contain lactate or acetate as bicarbonate precursors. Dextrose may be added to the solution to make an initial mildly hypertonic solution.

Polyionic crystalloid solutions are safe and can be used in large quantities without inducing electrolyte disturbances provided that circulating blood volume and renal function have been restored and are maintained. They can be used for most situations of dehydration and moderate acidemia or alkalemia and moderate electrolyte imbalances. They are not usually adequate for the treatment of severe acidemia or alkalemia, or severe hyponatremia, hypokalemia or hypochloremia.

For the treatment of severe acidemia or alkalemia, and severe hyponatremia, hypokalemia and hypochloremia, specific electrolyte solutions are necessary. Generally, they consist of a mixture of the common simple solutions with supplemented electrolytes to correct some major abnormality. These are considered necessary to correct abnormalities quickly that could not be corrected using balanced electrolyte solutions. These solutions are summarized in Tables 2.3 and 2.5. Many intravenous solutions for fluid therapy in calf diarrhea are available and it is recommended that they should contain 150 mmol/L of sodium, 5 mmol/L of potassium and about 50 mmol/L of a mixture of bicarbonate and precursors.[42]

When acidemia is not present it is not necessary to use a fluid containing bicarbonate.[43]

Mature cattle affected with metabolic alkalosis associated with diseases of the abomasum are usually hypokalemic, hypochloremic and dehydrated. For such cases, a balanced electrolyte solution containing sodium, chloride and potassium is satisfactory. A solution containing sodium (135–155 mEq/L), chloride (150–170 mEq/L) and potassium (10–20 mEq/L) is effective.[43] In recently calved dairy cattle, calcium borogluconate is commonly added to the mixture.

Table 2.5 Composition (mmol/L) and indications for use of electrolyte solutions used in fluid therapy.

Solution	Na^+	K^+	Cl^-	Mg^{2+}	Ca^{2+}	HCO_3^-	Lactate or acetate	Dextrose	Major indications
0.9% sodium chloride isotonic saline)	155		155						Expansion of circulating blood volume
1.3% sodium bicarbonate (isotonic)	155					156			Metabolic acidosis
1.3% sodium bicarbonate in 5% dextrose	155					156		5%	Metabolic acidosis
5% sodium bicarbonate (hypertonic)	600					600			Severe metabolic acidosis
Equal mixture of isotonic saline and isotonic sodium bicarbonate	155		78			78			Metabolic acidosis and dehydration
Balanced electrolyte solution (i.e. McSherry's solution)	138	12	100	5	3		50 (acetate)		Metabolic acidosis electrolyte losses and dehydration
Lactated Ringer's solution	130	4	111		3		28 (lactate)		Metabolic acidosis
High sodium, alkalinizing solution. Lactated Ringer's solution plus sodium bicarbonate (5 g/L)	190	4	111			60	27 (lactate)		Metabolic acidosis and hyponatremia
High sodium, high potassium, alkalinizing sodium Lactated Ringer's solution plus 1 g/L potassium chloride and 5 g/L sodium bicarbonate	190	18	125			60	27 (lactate)		Metabolic acidosis, hyponatremia, hypokalemia
High-potasium acidifying solution, isotonic saline plus 2.5-g potassium chloride/L	154	35	189						Metabolic alkalosis, hypochloremia, hypokalemia
Mixture of 1 L isotonic potassium chloride (1.1%), 2 L isotonic saline (0.9%) and 1 L dextrose 9%									Metabolic alkalosis in cattle with abomasal disease

Solutions containing potassium have been recommended for the treatment of the potassium depletion that occurs in calves with acute diarrhea and in inappetent ruminants and horses. However, in calves with severe acidemia and hyperkalemia, it is important to expand circulating blood volume, restore renal function and correct the strong ion (metabolic) acidosis before providing additional potassium, which may be toxic. Solutions containing potassium may be indicated following correction of the acidosis and dehydration. However, if the animal's appetite is returned to normal, the oral potassium intake will usually correct any existing deficiencies.

For the treatment of hypochloremic, hypokalemic, metabolic alkalosis, acidifying solutions can be used but preferably only if constant laboratory evaluation of the animal is possible. Without laboratory evaluation, the use of Ringer's solution, 0.9% NaCl or hypertonic saline for correction of strong ion (metabolic) alkalosis in adult cattle is recommended, along with the oral administration of potassium in animals that are inappetent. In experimentally induced hypochloremic hypokalemic metabolic alkalosis in 40–50 kg BW sheep, replacement of the chloride deficit using 2 L of hypertonic saline (1.8% sodium chloride) was effective in returning plasma sodium and chloride concentrations to normal within 12 hours, and the plasma potassium concentrations and acid–base balance returned to normal within 36 hours of treatment without providing potassium.[44] Small volumes of hypertonic saline are also effective for the treatment of experimentally induced hypochloremic, hypokalemic metabolic alkalosis in sheep.[45]

In summary, four different kinds of solutions are used in large animal practice:

- **Polyionic crystalloid solutions,** such as lactated Ringer's solution and acetated Ringer's solution, are indicated for dehydration and moderate degrees of acid–base and electrolyte imbalance
- **Hypertonic saline solution and an oral water load** represent a practical and inexpensive alternative to parenteral administration of large fluid volumes
- **Hypertonic or isotonic sodium bicarbonate,** such as 8.4%, 5.0% (hypertonic) or 1.3% (isotonic) solutions of sodium bicarbonate, are used for severe strong ion (metabolic) acidosis and hyponatremia
- **Chloride-containing acidifying solutions,** such as Ringer's solution, are used for treatment of strong ion (metabolic) alkalosis.

Because cost is a major consideration in large animal fluid therapy, it may not be possible to use sterile solutions. Most of the above solutions can be formulated using the necessary salts mixed with distilled water, boiled water or ordinary tap water and are therefore prepared inexpensively.

Quantity of fluids required and routes of administration

The amount of fluid required depends on the degree of dehydration (an estimate of the volume losses which have already occurred), the continuous losses which are occurring during treatment, and the maintenance requirements of the animal during treatment presuming its dietary intake of water, electrolytes and nutrients is minimal. The fluids are usually given in two stages:

- **Hydration therapy** in the first 4–6 hours at a rate of 100–150 mL/kg BW intravenously
- **Maintenance therapy** (a combination of **continuous losses** and **maintenance requirements**) in the next 20–24 hours, depending on the severity and the course of the disease, at 60–80 mL/kg BW/24 hours intravenously (approximately 3–4 mL/kg BW/hour). In some cases of profuse diarrhea, the continuous losses and maintenance requirements will be about 150 mL/kg BW over a 24-hour period. The daily maintenance water requirements of adult horses range from 54–83 mL/kg BW, with a mean of 64 mL/kg BW.[46]

Some examples of the large quantities of fluid required for hydration and maintenance therapy in cases of acute diarrhea are outlined in Table 2.6.

Parenteral fluid therapy

The total amount of the estimated necessary hydration therapy should be given intravenously using indwelling intravenous catheters in the first 4–6 hours in order to expand and maintain circulating blood volume. If acidemia or alkalemia is present, it also should be treated immediately. Thus the most important abnormalities – decreased circulating blood volume and acid–base imbalance – are treated first. Restoring circulating blood volume will restore renal function, which will assist in correcting acid–base and electrolyte balance. The immediate correction of acidemia will return the tissues to their normal physiological activity. The intravenous route is preferred for hydration therapy and for the correction of severe acid–base and electrolyte imbalances. All other routes (intraperitoneal, subcutaneous and oral) are unsatisfactory in the presence of decreased circulating blood volume.

During the intravenous administration, the animal must be monitored for clinical and laboratory evidence of improvement or deleterious effects. A **favorable response** is indicated by urination within 30–60 minutes, an improvement in mental attitude and some evidence of hydration. **Unfavorable responses** include **dyspnea** because of pre-existing pneumonia or pulmonary edema because of too rapid administration, **failure to urinate** because of renal failure or paralysis of the bladder, and **tetany** because of the excessive administration of alkali. Unusual responses such as sweating, trembling and depression within several hours following the intravenous administration of electrolytes or other substances such as commercial amino-acids may occur if the infusion is contaminated during administration.[47] If a laboratory is available, the determination of PCV, bicarbonate and blood pH will provide an excellent monitoring system during the administration of the fluids.

Rate of administration

The rate of administration will depend on the size of the animal, the severity of the illness, the type of fluids being administered and the response of the animal to the fluids. In calves, isotonic saline (0.9% NaCl) and sodium bicarbonate solutions can be given at the rate of 1–3 L/h; in a mature horse, fluids may be given at the

Table 2.6 Examples of approximate amounts of fluid required for hydration and maintenance therapy.

Animal	Degree of dehydration (% of body weight)	Fluid required for: Hydration (L)	Maintenance (L/24 h)
Mature horse (500 kg)	8	40	25–50
	12	60	25–50
Newborn calf (50 kg)	8	4	2.5–5
	12	6	2.5–5
Mature cow (700 kg)	8	56	35–70
	12	84	35–70

rate of 10–12 L/h. Hypertonic solutions such as 5% sodium bicarbonate can be given to a mature horse at the rate of 3–5 L/h, followed by balanced electrolytes at 10–12 L/h. Solutions containing added potassium should be given cautiously, at the rate of 3–5 L/h. In a cow with severe dehydration and acidosis due to carbohydrate engorgement, fluids may be given at the rate of 10–12 L/h.

Adverse reactions in all species include **sudden muscle weakness** (suggests hypokalemia) and sudden **tachycardia** and **hyperventilation**, which suggest **overhydration**. When these occur the fluids should be stopped and the clinical findings assessed. If laboratory assistance is available, the determination of blood pH and bicarbonate may provide an explanation for the reaction.

Intravenous catheters and complications

The administration of large quantities of fluids intravenously to farm animals is best done with an indwelling **jugular vein** flexible catheter (10–14-gauge) that is appropriately secured to the animal's neck to prevent withdrawal from the vein. Standard aseptic technique must be used. A plastic, spring-like, coiled tube and suitable rubber tubing are used to deliver the fluids from large 20–25 L plastic containers. The coiled plastic tubing allows the animal to lie down or stand up without disrupting the catheter and tubing.[48] The use of a drip chamber in the rubber tubing system assists in determining the flow rate, which can be adjusted with a clamp. With a 12-gauge catheter, 25–30 L of fluids can be delivered as hydration therapy to a mature horse or cow.

Auricular vein of cattle

The short neck, thick skin and, in some breeds, pendulous dewlap of cattle make it difficult to introduce and secure indwelling jugular catheters for long-term use. The auricular vein of adult cattle can be successfully catheterized with an over-the-needle, 14-gauge catheter, 5 cm long, permitting 20 L of rehydration solution to be delivered over 4 hours.[49]

Cecal catheters in horses

Percutaneous cecal catheters have been used to deliver fluid solutions in ponies.[50] The advantages include less cost but complications include peritonitis, diarrhea, laminitis and hypocalcemia.

Thrombophlebitis

Long-term jugular vein catheterization (over a period of a few days) in adult cattle and particularly horses can result in thrombophlebitis, suppurative phlebitis, and catheter sepsis. Inspection of the affected jugular vein reveals swelling, firmness and moderate pain. Careful digital and visual inspection are necessary to determine the patency of the vein; in about 50% of cases the vein is completely thrombosed and occluded and cannot be used for intravenous administration for 2–3 weeks. The extent and severity of the thrombophlebitis can be determined by ultrasonography of the neck and patency of the vein can be assessed by compressing the vein with the transducer head.[51]

The development of thrombophlebitis is dependent on the method used for skin preparation and the catheterization technique. Careful preparation of the skin and aseptic technique during insertion and placement of the catheter are crucial in preventing this complication.[52] Heparin subcutaneously, 150 IU/kg BW immediately after insertion of the catheter and repeated every 12 hours, has been used prophylactically[52] but this is not deemed necessary with good technique. Alternating catheters between jugular veins every 48–72 hours is standard practice in equine fluid therapy but despite this precaution complications occur in 20–50% of horses whose jugular veins are catheterized for 48 hours.[53] By using catheters made of materials that are less thrombogenic, inserting them in an aseptic manner and observing simple management practices, the duration of catheter survival increases to about 14 days. The least reactive catheter is Silastic, followed by polyurethane; polytetrafluoroethylene causes most reaction. Catheters that are soft are superior to stiff and rigid ones.

A retrospective study of the risk factors associated with vein thrombosis in horses treated with intravenous fluids in a veterinary teaching hospital found that the use of carboy fluids, diarrhea and fever were related; the incidence was lower in horses that had general anesthesia, surgery and received antimicrobial agents.[54] A variety of aerobic bacteria were cultured from about 50% of the intravenous catheters removed from horses.[55] Bacteria were isolated from 7% of skin swabs taken from the area around the catheter after surgical preparation with iodine soap and before and after removal of the catheter. However, there was no correlation between bacterial culture and the condition.

Oral fluid therapy

Whenever possible, the oral route can be used to deliver the maintenance requirements. Provided there are no abnormalities of the digestive tract that interfere with oral administration or the absorption of the fluids, the oral route is preferred for maintenance therapy. In ruminants such as adult cattle, rumen function must be present for significant absorption of fluids and electrolytes. The oral administration of large quantities of fluid to cattle with rumen atony results in sequestration of the fluid in the rumen and the development of metabolic hypochloremic, hypokalemic alkalosis.

Oral fluid therapy in calves and adult cattle

For diarrheic calves, the total 24-hour maintenance requirement is calculated and given orally in divided doses every 2–4 hours. Compared to parenteral therapy, there is less danger from overhydration and electrolyte toxicity, and in acute diarrhea the maintenance of oral fluid and electrolyte intakes will replace continuous losses that are occurring during the diarrhea. Livestock owners should be informed of the value of providing newborn animals affected with diarrhea associated with dehydration, depression, inactivity or failure to suck with oral fluids and electrolytes as soon as possible and of the value of continuing this treatment until the animal has returned to normal. Oral electrolyte solutions and water should be made available at all times to animals affected with diarrhea and other diseases in which there are continuous losses of fluid and electrolytes. The exception is cattle affected with carbohydrate engorgement, in which the water supply should be restricted to one-half or less until the animals begin to eat.

Calves with dehydration and diarrhea absorb electrolyte solutions almost as effectively as healthy calves. The important principle underlying the efficacy of oral fluid therapy is the use of low concentrations of glucose (about 2%) to promote sodium absorption from the intestine.[56] Water follows passively and, because sodium is the osmotic skeleton of the extracellular fluid, fluid is held predominantly where it is needed in the extracellular space, including plasma. Amino acids, such as glycine, also act like glucose to promote sodium absorption. In enterotoxigenic colibacillosis in calves, the glucose and amino acid cotransport mechanisms for sodium transport into epithelial cells are intact.[57] Thus, water and salt, together with glucose and glycine, facilitate the absorption of sodium and water in calves with diarrhea.

A high-calorie hypertonic oral rehydration solution containing glutamine was more effective in correcting plasma, extracellular fluid and blood volume than conventional solutions with a lower calorie content and without glutamine.[58] Glutamine also promotes enteric sodium uptake and may be important in sustaining villus form and function. The higher-

calorie solution (7.5% glucose) also sustains blood glucose levels at a higher level than conventional solutions. An effective oral fluid should also contain or yield sufficient bicarbonate to correct metabolic acidosis.

A variety of oral and parenteral electrolyte replacement solutions are available commercially.[59] Most preparations are in the form of powders to be mixed with water. They contain sodium, chloride, potassium, glucose, glycine and bicarbonate or its precursors (acetate or propionate).

The sodium bicarbonate included in oral fluids for the acidosis in calf diarrhea is usually effective directly and quickly. There is speculation that sodium bicarbonate may interfere with milk clotting in the abomasum, which requires an acidic environment for the action of rennin.[60] There is no direct evidence that oral fluids containing sodium bicarbonate interfere significantly with clotting of milk in the abomasum. Nevertheless, some oral electrolyte solutions for diarrheic calves contain acetate, propionate or citrate, which, when absorbed, act as bicarbonate precursors;[57] it should be noted that gluconate is not metabolized in calves and probably not in other large animals. Because of their acidic pH, it is claimed that these fluids do not interfere with abomasal clotting of milk but, as already stated, there is no direct evidence to support the claim and no evidence that the final outcome in naturally occurring cases of diarrhea in calves is superior when oral fluids containing metabolizable bases (rather than bicarbonate) are used. Furthermore, the oral fluids containing the base precursors are most effective in diarrheic calves with a blood pH over 7.2 (see Colibacillosis of calves, Ch. 18).

The **alkalinizing effects of commercial oral electrolyte solutions** have been compared in healthy calves.[61,62] A sodium bicarbonate-rich solution induced the best alkalinization effect. The preparation should not be mixed with milk but given one hour before or after feeding milk because any fluid substance added to milk changes the physicochemical characteristics of milk and may interfere with optimum clotting of milk by rennin in the abomasum, although the clinical significance of this effect remains uncertain. Bicarbonate-containing oral electrolyte solutions will restore acid–base imbalance in calves with viral-induced diarrhea much more effectively than solutions without bicarbonate.

The **continued feeding of milk to diarrheic calves** while they are receiving oral fluids and electrolytes **is controversial**.[61] It has been conventional to withhold milk from diarrheic calves for 1–2 days and gradually reintroduce milk over the next few days when there is evidence of recovery. An extreme practice was to totally deprive the calf of milk until the diarrhea ceased. The rationale was that the ability of the calf's intestine to digest milk was impaired. It is known that lactose digestion is impaired in the rotavirus and coronavirus diarrheas of young calves. It was also thought that the presence of milk in the intestine would provide a substrate for continued growth of enteric pathogens.

Another different practice was to continue feeding milk to diarrheic calves because it resulted in more rapid recovery from diarrhea, less debilitation, continued weight gain and improved circulating plasma volume. This is based on the premise that continuous feeding provides the intestinal mucosa with nutrients.

In experimentally induced diarrhea in calves, the continued feeding of milk during the course of the diarrhea sustained growth, resulted in greater fat stores, facilitated regeneration of the intestinal mucosa and resulted in less thymic atrophy than calves deprived of milk.[61] However, the number of calves in the experiment was small and extrapolation of the results to the naturally occurring disease is not yet warranted. Whole milk and an acidic oral fluid therapy given to calves with naturally occurring diarrhea did not adversely affect the calves or prolong or worsen the diarrhea, and promoted body weight gain.[63] However, none of the calves was severely dehydrated or acidemic and treatment was begun very early in the stage of diarrhea (see also *E. coli* in Ch. 18).

Oral fluid therapy in horses

Intravenous fluid and electrolyte therapy has been used extensively for the treatment of dehydration and electrolyte disturbances in the horse with diarrhea. However, oral fluid therapy, as used in calves, has not been employed to the same extent. It may be an effective, practical and economical method of rehydration of horses with diarrhea that has not yet been fully explored.[64,65]

In the horse with acute diarrhea, several factors contribute to the nature of the fluid and electrolyte losses. There are increases in fecal sodium and water loss but the fecal potassium excretion may remain unchanged.[64] Experimentally induced diarrhea (castor oil) in adult horses results in dehydration, metabolic acidosis and large fecal losses of sodium and urinary losses of potassium.[66] Plasma volume decreased while horses were clinically dehydrated. The lack of feed intake, which affects primarily the potassium intake, can result in losses of 2500–3000 mmol of potassium per day. Although urinary water and potassium losses are reduced, potassium depletion continues; thus potassium losses are very high and need to be replaced, especially in the anorexic horse. The large potassium deficit in diarrheic horses should also be considered when formulating the composition of oral fluids. Administration of 30–40 g potassium chloride or, if chloride administration is inappropriate, 30–40 g potassium bicarbonate in 2–4 L of water given by nasogastric tube several times daily to an inappetent horse with diarrhea can complement intravenous fluid therapy and replace the potassium deficit.

The optimum electrolyte composition of oral fluids and the amount to be used have not yet been determined for the horse. The amount given depends on the degree of dehydration. Dehydration in horses becomes clinically apparent when about 5% of body weight has been lost. In a 500 kg horse, assuming 90% water loss, the fluid deficit is about 23 L.[64] Abdominal discomfort may occur following the nasogastric tube administration of a series of 8–10 L doses of oral rehydration fluid.[67] The administration of large amounts may result in rapid transit through the stomach and intestines and decreased absorption. A slower rate of administration, such as 8–10 L every few hours, may be tolerated more effectively and the transit time in the intestine may be decreased, enhancing absorption. Volumes of 6–8 L can be given by nasogastric tube as often as every 15–20 minutes by funnel; as much as 20–30 L is possible during the first hour and 40 L is possible during a 2-hour period.[68] Oral fluids may also be administered through a small-diameter indwelling nasogastric tube, as is used for prolonged enteral nutrition of horses with dysphagia.[65]

Commercially available **oral electrolyte solutions** are inadequate for horses because the concentrations of sodium and potassium are too low to adequately replace losses. When treating horses with acute diarrhea, the ratio of sodium to chloride ions in the oral solution should be approximately 1.4:1, and the need for glucose in an oral rehydration solution for adult horses has not been clearly demonstrated. One formulation contained 5.27 g of NaCl, 0.37 g of KCl and 3.78 g $NaHCO_3$ per liter of tap water; this produced a suitable electrolyte composition for oral administration (Na 135 mmol/L; K 5 mmol/L; Cl 95 mmol/L; HCO_3 45 mmol/L).[69]

Oral administration of bicarbonate will result in a pronounced alkalemia within 3–6 hours, with the maximum change in

pH occurring at a sodium bicarbonate dose of 1 g/kg BW (which represents 40% of normal extracellular sodium). Doses above this level do not induce additional alkalinization, presumably because of limited absorption of bicarbonate from the intestinal tract. The oral administration of sodium bicarbonate to normal mature resting horses without ad libitum access to water induces metabolic alkalosis, hypernatremia, hypokalemia and hyperosmolality for at least 8 hours.[70] The oral doses were 0.25, 1 and 1.5 g/kg BW in 3 L water; the intravenous dose was 0.25 g/kg BW in 3 L water. The effects were dose-dependent: in the horses given the 1 and 1.5 g/kg BW oral doses, the hypercapnia persisted for 12 hours, whereas hypercapnia lasted 2 hours in horses given the 0.25 g/kg BW dose orally or intravenously. The effects of these large doses of sodium bicarbonate on the renal function of horses indicated increases in urine flow, fractional clearance of electrolytes and bicarbonate, electrolyte-free water reabsorption, urine concentrations of sodium and bicarbonate, urine excretion, clearance of sodium and bicarbonate, urine pH and anion gap.[70]

The temperature or glucose concentration of the fluid does not appear to be important, as the rate of fluid absorption was similar in dehydrated horses administered an oral rehydration solution at 5°C, 21°C or 37°C or containing glucose at 0%, 2.5% or 3.5%.[71] The tonicity of the oral rehydration solution is of minor clinical importance; however, oral administration of hypertonic solutions (628 mosmol/kg BW) to dehydrated horses caused a transient increase in plasma protein concentration that was attributed to movement of water into the bowel lumen.[71] A practical limitation of oral rehydration solutions in horses is that they should be ingested voluntarily rather than by nasogastric intubation. This limitation has led to recent interest in the oral administration of pastes.

The oral administration of an **electrolyte paste** has been shown to be effective in correcting mild to moderate dehydration in horses, provided animals are monitored to ensure that they drink water.[72] Oral electrolyte pastes may be formulated as follows: 30 g of 1:1 mixture of sodium chloride and potassium chloride, potassium chloride and sodium bicarbonate, or potassium chloride and potassium carbonate, and administered every 6 hours; 120 g of the latter mixture provides 1400 mmol or more of potassium in a 24-hour period.[65] Administration of higher doses of oral pastes (0.5 g of NaCl/kg BW, 0.5 g of KCl/kg BW or a mixture of 0.25 g of NaCl/kg BW and 0.25 g of KCl/kg BW) to dehydrated horses induced a transient period of hyperhydration and apparent plasma volume expansion that lasted 12 hours.[72] Although the absorbed electrolytes from an oral paste are subsequently eliminated via the urine, this treatment is potentially of benefit in horses with disease processes associated with ongoing fluid losses, such as diarrhea.

There is no published information on the use of oral fluid therapy in horses that are diarrheic as a result of disease of the small intestine such as enteritis, or proximal enteritis (duodenitis). It would seem unlikely that oral fluid therapy would be indicated or effective for anterior duodenitis. In horses with colitis, the small intestinal absorptive capacity is probably intact and oral fluid therapy prior to transport of the horse to a clinical center for intensive fluid therapy may delay the onset of more serious complications. Horses with mild dehydration can be rehydrated effectively with oral fluid therapy. Horses treated with oral fluid therapy must be monitored clinically, and the hematocrit, total plasma protein concentration and serum electrolytes should be measured.

Oral fluid therapy in horses with impaction of the large colon provides an effective and inexpensive treatment and should be regarded as the initial treatment of choice. In general, 6–8 L of water can be administered by nasogastric tube and funnel (gravity flow) every 15–20 minutes;[68] the administered fluid is rapidly transported to the large intestine. It is generally recommended that the osmolality of the fluids should be isotonic, ranging from 280–360 mosmol/L; the upper range of tonicity which is safe to administer is unknown. Oral administration of 60 L of lactated Ringer's solution or an isotonic solution over 12 hours was superior in hydrating the contents of the right dorsal colon when compared to intravenous administration of an equivalent volume of lactated Ringer's solution or enteral administration of 1 g/kg BW of $MgSO_4.7H_2O$ (Epsom's salts) or anhydrous Na_2SO_4 as a 1 L solution.[69,73] Moreover, enteral administration of Epsom's salts has been associated with hypermagnesemia, and anhydrous Na_2SO_4 has been associated with hypocalcemia.[73]

Fluid and electrolyte therapy in newborn piglets and lambs

The most common cause of fluid and electrolyte imbalance in newborn piglets and lambs is acute neonatal diarrhea. There is severe dehydration, acidemia, hyponatremia and, in some cases, hyperkalemia due to the acidosis. Balanced electrolyte solutions or isotonic saline and sodium bicarbonate initially followed by balanced electrolytes are indicated and successful. These are given subcutaneously or intraperitoneally at the rate of 15 mL per piglet every 2 hours plus the same amount orally. The safe amount of sterilized porcine serum or saline and 5% dextrose that can be given to piglets is equivalent to about 8% BW intraperitoneally, in two divided doses given 8 hours apart. Lambs are also treated subcutaneously (30–40 mL) and orally (50–100 mL) every 2 hours.

Parenteral nutrition

Parenteral nutrition is used to provide adequate nutrition intravenously, as long as necessary, when feeding by the gastrointestinal tract is impractical, inadequate or impossible. The term parenteral nutrition is preferred to total parenteral nutrition because the complete nutritional requirements of large animals are either not completely known or not addressed by intravenous fluid administration. It should be recognized that enteral nutrition represents state-of-the-art medicine because enteral nutrition supports the repair, maintenance and growth of the gastrointestinal tract to a much greater extent than does parenteral nutrition. It should also be recognized that parenteral nutrition should only be contemplated after at least 5 days of inappetence.

The technique is used to supply the nutrient requirements, most importantly protein, of the animal until it returns to normal. In calves affected with persistent diarrhea due to chronic disease of the alimentary tract, or that cannot or will not eat, total intravenous feeding may be indicated.[74] High concentrations of glucose, protein hydrolysates, lipid emulsions and electrolytes are given by continuous slow intravenous infusion over a period of several days. Some encouraging results in calves have been published but the cost-effectiveness of the technique has not been examined.[74]

Parenteral nutrition is an acceptable method of maintaining nutrition in the healthy horse over a period of 10 days.[75] Body weight was maintained at 94% of initial values without clinical evidence of dehydration. No problems were encountered with the long-term intravenous catheterization. The total daily amounts given are calculated on the basis of daily caloric requirement. The intravenous catheter must be inserted down into the cranial vena cava, where a large volume of blood will dilute the hypertonic concentration of the solution. The potential problems associated with parenteral nutrition include difficulty in the maintenance of a steady intravenous drip,

hypertonicity of the solutions used, venous thrombosis, excessive diuresis, catheter sepsis and bacterial contamination of the solutions.

Pain

THE PROBLEM OF PAIN

Pain is a distressing sensation arising from stimulation of specific end-organs in particular parts of the body and perceived in the thalamus and cerebral cortex. Pain is basically a protective mechanism to ensure that the animal moves away from noxious (damaging) influences, but endogenous pain, arising from internal damaging influences, causes its own physiological and pathological problems that require the veterinarian's intervention. In humans, there is an additional psychological parameter to pain and, although it is customary to transpose attitudes from pain in humans to animals, this is a courtesy rather than an established scientific principle.

A major difficulty with pain in animals is the difficulty of pain measurement. Pain is a subjective sensation known by experience and which can be described by illustration, but measurement of pain is an indirect activity related to its effects and is an objective phenomenon. A panel report on recognition and alleviation of pain in animals proposes a simplified classification for animal pain and distress as: pain, anxiety and fear, stress, suffering, comfort, discomfort and injury.[1] The recommendations are directed at academics, teachers and researchers using laboratory animals, and the pharmaceutical industry.

Pain is assessed in animals by three methods: 1) **observation of behavior**; 2) measurement of physiological parameters, including heart rate, blood pressure, sweating and polypnea, that indicate **sympathetic activation**; and 3) measurement of the plasma concentration of factors that indicate sympathetic activation, such as plasma cortisol, epinephrine, norepinephrine and non-esterified fatty acid concentrations. Because of the lability and expense of epinephrine and norepinephrine analyses, and the poor specificity of increased plasma non-esterified fatty acid concentration for pain, the most commonly utilized laboratory measure of pain is **plasma cortisol concentration**. Cortisol concentrations have also been measured in saliva, urine and feces in order to provide a more accurate indicator of basal stress, as plasma cortisol concentrations increase rapidly in response to handling and restraint for blood sampling.

Pain in agricultural animals is a matter of ever-increasing concern. Many agricultural practices that are thought to be necessary to avoid later painful disease or injury (e.g. dehorning of cattle, sheep and goats; tail docking in lambs; the Mules operation in Merino sheep; tooth clipping in baby pigs, to improve animal production (e.g. castration, spaying) or to facilitate in animal identification (branding, eartagging, tattooing or ear notching) are carried out by producers without anesthetic. It is not our purpose to engage in a discussion on the subject of animal welfare or the prevention of cruelty.

ADVANCES IN ATTITUDE TOWARD PAIN

There is now a greater awareness of the existence of pain in animals and the detrimental effects of pain,[2] which has led

to widespread implementation of post-operative pain control.[3] New and improved analgesics are being developed and marketed as a result of increased basic and clinical research in pain. The detrimental effects of pain include:

- Suffering and stress resulting in delayed healing
- Increased catabolism and decreased feed intake
- Prolonged recovery and longer recumbency, with a greater risk of postoperative complications
- The potential to cause ineffective respiratory ventilation with the development of respiratory acidosis and acidemia
- Self-mutilation
- The potential of acute pain to lead to chronic pain.

Pain may be clinically beneficial by acting as a protective mechanism by moving the animal away from the noxious stimulus and providing immobility of the affected part, thereby promoting healing. Pain is a valuable diagnostic aid but, once identified, it is our obligation to treat the pain and remove or modify its source if possible.

Once it is accepted that pain is detrimental it then becomes important to recognize and evaluate the severity of pain. In the past, veterinary science has used an anthropomorphological approach to the assessment of whether or not an animal is in pain. It is a reasonable elementary approach to compare the effects of pain in animals with those in humans because there are many more similarities in the neuroanatomical, physiological and behavioral data between humans and animals than there are differences. However, because of the inherent behavioral and social differences between humans and animals, this approach is limited. Current research on pain in animals includes visual and subjective assessment of pain supported by physiological and clinicopathologic measurements. These studies have increased the awareness of the problem of pain in veterinary medicine and resulted in improved information on the use of appropriate analgesics.

ETIOLOGY

Pain sensations are aroused by different stimuli in different tissues and the agents that cause pain in one organ do not necessarily do so in another. In animals there are three types of pain:

- **Cutaneous (or superficial)**
- **Visceral**
- **Somatic (or musculoskeletal).**

The causes of each type of pain are listed below.

Cutaneous or superficial pain

Cutaneous or superficial pain is caused by agents or processes that damage the skin, such as burning, freezing, cutting and crushing. Fire burns, frostbite, severe dermatitis, acute mastitis, laminitis, infected surgical wounds, footrot, crushing by trauma, conjunctivitis and foreign body in the conjunctival sac are all common causes of pain.

Visceral pain

Examples of visceral pain include:

- Inflammation of serosal surfaces, as in peritonitis, pleurisy and pericarditis
- Distension of viscera, including the stomach, intestines, ureters and bladder
- Swelling of organs as in hepatomegaly and splenomegaly
- Inflammation, as in nephritis, peripelvic cellulitis and enteritis
- Stretching of the mesentery and mediastinum.

In the nervous system, swelling of the brain caused by diffuse edema, or of the meninges caused by meningitis, are potent causes of pain. Inflammation of (neuritis) or compression of (neuralgia) peripheral nerves or dorsal nerve roots are also associated with severe pain.

Musculoskeletal (somatic) pain

Muscular pain can be caused by lacerations and hematomas of muscle, myositis and space-occupying lesions of muscle. Osteomyelitis, fractures, arthritis, joint dislocations, sprains of ligaments and tendons are also obvious causes of severe pain. Among the most painful of injuries are swollen, inflamed lesions of the limbs caused by deep penetrating injury or, in cattle, by extension from foot rot. Amputation of a claw, laminitis and septic arthritis are in the same category. Ischemia of muscle and generalized muscle tetany, as occurs in electroimmobilization,[4] also appear to cause pain.

The trauma of surgical wounds is a controversial topic in animal welfare, especially that associated with minor surgical procedures such as dehorning, tail docking and castration in farm animals. From clinical observation supported by some laboratory examinations, e.g. salivary cortisol concentrations after castration in calves and lambs, it appears that pain after these procedures is short-lived, up to about 3 hours.[5]

PATHOGENESIS

Pain receptors are distributed as end-organs in all body systems and organs. They are connected to the central nervous system by their own sensory nerve fibers with their cell bodies in the dorsal root ganglion of each spinal nerve and via some of the cranial nerves. Intracord neurons connect the peripheral neurons to the thalamus, where pain is perceived, and to the sensory cerebral cortex, where the intensity and localization of the pain are appreciated and the responses to pain are initiated and coordinated.

The stimuli that cause pain vary between organs. The important causes include:

- **Skin** – cutting, crushing, freezing, burning
- **Gastrointestinal tract** – distension, spasm, inflamed mucosa, stretching of mesentery
- **Skeletal muscle** – ischemia, traumatic swelling, tearing, rupture, hematoma
- **Synovial membranes and cartilage of joints** – inflammation.

Nociception is the normal physiological process by which pain is perceived. When a tissue is injured by mechanical, thermal or chemical means, **peripheral nociceptors** (specialized free nerve endings of afferent neurons) are depolarized and the initial stimulus is felt as pain.

Peripheral nociceptors are located in skin, fascia, muscles, tendons, blood vessels, joint capsules, periosteum, subchondral bone, pleura, peritoneum and viscera. Five classes of peripheral nociceptor are currently recognized: 1) thermal nociceptors activated by temperatures above 52°C or below 5°C; 2) mechanoheat nociceptors activated by pressure and temperature; 3) polymodal nociceptors; 4) visceral nociceptors; and 5) silent nociceptors. The **first pain** or initial sharp stinging following injury is due to activation of large-diameter fast-conduction myelinated nerve fibers called **Type I Aδ fibers** (thermal nociceptors) or **Type IIAδ fibers** (mechanoheat nociceptors). The **second pain** or slow pain following injury is due to activation of small-diameter unmyelinated slow-conduction fibers called **C-fibers**; these fibers transmit a painful stimulus that is perceived as a sustained burning sensation that persists past cessation of the initial sharp painful sensation. Visceral nociceptors are activated by diffuse stimulation instead of direct local noxious stimuli. Silent nociceptors are mechanoheat nociceptors that are activated when sensitized by release of proinflammatory mediators (such as bradykinin, histamine, leukotrienes, eicosanoids, serotonin, substance P, adenosine triphosphate (ATP), low tissue pH and other constituents of inflammation) into damaged tissues, thereby establishing **peripheral hyperalgesia**. The hyperalgesia during acute pain is believed to promote healing at the injured site.

Central hypersensitivity and pre-emptive analgesia

A state of altered central processing can also occur in response to chronic activation of peripheral nociceptors, called **central hypersensitivity** or 'wind up'. This central hypersensitivity results in a modified response to subsequent afferent inputs, which last between 10 and 200 times the duration of the initiating stimulus. The net result is that stimuli previously perceived as innocuous, such as touch or pressure, become perceived as painful after the system is sensitized. Preinjury treatment with opioids or local anesthetics prevents or decreases the development of central hypersensitivity and behavioral indicators of pain but opioids and local anesthetics are less effective if administered after the injury is initiated. It is the establishment of central hypersensitivity that makes pain much more difficult to control once it is established and why analgesics are less effective at this time. Thus the combination of peripheral hyperalgesia (particularly associated with substance P) and central hypersensitivity results in what is called clinical pain.

It has been suggested that by preventing the surgical afferent stimuli from entering the spinal cord, the facilitation of spinal nociceptive processing could be prevented and this would decrease the severity of postoperative pain. This is known as the concept of **pre-emptive analgesia**. Presurgical administration of an analgesic is more effective than post-surgical administration of the same dose; this is relevant to the control of pain associated with elective surgery. Many studies (primarily in humans) have demonstrated that presurgical administration of local anesthetic agents and the administration of NSAIDs or opioids before the patient is recovered from anesthesia are appropriate methods for instituting pre-emptive analgesia.

The physiological responses to pain are described below. Normal responses include the release of the morphine-like endorphin from the brain,[6] providing an endogenous analgesic system, and also cortisol release from the adrenal cortex[7] in response to any stress. The clinical response to pain varies not only with the personality of the patient (some are more stoical than others) but also with various other influences. For example, distraction, as in walking a horse with colic, application of an alternative pain in the forced elevation of the tail of a cow (tail jack), and application of local anesthetic agents all tend to relieve pain. In agricultural animals pain elicits behavioral, physiological and clinicopathological changes. The behavioral responses can be interpreted as a form of distraction, a displacement activity, or as providing an alternative pain. The physiological and clinicopathological responses are part of the fight or flight phenomena and reflect sympathetic activation.

CLINICAL FINDINGS

The general clinical findings of pain are described here and the indications of pain associated with individual body systems or organs are described within each category.

Physiological responses

Physiological responses to pain are manifested by the following signs, the severity of the pain determining the degree of response:

- Tachycardia
- Polypnea
- Pupillary dilatation
- Hyperthermia
- Sweating.

The cardiovascular responses of tachycardia and hyperthermia may contribute to a fatal outcome in animals with reduced cardiovascular reserve, for example when dehydration, acid–base imbalance and endotoxic shock are also present.

Behavioral responses

These include abnormal posture and gait when the pain is musculoskeletal (e.g. somatic). The gait abnormalities include lameness, a shuffling gait and rapid shifting of weight from one leg to another. These are subjects of importance in orthopedic surgery.

The behavioral responses to pain may also include unrelated activities such as **rolling, pawing, crouching or grinding of teeth** when the pain is visceral. However, the behavioral activities may also be related to the site of the pain, e.g. the horse with colic that looks at its abdomen, or to a particular function, such as pain manifest on coughing, walking, defecating, urinating, etc. The behavioral aspects of severe pain are very important in the horse with severe unrelenting visceral pain due to colic. The rolling, falling and lunging upwards and backwards (often falling against walls) can result in severe injury and causes panic in many owners.

Generally, somatic pain is more localized and easily identified than visceral pain. Injuries to limbs are usually identifiable by fractures or localized tendon strain or muscle injury. With severe somatic pain, as with a fracture or septic arthritis, the limb is carried off the ground and no weight is taken on the limb. With lesser lesions more weight-bearing activity is undertaken.

One of the notable factors affecting pain in animals is the analgesic effect of the animal lying on its back or of its adopting a defeated, supine posture. This may be related to the release of endorphins.[7]

More general behavioral responses to pain include **decreased appetite** and average daily rate of gain, adoption of an anxious expression (ears retracted), disinclination to be examined and aversion to returning to a particular location where pain has been experienced previously. **Moaning, grunting and grinding of the teeth** (odontoprisis or bruxism) are generally indicative of pain. If the vocalization occurs with each respiration, or each rumination, the pain appears likely to arise from a lesion in the thoracic or abdominal cavities. When teeth-grinding is associated with head-pressing it is thought to indicate increased intracranial pressure such as occurs with brain edema or lead poisoning. Grinding of the teeth as a sole sign of pain is usually associated with subacute distension of segments of the alimentary tract. More extreme kinds of vocalization caused by pain include moderate bellowing by cattle, bleating in sheep and goats, and squealing in pigs.

Elicitation of pain by the veterinarian

This is an essential part of a clinical examination. The techniques include the following:

- Pressure by palpation, including firm ballottement with the fist and the use of a pole to depress the back in a horse or to arch the back upwards from below in a cow
- Pressure by compression, as with hoof testers for detecting the presence of pain in the hoof
- Movement by having the animal walk actively or by passively flexing or extending limbs or neck
- Stimulation of pain related to coughing by eliciting the cough reflex
- Relief of the pain by correction of the lesion.

Periodicity and duration of pain

Limited duration of pain can be the result of natural recovery or of surgical or medical correction of the problem. Constant pain results from a static state whereas periodic or intermittent pain is often related to periodic peristaltic movement. In humans and in companion animals some importance also attaches to observing the time of onset of pain, whether it is related to particular functions or happenings and whether the patient gains relief by adopting particular postures or activities. These factors are unlikely to be of importance as an aid to a diagnosis in agricultural animals.

TREATMENT

Several aspects concerning the relief of pain in agricultural animals are important. Cost has always been a deterrent to the use of local anesthetics and analgesics. However, with changing attitudes towards animal pain, this issue is more frequently examined. Treatment of the causative lesion is a major priority, but the treated lesion may remain painful for varying lengths of time. Relief and the control of pain should be a major consideration and the following principles require consideration:

- Relief of pain is a humane act. Improved, less painful methods of castration, dehorning, tail-docking, Mules operation in sheep, spaying cattle and treating painful lesions of the hooves of farm animals must be explored and implemented. Surgical operations such as laparotomies must be performed using appropriate analgesia
- Analgesia may obscure clinical findings that may be necessary to observe, properly diagnose or maintain surveillance of a case. This is of major importance in equine colic
- Control of pain is necessary to prevent animals from inflicting serious self-injury associated with uncontrollable behavior as a result of severe visceral pain (see Equine colic)
- Analgesics for visceral pain are readily available and relatively effective
- A major problem in the clinical management of pain is for cases of severe, slowly healing, infected traumatic wounds of the musculoskeletal system. Pain is likely to be very severe, continuous and to last for periods of up to several weeks. Affected animals cannot bear weight with the affected limb, have great difficulty in moving, lose much weight and prefer prolonged recumbency. At the present time, there are no effective analgesics available that can be administered easily and daily for a few weeks without undesirable side-effects. The development of such products is urgently required.

Analgesia

The analgesic agents and techniques available include the following:

- Surgical procedures, e.g. neurectomy by section of peripheral nerves, as practiced in horses
- Local destruction of peripheral nerves by chemical means, e.g. the epidural injection of agents such as ethyl alcohol may prevent straining
- Local destruction of peripheral nerves by thermal means, e.g. cautery of the wound edge after gouge dehorning in calves[8]
- Analgesia using nonopiate drugs when sedation is not required or is contraindicated
- Opiate analgesics (narcotic analgesics).

Analgesic agents

There are five main types of analgesic agent administered parenterally or topically to large animals: 1) **local anesthetic agents** such as lidocaine, mepivacaine and bupivacaine; 2) **nonsteroidal anti-inflammatory drugs (NSAIDs)** such as flunixin meglumine, ketoprofen, phenylbutazone and meloxicam; 3) **α_2-agonists** such as xylazine and detomidine; 4) **opioids** such as morphine, fentanyl, butorphanol and buprenorphine; and 5) **vanilloids** such as capsaicin. In general, local anesthetic agents, α_2-agonists and opioids are used to provide short-term analgesia (hours), and parenteral NSAIDs and topical vanilloids are used to provide long-term analgesia (days to months). Standard anesthesiology texts should be consulted regarding techniques for local analgesia using regional or peripheral nerve blocks and local anesthetic agents, or for general analgesia using α_2-agonists and opioids.

Local anesthetic agents

Lidocaine, mepivacaine and bupivacaine exert their analgesic effect by addressing both the first pain and second pain after injury by blocking the voltage-gated sodium channels in peripheral nerves, thereby preventing propagation of depolarization. Type IAδ, type IIAδ and C-fibers are blocked before other sensory and motor fibers, meaning that it is possible (but sometimes a clinical challenge) to selectively block pain while leaving the animal able to maintain normal motor function. The main advantages of local anesthetic agents are their cost and predictable and local effect, the main disadvantage is short duration of action. Topical formulations of lidocaine (2.5%) and prilocaine (2.5%) are available that appear to be useful for transdermal administration of a local anesthetic in large animals prior to intravenous catheter placement, venipuncture, arthrocentesis or collection of cerebrospinal fluid.[9]

Nonsteroidal anti-inflammatory drugs

These drugs appear to exert most of their analgesic effect by addressing the **second pain** (slow pain) due to sensitization of C-fibers by eicosanoids; NSAIDs are not currently believed to exert a central analgesic effect. Animals receiving NSAIDs should be normally hydrated in order to minimize potential renal effects such as tubular nephrosis and papillary necrosis (see diseases of the kidney).

Flunixin meglumine

This NSAID has excellent anti-inflammatory, antipyretic and analgesic properties, and is the preferred NSAID for acute soft tissue or visceral pain, although it is also efficacious against musculoskeletal pain. Flunixin meglumine provides excellent analgesia in equine colic and postsurgical pain. In a comparison of three NSAIDs used to minimize postsurgical pain in horses, flunixin meglumine (1 mg/kg BW), phenylbutazone (4 mg/kg BW) or carprofen (0.7 mg/kg BW) were administered once intravenously.[10] All three NSAIDs were effective in controlling postsurgical pain but the duration of clinical effect was longer for flunixin meglumine (12.8 h) than carprofen (11.7 h) or phenylbutazone (8.4 h).

The usual loading dose is 1.1–2.2 mg/kg BW (ruminants) or 1.1 mg/kg BW (horses) followed by a maintenance dose of 1.1 mg/kg BW every 24 hours,[11] although some studies have administered repeated injections at 8–12 hours. Flunixin meglumine is usually administered once or twice a day for its analgesic effect and is usually administered parenterally (preferably intravenously because of the rare instances of myonecrosis following intramuscular injections, particularly in horses), although oral formulations exist. Intramuscular doses are rapidly absorbed, with the maximal concentration occurring within 1 hour. Large doses given to individual ponies may, however, be toxic.[12] Toxic effects are similar to those with phenylbutazone and include ulceration of the colon, stomach and mouth; the latter two are most evident when administered orally.

Ketoprofen

This NSAID has anti-inflammatory, antipyretic and analgesic properties, and is labeled in Europe for the treatment of pain in cattle associated with mastitis, lameness and trauma (3.3 mg/kg BW, intravenously or intramuscularly, every 24 h for 3 d). Oral formulations are also available in Europe for the treatment of suckling calves. On theoretical grounds, ketoprofen may have superior analgesic properties to currently available NSAIDs because it blocks both the cyclooxygenase and 5-lipoxygenase branches of the arachidonic acid cascade as well as potentially having antibradykinin activity. However, the latter two effects have not been demonstrated in large animals at recommended dose rates.[13] Ketoprofen has been shown to provide analgesia for several hours after gouge dehorning of calves[14] and surgical castration of calves.[15]

Phenylbutazone

This NSAID is used extensively as an analgesic for horses, especially for

musculoskeletal pain. It is most effective for the relief of mild to moderate musculoskeletal pain. The half-life of the drug in plasma is about 3.5 hours so that repeated treatment is recommended. A plasma concentration of 20 μg/mL appears to be clinically effective in horses, whereas a plasma concentration of 60–90 μg/mL appears to be clinically effective in cattle.[16]

After oral use in horses the peak levels in plasma are reached at 2 hours, but after intramuscular injection this does not occur until after 6 hours, so that the oral or intravenous routes are the usual routes of administration. Unless care is taken to inject the drug slowly when using the intravenous route, severe phlebitis, sometimes causing complete obstruction of the jugular vein, may result. For horses the recommended dose rate is 4.4 mg/kg BW daily for 5 days orally or intravenously. Treatment on day 1 may be at 4.4 mg/kg BW twice, constituting a loading dose.[17] Treatment beyond 5 days may be continued at minimal effective dose rates. However, prolonged use, especially in ponies, at a dose of 10–12 mg/kg BW daily for 8–10 days, may be followed by ulceration of alimentary tract mucosa, including the oral mucosa, and fatal fluid retention due to hypoproteinemia.[18] The pathogenesis of these lesions is thought to be due to a widespread phlebopathy.[19] Phenylbutazone should not be used if there is pre-existing gastrointestinal ulceration, clotting deficits or cardiac or renal dysfunction. Its use should be under close veterinary supervision so that the dose rate may be kept to a minimal effective level and so that it is used only when there is a clear clinical indication to do so. It should be withdrawn if there is no indication of a therapeutic response or if signs of toxicity appear. If there is doubt about toxicity or a prolonged course is advised, periodic hematological examinations are recommended.

For cattle, the recommended oral dose is 10–20 mg/kg BW initially followed by daily doses of 4–6 mg/kg BW or every other dose of 10–14 mg/kg BW.[16,20] Clearance is slowed in neonates, so the dosage protocol would need to be adjusted in suckling calves.[21] Phenylbutazone is moderately effective in cattle with painful conditions of the limbs. In most countries phenylbutazone is not approved for use in food-producing animals because of the risk of drug residues in the food chain and the known toxicity of phenylbutazone in humans.

Salicylates

Aspirin or acetylsalicylic acid is the most commonly administered analgesic in cattle but is not very effective and there is limited clinical evidence of its efficacy. The recommended dose rate is 100 mg/kg BW orally every 12 hours,[22] and oral administration is most common. Because there may be limited absorption from the small intestine, the salicylates may be given intravenously (35 mg/kg BW every 6 h in cattle; 25 mg/kg BW every 4 h in horses), but this is no longer practiced with the widespread availability of flunixin meglumine and phenylbutazone.

Carprofen

This is the safest NSAID, because of its weak inhibition of peripheral prostaglandins.

Diclofenac

This NSAID, when given to lambs before castration with bloodless castrators, significantly reduced the time spent trembling or in abnormal postures following the castration procedure.[23]

Xylazine

Xylazine was shown to be the most effective analgesic for the relief of experimentally induced superficial, deep and visceral pain in ponies when it was compared to fentanyl, meperidine (pethidine), methadone, oxymorphone and pentazocine.[24] However, its short duration of action and the accompanying sedation and decreased gastrointestinal motility and increased urine formation limit its use to short-term analgesia.

Narcotic analgesics

Meperidine (Demerol, pethidine) is extensively used as an analgesic for visceral pain in the horse. Methadone hydrochloride and pentazocine are also used, to a limited extent, and their use is detailed in the treatment of colic in the horse. Butorphanol, a synthetic narcotic used alone[25] or in combination with xylazine,[26] provides highly effective analgesia in horses. In general, narcotic analgesics are not as effective in ruminants because they have a different distribution of mu and kappa receptors to monogastric animals.

Narcotic agents are used in somatic pain in humans and may have wider applicability in animals. A recent clinical application has been transdermal delivery of fentanyl, which is a potent mu and kappa agonist opioid analgesic drug that is highly lipid-soluble. Fentanyl patches have been applied to the skin of horses, pigs, sheep, goats and llamas. The rate and magnitude of uptake is dependent on core temperature and environmental temperature (and therefore blood flow to the skin at the site of the patch), thickness of the skin at the site of the patch and adherence of the patch to the skin.[27] A significant limitation to the use of opioids is their addictive nature in humans, necessitating storage under strict control with written records of their usage required in most countries.

Vanilloids

Capsaicin is derived from hot chili peppers (*Capsicum annum*) and is the main vanilloid used in horses; these agents are characterized by their ability to activate a subpopulation of nociceptor primary afferent neurons. Capsaicin induces a transient primary hyperalgesia that is followed by a sustained period of desensitization that is species-, age-, dose- and route-of-administration-dependent. The sustained densensitization is responsible for capsaicin's efficacy as an analgesic agent. Capsaicin therefore has dual effects: initial transient primary hyperalgesia (manifest as a burning sensation) and long-term desensitization. Topical application of capsaicin ointment over the site of the palmar digital nerves has been used in horses as an adjunctive method of analgesia in equine laminitis, with demonstrated efficacy.[28] The major clinical disadvantage of using capsaicin is the initial transient primary hyperalgesia.

Balanced analgesia

Because multiple mechanisms for pain modulation all act together, the concept of **balanced analgesia** has been proposed, similar to the way in which the use of different combinations of sedative and anesthetic agents results in the best aspects of each agent producing balanced anesthesia.[2] Among horses receiving NSAIDs at the end of an anesthetic, those that received butorphanol during surgery required less additional analgesia compared to those that did not receive any opioid. Thus, combinations of drugs can be used to produce sequential blocks in nociceptive pathways.

Administration routes

The main routes used for administration of analgesics have been local infiltration, subcutaneous, intramuscular and intravenous. Other routes, including the **oral, epidural, intra-articular** and **topical**, are now being explored.[2]

Xylazine and **lidocaine** given as **epidural analgesia** abolished pain and tenesmus in cows with acute tail-head trauma which was characterized by acute, intense pain and discomfort, severe tenesmus and a limp tail.[29] Extended pain relief was required for up to 3 weeks. Xylazine in the epidural space has also been used to provide analgesia for the castration of bulls.[30] In the horse epidural analgesia using a combination of butorphanol and local anesthetics has been used to provide perineal analgesia.[2]

Supportive therapy

The application of moist heat to a local lesion causing pain is effective and makes

medical sense. Its value depends on how frequently and for how long it can be applied.

Providing adequate bedding is important for an animal that is recumbent for long periods or that is likely to injure itself while rolling. A thick straw pack is most useful if it can be kept clean and densely packed. Sawdust is most practical but has the problem that it gets into everything, especially dressings and wounds. Rubber floors and walls, as in recovery wards, are effective but are usually available only for short periods.

The provision of adequate amounts and quality of feed and water is essential, especially if the animal is immobilized and because appetite is often poor.

Distracting a horse with colic by walking it continuously is a common practice to prevent the animal from behavioral activities such as rolling, which may cause self-inflicted injuries. It is valuable, but has obvious limitations.

Stress

Stress is a systemic state that develops as a result of the long-term application of stressors. It includes pain, which is discussed above. **Stressors** are environmental factors that stimulate homeostatic, physiological and behavioral responses in excess of normal. The most objective measure of the presence and magnitude of stress is the plasma cortisol concentration. The importance of stress is that it may:

- Lead to the development of psychosomatic disease
- Increase susceptibility to infection
- Represent an unacceptable level of consideration for the welfare of animals
- Reduce the efficiency of production.

The general adaptation syndrome, described in humans, has no counterpart in our animals and it is lacking in accurate definitions, precise pathogenesis and general credibility.

CAUSES OF STRESS

For animals, a satisfactory environment is one that provides thermal comfort, physical comfort, control of disease and behavioral satisfaction. An environment that is inadequate for these factors will lead to stress. The environmental influences that elicit physiological responses from animals are outlined below and some can be classified as stressors. The effects of most of these influences on production or performance indices have been measured quantitatively and many of them have been equated with blood levels of adrenal corticosteroids, which quantify them as stressors in the different species:

- **Road transportation** for prolonged periods, especially during inclement weather and when overcrowded, is considered to be a major stress associated with an increased incidence of infectious disease in all farm animal species. The effects of prolonged road transportation have been measured in young calves,[1] cattle,[2] sheep[3,4] and horses[5]
- **Climate**, especially temperature, either as excessive heat or cold, is a stressor. In particular, a change of climate places great pressure on heat production and conservation mechanisms in, for example, conditions of sudden wind and rain, which affect the comfort of animals
- **Excessive physical effort**, as in endurance rides for horses, struggling in restrained animals, fear, and the excitement and fear in capture myopathy syndrome in wildlife, are all potential stressors
- **Pain**, especially analgesia-masked pain in severe colic in horses, is a stressor. The pain of dehorning and castration of farm animals is also a transient stressor, depending upon the species and method used
- **Crowding** – temperature, humidity, the physical exhaustion associated with standing up for long periods, being walked on, difficulty in getting to food and water, etc. are relevant. Two other factors could be important. One is the effect of crowding on behavior. For example, pigs in overcrowded pens appear to bite one another more than when they are housed at lower densities, and are more restless than normal when temperatures in the pens are high. The biting is much more severe between males than between females. Also, it is known that pigs bite each other when establishing precedence in a group, e.g. after mixing of batches, and that this is more severe when feed is short. The other possible factor that might affect the animal's response to crowding is a psychological appreciation of the unattractiveness of crowding (or of isolation). This, however, is an unknown phenomenon in animals
- **Presence or absence of bedding**. This is a comfort factor separate from temperature and wetness. Whether comfort affects physiological mechanisms is not currently known
- **Housing** generally includes the matter of comfort as well as that of maintaining moderate temperatures, but whether there is a factor other than the physical is not known
- **Nutritional deficiencies** including lack of energy, bulk and fluid
- **Quietness versus excitement.** Harassment by humans or other animals sufficient to cause fear does elicit stress response in animals and this is thought to be one of the significant causes of stress-related diseases in animals. Thus, transportation, entry to saleyards, feedlots, fairs and shows, and simply the mixing of several groups so that competition for superiority in the social order of the group is stimulated, are causes of stress. Entry to an abattoir, which has the additional fear-inspiring factors of noise and smell, is likely to be very stressful for those reasons, but it is unlikely that a fear of impending death is relevant. Such situations are stressful to the point of causing marked elevation of plasma epinephrine concentrations

Herding and flocking instincts. Animal species that are accustomed to be kept as herds or flocks may be distressed for a period if they are separated from the group.

PATHOGENESIS

Stress is thought to develop when the animal's mechanisms concerned with adapting its body to the environment are extended beyond their normal capacities. The daily (circadian) rhythm of homeostatic and physiological changes in response to normal daily changes in environment requires the least form of adaptation. Marked changes in environment, such as a dramatic change in weather, on the other hand, place a great strain on adaptation and are classified as stressors.

The body systems that are principally involved in the process of adaptation to the environment are the endocrine system for the long-term responses and the nervous system for the sensory inputs and short-term responses. The endocrine responses are principally the adrenal medullary response, related to the 'flight or fight' situation, which requires immediate response, and the adrenal cortical response, which becomes operative if the stressful situation persists.

In humans, a large part of the 'stress' state is the result of stimuli arising in the cerebral cortex and is dependent on the capacity to develop fear and anxiety about the effect of existing or anticipated stressful situations. Whether or not these psychological inputs play any part in animal disease is important, but undecided. The evidence seems to suggest that psychic factors do play such a part but that it is relatively minor.

The critical decision in relating 'stress' to disease is to decide when an environmental pressure exceeds that which the animal's adaptive mechanisms can reasonably accommodate – in other words, to define when each of the pressures outlined above does, in fact, become a stressor. There is a great dearth of definition on the subject. Probably the most serviceable guideline is: 'Stress is any stimulus, internal or external, chemical or physical or emotional, that excites neurons of the hypothalamus to release corticotrophin-releasing hormone at rates greater than would occur at that time of the day in the absence of the stimulus'. This definition uses 'stress' where 'stressor' would have been more common usage. Other than that, it is acceptable. The critical threshold of stress occurs in the adrenal cortex, and its physical determination is subject to a chemical assay of adrenocorticotropic hormone (ACTH). This was the basis of the original 'Stress and the general adaptation syndrome' as set down by Selye. The original concept is still attractive because of its simplicity and logic. However, evidence supporting the hypothesis remains limited. The importance of the concept for our animals is unproven. The deficiency in evidence is that of obtaining a standard response to a standard application of a stimulus. There is a great deal of variation between animals, and stimuli that should be significant stressors appear to exert no effect at all on adrenocortical activity.

Stress and road transportation

The response of different farm animal species to the effects of road transportation has been examined. In unaccustomed cattle that are forced to run and are then herded together, there are increases in the hematocrit and blood concentrations of catecholamines, cortisol, total lipid, glucose and lactose.[6] Transportation of calves, 4–6 months of age, for only 4 hours results in a leukocytosis with neutrophilia, a decrease in T-lymphocyte population, a suppression of lymphocyte blastogenesis and enhancement of neutrophil activity.[7] The effects of road transportation on cattle varies according to age: the transportation of 1–3-week-old calves for up to 18 hours was not as stressful as in older calves.[1,2] The lack of response of the younger calves to transport may be due to their lack of physiological adaptation to coping with the transportation.[1] During transportation, plasma cortisol concentrations and serum creatine kinase activities increase. There is clinical evidence of dehydration and increases in serum non-esterified fatty acid, β-hydroxybutyrate and urea concentrations, which reflect changes in normal feeding patterns.[2] Based on the physiological measurements and subjective measurements of behavior, a 15-hour transportation period under good conditions is not unacceptable with regard to animal welfare.[2] Transportation is exhausting and causes dehydration but lairage facilitates recovery from both.[8] When sheep are subjected to a journey of up to 24 hours it is best to be done as an uninterrupted trip, because it is the initial stages of loading and transport that are most stressful.[3,4] In a 15-hour road journey in sheep, the major change in hormone release occurs during the first 3-hour period and is much less in the remaining 12 hours.[9]

The effects of road transport on indices of stress in horses have been examined.[5] A road journey lasting up to 24 hours is not particularly stressful for horses, if they are healthy, accustomed to the trailer and their travel companions, permitted to stop at least as frequently as every 3.75 hours and traveling in a well-ventilated trailer.[5] There was no indication that road transport was a risk factor for pulmonary disease; however, confinement of horses with their heads elevated for up to 24 hours (similar to during transportation) results in bacterial colonization and multiplication within the lower respiratory tract.[10] Horses are also less physically stressed when facing backwards in a trailer.[11]

Based on plasma cortisol concentrations, confinement of young bulls on a truck and motion are considered stressful factors in road transport.[12] Transport stress increases fecal, urine and tissue losses, with most of the increased loss taking place during the first 5–11 hours of transport.[13] During transportation of feeder calves (195 kg) the major portion of transport stress occurs during the early phases of transport; longer periods may not add significantly to the overall stress imposed on the calf. It is possible that the major stress may be related to the handling of the animals during loading and unloading.[2]

Other possible sources of stress

Dehorning dairy calves at 8 weeks of age resulted in an increase in plasma cortisol concentration within 1 hour after the procedure but there was no evidence of prolonged stress.[14]

The effects of maternal dietary restriction of protein and/or metabolizable energy on the humoral antibody response in cows and the absorption of immunoglobulins by their cold-stressed calves indicates that there were no major or sustained differences compared to controls.

Different types of stress also result in distinctive changes in the plasma concentrations of metabolites and hormones.[15] An environmental stress, such as noise, will stimulate a hypothalamic–adrenal–cortex response; while a sympathetic–adrenal–medulla response occurs with a stressor such as transportation.[15]

CLINICAL PATHOLOGY

The direct criterion of stress is the assay of plasma ACTH; stress may be indirectly assayed using plasma cortisol concentration, which is a less expensive and more widely available assay. Salivary cortisol concentration is a good indicator of stress in sheep. Saliva samples are easy to collect and the laboratory assay is simple to perform. It needs to be remembered that elevation of plasma and saliva cortisol concentrations are a normal physiological response and do not necessarily imply the existence of a damaging state in the environment.

During prolonged periods of road transportation of cattle and sheep, there

are significant changes in serum concentrations of total proteins, non-esterified fatty acids (NEFAs), glucose, creatine kinase, β-hydroxybutyrate and urea. These changes can be used to assess the degree of stress and the deprivation from feed and water during transportation.[16] Prolonged feed deprivation reduces liver glycogen stores and increases concentrations of NEFAs and ketones in the plasma. Dehydration will elevate the concentrations of plasma proteins and the osmolality of the blood. Physical stress such as fatigue or exercise will result in increases in creatine kinase. Psychological stressors such as fear result in elevations of cortisol and corticosterone.

STRESS SYNDROMES

Stress-related psychosomatic disease

In humans there is a significant neuronal input from the cerebral cortex to the hypothalamus in response to the psychological pressure generated by stress. Inability to monitor anxiety and feelings of harassment in our animals makes it impossible to determine the presence or otherwise of psychological stress in them. However, psychosomatic diseases as they occur in humans are almost unknown in farm animals. The pathogenesis of psychosomatic disease appears to be based on the ability of the cerebral cortex to effectively override the normal feedback mechanisms by which the pituitary gland regulates the secretion of corticosteroids from the adrenal cortex. In other words, the normal adaptive mechanisms do not operate and hyperadrenocorticism and adrenal exhaustion develop.

Stress and susceptibility to infection

Field observations support the view that stress reduces resistance to infection. This seems to be logical in the presence of higher than normal adrenocortical activity. The most intensively explored relationship of this kind has been that of exposure of calves to weaning and transportation and their subsequent susceptibility to shipping fever. The prevalence appears to be increased and is still further enhanced by the introduction of other stress factors.

Stress and animal welfare

The harassment of domesticated animals by humans has become a matter of great concern for the community at large. Intensive animal housing has become an accepted part of present-day agribusiness but the consuming public is inclined to the view that these practices are cruel. The literature that has built up around the argument sets out to demonstrate that environmental stress in the shape of intensive housing, debeaking, tail docking and so on is sufficient to cause a stress reaction as measured by increased corticosteroid secretion. Such has not turned out to be the case and this is understandable in the light of the known variation among animals in their response to environmental circumstances requiring their physiological adaptation. If it could be shown that this relationship did exist and that the increased adrenocortical activity caused reduction in resistance to infection, the task of the responsible animal welfare person would be much easier. The absence of this experimental data makes the continuing argument less resolvable, but it is now generally accepted that producers have a responsibility to their animals and to society generally to maintain an acceptable standard of humane care of animals. These arguments are usually expressed as codes of animal welfare, to which most concerned people conform. However, they are not statutory directives and are not capable of active enforcement. Some courts of law accept them as guidelines on what the human–animal relationship in agriculture should be. Many aspects of the codes are arbitrary and are understandably heavily sprinkled with anthropomorphic sentiments. The study of ethology, which has expanded greatly during the recent past, may eventually provide some answers to this active, often bitterly fought-over field.

The status of animals used in experiments has always been a bone of contention between the experimenters and some sections of the general public. In general, these arguments revolve around anthropomorphic propositions that animals are subject to fear of pain, illness and death in the same way as human beings. There is no consistent evidence in physiological terms that supports these views. However, the public conscience has again achieved a good deal of acceptance to its view that animal experimentation should be controlled and restricted, and carefully policed to avoid unnecessary experiments and hardship in animals under our control.

Stress and metabolic disease

There is an inclination to label any disease caused by a strong pressure from an environmental factor as a 'stress' disease, for instance hypocalcemia of sheep and hypomagnesemia of cattle in cold weather, acetonemia and pregnancy toxemia of cattle and sheep on deficient diets, white muscle disease of calves and lambs after vigorous exercise. These diseases do have environmental origins, but their causes are much simpler than a complex interaction of the cerebral–cortical–hypothalamic–adrenocortical axis. They can be prevented and cured without any intervention in the 'stress' disease pathogenesis. This is not to say that there is no adrenocortical basis for the pathogenesis of the above-listed diseases, but attempts to establish the relationship have so far been unsuccessful.

Stress and its effect on economic performance

The constant struggle for domination of other animals in an animal population is most marked in chickens and pigs and the relationship between status in the hierarchy and productivity in these species has been established, with the low-status animals producing less well. It is also known that birds that are highly sensitive and easily startled are poor producers; they are easily identified and culled.

The relationship between stress and production appears to be a real one. For example, heat stress in the form of high environmental temperatures reduces roughage intake and hence milk production in lactating dairy cows and the relationships between stress and infertility and stress and mastitis in cattle are also well documented. The sensitivity of animals to environmental stress is greatest at times when they are already affected by metabolic stresses, e.g. during late pregnancy and early lactation. The adoption of a policy of culling erratic, excitable animals appears to have an economic basis.

MANAGEMENT OF STRESS

The widespread public debate about the welfare of food-producing domestic animals dictates that veterinarians, animal scientists and the livestock industry must develop systems of handling and housing that will minimize stressors and provide an environment that makes the animals most contented and at the same time most productive. In civilized human society it should be realistic to expect that the animals that we use for food production or as companions should live their lives free from abuse or adverse exploitation. It will be necessary to determine how best to monitor the wellbeing of animals and determine whether or not they are under stress. Guidelines dealing with codes of practice for livestock production are available in many countries. In addition to housing, handling and experimental intervention, it will also be important to give due care to the appropriate selection and use of anesthetics and analgesics when pain is being inflicted, as in dehorning and castration. The effects of sedatives such as acepromazine and xylazine on the stress response in cattle has been examined but the results are inconclusive.[17]

The welfare of animals during transportation is a major issue that has

resulted in legislation governing the transport of animals and to define acceptable and unacceptable procedures.[16] Many countries now have codes of practice for the handling and transportation of animals. Welfare is determined by the length of the trip and the conditions under which animals are transported, including stocking density, ventilation, temperature and humidity, noise and vibration. Prolonged deprivation of feed and water during long transportation results in hunger and thirst, and methods to minimize these consequences must be examined.[16]

Localized infections

Localized infections are common in farm animals and many are bacterial infections secondary to traumatic injuries. Because most of them have a surgical outcome, by incision and drainage or by excision or amputation, they are not usually included in medical textbooks. They are presented briefly here because of their importance in the differential diagnosis of causes of toxemia and also because of their space-occupying characteristics, causing compression of other structures. Also, the initial treatment is often medical, especially if the location of the lesion cannot be identified.

ETIOLOGY

Abscesses and similar aggregations of pyogenic material in certain anatomical locations are described elsewhere in this book. The common ones include: pharyngeal, retroperitoneal, hepatic, splenic, pulmonary, cerebral, pituitary, spinal cord and subcutaneous abscesses. Other similar lesions include embolic nephritis, guttural pouch empyema, lymphadenitis, pharyngeal phlegmon, osteomyelitis tooth root abscesses and infections of the umbilicus and associated vessels.

More widespread accumulations of necrotic/toxic pyogenic debris occur and are described under the headings of: pericarditis, pleurisy, peritonitis, metritis, mastitis, meningitis and pyelonephritis.

Other pyogenic lesions worthy of note include the following:

- **Inguinal abscess in horses.** Some of these probably originate as postcastration infections, but some obviously have other origins, possibly as a lymphadenitis arising from drainage of a leg with a chronic skin infection
- **Traumatic cellulitis and phlegmon in soft tissue,** especially skeletal muscle. The neck is a common site of infection in the horse, with lesions resulting from infected injection sites or the injection of escharotic materials, e.g. iron preparations intended only for intravenous administration. Penetrating traumatic wounds, often severely infected, are among the serious occurrences to the legs and hooves of horses and cattle. These commonly penetrate joint capsules, bursae and tendon sheaths, and under-run periosteum. In cattle, the common causes are agricultural implements, in horses they are more commonly caused by running into protruding objects, including stakes and fencing material
- **Abscessation and cellulitis of the tip or the proximal part of the tail.** Occurs in steers in feedlots and rarely extends to the hindquarters and the scrotum;[1] the cause is presumed to originate from the presence of an aggregate of feces on the tip of the tail (manure ball) which gets caught in fencing material. Bacterial isolated from the lesion indicates a mixed infection
- **Perirectal abscess** occurs in horses, caused usually by minor penetrations of the mucosa during rectal examination. Some of these rupture into the peritoneal cavity, causing acute, fatal peritonitis. Others cause obstruction of the rectum and colic because of the pain and compression that result.[2] They are readily palpable on rectal examination
- **Perivaginal abscess** occurs in heifers and cows, caused by vaginal tears during parturition, particularly after dystocia. Occasionally these rupture into the peritoneal cavity, causing acute, fatal peritonitis. More commonly, the abscess causes obstruction of the rectum and urethra, with the animal exhibiting signs of abdominal pain and stranguria because of the pain and compression that results. Perivaginal abscesses are readily palpable on rectal and vaginal examination
- **Urachal abscess** – see omphalitis
- **Pituitary abscess** occurs in cattle as a single entity or in combination with other lesions.[3] Pituitary abscesses cause a wide range of signs with emphasis on dysphagia due to jawdrop, blindness and absence of a pupillary light reflex, ataxia and terminal recumbency with nystagmus and opisthotonos.[4] A high-quality *Arcanobacterium (Actinomyces or Corynebacterium) pyogenes* vaccine against the disease is reported to have performed well[5] but theoretically should provide minimal to no efficacy against pituitary abscesses.
- **Facial abscess in cattle and goats.** Facial abscesses secondary to injury of the cheek mucosa caused by plant awns are common in beef cattle being fed hay containing a variety of awns that may penetrate the oral mucosa. *A. pyogenes* is the commonly isolated bacterium. Localized abscesses of the face and neck are common in some flocks of goats.[6] *A. pyogenes* is most commonly isolated, followed by *Corynebacterium pseudotuberculosis* and *Staphylococcus* spp. The abscesses are most common on the jaw and sternal, facial and cervical regions
- **Tooth root abscesses in llamas, alpacas, goats and sheep.** Tooth root abscesses are a common dental disease of llamas and alpacas. Tooth root abscesses can arise without a known cause or may result from trauma, foreign body migration (such as grass seeds), malocclusion and abnormal tooth wear, and periodontal disease.[7] *Fusobacterium necrophorum* and *A. pyogenes* are most commonly isolated from tooth root abscesses in New World camelids. Tooth root abscesses are most frequently found in mandibular molar teeth in New World camelids, the mandibular incisors in pigs and the first maxillary molar in horses.[7]

Bacterial causes of localized infection

These include those bacteria that are common skin contaminants in animals, including *A. pyogenes*, *F. necrophorum*, streptococci and staphylococci. Clostridial infections are common but occur sporadically. They are described under

Malignant edema. *C. pseudotuberculosis* is common as a cause of local suppuration in horses and is the specific cause of caseous lymphadenitis of sheep. *Rhodococcus equi* also causes pulmonary and subcutaneous abscesses in horses and cervical lymphadenitis in pigs. Strangles, *R. equi* infection in foals, melioidosis and glanders are all characterized by extensive systemic abscess formation. *Histophilus somni* causes systemic abscess formation in sheep. *Mycobacterium phlei* and other atypical mycobacteria are rare causes of local cellulitis and lymphadenitis/lymphangitis manifesting as 'skin tuberculosis' in cattle. Streptococcal cervical abscess in pigs is another specific abscess-forming disease.

PORTAL OF ENTRY

Most localized infections begin as penetrating wounds of the skin, caused accidentally or neglectfully because of failure to disinfect the skin adequately before an injection or incision, as in castration, tail docking, etc.

Metastatic implantation from another infectious process, especially endocarditis, carried by blood or lymph, is the next most common cause. In this way a chain of lymph nodes can become infected. Cranial and caudal vena caval syndromes produce similar embolic showers in the lungs.

PATHOGENESIS

The local infection may take the form of a circumscribed aggregation of bacterial debris and necrotic tissue, known as an **abscess**. This may be firmly walled off by a dense fibrotic capsule or be contiguous with normal tissue. When such an abscess occurs in a lymph node, it is a **bubo**. When the infective material is purulent but diffusely spread through tissues, especially along fascial planes, it is known as a **phlegmon**, and when it is inflammatory but not purulent the same lesion is a **cellulitis**.

The species of bacteria in the abscess determines the type of pus present and its odor. Staphylococci produce large quantities of thick yellow pus, streptococci produce less pus and more serous-like exudates. Pus associated with *A. pyogenes* is deep-colored, yellow or green in color and very thick and tenacious. The pus of *F. necrophorum* is very foul-smelling and usually accompanied by the presence of gas.

Deposition of bacteria in tissues is sufficient to establish infection there in most instances. Conditions that favor abscess development include ischemia, trauma and the presence of a cavity or a hematoma. A continuing process of pus formation results in enlargement to the stage of pointing and rupturing of an abscess, or spread along the path of least resistance into a nearby cavity or vessel, or discharge to the exterior through a sinus. Continuing discharge through a sinus indicates the persistence of a septic focus, usually a foreign body, such as a grass seed, a sequestrum of necrotic bone or an osteomyelitis lesion.

CLINICAL FINDINGS

The clinical signs of abscesses and other local aggregations of pyogenic lesions are described under each of the headings listed under etiology. General clinical findings which suggest the presence of a localized infection, which is not readily obvious clinically, include the following:

- Fever, depression, lack of appetite – the signs of toxemia
- Pain resulting in abnormal posture, e.g. arching of the back, or gait abnormality, including severe lameness
- Weight loss, which can be dramatic in degree and rapidity
- Obstruction of lymphatic and venous drainage, which can cause local swelling and edema. Sequels to these developments include extensive cellulitis if there is a retrograde spread of infection along lymph drainage channels, and phlebitis and thrombophlebitis when there is stasis in the veins
- Careful palpation under anesthesia or heavy sedation may be necessary to overcome the muscle spasm caused by pain. Calves with extensive abscessation emanating from the navel, and horses with inguinal abscesses, can only be satisfactorily examined by deep abdominal and rectal palpation
- Radiological examination may elicit evidence of osteomyelitis, and examination of a fistulous tract may be facilitated in this way, especially if a radiopaque material is infused into the track.

CLINICAL PATHOLOGY

Hemogram

A complete blood count is helpful in supporting a diagnosis of local abscess. Unless the infection is completely isolated by a fibrous tissue capsule or is small in size relative to the size of the animal (tooth root abscess or osteomyelitis), there will be a leukocytosis with a left shift and an elevation of polymorphonuclear leukocytes in acute lesions or of lymphocytes and monocytes in more chronic ones. A moderate normochromic anemia is usual in chronic lesions, and mild proteinuria is common.

Sample of lesion for culture and staining

Attempts to identify the presence of an infectious agent and to establish its identity are usually undertaken but care is necessary to avoid spreading infection from a site in which it is presently contained. Techniques used include paracentesis, careful needle aspiration from an abscess, blood culture (with the chances of isolation of bacteria being very small unless there is phlebitis or endocarditis) and aspiration of cerebrospinal fluid.

The isolation of bacteria from a well-contained abscess may be difficult because of the paucity of organisms. Special techniques may be necessary and examination of a smear stained with Gram stain, and perhaps also with Ziehl–Neelsen stain if the circumstances suggest it, is an essential part of the examination. Determination of sensitivity of the bacteria to antibiotics is usually undertaken.

Necropsy findings

The presence and location of the local infection can be demonstrated at necropsy.

TREATMENT

Drainage of abscesses

Surgical drainage of readily accessible intact abscesses is the treatment of choice and in most cases the only effective method of therapy. A needle aspirate may be indicated when the nature of the lesion is uncertain. The site is prepared surgically and the abscess is drained, flushed and topically medicated. If the abscess has not yet pointed with a soft spot, hot fomentations and hydrotherapy may aid in the maturation of a superficial abscess. An analgesic may be required during this stage of therapy. Tooth root abscesses require extraction of the affected tooth to effect a cure.[7]

Antimicrobial agents

Antimicrobial agents given parenterally can be used for the treatment of deep abscesses not readily accessible to surgical drainage. Ideally, a sample of the contents of the abscess should be cultured and antimicrobial susceptibility determined. The agent must achieve high plasma concentrations to facilitate penetration into an abscess and daily treatment for several days is usually necessary. However, antimicrobial agents alone may be ineffective, even if the organism appears sensitive to the drug in vitro in cases where the abscess is surrounded by a dense capsule – presumably the capsule prevents diffusion of the drug into the abscess cavity. Lipophilic antibiotics, such as rifampin, florfenicol or macrolides, are theoretically advantageous in penetrating into abscesses. Rifampin should be administered with another antimicrobial agent in order to delay the development of antibiotic resistance.

Disturbances of appetite, food intake and nutritional status

Hunger is a purely local subjective sensation arising from gastric hypermotility caused in most cases by lack of distension by food.

Appetite is a conditioned reflex depending on past associations and experience of palatable foods, and is not dependent on hunger contractions of the stomach. The term appetite is used loosely with regard to animals and really expresses the degree of hunger as indicated by the food intake. When we speak of variations from normal appetite we mean variations from normal food intake, with the rare exception of the animal that demonstrates a desire to eat but fails to do so because of a painful condition of the mouth or other disability. Variation in appetite includes increased, decreased or abnormal appetite.

Hyperorexia, or increased appetite, due to increased hunger contractions, is manifested by **polyphagia** or increased food intake. Partial absence of appetite (**inappetence**) and complete absence of appetite (**anorexia**) are manifested by varying degrees of decreased food intake (**anophagia**).

Abnormal appetites include cravings for substances, often normally offensive, other than usual foods. The abnormal appetite may be perverted, a temporary state, or depraved, the permanent or habit stage. Both are manifested by different forms of **pica** or **allotriophagia**.

POLYPHAGIA

Starvation, functional diarrhea, chronic gastritis and abnormalities of digestion, particularly pancreatic deficiency, may result in polyphagia. Metabolic diseases, including diabetes mellitus and hyperthyroidism, are rare in large animals but are causes of polyphagia in other species. Internal parasitism is often associated with poor growth response to more than adequate food intakes.

Although appetite is difficult to assess in animals it seems to be the only explanation for the behavior of those that grossly overeat on concentrates or other palatable feed. The syndromes associated with overeating are dealt with under the diseases of the alimentary tract (Chs 5 and 6).

ANOPHAGIA OR APHAGIA

Decreased food intake may be due to physical factors, such as painful conditions of the mouth and pharynx, or to lack of desire to eat. Hyperthermia, toxemia and fever all decrease hunger contractions of the stomach. In species with a simple alimentary tract a deficiency of thiamin in the diet will cause atony of the gut and reduction in food intake. In ruminants a deficiency of cobalt and a heavy infestation with Trichostrongylidae helminths are common causes of anophagia, and low plasma levels of zinc have also been suggested as a cause. In fact alimentary tract stasis due to any cause results in anophagia. Some sensations, including severe pain, excitement and fear, may override hunger sensations and animals used to open range conditions may temporarily refuse to eat when confined in feeding lots or experimental units. Some sheep that have been at pasture become completely anophagic if housed. The cause is unknown and treatment, other than turning out to pasture, is ineffective.

A similar clinical sign is feed aversion, seen most commonly in pigs, which is rejection of particular batches of feed that are contaminated by fungal toxins, e.g. *Fusarium* spp., or by the plant *Delphinium barbeyi*.

One of the important aims in veterinary medicine is to encourage an adequate food intake by sick and convalescing animals. Alimentary tract stimulants applied either locally or systemically are of no value unless the primary disease is corrected first. To administer parasympathomimetic drugs parenterally when there is digestive tract atony due to peritonitis is unlikely to increase food intake. In cattle, the intraruminal administration of 10–20 L of rumen juice from a normal cow will often produce excellent results in adult cattle that have been anorexic for several days, provided the primary cause of the anorexia is corrected. The provision of the most palatable feed available is also of value.

Parenteral or oral fluid and electrolyte therapy is indicated in animals that do not eat or drink after a few days. For animals that cannot or will not eat, or in those with intractable intestinal disease, the use of total intravenous feeding (parenteral nutrition) may be indicated. The subject of therapeutic nutrition for farm animals that cannot or will not eat appears to have been ignored. However, in most cases farm animals will begin to eat their normally preferred diets when the original cause of the anophagia or aphagia is removed or corrected. Intensive fluid therapy may be necessary during the convalescence stage of any disease that has affected feed intake and that may result in a mild depression of serum electrolytes.

A reduced feed intake in high-producing dairy cattle during the first few days or weeks of lactation and in fat beef cattle in late pregnancy may result in fatty infiltration and degeneration of the liver and high mortality. Treatment with glucose parenterally and propylene glycol orally to minimize the mobilization of excessive amounts of body fat is indicated.

In nervous anophagia the injection of insulin in amounts sufficient to cause hypoglycemia without causing convulsions is used in human practice, and in animals the use of tranquilizing drugs may achieve the same result.

In ruminants the effects of blood glucose levels on food intake are controversial, but it seems probable that neither blood glucose nor blood acetate levels are important factors in regulating the appetite. The anorexia that is characteristic of acetonemia and pregnancy toxemia of ruminants appears to be the result of the metabolic toxemia in these diseases. Electrolytic lesions in the hypothalamic region can stimulate or depress food intake depending on the area affected. This indicates the probable importance of the hypothalamus in the overall control of appetite.

REVIEW LITERATURE

Langhans W, Scharrer E. Pathophysiology of inappetence. J Vet Med Assoc 1986; 33:401–413, 414–421.

PICA OR ALLOTRIOPHAGIA

Pica is the ingestion of materials other than normal food and varies from licking to actual eating or drinking. It is associated in most cases with dietary deficiency, either of bulk or, in some cases, more specifically fiber, or of individual nutrients, particularly salt, cobalt or phosphorus. It is considered as normal behavior in rabbits and foals, where it is thought to be a method of dietary supplementation or refection of the intestinal bacterial flora. Boredom, in the case of animals closely confined, often results in the development of pica. Chronic abdominal pain due to peritonitis or gastritis and central nervous system disturbances, including rabies and nervous acetonemia, are also causes of pica.

The type of pica may be defined as follows: **osteophagia** is the chewing of bones; **infantophagia** is the eating of young; **coprophagia** is the eating of feces. Other types include wood-eating in sheep, bark-eating, the eating of carrion and cannibalism. Salt hunger can result in coat-licking, leather-chewing, earth-eating and the drinking of urine. Urine drinking may also occur if the urine is mixed with palatable material such as silage effluent. Bark-eating is a common vice in horses, especially when their diet is lacking in fiber, e.g. when they are grazing irrigated pasture.

Cannibalism

Cannibalism may become an important problem in housed animals, particularly swine, which bite one another's tails, often resulting in severe local infections. Although some cases may be due to protein, iron or bulk deficiency in the diet, many seem to be the result of boredom in animals given insufficient space for exercise. A high ambient temperature and generally limited availability of food also appear to contribute. Male castrates are much more often affected than females and the bites are also much more severe in males. Provision of larger pens or a hanging object to play with, removal of incisor teeth and the avoidance of mixing animals of different sizes in the same pen are common control measures in pigs. In many instances only one pig in the pen has the habit and his removal may prevent further cases. One common measure that is guaranteed to be successful in terms of tail-biting is surgical removal of all tails with scissors during the first few days of life, when the needle teeth are removed. Unfortunately the cannibalistic tendency may then be transferred to ears. As in all types of pica, the habit may survive the correction of the causative factor.

Infantophagia

Infantophagia can be important in pigs in two circumstances. In intensively housed sows, especially young gilts, hysterical savaging of each pig as it is born can cause heavy losses. When sows are grazed and housed at high density on pasture it is not uncommon to find 'cannibal' sows who protect their own litters but attack the young pigs of other sows. This diagnosis should be considered when there are unexplained disappearances of young pigs.

Significance of pica

Pica may have serious consequences: cannibalism may be the cause of many deaths; poisonings, particularly lead poisoning and botulism, are common sequelae; foreign bodies lodging in the alimentary tract or accumulations of wool, fiber or sand may cause obstruction; perforation of the esophagus or stomach may result from the ingestion of sharp foreign bodies; grazing time is often reduced and livestock may wander away from normal grazing. In many cases the actual cause of the pica cannot be determined and corrective measures may have to be prescribed on a basis of trial and error.

STARVATION

Complete deprivation of food causes rapid depletion of glycogen stores and a changeover in metabolism to fat and protein. In the early stages there is hunger, increase in muscle power and endurance, and a loss of body weight. In sheep there is often a depression of serum calcium levels sufficient to cause clinical hypocalcemia. The development of ketosis and acidosis follows the increased fat utilization. A marked reduction in feed intake in pony mares in late pregnancy is often a precursor of hyperlipemia, a highly fatal disease discussed in Chapter 28 on metabolic diseases. The most pronounced biochemical change in ponies occurring as a result of experimental food deprivation is a lipemia, which reaches a peak by the eighth day of fasting but quickly returns to normal when feeding is resumed. This degree of change in blood lipids appears to be a characteristic of ponies and horses; it is much higher than occurs in pigs.

In lactating cows, a short period of starvation results in depression of plasma glucose and an increase in plasma lipid concentrations. Milk yield falls by 70%. On refeeding most levels return to normal in 5 days but blood lipid and milk yield may take as long as 49 days to recover to normal levels. In horses, fecal output falls to zero at day 4 and water intake is virtually nil from that time on, but urine volume is maintained. In spite of the apparent water imbalance there is no appreciable dehydration, plasma protein levels and PCV staying at normal levels. A significant loss of skin turgor (increase in skin tenting) due to the disappearance of subcutaneous fat as cachexia develops may occur. Muscular power and activity decrease and the loss of body weight may reach as high as 50–60%. The metabolic rate falls and is accompanied by a slowing of the heart and a reduction in stroke volume, amplitude of the pulse and blood pressure. The circulation is normal as indicated by mucosal color and capillary refill.

In the final stages, when fat stores are depleted, massive protein mobilization occurs and a premortal rise in total urinary nitrogen is observed, whereas blood and urine ketones are likely to diminish from their previous high level. Great weakness of skeletal and cardiac musculature is also present in the terminal stages and death is due to circulatory failure. During the period of fat utilization there is a considerable reduction in the ability of tissues to utilize glucose and its administration in large amounts is followed by glycosuria. In such circumstances readily assimilated carbohydrates and proteins should be given in small quantities at frequent intervals but fatty foods may exacerbate the existing ketosis. Diets for animals that have been through a period of great nutritional stress because of deprivation of food or because of illness are described below under inanition.

Starvation of farm livestock is an animal welfare issue with economic and ethical considerations. When starving animals are identified by a neighboring farmer or veterinarian they are commonly reported to the appropriate authorities, which may be provincial or state appointed inspectors (animal care officers) who have the authority to take appropriate action. The animals are examined and corrective action is taken, including possession of the animals and relocating them to a commercial feeding facility.[1] Predicting survival of starved animals is a major challenge. Economics becomes an important aspect because the financial costs of stabilizing a group of starved horses may exceed their free market price. Responsible management of chronically starved commercial animals should include options for immediate euthanasia. Ethical considerations include deciding if certain severely starved animals should be euthanized. In some cases, enforcement officers may be reluctant to recommend mass euthanasia of otherwise healthy horses based on personal aversion.[1]

Chronically starved horses lose body weight, become weak and their body condition score may decline to below 2 on the basis of 1–9, and death is common, especially during cold weather.[1] Chronically starved horses frequently respond poorly to refeeding. About 20% of severely malnourished horses can be expected to die in spite of attempts at refeeding.[2] Recovery of severely malnourished horses to an average body condition score may require 6–10 months.[3]

INANITION (MALNUTRITION)

Incomplete starvation – inanition or malnutrition – is a more common field condition than complete starvation. The diet is insufficient in quantity; all essential nutrients are present but in suboptimal

amounts. The condition is compatible with life, and in general the same pattern of metabolic change occurs as in complete starvation but to a lesser degree. Thus ketosis, loss of body weight and muscular power and a fall in metabolic rate occur. As a result of the reduction in metabolic activity there is a fall in body temperature and respiratory and heart rates. In addition there is mental depression, anestrus in cows but not ewes, and increased susceptibility to infection. This increased susceptibility to infection that occurs in some cases of malnutrition cannot be accepted as a general rule. In the present state of knowledge it can only be said that '*some* nutritional influences affect resistance to *some* forms of infection'.

A significantly reduced food intake also increases susceptibility to some poisons, and this has been related to the effects of starvation on hepatic function. In ruminants, the effects of starvation on the activity of liver enzymes is delayed compared to the effects in monogastric animals, due apparently to the ability of the ruminal store of feed to cushion the effect of starvation for some days. The most striking effect of short-term malnutrition in sheep and cattle compared to rats was the very rapid and large accumulation of neutral fat in hepatocytes. If there is a relative lack of dietary protein over a long period of time, anasarca occurs, particularly in the intermandibular space.

Malnutrition makes a significant contribution to a number of quasi-specific diseases, 'weaner ill-thrift' and 'thin sow syndrome' among them, and these are dealt with elsewhere.

Controlled malnutrition in the form of providing submaintenance diets to animals during periods of severe feed shortage is now a nutritional exercise with an extensive supporting literature. For pastured animals it is a fact of economic life that significant loss of body weight is planned and tolerated for some parts of each year because the well-known phenomenon of compensatory growth enables the animal to make up the lost weight, with no disadvantage, during the times of plenty. Animals fed on submaintenance diets undergo metabolic changes reflected in blood and tissue values as well as the more significant changes in weight. Experimental restriction of feed intake to 65% of normal levels in nonlactating, nonpregnant heifers does not cause significant falls in serum calcium and phosphorus levels, nor in plasma glutamic oxaloacetic transaminase (GOT), aspartate transferase (AST), lactate dehydrogenase (LDH) or creatine phosphokinase (CPK) activities. Serum alkaline phosphatase (AP) activity was also maintained. In sheep that are losing weight because of undernutrition there is a significant decrease in plasma creatinine concentration.

Experimental feed restriction, followed by fasting, followed by ad libitum access to feed, such as might occur in nature, had no serious ill-effects on goats. The goats lost weight significantly but did not overeat on being allowed access to feed.

A deficiency of one or more specific dietary essentials also causes a form of partial starvation and is dealt with in Chapter 30.

Outbreaks of incomplete starvation may occur in cattle, sheep and horses that are kept outdoors during the cold winter months in regions of the northern hemisphere. The feed usually consists of poor-quality grass hay or cereal grain straw and no grain supplementation. During prolonged exposure to the cold environment the animals will increase their daily intake in an attempt to satisfy maintenance requirements and, in cattle, abomasal impaction with a high case mortality may occur. Animals affected with severe inanition are usually weak and recumbent and may or may not eat when offered a palatable feed.

Malnutrition and starvation may occur in calves under 1 month that are fed poor-quality milk replacers containing excessive quantities of nonmilk carbohydrates and proteins. The diet is not well digested by young calves and chronic diarrhea and gradual malnutrition occur. Affected calves recover quickly when fed cows' whole milk for several days. At necropsy there is a marked reduction in muscle mass, lack of depot fat and serious atrophy of fat. Starvation may also occur in beef calves sucking poorly nourished heifer dams with an insufficient supply of milk. The mortality will be high during cold weather when the maintenance requirements are increased. Affected calves will initially suck vigorously and persistently, they will attempt to eat dry feed, drink surface water and urine and bawl for several hours. Eventually they lie in sternal recumbency with their head and neck turned into their flanks and die quietly. The response to therapy is usually unsatisfactory and the case fatality rate is high. The convalescence period in survivors is prolonged and treatment is usually uneconomic. Affected animals must be brought indoors and kept warm and well bedded during treatment and realimentation. Initially, fluid therapy using balanced electrolyte solutions containing glucose and amino acids may be necessary to restore the animal's strength and appetite. This is followed by the provision of controlled amounts of a highly palatable digestible diet. High-quality legume hay is excellent, small amounts of ground grain are of value and the daily administration of a multiple B vitamin and mineral mixture will replenish those lost during inanition. Skim-milk powder is an excellent source of carbohydrate and protein for young animals that have been partially starved. Adult animals cannot digest large quantities of milk powder because of the relative lack of the appropriate digestive enzymes.

Horses that have been ill with a poor appetite should be tempted with green grass first, and failing that tried with good-quality hay – preferably alfalfa. It is best to dilute it with good grass hay to begin with, and increase the mix to 100% legume hay over a week. An average horse will require 1.5–2 kg BW/day. Grain can be added, mixed with molasses or as a mash. Low-fiber diets are recommended to ensure maximum digestibility. A supplement of B vitamins may be advantageous until full appetite and intake are regained. Horses with broken jaws or that are unable to eat at all for some reason can be allowed to go without food for 3 days, but beyond that time they should be fed by stomach tube. A suitable ration is:

- Electrolyte mixture (NaCl, 10 g; $NaHCO_3$, 15 g; KCl, 75 g; K_2HPO_4, 60 g; $CaCl_2$, 45 g; MgO, 24 g) **210 g**
- Water **21 L**
- Dextrose, increased from 300 g/d in 7 days to **900 g**
- Dehydrated cottage cheese, increased from 300 g/day in 7 days to **900 g**

The ration is divided into two or three equal amounts and fed during one day. Adult horses that are weak and recumbent may be supported in a sling to avoid decubitus ulceration and other secondary complications associated with prolonged recumbency.

THIRST

Thirst is an increased desire for water manifested by excessive water intake (polydipsia). There are two important causes of thirst: dryness of the pharyngeal and oral mucosae increases the desire for water, irrespective of the water status of body tissues; in addition, cellular dehydration due to a rise in blood osmotic pressure causes increased thirst. Specific observations in ponies have shown that water intake is increased in response to either an increase in the osmotic pressure of tissue fluid or a decrease in the volume of their body fluids.

Cellular dehydration occurs commonly in many cases of dehydration due to

vomiting, diarrhea, polyuria and excessive sweating. Increased thirst in early fever is due to changes in cell colloids leading to increased water retention. A marked polydipsia and polyuria occur in salt deficiency in lactating dairy cattle, in addition to weight loss, a fall in milk production and salt hunger. Salivary sodium levels are best used for diagnosis. A similar syndrome occurs in the 'thin sow syndrome'.

In humans, several other factors appear to exert some effect on water intake: a deficiency of potassium and an excess of calcium in tissue fluid both increase thirst; an increased thirst also occurs in uremia irrespective of the body's state of hydration. It has been suggested that these chemical factors may cause direct stimulation of the thirst center in the hypothalamus. Clinically, diabetes insipidus produces by far the most exaggerated polydipsia.

The clinical syndrome produced by water deprivation is not well defined. Animals supplied with saline water will drink it with reluctance and, if the salinity is sufficiently great, die of salt poisoning. Cattle at pasture that are totally deprived of water usually become quite excited and are likely to knock down fences and destroy watering points in their frenzy. On examination they exhibit a hollow abdomen, sunken eyes and the other signs of dehydration. There is excitability with trembling and slight frothing at the mouth. The gait is stiff and uncoordinated and recumbency follows. Abortion of decomposed calves, with dystocia due to failure of the cervix to dilate, may occur for some time after thirst has been relieved and cause death in survivors. At necropsy there is extensive liquefaction of fat deposits, dehydration and early fetal death in pregnant cows.

Experimental water deprivation has been recorded in camels and lactating and nonlactating dairy cows. In camels death occurred on the seventh to ninth day of total deprivation; body weight loss was about 25%. Lactating cows allowed access to only 50% of their regular water supply become very aggressive about the water trough, spend more time near it and lie down less. After 4 days milk yield is depressed to 74% and body weight to 86% of original figures. There is a significant increase in serum osmolality with increased concentrations of urea, sodium, total protein and copper. The PCV is increased, as are activities of creatinine kinase and serum AST. With complete deprivation for 72 hours, the changes are similar but there are surprisingly few clinical signs at that time. The composition of the milk does not change markedly and blood levels return to normal in 48 hours. After deprivation of half of their water intake, cattle reduced their water loss by all routes, but plasma and total blood volumes were unchanged.

Sheep, even pregnant ewes, are capable of surviving even though access to water is limited to only once each 72 hours, but there is a significant loss (26%) of body weight. Deprivation of water that allows access to water only once every 96 hours is not compatible with maintaining the pregnancy.

Weight loss or failure to gain weight (ill-thrift)

This section is concerned with the syndrome of weight loss in the presence of an adequate food supply and a normal appetite. In the absence of any primary disease, an animal or group of animals that presents with this as the problem is a major diagnostic dilemma. Several poorly identified diseases in this category are 'weaner ill-thrift', 'thin sow syndrome', 'thin ewe syndrome', 'weak calf syndrome' (see Ch. 36).

Errors by the owner in the estimation of body weight can lead to inadequate feeding if the ration is based on the requirements needed for growth and maintenance per unit of body weight. Scales are rarely available and estimations by weight-bands are generally inaccurate and subject to too much variability. A reasonably satisfactory alternative used in cattle, sheep and horses is a body condition score estimated on the basis of the amount of body covering of muscle, fat and connective tissue.

Detailed below is a checklist of causes that should be considered when an animal has a weight loss problem in the absence of signs indicative of a primary wasting disease.

NUTRITIONAL CAUSES

'Hobby farm malnutrition' is a surprisingly common cause, especially in companion horses. Inexperienced owners keep their animals where they are not able to graze pasture and are entirely dependent on stored feed, but underfeed for economy's sake. A knowledge of the animals' needs and of the approximate energy and protein values of feeds are necessary to prepare an appropriate ration. In a hospital situation any horse presented with a weight loss problem and without a potential diagnosis on first examination should be weighed, fed an energy-rich diet ad libitum for 4 days, then re-weighed. A horse that has previously been underfed will gain 3–5 kg in weight per day.

The feed must be inspected. Mature meadow hay may be efficient only as a filler, and poorly filled oat grain may be very poorly nutritive on a weight basis. Gentle animals that are fed in a group with others may be physically prevented from getting a fair share of available feed, especially if **trough space** is inadequate.

This problem is also common when urban people try to raise a few veal calves or sheep to help defray the costs of their rural acreage. It is common in these circumstances to equate rough meadow grass with proper nutrition for young or pregnant ruminants.

Other considerations are as follows:

- Diets that are inadequate in total energy because they cannot replace the energy loss caused by the animal's level of production can be important causes of weight loss in heavy-producing animals. This subject is discussed under the heading of production disease. An example is acetonemia of high-producing cows in which body stores of fat and protein are raided to repair the energy deficiency of the diet
- Malnutrition as a result of a ration that is deficient in an essential trace element is unusual in the management situation being discussed. A nutritional deficiency of cobalt does cause weight loss in ruminants but is likely to have an area effect rather than cause weight loss in single animals. Copper, salt, zinc, potassium, selenium, phosphorus, calcium and vitamin D deficiencies are also in this category. Experimental nutritional deficiencies of riboflavin, nicotinic acid, pyridoxine and pantothenic acid in calves and pigs can also be characterized by ill-thrift
- Inadequate intake of an adequate supply of feed is dealt with under diseases of the mouth and pharynx and is not repeated here, but it is emphasized that the first place for a clinician to look in a thin animal is its mouth. The owner may have forgotten just how old the animal is and one often finds a cow without any incisor teeth attempting to survive on pasture
- Other factors that reduce an animal's food intake when it is available in adequate amounts include anxiety, the excitement of estrus, new surroundings, loss of newborn, bad weather, tick or other insect worry and abomasal displacement.

EXCESSIVE LOSS OF PROTEIN AND CARBOHYDRATES

- **Glucose loss in the urine** in diabetes mellitus or chronic renal disease, the former indicated by hyperglycemia and both by glycosuria, are obvious examples of weight loss as a result of excessive metabolic loss of energy
- **Protein loss in the feces**. Cases of protein-losing gastroenteropathy are unusual and are difficult to identify without access to a radioactive isotope laboratory. The loss may occur through an ulcerative lesion, via a generalized vascular discontinuity or by exudation through intact mucosa as a result of hydrostatic pressure in blood vessels, e.g. in verminous aneurysm, or lymphatics in cases of lymphangiectasia of the intestine. The identification of a neoplasm (lymphosarcoma or intestinal or gastric adenocarcinoma are the usual ones) or of granulomatous enteritis is not possible without laparotomy and biopsy of the alimentary segment. One is usually led to the possibility of this as a diagnosis by either a low serum total protein or low albumin level in a normal total protein level, and in the absence of other protein loss as set out below
- **Proteinuria** for a lengthy period can cause depletion of body protein stores, resulting in weight loss. Chronic glomerulonephritis is the usual cause. Examination of the urine should be part of every clinical examination of a patient, but is not commonly so in horses because of the difficulty of obtaining a specimen without recourse to catheterization. Moving the horse into a box stall with fresh straw, or the intravenous injection of furosemide, are possible methods when straightforward collection is not possible. The latter provides an abnormally dilute sample
- **Internal and external parasitoses** in which blood sucking is a significant pathogenetic mechanism can result in severe protein loss, as well as anemia per se.

FAULTY DIGESTION, ABSORPTION OR METABOLISM

Faulty digestion and absorption are commonly manifested by diarrhea, and diseases that have this effect are dealt with under the heading of malabsorption syndromes (see Enteriti). In grazing ruminants, the principal causes are the nematode worms *Ostertagia*, *Nematodirus*, *Trichostrongylus*, *Chabertia*, *Cooperia* and *Oesophagostomum* and the flukes *Fasciola* and *Paramphistomum*. In cattle there are, in addition, tuberculosis, coccidiosis, sarcosporidiosis and enzootic calcinosis. In sheep and goats there are Johne's disease, viral pneumonia without clinical pulmonary involvement, and hemonchosis. In horses there are strongylosis, habronemiasis and heavy infestations with botfly larvae. In pigs there are stephanuriasis, hyostrongylosis (including the 'thin sow syndrome'), infestation with *Macracanthorhynchus hirudinaceus*, and ascariasis. Gastrointestinal neoplasia must also be considered as a possible cause

- Chronic villous atrophy occurs most severely with intestinal parasitism or as a result of a viral infection
- Other lesions caused by parasitic invasion that affect digestion and absorption are gastric granuloma associated with *Habronema* spp. in horses and verminous arteritis, also in horses
- Abnormal physical function of the alimentary tract, as in vagus indigestion of cattle and grass sickness in horses, can be a potent cause of failure to absorb nutrients, but the syndrome is usually manifested by poor food intake and grossly abnormal feces
- Inadequate utilization of absorbed nutrients is a characteristic of chronic liver disease. It is usually distinguishable by a low serum albumin level, by liver function tests and by serum enzyme estimations. A clinical syndrome including edema, jaundice, photosensitization and weight loss is a common accompaniment
- Neoplasia in any organ. The metabolism of the body as a whole is often unbalanced by the presence of a neoplasm so that the animal wastes even though its food intake seems adequate
- Chronic infection, including specific diseases such as tuberculosis, sarcocystosis, East Coast fever, trypanosomiasis (nagana), maedi-visna, caprine arthritis–encephalitis, enzootic pneumonia of swine and nonspecific infections such as atrophic rhinitis of pigs, abscess, empyema and chronic peritonitis have the effect of reducing metabolic activity generally as well as reducing appetite. Both effects are the result of the toxemia caused by tissue breakdown and of toxins produced by the organisms present. Less well understood are the means by which systemic infections, e.g. equine infectious anemia, scrapie in sheep and other slow viruses, produce a state of weight loss progressing to emaciation
- Food refusal is a well-recognized syndrome in pigs, due in some cases to mycotoxins in the feed, and 'off feed effects' are similarly encountered in feedlot cattle on rations containing a large proportion of wheat grain
- Many diseases of other systems, e.g. congestive heart failure, are manifested by weight loss because of inadequate oxygenation of tissues.

Determination of the **specific cause of weight loss in an individual animal** depends first on differentiation into **one of the three major groups**:

- Nutritional causes, diagnosed by assessment of the animal's total food intake
- Protein or carbohydrate loss in the animal's excretions, diagnosed by clinicopathological laboratory tests
- Faulty absorption of the food ingested, diagnosed by tests of digestion as set out in Chapter 5.

Shortfalls in performance

The present-day emphasis on the need for economically efficient performance by farm animals introduces another set of criteria, besides freedom from disease, to be taken into consideration when deciding an animal's future. The same comment applies, and much more importantly, when a herd's productivity is being assessed. This is usually done by comparing the subject herd's performances to that of peer herds, or animals in similar environmental and management conditions.

It is usual to use the production indexes that are the essential outputs of the particular enterprise as the criteria of productivity. Thus, in dairy herds the criteria could be:

- Milk or butterfat production per cow per lactation (liters per cow or liters per hectare)
- Reproductive efficiency as mean intercalving interval
- Percentage calf survival to 1 year of age
- Longevity as percentage mortality per year or average age of cows in herd plus culling rate per year
- The culling rate needs to differentiate between sale because of disease or poor production and sale as a productive animal
- Acceptability of product at sale – as indicated by bulk tank milk somatic

cell count, rejection of milk because of poor-quality, low-fat content, low solids-not-fat content.

If it is decided that performance falls too far short of the target, an investigation is warranted. Some targets for productivity in each of the animal industries are available, but they vary a great deal between countries depending on the levels of agriculture practiced and the standards of performance expected. For this reason, they are not set down here; nor is the degree of shortfall from the target that is acceptable – this depends heavily on the risk aversion or acceptability in the industry in that country. For example, if the enterprise is heavily capitalized by high-cost housing and land, the standard of performance would be expected to be higher than in a more exploitative situation where cattle are pastured all year. In the latter, a reasonable flexibility could be included in the assessment of productivity by permitting it to fall within the scope of 2 SD of the mean productivity established by peer herds.

If it is decided that performance is below permissible standards an investigation should be conducted and should include the following groups of possible causes:

- Nutrition – its adequacy in terms of energy, protein, minerals, vitamins and water
- Inheritance – the genetic background of the herd and the quality of its heritable performance
- Accommodation – to include protection from environmental stress by buildings for housed animals and terrain and tree cover for pastured animals; also consideration of population density as affecting access to feed, water and bedding areas
- General managerial expertise – the degree of its application to the individual flock or herd. This is difficult to assess and then only indirectly, e.g. the efficiency of heat detection, achievement of planned calving pattern
- Disease wastage – as clinical disease or, more particularly, subclinical disease. The latter may include such things as quarter infection rate as an index of mastitis, fecal egg counts relative to parasite burden, metabolic profile relative to metabolic disease prevalence rate, etc.

These investigations tend to require special techniques in addition to the clinical examination of individual animals. They are mostly self-evident, but attention is drawn to the section on examination of a herd or flock in Chapter 1. It will be apparent that there is a great deal of merit in having herds and flocks under constant surveillance for productivity and freedom from disease, as is practiced in modern herd health programs. Monitoring performance and comparing it with targets is the basis of that system.

The specific syndromes that fall within this category of disease, and which are dealt with elsewhere in this book are ill-thrift of weaner sheep, 'thin sow syndrome', 'weak calf syndrome', 'poor performance syndrome' of horses, 'low butterfat syndromes' and 'summer slump' of milk cows. Two performance shortfalls encountered commonly by field veterinarians are ill-thrift in all species and poor performance syndrome in horses, presented in the two sections following. More specialized problems are dealt with in *Herd health* (details below).

Physical exercise and associated disorders

EXERCISE PHYSIOLOGY

The act of performing physical work requires expenditure of energy at rates above the resting metabolic rate. Increases in metabolic rate can be supported by anaerobic metabolism through the use of intramuscular adenosine triphosphate stores and conversion of glycogen or glucose to lactate for short periods of time. Ultimately, however, all energy is derived by aerobic metabolism and is limited by the rate of delivery of oxygen to tissue and its utilization in mitochondria. To support the increased energy expenditure required to perform work such as racing, carrying a rider or pulling a cart, the metabolic rate is increased. Increases in metabolic rate are supported by increases in oxygen delivery to tissue and carbon dioxide removal. Increased oxygen consumption is dependent upon an increase in oxygen delivery to tissues which is possible by increases in cardiac output, muscle blood flow and, in horses, an increase in hemoglobin concentration with a concomitant increase in the oxygen-carrying capacity of blood. The increased transport of oxygen from the air to the blood is accomplished principally by increases in respiratory rate and tidal volume. Factors that affect oxygen transport from the air to the mitochondria have the potential to impair performance. For instance, laryngeal hemiplegia reduces minute ventilation and exacerbates the normal exercise-associated hypoxemia in horses, atrial fibrillation decreases cardiac output and hence oxygen delivery to tissues and anemia reduces the oxygen-carrying capacity of the blood.

The increase in cardiac output with exercise of maximal intensity in horses is very large – horses have a cardiac output of about 75 (mL/min)/kg at rest and 750 (mL/min)/kg (300 L/min for a 400 kg horse) during maximal exercise. Associated with the increase in cardiac output are increases in right atrial, pulmonary arterial and aortic blood pressures. Systemic arterial blood pressure during exercise increases as the intensity of exercise increases with values for systolic, mean and diastolic pressures increasing from 115, 100 and 80 mmHg (15.3, 13.3 and 10.6 kPa) at rest to 205, 160 and 120 mmHg (27.3, 21.3 and 16kPa), respectively, during intense exercise.

Pulmonary artery pressure increases from a mean of approximately 25 mmHg (3.3 kPa) to almost 100 mmHg (13.3 kPa) during intense exercise. The increase in pulmonary artery pressure with exercise may contribute to exercise-induced pulmonary hemorrhage.

The increase in metabolic rate during exercise causes a marked increase in metabolic heat generation with a subsequent increase in body temperature. The increase in body temperature is dependent on the intensity and duration of exercise and the ability of the horse to dissipate heat from the body. Intense exercise of short duration is associated with marked increases in body temperature but such increases rarely cause disease. However, prolonged exercise of moderate intensity, especially if performed in hot and humid conditions, may be associated with rectal temperatures in excess of 42.5°C (108.5°F). Heat is dissipated primarily by evaporation of sweat from the skin surface. Sweating results in a loss of body water and electrolytes, including sodium, potassium, calcium and chloride. The size of these losses can be sufficient to cause dehydration and abnormalities of serum electrolyte concentrations and also impaired cardiovascular and thermoregulatory function.

Recovery from exercise is influenced by the fitness of the individual, with fitter horses recovering more rapidly, the intensity and duration of the exercise bout, and activity during recovery. Horses allowed to walk after a bout of intense exercise recuperate more quickly than do horses that are not allowed to walk. Recovery is delayed if the horse cannot drink to replenish body water or in hot and humid conditions.

POOR RACING PERFORMANCE AND EXERCISE INTOLERANCE IN HORSES

The definition of poor racing performance is difficult. Horses that have a proven record of performing well and that then fail to perform at their previous level are readily apparent and a physical cause of the reduction in performance can often be identified. More difficult are the horses that do not have a history of satisfactory performance and are best labeled as 'failure to perform to expectation'. Horses in this group may indeed have a clinical abnormality but commonly the reason is lack of innate ability or inadequate training – both causes that must be raised with the owner and trainer carefully and tactfully, and only after a thorough examination of the horse.

Exercise intolerance in race horses is best defined as the inability to race at speeds previously attained by that horse or attained by peers. In its most extreme form exercise intolerance is evident as failure to complete the race, whereas its mildest form is evident as a slight decrement in performance, such as losing a race by several lengths or one or two seconds, or failure to perform to expectation.

APPROACH TO THE HORSE WITH EXERCISE INTOLERANCE

Horses with a history of a recent decrement in performance or those that are not performing to expectation should be examined in a systematic fashion.

History

A detailed history should be collected that focuses on documenting the reduction in performance, its time course and the presence and evolution of any clinical signs. This can be accomplished by asking the following questions of the owner or trainer:

- **What evidence is there of poor performance?** This query should focus on providing objective evidence of a reduction in performance through examination of race times or results. This also allows the severity of the reduction in performance to be documented
- **What is the horse's training schedule?** The training regimen should be appropriate for the horse's level of competition
- **Describe the horse's exercise intolerance.** Does it start the race strongly and 'fade' in the last part of the race, or is it unable to maintain a suitable speed for the complete race? Is the horse slow to recover its normal respiratory rate after exercise? Can it sweat? Does it consistently veer or 'pull' towards one side?
- **Is there any history of illness in this horse or other horses in the same stable or at the race track?** Has the horse had a fever or been inappetent? Is the horse on any medication? Specific attention should be paid to any history of respiratory disease
- **Does the horse make an unusual noise associated with respiration when running?** Horses with upper airway obstructions almost always make an abnormal noise during exercise
- **Does the horse cough either at rest, during or after exercise?** Coughing may be an indication of lower respiratory tract disease
- **Has the horse ever had blood at the nostrils after exercise or has it been diagnosed as having exercise-induced pulmonary hemorrhage?**
- **Is the horse lame?** Does it ever show signs of muscle stiffness or abnormal gait?
- **What is the history of anthelmintic administration?**

Clinical examination

A thorough clinical examination should be performed. The physical examination should include a detailed examination of the musculoskeletal, cardiovascular and respiratory systems and may include the collection of samples of body fluids for laboratory analysis. Ancillary testing, such as radiography, endoscopy, nuclear scintigraphy and stress testing, may be available at larger centers.

The horse should be examined at rest for evidence of musculoskeletal disease and then should be observed at the walk and trot for signs of lameness. Subtle lameness that is sufficient to impair performance may be difficult to detect in a horse slowly trotting, and other examinations, such as observation during and after high-speed running at a track, radiography and nuclear scintigraphy, may be necessary. The major muscle groups, including the quadriceps, should be palpated for firmness or pain suggestive of rhabdomyolysis.

The heart should be auscultated carefully for evidence of valvular incompetence or arrhythmias. Mild (grade II–III/VI) systolic ejection murmurs heard loudest on the left thorax are common in fit race horses and should not be mistaken for evidence of valvular disease. Electrocardiography to diagnose abnormalities of rhythm or echocardiography to demonstrate the extent of valvular lesions are indicated if abnormalities are detected on cardiac auscultation.

The respiratory system should be carefully examined by auscultation of the thorax in a quiet area. The thorax should be auscultated initially with the horse at rest; if no abnormalities are detected the horse's tidal volume should be increased by rebreathing air from a large bag held over its nose, or by exercise. Radiography of the thorax may demonstrate changes consistent with exercise-induced pulmonary hemorrhage, recurrent airway obstruction or pneumonia. Aspirates of tracheal fluid or bronchoalveolar lavage fluid should be examined for evidence of inflammation or hemorrhage. The upper respiratory tract, including pharynx, larynx, trachea and carina, should be examined with a flexible endoscope.

Laboratory testing

Collection of blood and urine samples for laboratory analysis are indicated if specific abnormalities are detected on physical examination. For instance, exercise-associated rhabdomyolysis can be confirmed by measurement of serum creatine kinase and aspartate aminotransferase activity. However, blood samples are often submitted for analysis as a matter of routine. Specific attention should be paid to the hemogram, in particular the white blood cell count, for evidence of inflammation and the hematocrit for evidence of anemia. Care should be taken to not assign minor abnormalities an undue significance until corroborating evidence is obtained. Tracheal or bronchoalveolar lavage fluid may provide evidence of lower respiratory tract disease. Examination of feces for helminth ova may demonstrate parasitism.

Exercise stress testing

Examination of horses during and after high-speed exercise on a treadmill is now routine in many referral centers. Values of a number of performance-related variables have been determined for Standardbred and Thoroughbred race horses, with better athletes having greater aerobic capacity. However, at this time the main use of high-speed exercise testing is detection of exercise-induced arrhythmia, such as paroxysmal ventricular tachycardia or atrial fibrillation, rhabdomyolysis and upper airway obstruction. Upper airway obstruction is a common cause of poor performance that can often be diagnosed by rhinolaryngoscopic examination of horses at rest or after brief nasal occlusion. However, some causes of obstruction are best diagnosed using rhinolaryngoscopy during exercise.

CAUSES OF EXERCISE INTOLERANCE OR POOR PERFORMANCE

Any disease that adversely affects the normal function of a horse has the potential to impair performance. Listed below are some common causes of exercise intolerance in race horses.

Musculoskeletal system

- Lameness is a common cause of poor performance. Subtle lameness may be difficult to detect but may be sufficient to cause a decrement in performance. Causes and diagnosis of lameness are discussed in textbooks on that topic and are not further covered here
- Rhabdomyolysis.

Cardiovascular system

Poor performance attributable to cardiovascular disease may be caused by:

- Atrial fibrillation, usually readily diagnosed by electrocardiographic examination. Paroxysmal atrial fibrillation induced by exercise that resolves soon after exercise ceases causes poor performance and is difficult to diagnose
- Ventricular arrhythmias
- Valvular incompetence, such as mitral or tricuspid regurgitation secondary to acquired or congenital disease. Endocarditis is rare in horses
- Congenital anomalies including ventricular septal defect
- Myocarditis or myocardial disease (rare)
- Aorto-iliac thrombosis.

Respiratory system

Upper airways (see Obstructive diseases of the equine larynx)

- Laryngeal hemiplegia
- Intermittent dorsal displacement of the soft palate
- Epiglottic entrapment
- Epiglottic hypoplasia
- Arytenoid chondritis
- Pharyngeal cysts
- Upper air obstruction associated with hyperkalemic periodic paralysis
- Guttural pouch empyema
- Retropharyngeal abscesses
- Redundant or flaccid alar folds.

Lower airways

- Pneumonia secondary to influenza virus or equine herpesvirus-1 or –4 infection
- Parasitic pneumonia due to *Dictyocaulus arnfieldi*
- Severe exercise-induced pulmonary hemorrhage
- Lower airway inflammatory disease and recurrent airway obstruction
- Granulomatous pneumonia.

Hematologic and biochemical abnormalities

Anemia

- Parasitism, especially caused by *Strongylus* sp. and cyathostomes
- Chronic disease, such as the presence of an abscess
- Equine infectious anemia
- Piroplasmosis
- Gastric ulceration (anemia is an unusual manifestation of this disease)
- Iron deficiency
- Administration of inhibitors of folic acid synthesis or prolonged oral administration of inactive folic acid
- Phenylbutazone toxicity
- Excessive phlebotomy
- Gastric squamous cell carcinoma
- Administration of recombinant human erythropoietin.

Hypoproteinemia

- Parasitism, especially caused by *Strongylus* sp. and cyathostomes
- Malnutrition, especially inadequate protein intake
- Protein losing enteropathy such as lymphosarcoma or granulomatous enteritis

Electrolyte abnormalities

- Hypokalemia and hyponatremia secondary to excessive loses in sweat and inadequate intake.

Nervous system disease

- Spinal ataxia caused by cervical compressive myelopathy (static or dynamic, equine protozoal myeloencephalitis, and equine degenerative myelopathy
- Sweeney
- Stringhalt.

Miscellaneous

- Hypothyroidism (very rare)
- Pituitary tumor (equine Cushing's disease
- Iatrogenic hypoadrenocorticism
- Hepatic disease of any cause, but beware of iron overload
- Renal disease
- Secondary nutritional hyperparathyroidism
- Malnutrition
- Performance-altering drug administration such as β-adrenergic antagonists or sedatives.

TREATMENT

Treatment should be directed towards correcting the underlying disease. Routine administration of hematinics to horses with a normal hemogram is unnecessary. If after careful and comprehensive examination an organic cause for the poor performance is not found, attention should be given to the horse's training program. Training programs for horses are described elsewhere (see below).

REVIEW LITERATURE

Hinchcliff KW, Kaneps AJ, Geor RJ. Equine sports medicine and surgery: basic and clinical sciences of the equine athlete. Edinburgh, UK: Elsevier Health Sciences 2004.

EXERCISE-ASSOCIATED DISEASES

Many exercise-induced diseases are associated with specific activities. For instance, heat stroke and exhaustion are very rare in Standardbred and Thoroughbred horses raced over distances of up to 3 miles (5 km) but common in horses participating in endurance races (50–100 km) or the second day of three-day event competitions. Conversely, exercise-induced pulmonary hemorrhage occurs only in horses that race at high speed. The exercise-associated diseases exertional rhabdomyolysis, synchronous diaphragmatic flutter, hyperthermia and exercise-induced pulmonary hemorrhage are dealt with in other sections of this book.

EXHAUSTION

All physical work, if of sufficient intensity and duration, causes fatigue. The mechanisms underlying fatigue vary with the type of work or exercise performed. Thus fatigue in a race horse running 3 km at high speed has a different genesis from fatigue in an endurance horse that has run 100 km at low speed. Typically, Standardbred and Thoroughbred racehorses recovery quickly and exhaustion rarely occurs. However, horses performing endurance exercise require longer to recover, and the processes associated with fatigue may progress to the extent that recovery is delayed or impossible without treatment. The failure to recover and the clinical and clinicopathologic signs associated with this have been labeled 'exhausted horse syndrome'.

The exhausted horse syndrome is associated with endurance races, three-day eventing, trail riding and fox and bird hunting – all activities in which there is prolonged submaximal exercise. The likelihood of the disorder is increased in unfit horses or when horses are exercised in hot and humid conditions, especially if they are not accustomed to such conditions.[1]

Pathogenesis

The pathogenesis of exhaustion is complicated but probably involves depletion of body glycogen and electrolytes, especially sodium, chloride and potassium, hypovolemia due to large losses of water in sweat, hyperthermia and acid–base disturbances. Endurance exercise is associated with the production of large

amounts of heat, which are dissipated primarily by evaporation of sweat.[2] Approximately 11 L of sweat are lost each hour during submaximal exercise, and this loss causes a significant decline in total body water, sodium, potassium and chloride content and serum concentrations of these ions.[3] Loss of chloride causes a metabolic alkalosis. Hypovolemia impairs thermoregulation by reducing blood flow to the skin and probably results in a reduction in gastrointestinal blood flow contributing to intestinal ischemia and development of ileus.[4] Body temperature increases to dangerous levels (43°C, 109°F) and the horse cannot continue to exercise. If the exercise-induced abnormalities are sufficiently severe then the combination of hyperthermia and dehydration may initiate a cascade of events terminating in shock, multiple organ failure and death.[1]

Clinical signs

The clinical signs of the exhausted horse syndrome include failure to continue to exercise, depression, weakness, failure to eat and drink, delayed return of heart rate and rectal temperature to normal values, poor skin turgor and capillary refill time, a stiff stilted gait consistent with rhabdomyolysis, and decrease or absent borborygmi.[1] Urine is concentrated and the horse ceases to urinate.

Clinicopathologic examination reveals hemoconcentration, hypochloremia, hypokalemia and variable changes in serum sodium concentration. There is usually a metabolic alkalosis (increased blood bicarbonate concentration), although some severely affected horses will also have a metabolic acidosis associated with increased blood lactate concentration. Serum creatinine and urea nitrogen concentrations are increased because of dehydration and/or renal disease. Serum creatine kinase activity may be markedly increased in horses with rhabdomyolysis.

Treatment

Treatment consists of rapid restoration of hydration status, correction of electrolyte and acid–base abnormalities and reduction in body temperature. Fluid therapy is addressed in detail elsewhere. Suitable fluids for administration to exhausted horses are Ringer's solution, isotonic sodium chloride with added potassium chloride (10 mEq/L) and calcium gluconate (10–20 mL of 24% solution per liter), or lactated Ringer's solution. Theoretically, lactated Ringer's solution should not be given to horses with metabolic alkalosis, but clinical experience indicates its safety and efficacy.[1]

Horses should be aggressively cooled by application of cold water or water and ice. In spite of folk lore to the contrary, application of ice cold water to hyperthermic horses is not dangerous or associated with rhabdomyolysis.[5] NSAIDs, for pain relief and prophylaxis of the effects of endotoxemia, can be given when the horse is no longer hypovolemic.

Prevention

Prevention rests in ensuring that participating horses are adequately trained for the event and acclimated to the environmental conditions. Horses should be healthy, preferably as determined by a veterinary examination before the race, and should be monitored during the event for signs of excessive fatigue, dehydration or hyperthermia.

Diagnosis and care of recumbent adult horses

Diagnosis and management of adult horses that are recumbent can be challenging. The large size of adult horses, the variety of conditions that can cause recumbency, the difficulty in performing a thorough clinical examination and the need for prolonged and intensive care all present formidable obstacles to management of recumbent horses. Causes of prolonged (> 8 h) recumbency in horses are listed in Table 2.7. Other causes of acute recumbency of shorter duration are usually obvious on initial examination and include septic or hemorrhagic shock, such as occurs in horses with colic or internal or external hemorrhage.

EXAMINATION OF THE RECUMBENT HORSE

History

Careful questioning of the horse's attendants can reveal valuable information regarding the cause of recumbency. Causes such as observed trauma, foaling and excessive unaccustomed exercise are readily determined from the history. In addition to inquiries about the cause of the recumbency, estimates of the duration of recumbency should be obtained from the attendants. This can often be best elicited by asking when the horse was last observed to be standing. A history of recent illness, abnormal behavior or unusual use immediately before the horse became recumbent is useful. The horse's age, sex, breed and use should be determined. Information regarding management, vaccination and deworming status, feeding and health of other horses can be revealing. Outbreaks of recumbency suggest either an infectious (equine herpesvirus-1) or toxic (botulism, ionophore) cause. Questions should be directed toward discerning the cause of the horse's recumbency rather than collecting information.

Physical examination

Physical examination of recumbent horses is challenging but should be as complete as practical and safe. The examination should begin with a general assessment of the horse and its surroundings and can be directed at answering a series of questions:

- Are the surrounding conditions safe for the horse and people? Is the footing sound?
- Is there evidence of the horse struggling or thrashing?
- Has the horse defecated and urinated recently?
- Is there evidence of exposure to toxins or physical evidence of the reason for recumbency?

Examination of the horse should begin with measurement of heart rate, respiratory rate and temperature (rectal temperature might not be accurate if there is dilation of the anus), examination of mucous membranes and an assessment of its hydration, body condition and level of consciousness. The horse should be thoroughly examined for evidence of trauma. Although the examination should be complete, initial examination of cases for which the cause of recumbency is not immediately obvious should focus on the nervous and musculoskeletal systems.

- Is the horse alert and able to sit in sternal recumbency or is it unconscious and in lateral recumbency? Can the horse rise with assistance?
- Is the horse's mentation normal?
- Are there any spontaneous voluntary or involuntary movements?
- Can the horse eat and drink?
- Are the cranial nerves normal?
- Is there evidence of trauma to the head or neck?
- Is there evidence of paresis or paralysis? Are only the hind limbs involved or are both the hind limbs and forelimbs involved?
- Are the peripheral reflexes normal (withdrawal, patellar, cervicofacial, cutaneous, anal, penile)?

Table 2.7 Causes and diagnostic features of recumbency of more than 8 hours duration in adult horses

Cause	Clinical signs and diagnosis	Treatment	Prognosis and comments
Neurologic disease			
Botulism	Horse alert. Flaccid paralysis, dysphagia, weak corneal or palpebral reflex. Often multiple animals affected. Toxin isolation in mice	Administration of specific antitoxin or multivalent antitoxin. Supportive care	Can require prolonged treatment. Prognosis poor for recumbent horses
Tetanus	Horse alert. Rigid paralysis. Signs worsened by stimuli. Often history of recent wound and lack of vaccination	Tetanus antitoxin (IV or intrathecally). Penicillin. Wound debridement. edation (acepromazine, chloral hydrate). Minimize stimulation (dark, quiet stall)	Guarded prognosis
Trauma – vertebral	Alert horse. Signs depend on site of lesion. Can be difficult to detect vertebral fractures in adult horses. Radiography	None specific	Poor prognosis
Trauma – cranial	Unconscious or severely altered mentation. Seizures. Head wounds. Blood from ears and nostril. Imaging (radiography, CT, MRI)	Anti-inflammatory drugs including flunixin meglumine, phenylbutazone, corticosteroids. Drugs to reduce swelling (mannitol and hypertonic saline). Control of seizures (diazepam, midazolam, barbiturates). Heroic craniotomy	Very poor prognosis
Cervical vertebral instability	Alert horse. Acute-onset ataxia and recumbency. Young horse (< 4 years old). Radiography and myelography	Anti-inflammatory drugs. Rest. Surgical vertebral stabilization	Poor prognosis
Vestibular disease	Normal to depressed, depending on cause. Signs of vestibular disease include circling and falling to one side, head tilt and nystagmus. Diagnosis by endoscopic examination of guttural pouches, radiography of skull and examination of CSF	Antibiotics, anti-inflammatory disease. Surgical or medical treatment of guttural pouch disease	Poor to guarded prognosis
Equine herpesvirus-1 myoencephalopathy	Usually alert horse. Recumbency follows period of posterior ataxia with fecal and urinary incontinence. Fever in early stages of disease. CSF xanthochromic. Viral isolation or detection of virus by PCR. Serology. Often multiple horses affected	Supportive care	Guarded prognosis. Affected horses can be infectious
Arboviral encephalitis (Eastern, Western, West Nile, Japanese B	Alert horse or altered mentation, depending on the disease. CSF consistent with inflammation. Viral isolation or detection by PCR. Serology	Supportive care. Dexamethasone for West Nile encephalitis	Epidemiology is characteristic. Prognosis is poor for recumbent horses. Vaccines available
Migrating parasite larvae (Table 35.2)	Mentation depends on anatomic site of parasite. Eosinophils in CSF	Ivermectin 400 μm/kg orally. Corticosteroids	Sporadic disease
Neoplasia (melanoma, lymphosarcoma, cholesterol granuloma, Table 35.2)	Alert horse. Signs of spinal cord compression. Diagnosis by imaging (radiography, myelography, CT). CSF usually normal	No specific treatment	Hopeless prognosis
Equine motor neurone disease	Alert horse. Good appetite. Profound muscle weakness and atrophy. Prolonged periods of recumbency but usually able to stand when stimulated	Supportive care. Vitamin E	Guarded to poor prognosis. Lifelong disease
Equine protozoal myeloencephalitis	Variable mentation and signs of neurologic disease. Diagnosis based on neurologic examination and results of Western blot of CSF or serum	Antiprotozoal medications	Guarded to fair prognosis
Rabies	Variable mentation. Protean signs of neurologic disease. Important zoonosis. Diagnosis by immunofluorescent antibody testing of brain	No treatment. If suspected then appropriate barrier isolation measures must be instituted until the horse dies or recovers, or another diagnosis is confirmed	Rare cause of recumbency in horses
Postanesthetic myelopathy	Acute-onset posterior paresis evident on recovery from general anesthesia	Supportive care	Poor to hopeless prognosis

Table 2.7 *(Cont'd)* Causes and diagnostic features of recumbency of more than 8 hours duration in adult horses

Cause	Clinical signs and diagnosis	Treatment	Prognosis and comments
Musculoskeletal disease			
Acute rhabdomyolysis (exertional, atypical)	Alert horse. History of unaccustomed or strenuous exercise. Painful. Sweating. Firm painful muscles. Pigmenturia. High CK and AST in serum	Fluid diuresis. Pain control. Supportive care	Guarded to fair prognosis. Can recur. Can progress to acute renal failure
Laminitis	Alert horse. Assumes sternal recumbency easily. Bounding digital pulses. Pain on application of hoof tester to feet	Pain control. Corrective shoeing	Guarded to poor prognosis for long-term care
Fracture of long bone or pelvis	Horse usually able to stand on three legs. Bilateral fracture of femurs. Diagnosis by physical examination and radiography	Euthanasia	
Foaling paralysis (obturator nerve paresis)	Dystocia. Mare unable to stand after difficult foaling. Legs excessively abducted	Supportive care. Anti-inflammatory drugs. Sling horse	Guarded prognosis
Bilateral femoral nerve paresis	Occurs in horses suspended by the hind limbs during anesthesia	Supportive care	Guarded prognosis
Hyperkalemic periodic paralysis	Alert horse. Anxious. Muscle fasciculations. Muscle weakness. High serum potassium concentration. Electromyography. Unusual for recumbency to persist for < 1–2 h. Diagnosis by detection of appropriate genome	Administration of dextrose or calcium solutions. Prevention by administration of acetazolamide, feeding low K^+ diet and selective breeding	Guarded to good prognosis. Lifelong care needed
Environmental			
Heat stress/exhaustion	Depressed mentation. Compatible history of exercise in hot and humid conditions or exposure to extreme heat. Hyperthermia	Rapid cooling. Administration of fluids	Guarded to poor prognosis. Death often associated with DIC
Hypothermia[1]	Depressed mentation. History of exposure to extreme cold. Hypothermia	Warming. Prolonged care necessary	Guarded to poor prognosis
Lightning strike	Horses at pasture. History of electrical storm activity. One or more horses can be affected. There can be evidence of burns, fractures of long bones or the axial skeleton, or vestibular disease	Supportive care. Euthanasia for animals with severe disease	
Gunshot wounds	Horses at pasture. Often during hunting season. Can be malicious. Physical examination variable. Entry hole, and exit hole, can be difficult to identify	Supportive care, depending on site of wound	Horses that have been shot and are recumbent have a poor prognosis
Metabolic			
Starvation, inanition	Alert horse. Grade 1 or 2 of 9 body condition score	Careful refeeding and supportive care	Poor to fair prognosis
Hypocalcemia, hyponatremia	Depressed mentation. Seizures. Confirmed by measurement of serum electrolyte concentrations. Unusual cause of recumbency in adult horses	Correction of electrolyte deficit. Gradual correction of hyponatremia	Good prognosis
Liver disease	Depressed, seizures, head pressing. Jaundice. Elevated serum concentrations of bilirubin, ammonia, and bile acids and increased activity of gammaglutamyl transpeptidase, sorbitol dehydrogenase	Supportive care. Provision of hydration and nutrition. Correction of hypoglycemia. Administration of lactulose	Poor prognosis. History of exposure to hepatotoxins
Hypoglycemia	Seizures. Measurement of blood glucose concentrations. Iatrogenic or malicious, associated with insulin administration. Unusual cause in adult horses	Administration of glucose intravenously	
Water deprivation	Variable mentation from normal to seizures. Associated with inadequate water intake (e.g. broken bore or dry tank supplying horses at pasture)	Judicious rehydration. Provision of unrestricted access to water can result in water intoxication	Cause is usually obvious (lack of access to water). Guarded prognosis
Senile collapse	Alert horse. Old horse. History of progressive weakness. No other causes of recumbency identified	Supportive care. Correction of metabolic abnormalities. Provision of good-quality nutrition	Poor prognosis
Intoxications			
Ionophores (monensin, salinomycin, etc.;	Alert. Acute-onset colic and muscle weakness. Recumbency. Diagnosis is based on history of exposure and measurement of drug concentrations in blood or tissues, and feed	Supportive. No specific treatment	Poor to guarded. Horses surviving the acute episode can have exercise intolerance due to persisting myocardial disease

AST, aspartate transferase; CK, creatine kinase; CSF, cerebrospinal fluid; CT, computed tomography; DIC, disseminated intravascular coagulation; IV, intravenously; MRI, magnetic resonance imaging; PCR, polymerase chain reaction.

- Is cutaneous sensation present in all regions? If not, what are the anatomic boundaries of desensitized areas?
- Is the position of the limbs normal? Is there evidence of crepitus, swelling or unusual shape of the limbs or axial skeleton?
- Are the horse's feet normal? Does it have laminitis? What is the response to application of hoof testers?
- Are abnormalities detected on rectal examination (fractured pelvis, distended bladder, fecal retention, pregnancy), provided that it is safe to perform one?

Other body systems should be evaluated as indicated or necessary. The heart and lungs should be auscultated, although detecting abnormal lung sounds in a recumbent horse is difficult. The horse should be rolled so that a complete examination can be performed. Assisting the horse to stand using a rope tied to the tail and thrown over a rafter, or preferably using a sling, can be useful in assessing the severity of the horse's illness (can it stand at all?) and in facilitating a complete physical examination. If there is a suspicion that the horse has colic a nasogastric tube should be placed to check for accumulation of liquid gastric contents, a rectal examination performed and peritoneal fluid collected.

Ancillary diagnostic testing includes radiography of limbs and/or axial spine as indicated by the history or physical examination; myelography if a compressive lesion of the cervical spinal cord is suspected; endoscopic examination of the pharynx and guttural pouches (especially in horses with a history of falling, see Rupture of the longus capitus muscle, ultrasonography of the chest and abdomen; collection of cerebrospinal fluid; and electromyography.

Hematologic abnormalities are sometimes reflective of the causative disease. Serum **biochemical abnormalities** are reflective of the causative disease and in addition are influenced by muscle damage caused by the horse being recumbent (increased creatine kinase and aspartate aminotransferase activity), inappetent (increased total and indirect bilirubin, and triglyceride concentrations), and unable to drink or gain access to water (increased serum urea nitrogen, creatinine, sodium, chloride, total protein and albumin concentrations). Cerebrospinal fluid is reflective of any inciting disease but is usually normal.

MANAGEMENT AND CARE

The principles of care are treatment of the primary disease, prevention of further illness or injury, assisting the horse to stand, and provision of optimal nutrition and hydration.

Treatment of the primary disease is covered in other sections of this book. Similarly, maintenance of hydration and electrolyte status is covered elsewhere. Maintenance of normal hydration is sometimes problematic in recumbent horses because of limited access to water and unwillingness to drink. Provision of fresh, palatable water is essential. Intravenous or enteral (nasogastric intubation) administration of fluids and electrolyte solutions might be necessary in some recumbent horses, especially early in their illness.

Horses with diseases that cause recumbency often have problems with fecal and urinary incontinence or retention. Catheterization of the urinary bladder might be necessary to relieve distension in horses with neurogenic upper motor bladder or lower motor bladder dysfunction, or in male horses that are reluctant to urinate when recumbent. Catheterization of the bladder is often repeated. To minimize the risk of iatrogenic cystitis, the procedure should be performed aseptically. Administration of bethanechol might increase detrusor muscle tone and aid urination, and phenoxybenzamine (0.5 mg/kg intravenously over 15 min) might decrease sphincter tone in horses with upper motor neurone bladder.

Horses that can eat should be fed a balanced, palatable and nutritious diet. Tempting horses with reduced appetite with treats such as apples, carrots and horse treats might stimulate appetite for hay and grain. Horses that are unable to eat should be fed through a nasogastric tube. Slurries of alfalfa pellets or commercial diets can be administered through nasogastric tubes. The maintenance needs of a sedentary 425 kg horse are approximately 15–18 Mcal/d. The maintenance needs of a recumbent horse are unknown, but are probably less than that of normal sedentary horses.

COMPLICATIONS – PREVENTION

A major challenge in managing recumbent horses is preventing further injury. Recumbent horses often make repeated efforts to stand, which, while encouraging to all involved, can result in further injury. Horses attempting to stand can injure their head, especially the periorbital regions, and skin over bony prominences such as over the wing of the ilium. Minimizing further injury is achieved by use of a sling or tail rope to assist horses to stand, housing in a padded stall with deep, soft bedding (although this can interfere with the horse's ability to stand), and protection of the head and distal limbs with a helmet and bandages, respectively. Recumbent horses kept in well-grassed pasture often do well and have minimal self-inflicted trauma.

Decubital ulcers occur over pressure points such as the wing of the ilium, point of the shoulder and zygomatic arch, and can become severe. Recumbent horses that paddle can abrade the skin over limb joints with subsequent increased risk of septic arthritis. Bandages, helmets, ointments such as silver sulfadiazine paste, and soft bedding minimize but do not eliminate these abrasions. Recumbent horses that cannot or do not voluntarily move from side to side should be rolled every 2–4 hours.

Peripheral pressure neuropathy can occur in recumbent horses. The radial nerve and facial nerve are most often affected. Prevention is achieved by use of padded bedding, slings, frequent rolling and a helmet.

Recumbent horses can sustain muscle damage from pressure on large muscle groups. For large or well-muscled horses this can result in large increases in serum creatine kinase activity and myoglobinuria. Myoglobinuria can cause acute renal failure, although this degree of myoglobinuria in recumbent horses is unusual.

Pneumonia can occur as a result of recumbency. Horses that are dysphagic are at increased risk of aspiration of feed material and saliva, and hence development of aspiration pneumonia. Horses receiving corticosteroids are at increased risk of bacterial and fungal (*Aspergillus* spp.,) pneumonia. While not every recumbent horse should be administered antimicrobials, this is indicated in horses at increased risk of developing pneumonia. Antimicrobials should have a broad spectrum, including activity against *Streptococcus* spp., such as a combination of penicillin and an aminoglycoside.

Slinging horses is labor-intensive and requires the use of a sling that is designed for use with horses. Horses should not be lifted using hip slings intended for use with cattle. Use of these slings to lift horses by grasping over the wing of each ilium is inhumane and unsuccessful. Horses in slings should be closely monitored and not allowed to hang in the sling. The horses should be assisted to stand in the sling every 6 or 8 hours. The sling should be used to help the horse to get up and provide some support while it is standing, but the horse should not have all its weight borne by the sling for more than a few minutes. Horses that have an excessive amount of weight borne by the sling for a prolonged period of time have trouble breathing and are likely to develop colic, rupture of the urinary bladder, diaphragmatic hernia or rectal prolapse.

Potentially catastrophic complications include septic arthritis, radial nerve injury, bladder rupture, diaphragmatic hernia, rectal prolapse, colon torsion and long bone fracture. The risk of these complications can be minimized by the practices detailed above, but cannot be eliminated.

Sudden or unexpected death

When an animal is found dead without having been previously observed to be ill, a diagnosis, even after necropsy examination, is often difficult because of the absence of a detailed history and clinical findings. A checklist of diseases for consideration when sudden or unexpected death occurs in a single animal or group of animals is provided below. Details of each of the diseases listed are available in other sections of this book. The list applies particularly to cattle, but some occurrences in other species are noted. It is necessary to point out the difference between 'found dead' and 'sudden death'.

When animals are observed infrequently, for example at weekly intervals, it is possible for them to be ill with obvious clinical signs for some days without being observed. In these circumstances the list of possible diagnoses is very large. It is also correspondingly large when animals are kept together in large groups and are not observed as individuals. This is likely to happen in beef cattle, especially in feedlots or as calves with dams at pasture, when the animals are unaccustomed to human presence and move away when approached. The list below refers to animals that are closely observed as individuals at least once daily.

SUDDEN OR UNEXPECTED DEATH IN SINGLE ANIMALS

SPONTANEOUS INTERNAL HEMORRHAGE

This condition could be due to cardiac tamponade in cows, ruptured aorta or atrium, inherited aortic aneurysm or verminous mesenteric arterial aneurysm in horses and esophagogastric ulcer or intestinal hemorrhagic syndrome in pigs.

RUPTURE OF INTERNAL CAROTID ARTERY ANEURYSM

This condition may occur secondary to mycosis of guttural pouch of the horse. In one survey of sudden deaths in horses while racing, most (68%) were undiagnosed, although it was assumed that they died of exercise-associated ventricular arrhythmias. Of those that were diagnosed, most were due to spontaneous hemorrhage.[1] Similar conclusions have resulted from other surveys.[2] Most reported cases of sudden death in the horse are the result of cardiovascular accidents.[3,4]

Fracture of the pelvis can result in fatal hemorrhage within the gluteal muscles of the horse[5] and rupture of the middle uterine artery at parturition in cattle may occur with uterine prolapse.

PERACUTE ENDOGENOUS TOXEMIA

This condition can arise from rupture of the stomach of horses, abomasum of cows and colon in mares at foaling. Large amounts of gastrointestinal contents are deposited rapidly into the peritoneal cavity. In newborn animals, especially foals, fulminating infections are the commonest cause.

Peracute exogenous toxemia in a single animal could be as a result of snakebite, but the snake would have to be very poisonous and the animal of small body weight to cause death without any observable illness.

TRAUMA

Trauma may cause death by either internal hemorrhage or damage to the central nervous system, especially the brain or atlanto-occipital joint sufficient to damage the medulla oblongata. In most cases the trauma is evident: there has been fighting, or a fall has occurred, or the animal has attempted to jump an obstacle. In horses a free gallop downhill may result in a serious fall or collision with, for example, a wall, especially if the ground is slippery.

Inapparent trauma usually occurs when animals are tied up by halter and rush backwards when frightened or are startled by an electric fence and the halter shank is long. Sometimes the animal will plunge forward and hit its forehead between the eyes on a protruding small object such as a bolt used in a fence. Sadism, especially by the insertion of whip handles or pitchfork handles into the anus or vulva, may also be inapparent.

GASTROINTESTINAL CONDITIONS

Gastric rupture in the horse may occur following overeating highly fermentable feed, administration of excessive quantities of fluids by nasogastric tube, gastric impaction or when gastric motility is markedly reduced in acute grass sickness or gastric distension with fluid. Peracute enteritis in the horse can cause rapid unexpected death.

Volvulus or gastrointestinal accidents account for almost 50% of sudden deaths in sows, followed next by gastric ulceration, retained fetuses and toxemia.[6]

Recumbent cattle that become lodged in a small hollow in the ground may die of bloat[7] because the cardia becomes covered with ruminal fluid and eructation is not possible.

IATROGENIC DEATHS

These may be due to overdose with intravenous solutions of calcium salts in an excited cow, too-rapid fluid infusion in an animal with pulmonary edema, intravenous injection of procaine penicillin suspension, and intravenous injections of ivermectin in horses. These are not hard to diagnose and the producer or veterinarian is usually obviously embarrassed.

One of the most sudden death occurrences is the anaphylactoid reaction in a horse to an intravenous injection of an allergen such as crystalline penicillin. Death occurs in about 60 seconds. Intra-arterial injections of penicillin or phenothiazine tranquilizers have also been reported to cause sudden death.[3]

SUDDEN DEATH IN HORSES

An analysis was made of the causes of death in horses and ponies over 1 year of age that died suddenly and unexpectedly.[8] No cause of death was found in 31% of cases and 16% died from the following causes: hemorrhage in the respiratory tract, central nervous system and adverse drug reactions. Cardiovascular lesions were the cause in 14% and the remaining 3% had lesions of the gastrointestinal tract.

Sudden death in racehorses is commonly due to massive hemorrhage into the lungs, abdomen or brain.[5] In horses that were found dead but appeared normal when last seen, the cause of death was not determined in 33%. Lesions of the gastrointestinal tract were the cause of death in 39% and respiratory tract lesions in 9%. Lesions of both the central nervous system and cardiovascular system were the cause of death in 5%. The remaining 10% had miscellaneous causes.

SUDDEN OR UNEXPECTED DEATH IN A GROUP OF ANIMALS

The diseases listed below could obviously affect single animals if the animals were housed or run singly.

LIGHTNING STRIKE OR ELECTROCUTION

This usually affects a number of animals that are found together in a pile or group. Rarely, electrical current only electrifies a contact object intermittently and deaths will be intermittent. In most cases the history and an examination of the environment reveals the cause.

NUTRITIONAL DEFICIENCY AND POISONING

At pasture, sudden death may come from the sudden exposure of the cattle to plants that cause bloat, hypomagnesemia, cyanide or nitrite poisoning, fluoroacetate poisoning, fast death factor (produced by algae in a lake or pond) or acute interstitial pneumonia. Acute myocardiopathy in young animals on diets deficient in vitamin E or selenium is in this group, as is inherited myocardiopathy in Herefords. Gross nutritional deficiency of copper in cattle causes 'falling disease', a manifestation of acute myocardiopathy.

Acute myocardiopathy and heart failure is associated with poisons in *Phalaris* spp. pasture, grass nematodes on *Lolium rigidum*, the hemlocks *Cicuta* and *Oenanthe* spp. and the weeds *Fadogia*, *Pachystigma*, *Pavette*, *Ascelapius* and *Aeriocarpa*, *Crystostegia* and *Albizia*, *Cassia* spp. The trees oleander and yew (*Taxus* spp.) may also be causes, and those species containing fluoroacetate, such as the gidgee tree and the weeds *Gastrolobium*, *Oxylobium*, *Dichapetalum* and *Ixioloena* spp. may be implicated. There are a number of plants that cause cardiac irregularity and some sudden deaths, e.g. *Urginea*, *Kalanchoea* spp., but more commonly congestive heart failure is caused. Monensin, lasolocid and salinomycin toxicities are increasingly common causes in horses and, to a less extent, cows.

ACCESS TO POTENT POISONS

Access to potent poisons may occur in housed animals or in those fed prepared feeds.

There are few poisons that cause sudden death without premonitory signs. Cyanide is one, but is an unlikely poison in these circumstances. Monensin, mixed in a feed for cattle that is then fed to horses, or fed in excess to cattle, does cause death by heart failure. Organophosphates are more likely, but clinical signs are usually apparent. Lead is in a similar category; however, very soluble lead salts can cause death quickly in young animals.

DISEASES ASSOCIATED WITH INFECTIOUS AGENTS

These cause septicemia or toxemia, and include anthrax, blackleg, hemorrhagic septicemia and (especially in sheep, but occasionally in cattle) peracute pasteurellosis. In pigs, mulberry heart disease and perhaps gut edema should be considered. In horses, colitis is probably the only disease that will cause sudden death. In sheep and young cattle, enterotoxemia associated with *C. perfringens* should be included and this may be involved in rumen overload in feedlot cattle on heavy grain feed. Circumstances, feeding practices, climate and season of the year usually give some clue as to the cause.

NEONATAL AND YOUNG ANIMALS

In very young, including neonatal, animals, congenital defects that are incompatible with life – prematurity, septicemia because of poor immune status or toxemia associated with particular pathogens, especially *E. coli*, and hypothyroidism – are important causes of sudden death.

ANAPHYLAXIS

Anaphylaxis after injection of biological materials, including vaccines and sera, is usually an obvious diagnosis, but its occurrence in animals at pasture can cause obscure deaths. In these circumstances it usually affects one animal and clinical illness is often observed. A similar occurrence is sudden death in a high proportion of piglets injected with an iron preparation when their selenium–vitamin E status is low.

PROCEDURE FOR INVESTIGATION OF SUDDEN DEATH

This is as follows:

- Keep excellent records because of the probability of insurance enquiry or litigation
- Take a careful history, which may indicate changes of feed composition or source, exposure to poisons or administration of potentially toxic preparations
- Make a careful examination of the environment to look for potential sources of pathogens. Be especially careful of your personal welfare if electrocution is possible – wet concrete floors can be lethal when combined with electrical current unless you are wearing rubber boots
- Carefully examine dead animals for signs of struggling, frothy nasal discharge, unclotted blood from natural orifices, bloat, pallor or otherwise of mucosae, burn marks on body, especially on the feet, or signs of trauma or of having been restrained. Pay particular attention to the forehead by palpating the frontal bones – these may have been fractured with a heavy blunt object without much damage to the skin or hair
- Ensure that typical cadavers are examined at necropsy, preferably by specialist pathologists at independent laboratories, where opinions are more likely to be considered authoritative and unbiased
- Collect samples of suspect materials for analysis. Preferably, collect two samples, one to be analyzed and one to be made available to a feed company, if indicated.

Diseases of the newborn

3

This chapter considers the principles of the diseases that occur during the first month of life in animals born alive at term. Diseases causing abortion and stillbirth are not included. The specific diseases referred to are presented separately under their own headings.

The inclusion of a chapter on diseases of the newborn, and at this point in the book, needs explanation. The need for the chapter arises out of the special sensitivities which the newborn have:

- Their immunological incompetence
- Their dependence on adequate colostrum containing adequate antibodies at the right time
- Their dependence on frequent intake of readily available carbohydrate to maintain energy
- Their relative inefficiency in maintaining normal body temperature, upwards or downwards.

All these points need emphasizing before proceeding to the study of each of the body systems.

There are no particular aspects of a clinical examination that pertain only to or mostly to neonates. It is the same clinical examination as is applied to adults, with additional, careful examination for congenital defects and diseases, which may involve the umbilicus, the liver, the heart valves, the joints and tendon sheaths, eyes and meninges. Although one should avoid any suggestion that an examination of an adult could be cursory, it is necessary to ensure that an examination of a newborn animal is as complete as practically possible. This is partly for an emotional reason: the neonate always evokes a sentimental reaction. It is also important for the economic reason that in most species the offspring, when already on the ground, represents a very considerable part of the year's investment and productivity. There is also the much greater susceptibility to infectious disease, dehydration and death, and diagnosis and treatment must be reasonably accurate and rapid. Supportive therapy in the form of fluids, electrolytes and energy and nursing care are especially important in the newborn in order to maintain homeostasis.

Perinatal and postnatal diseases

One of the difficulties in the study of these diseases is the variation in the type of age classification that occurs between publications, which makes it difficult to compare results and assessments. The term perinatal is usually used to describe morbidity or mortality that occurs at birth and in the first 24 hours of life. The term neonatal is usually used to describe morbidity or mortality between birth and 14 days. However, there is variation in the use of these terms. To ensure that our meanings are clear, we set out below what we think is the most satisfactory classification of all the diseases of the fetus and the newborn, which is adapted from a scheme proposed for lambs. The importance of this type of classification is with the assessment of risk for a given type of disease and in the prediction of likely causes that should be investigated by further examinations. This approach is not of major importance in the assessment of disease in an individual animal, although it is of importance in helping establish the priority in diagnostic rule-outs. The classification is, however, of considerable value in the approach to perinatal morbidity and mortality in large flocks or herds where an assessment of the age occurrence of morbidity and mortality can guide subsequent examinations to the probable group of cases, with optimal expenditure of investigative capital.

GENERAL CLASSIFICATION

FETAL DISEASES

These are diseases of the fetus during intrauterine life, e.g. prolonged gestation, intrauterine infections, abortion, fetal death with resorption or mummification, goiter.

PARTURIENT DISEASES

These are diseases associated with dystocia, causing cerebral anoxia or fetal hypoxemia, and their consequences and predispositions to other diseases; injury to the skeleton or soft tissues and maladjustment syndrome of foals are also included here.

POSTNATAL DISEASES

These are divided into early, delayed and late types:

- **Early postnatal disease** (within 48 hours of birth). Deaths that occur during this period are unlikely to be caused by an infectious disease unless it has been acquired congenitally. Most diseases occurring in this period are noninfectious and 'metabolic', e.g. hypoglycemia and hypothermia due to poor mothering, hypothermia due to exposure to cold, low vigor in neonates due to malnutrition. Congenital disease will commonly manifest during this period but may sometimes manifest later. Infectious diseases are often initiated during this period but most manifest clinically at a later age because of their incubation period; some, e.g. navel infection, septicemic disease and enterotoxigenic colibacillosis, have a short enough incubation to occur during this period

- **Delayed postnatal disease** (2–7 days of age). Desertion by mother, mammary incompetence resulting in starvation and diseases associated with increased susceptibility to infection due to failure of transfer of colostral immunoglobulins (the predisposing causes to these occur in the first 12–24 hours of life). Examples include colibacillosis, joint ill, lamb dysentery, septicemic disease, most of the viral enteric infections in young animals, e.g. rotavirus and coronavirus
- **Late postnatal disease** (1–4 weeks of age). There is still some influence of hypogammaglobulinemia, with late-onset enteric diseases and the development and severity of respiratory disease in this period, but other diseases not directly associated with failure of transfer of immunoglobulins such as cryptosporidiosis, white muscle disease and enterotoxemia start to become important.

GENERAL EPIDEMIOLOGY

Diseases of the newborn and neonatal mortality are a major cause of economic loss in livestock production. In cattle, sheep and pigs the national average perinatal mortalities exceed by far the perinatal mortality experienced in herds and flocks with good management. In these species the identification of the management deficiencies that are the cause of a higher than acceptable mortality in a herd or a flock is a most important long-term responsibility of the practicing veterinarian and, in most instances, is more important than the identification of the causal agent or the short-term treatment of individual animals with neonatal disease. In contrast, in horses the individual is of extreme importance and the primary thrust is in the treatment of neonatal disease.

All animals must be born close to term if they are to survive in a normal farm environment. Minimal gestational ages for viability (in days) for each of the species are:

Calf – 240
Foal – 300
Lamb – 138
Piglet – 108.

LAMBS

Mortality rates

Neonatal lamb mortality is one of the major factors in impairment of productivity in sheep-raising enterprises around the world.[1–3] Mortality can obviously vary with the management system (intensive versus extensive lambing, highly supervised versus minimally supervised, variations in the provision of shelter, etc.), and according to whether there is a particular disease problem in a given flock. Nonselective mortality surveys have shown population mortality rates in lambs, from birth to weaning, that vary from 9–35% and there are flocks that may exceed this upper figure in the face of a major problem. In well-managed flocks neonatal mortality is less than 10% and in some is below 5%. The majority of neonatal mortality is due to noninfectious disease.

Major causes

Surveys from various sheep-raising areas in the world consistently show that the majority of lamb mortalities can be attributed to three main causes:[1–4]

- The complex of hypothermia/exposure/hypoglycemia/starvation
- Stillbirth and dystocia/stillbirth
- Abortion.

These syndromes have a multifactorial etiology but can account for over 65% of the mortality that occurs in the first few days of life.[4,5]

Fetal disease

Infectious abortion can cause considerable fetal, parturient and postnatal mortality in infected flocks but it is a relatively minor cause of perinatal mortality overall. In contrast to other large animal species, abortion storms in sheep are often accompanied by significant mortality in liveborn animals. Many agents associated with abortion in ewes produce placentitis and cause abortion in late pregnancy. This frequently results in the birth of liveborn, growth-retarded and weak lambs that die during the first few days of life. Any investigation of perinatal mortality in sheep should also consider the presence of agents causing abortion, although abortion and the birth of dead lambs is always prominent in abortion outbreaks.

Parturient disease

Stillbirth occurs largely as a result of prolonged birth and fetal hypoxemia. Prolonged birth and dystocia is a particular problem in large single lambs.[6] Higher rates of stillbirth can also occur in flocks that are in poor condition. Prolonged birth is a major risk factor for subsequent postnatal disease.[4]

Postnatal disease

The **hypothermia/exposure/hypoglycemia/starvation complex** is the most important cause of postnatal disease. The determinants for the occurrence of this complex are the birth size of the lamb, the energy reserves of the lamb, and environmental factors at birth and during the following 48 hours which influence heat loss. These include environmental temperature, wind velocity and evaporative cooling determined by the wet coat of the lamb at birth or the occurrence of rain.

Birth size

Birth size is determined by the nutrition and genetics of the ewe, and by litter size which is also determined by the parity and genetics of the ewe. Reflecting these influences, most surveys of neonatal mortality in lambs show:

- A significant association between the body condition score or **nutrition of the late pregnant ewe** and perinatal mortality
- A relation between **birth weight** and mortality (depending upon the breed, a birth weight of less than 2.5–3.0 kg has increased risk for death)
- A higher mortality in lambs from **multiparous ewes**
- A pronounced effect of **litter size**, with mortality in lambs born as triplets being higher than in those born as twins, which in turn is higher than that in lambs born as singles.

These relationships can be confounded by an increase in mortality in large-birth-weight lambs born as singles because of dystocia and by the greater mortality in lambs born to **maiden ewes** associated with poor mothering and desertion.

Environmental factors

Environmental factors of temperature, wetness and wind also confound the above relationships; their influence varies according to the management system.

The identification of the above determinants of mortality is of more than academic value as almost all can be changed by the identification of **at-risk groups** and the institution of special management procedures, or by the identification and mitigation of adverse environmental factors.

Infectious disease

Infectious disease can be important in some flocks and occurs after 2 days of age. The major infectious diseases of lambs that cause mortality are enteritis and pneumonia.[7] Their prevalence varies with the management system – enteric disease and liver abscess are more common in shed lambing systems than with lambing at pasture.[8] Risk for pneumonia is greatest in very light or heavy lambs and in lambs from maiden ewes and ewes with poor milk production.[9]

Other factors

Other factors can be important in individual flocks or regions. Lambs found dead or missing may account for significant losses under some conditions, such as

mountain or hill pastures.[2] **Predation**, or predation injury, is an important cause of loss in some areas of the world and, depending upon the region, can occur from domestic dogs, coyotes, birds or feral pigs. **Poor mothering** and an inability of the ewe to gather and bond to both lambs of twins can be a problem in Merinos and can cause permanent separation of lambs from the ewe and subsequent death from starvation.

Management at lambing can also influence the patterns of mortality. Intensive stocking at the time of lambing to allow increased supervision can allow a reduction in mortality associated with dystocia and the hypothermia/exposure/hypoglycemia/starvation complex. It can ensure the early feeding of colostrum to weak lambs but it can also result in a greater occurrence of mismothering associated with the activities of 'robber' ewes and it also increases the infection pressure of infectious agents, resulting in an increased incidence of enteric and other disease.[7]

Mortality rate can differ between breeds and lambs from crossbred dams may have higher survival rates.

Recording systems

Simple systems for recording, determining and evaluating the major causes of lamb mortality in a flock, for determining the time of death in relation to birth and relating the deaths to the weather and management system are available.[4,10] These systems of examination are effective in revealing the extent of lamb losses and the areas of management that require improvement and are much more cost-effective than extensive laboratory examinations, which may give little information on the basic cause of the mortality. More intensive examination systems that combine these simple examinations with selected biochemical indicators of determinant factors are also described.[5]

DAIRY CALVES

Mortality rates

A 1992 review of publications on calf mortality reported mortality rates in dairy calves that varied from a low of approximately 2% to a high of 20% with mortality on individual farms varying from 0–60%.[11] A survey of calf mortality in 829 dairy operations in the USA showed considerable variation with region and with management system.[12] The best estimate for the average on-farm calf mortality rate is 6%.[11] This mortality is in addition to that associated with stillborn or weak-born calves which is reported to occur in 11% of primiparous and 5.7% of multiparous Holstein cows in the USA.[13]

The exact cause of death in these stillborn or weakborn calves is not known. In addition to the influence of parity, dystocia has a major influence on rates and rates are also higher where gestation length was shorter than 280 days. Calving-associated anoxia may be an important contributing factor in these deaths.[14]

Mortality in twin-born calves is approximately three times that of single-born calves. Disease morbidity rates also vary with the farm and, as might be expected, with the disease under consideration and the age of the calf.[12,15,16]

Major causes

Fetal disease and the postnatal septicemic, enteric and respiratory diseases are the most common causes of loss.

Fetal disease

Definition of fetal loss and abortion varies between studies but the median frequencies of observed abortions is approximately 2% and of fetal loss in dairy cattle diagnosed pregnant 6.5%.[17] The majority of these have no diagnosed cause.

Parturient disease

Calving in dairy cattle is usually supervised, but prolonged calving with consequent hypoxemia (and occurring with or without dystocia) and twin birth is associated with significantly higher risk for mortality in the first 21 days of life.[12,18,19]

Postnatal disease

Calves are at highest risk for death in the first 2 weeks of life and especially in the first week. Septicemic and enteric disease are most common during this period, with respiratory disease being more common after 2 weeks of age.[14,20,21] **Failure of transfer** of colostral immunoglobulins is a major determinant of this mortality.[12] The economic significance of neonatal disease can be considerable and the occurrence of disease as a calf can also subsequently affect days to first calving intervals and long-time survival in the herd.[14,22] Death also causes a loss of genetic potential both from the loss of the calf and the reluctance of the farmer to invest in higher-price semen in the face of a calf mortality problem.

Meteorological or **seasonal influences** may have an effect on dairy calf mortality rate and this can vary with the region. In cold climates during the winter months, an increase in mortality may be associated with the effects of cold, wet and windy weather, whereas in hot climates there may be an increase in mortality during the summer months in association with heat stress.

Management

Management is a major influence and in well managed dairy herds calf mortality usually does not exceed 5% from birth to 30 days of age. Risk factors for disease morbidity and mortality in dairy calves relate to the **infection pressure** to the calf and factors that affect its **nonspecific** and **specific resistance** to disease. It is generally recognized that mortality is associated with the **type of housing** for calves, calving facilities, the person caring for the calves and attendance at calving. Thus calves that are born in separate calving pens have a lower risk of disease than those born in loose housing or stanchion areas[23] and the value of good colostrum feeding practices is apparent.[11,12] Studies on the role of calf housing and the value of segregated rearing of calves in reducing infection pressure generally show beneficial health results[7,21,24,25] but the value of this system of rearing is probably best measured by its adoption in many dairies where climatic conditions allow this to be an option for housing young calves. The quality of management will be reflected in rates of failure of transfer of passive immunity and will also affect the infection pressure on the calf during the neonatal period. Quality of management is very hard to measure but is easily recognized by veterinary practitioners.

The epidemiological observations that calf mortality is lower when females or family members of the ownership of the farm manage the calves, rather than when males or employees perform these duties, is probably a reflection of this variation in quality of management and suggests that owner–managers and family members may be sufficiently motivated to provide the care necessary to ensure a high survival rate in calves. Even so, calf health can be excellent with some hired calf-rearers and very poor with some owner calf-rearers. Besides visual assessments of hygiene an effective **measure of the quality** of calf management can be provided by a measure of rates of failure of transfer of passive immunity.

BEEF CALVES

Mortality rates

Mortality in beef herds is usually recorded as birth to weaning mortality and has ranged from 3–7% in surveys, with higher rates in calves born to heifers; significantly higher mortality can occur in herds with disease problems.[26–31] The majority of this mortality occurs within the first week of life and most of it occurs in the parturient or immediate postnatal period as a result of prolonged birth or its consequences.[30–32]

Major causes

Dystocia resulting in death is common and dystocial calves, twin-born calves and calves born to heifers are at greater risk

for postnatal disease.[31–34] Enteric and respiratory disease occurs in outbreaks in some years and very cold weather can result in high loss from hypothermia. In a survey of 73 herds in the USA the overall mortality rate was 4.5% and causes were dystocia (17.5%), stillbirths (12.4%), hypothermia (12.2%), enteric disease (11.5%) and respiratory infections (7.6%).[31]

Fetal disease

Abortion rates appear to be lower than in dairy cattle, usually less than 1%.[30] The majority of these are not diagnosed as to cause but of those that are, infectious abortion is the most common diagnosis.[35]

Parturient disease

Accurate prospective and retrospective studies have shown that 50–60% of the parturient deaths in beef calves are associated with slow or difficult birth and that the mortality rate is much higher in calves born to heifers than from mature cows.[26,30,32] **Dystocial birth** can lead to injury of the fetus and to hypoxemia and may not necessarily be associated with fetal malposition. **Birth size** is highly heritable within all breed types of cattle[36] and perinatal mortality will vary between herds depending upon their use of bulls with high ease of calving ratings in the breeding of the heifer herd. Milk fever and over-fatness at calving are other preventable causes. Selective intensive supervision of calving of the heifer herd can also result in a reduction of perinatal mortality.

Postnatal disease

Scours and pneumonia are the next most important causes of mortality in beef calves, followed by exposure to extremely cold weather or being dropped at birth into deep snow or a gully. The incidence of diarrhea is greatest in the first 2 weeks of life and there is considerable variation in incidence between herds.[37] However, explosive outbreaks of diarrhea or exposure chilling can be significant causes of mortality in certain years.[29] The purchase of a calf for grafting, often from a market, is a significant risk for introduction of disease to a herd.

Body **condition score** of the dam can influence calf mortality, with high condition scores having a higher risk for dystocial mortality and low scores for infectious disease. Mortality from diarrhea is often higher in calves born to heifers, possibly because heifers are more closely congregated for calving supervision or because of a higher risk for failure of transfer of passive immunity in this age group. Congenital abnormalities can be an occasional cause of mortality in some herds.[27]

PIGLETS

Mortality rates

Preweaning mortality ranges from 5–48%, with averages ranging from 12–19%, of all pigs born alive.[38,39] More than 50% of the preweaning losses occur before the end of the second day of life. Mortality increases as the mean litter size increases and as the mean birth weight of the pig decreases. In most herd environments the minimal **viable weight** is approximately 1 kg. The mean number of piglets weaned is related to the size of the litter up to an original size of 14 and increases with parity of sows up to their fifth farrowing. Preweaning mortality is negatively correlated with herd size and farrowing crate utilization, and positively correlated with the number of farrowing crates per room.[39]

Major causes

Surveys of neonatal mortality in piglets have repeatedly indicated that the most important causes of death in piglets from birth to weaning are noninfectious in origin.[38-40] The major causes are **starvation and crushing** (75–80%) (although these may be secondary to, and the result of, hypothermia), congenital abnormalities (5%) and infectious disease (6%). The major congenital abnormalities are congenital splayleg, atresia ani and cardiac abnormalities. Infectious diseases may be important on certain individual farms but do not account for a major cause of mortality.

Fetal disease

Fetal disease rates in most herds are low unless there is an abortion storm or poor control of endemic infections such as parvovirus. In contrast to other species, the majority of abortions are diagnosed and are infectious.

Parturient disease

Stillbirths account for 4–8% of all deaths of pigs born and 70–90% are type II or intraparturient deaths, in which the piglet was alive at the beginning of parturition. The viability of newborn piglets can be accurately evaluated immediately after birth by scoring skin color, respiration, heart rate, muscle tone and ability to stand. Stillbirths are more commonly born in the later birth orders of large litters and it is a relatively common practice for sows to be routinely given oxytocin at the time of the birth of the first piglet in order to shorten parturition. Controlled trials have shown that, while oxytocin administration at this time will result in a significant decrease in farrowing time and expulsion intervals there is a significant increase in fetal distress, fetal anoxia and intrapartum death and an increase in piglets born alive with ruptured umbilical cords and meconium staining.[41]

Postnatal disease

The large percentage of mortality caused by **crushing** and trampling probably includes piglets that were starved and weak and thus highly susceptible to being crushed. The estimated contribution of crushing and starvation to neonatal mortality varies from 50–80%. The body condition score of the sow at the time of farrowing, the nursing behavior of the sow, her ability to expose the teats to all piglets and the sucking behavior of the piglets have a marked effect on survival.[42]

Cold stress is also an important cause of loss and the provision of a warm and comfortable environment for the newborn piglet in the first few days of life is critical. The lower critical temperature of the single newborn piglet is 34°C (93°F). When the ambient temperature falls below 34°C (93°F) the piglet is subjected to cold stress and must mobilize glycogen reserves from liver and muscle to maintain deep body temperature. The provision of heat lamps over the creep area and freedom from draughts are two major requirements.

Management

Minimizing the mortality rate of newborn piglets will depend on management techniques, which include:

- Proper selection of the breeding stock for teat numbers, milk production and mothering ability
- The use of farrowing crates and creep escape areas to minimize crushing injuries
- Surveillance at farrowing time to minimize the number of piglets suffering from hypoxia and dying at birth or a few days later
- Batch farrowing, which allows for economical surveillance
- Fostering to equalize litter size
- Cross-fostering to equalize non-uniformity in birth weight within litters
- Artificial rearing with milk substitutes containing purified porcine gammaglobulin to prevent enteric infection.[41]

FOALS

Mortality rates

Foals are usually well supervised and cared for as individual animals. Neonatal death is less frequent than in other species but equivalent rates of morbidity and mortality occur on some farms.[43] Infectious disease is important, along with structural and functional abnormalities that are undoubtedly better recognized and treated than in any of the other large animal species. In a large survey of thoroughbred mares in the UK, only 2% of newborn foals died;[44] only

41% of twins survived and 98% of singles survived. In contrast, a mortality rate of 22% between birth and 10 days is recorded in an extensively managed system.[45] Between 25–40% of mares that are bred fail to produce a live foal[46] and an extensive study of breeding records indicated that 10% of mares that are covered either aborted or had a non-surviving foal.[47]

Fetal disease

This is a major cause of loss and in one study infections accounted for approximately 30% of abortions.[46] In a retrospective study of 1252 fetuses and neonatal foals submitted for postmortem examination over a 10-year period in the UK, equine herpes virus and placentitis accounted for 6.5% and 9.8% of the diagnoses respectively.[48] The placentitis occurred in late gestation and was concentrated around the cervical pole and lower half of the allantochorion associated with ascending chronic infections of bacteria or fungi resident in the lower genital tract.

Parturient disease

Neonatal asphyxia, dystocia, placental edema and premature separation of the placenta, umbilical cord abnormality and placental villous atrophy are other important causes of mortality in this period. In the UK study[48] umbilical cord disorders accounted for 38.8% of the final diagnoses. Umbilical cord torsion usually resulted in death of the fetus in utero but the long cord/cervical pole ischemia disorder resulted in intrapartum death and a fresh fetus with lesions consistent with acute hypoxia.

Twins are at higher risk for spontaneous abortion.

Postnatal disease

Postnatal disease causing mortality from birth to 2 months of age includes: lack of maturity 36%, structural defect 23%, birth injury 5%, convulsive syndrome 5%, alimentary disorder 12%, generalized infection 11% and other (miscellaneous) 9%. Of the **infectious diseases**, gastrointestinal and septicemic disease have greatest importance.[49,50] Whereas in the past many of these conditions would have been fatal, there have been significant advances in the science of equine perinatology in the 1980s and 1990s and protocols for the treatment of neonatal disease have been developed that have been based on equivalents in human medicine. These have proved of value in the management and treatment of prematurity, immaturity, dysmaturity and neonatal maladjustment syndromes in newborn foals, as well as in enteric and septicemic disease. Different levels of intensive care have been defined that start from those that can be applied at the level of the farm and increase in sophistication, required facilities and instrumentation to those that are the province of a specialized referral hospital. Early followup studies indicate that this approach is of considerable value in foals with neonatal disease and that most surviving foals become useful athletic adults.[51]

SPECIAL INVESTIGATION OF NEONATAL DEATHS

The following protocol is a generic guide to the investigation of deaths of newborn animals. It will require modification according to the species involved.

1. Determine the duration of pregnancy to ensure that the animals were born at term
2. Collect epidemiological information on the problem. Where possible, the information should include the following:
   - What is the abnormality?
   - What is the apparent age at onset and the age at death?
   - What clinical signs are consistently associated with the problem?
   - What is the prevalence and proportional risk in particular groups (maternal, paternal, nutritional, vaccinated, etc.)?
   - What is the parity of the dam that gave birth to the animal and what proportional risk does this reflect within the group?
   - What is the birth history of affected animals? Are births supervised, what is the frequency of observation and what are the criteria for intervention? What is the proportional risk associated with prolonged birth?
   - Is there an effect of litter size and what is the health of the other litter mates?
   - Has there been any difference in management of the dams of the affected animals to the group as a whole?
   - What is the farm policy for feeding colostrum?
   - What have been the environmental conditions during the past 48 hours? In housed animals the quality of the environment should be measured objectively
3. Conduct a postmortem examination of all available dead neonates. The determination of body weight is essential and measures of **crown–rump length** can also give an indication of gestational age. In order of precedence the purpose of the postmortem examination is to determine:
   - The time of death in relation to parturition (e.g. fetal disease, parturient disease, early or delayed postnatal death). This can be determined from the state of the lungs, the nature of the severed end of the umbilical artery and the presence of a clot, the state of the brown fat deposits, whether the animal has walked and if it has sucked prior to death
   - The possibility that animals born alive have died because of cold stress, hypoglycemia and starvation. An indication can be obtained from an examination of the brown fat reserves, the presence or absence of milk in the gastrointestinal tract and fat in the intestinal lymphatics. The presence of subcutaneous edema in the hind limbs is also relevant
   - The possible presence of birth injury or trauma. In addition to examination of the ribs and liver for trauma and the presenting areas for subcutaneous edema, the brain should be examined for evidence of hemorrhage
   - The presence of infectious disease. If necessary samples can be submitted for examination
   - The presence of congenital disease
4. If abortion is suspected, specimens of fetal tissues and placenta are sent for laboratory examination. Examinations requested are pathological and microbiological for known pathogens for the species of animal under consideration
5. A serum sample should be collected from the dam for serological evidence of teratogenic pathogens followed by another sample 2 weeks later. Samples from unaffected dams should also be submitted. A precolostral serum sample from affected animals may assist in the diagnosis of intrauterine fetal infections
6. Investigate management practices operating at the time, with special attention to clemency of weather, feed supply, maternalism of dam and surveillance by the owner – all factors that could influence the survival rate.[51,52] Where possible, this should be performed using objective measurements. For example, in calf-rearing establishments the efficacy of transfer of colostral immunoglobulins should be established by the bleeding of a proportion of calves and actual measurement; food intake should be established by actual measurement, etc.

Congenital defects

Synopsis

Etiology Genetic, infectious, toxic and physical causes are recognized for some defects but the etiology of most is not known

Epidemiology Low but significant incidence in all animals. Epidemiology depends on cause

Clinical findings Congenital defects can be structural or functional. Clinical signs depend on organ system(s) affected

Clinical pathology Specific serological and chemical tests can be used in the diagnosis and control of some congenital disease and, if available, are detailed under specific disease headings

Necropsy findings Specific to the particular problem

Diagnostic confirmation Abnormalities of structure or function that are present at birth are obviously congenital defects. They may or may not be inherited, and inherited defects may or may not be manifest at birth

Control Avoidance of exposure to teratogenic agents. Vaccination for some teratogenic infections, identification of carriers for genetic defects

ETIOLOGY

Congenital disease can result from defective genetics[1,2] or from an insult or agent associated with the fetal environment. A neonate with a congenital defect is an adapted survivor from a disruptive event of a genetic or environmental nature or of a genetic–environmental interaction at one or more of the stages in the sequences of embryonic and fetal development.[3]

Genetic abnormalities, detailed in Chapter 35, may result in a wide spectrum of disorder that can vary from severe malformations with deformation to the presence of inborn errors of metabolism in animals that may be born apparently normal and develop storage disease later in life [3]

Susceptibility to injurious **environmental agents** depends upon the nature and the severity (dose size and duration of application) of the insult, and decreases with fetal age. Prior to attachment, the zygote is resistant to teratogens but susceptible to chromosomal aberrations and genetic mutations. Agents that disrupt blastula and gastrula stages and that interfere with normal apposition of the uterine mucosa are usually embryotoxic and induce early embryonic death.

The period during which an **organ system** is being established is a particularly critical period for that system and different teratogens, if applied at that time, can produce similar defects. One example would be the complex of arthrogryposis and cleft, which can occur in the calves of cattle grazing certain species of lupine,[4] in calves infected in utero with Akabane virus[5] and as an inherited disease in Charolais calves.[6]

Many noninherited congenital defects in animals occur in '**outbreaks**', which is a reflection of the exposure of the pregnant herd to a viral, plant or other teratogen during a period of fetal susceptibility. Because this occurs in early pregnancy it is often very difficult to determine the nature of this exposure at the time the animals are born.

Some teratogens are quite **specific** in the defect that they produce and their action may be limited to a single species; a tentative diagnosis as to cause can be based on this association. Others produce a wide variety of abnormality that may also occur with other teratogens and cause is less obvious.

The exact etiology of most congenital defects is unknown. Influences that are known to produce congenital defects are presented here.

Chromosomal abnormality and inheritance

Most chromosomal abnormalities are associated with poor fertility and early embryonic death.[7] A few are structural or numerical aberrations of chromosomes. The importance of chromosomal abnormality to congenital defects in farm animals has not been studied extensively but a study of 55 aborted and stillborn calves found six with an abnormal chromosome component.[8] Chromosomal abnormality is usually associated with multiple deformations.[8–11] Most chromosomal abnormalities are mutant genes and the majority are inherited as recessive traits. There are many examples among domestic animals (see Ch. 35).

Virus and other infections

Members of the *Bunyavirus* (Akabane virus, Cache valley virus and Rift Valley fever virus), *Orbivirus* (bluetongue virus, epizootic hemorrhagic disease virus and Chuzan virus), *Pestivirus* (bovine virus diarrhea virus, border disease virus, hog cholera virus) families, Japanese B encephalitis virus and Wesselsbron virus are recognized teratogens.[12] Other viruses also can result in fetal death without malformation. Examples are as follows:

- Akabane virus – this infection of pregnant cattle, sheep and goats causes arthrogryposis, microencephaly and hydrocephalus.[12] Infection of, and disease of, the fetus depends on the stage of pregnancy and the fetus's immunological status. In cattle infected between 76–104 days of pregnancy hydranencephaly predominates; arthrogryposis predominates with infections between 104–173 days gestation and poliomyelitis after 173 days. In sheep the window of susceptibility for congenital defects is between 30 and 50 days
- Cache valley virus – congenital infection of lambs with Cache valley virus[13] produces disease very similar to that produced by Akabane virus in cattle. The period of susceptibility for congenital defects is 36–45 days of pregnancy
- Rift valley fever virus infection of pregnant sheep results in placentitis and abortion but attenuated vaccine strains produce arthrogryposis and brain defects
- Bluetongue virus – vaccination of ewes with attenuated vaccine virus between days 35 and 45 of pregnancy causes a high prevalence of porencephaly in lambs. Natural infections of sheep (50–80 days of gestation) and cattle (60–120 days of gestation) can result in fetal death and resorption, or the birth of stillborn and weakborn animals and animals with hydrocephalus and hydranencephaly and occasionally arthrogryposis. Similar defects are produced by Chuzan, Aino and Kasba virus infections
- Bovine virus diarrhea – infection with cytopathogenic strains before 100 days can result in abortion and mummification, cerebellar hypoplasia and optic defects, including cataracts, retinal degeneration and hypoplasia and neuritis of the optic nerves. Other defects are brachygnathia, curly coats, abortion, stillbirth and mummification. Infection of the bovine fetus between 45 and 125 days of gestation with a noncytopathic biotype of the virus can result in the development of a persistently viremic and immunotolerant calf that is carried to term, born alive, remains persistently viremic and may later develop mucosal disease
- Border disease virus – the window of susceptibility is from 16–90 days gestation, and, depending upon the fetal age at infection and the presence of a fetal immune response, fetal infection may result in fetal death, growth retardation, the birth of persistently infected lambs or lambs born with hypomyelinogenesis, hydranencephaly and cerebellar dysplasia. Coat defects may also be seen
- Hog cholera virus – vaccination of sows with modified vaccine virus between days 15 and 25 of pregnancy produces piglets with edema, deformed noses and abnormal kidneys. Natural infection with field virus can cause reproductive inefficiency and cerebellar hypoplasia in piglets
- An unidentified virus is associated with the AII type of congenital tremor in pigs
- Congenital infection with Wesselsbron virus and with Rift Valley fever is recorded as producing central nervous system disease in cattle and sheep[14]
- Japanese B encephalitis virus in pigs can result in abortion or in the birth of weak, mummified or stillborn piglets and live piglets with neurological abnormalities. The window of susceptibility is from 40–60 days gestation
- Pseudorabies virus infection of the pregnant sow can result in myoclonia congenita in piglets
- Viral, bacterial and protozoal agents that produce abortion in animals can also produce intrauterine growth retardation and the birth of weakborn neonates that are highly susceptible to mortality in early life.

Nutritional deficiency

There are many congenital defects in animals that are known to be caused by deficiencies of specific nutrients in the diet of the dam. Examples are as follows:

- Iodine – goiter and increased neonatal mortality is caused in all species; prolonged gestation occurs in horses and sheep. Congenital musculoskeletal lesions are seen in foals (congenital hypothyroid dysmaturity syndrome). Deficiency may be due to a primary deficiency, or induced by nitrate or *Brassica* spp. Syndromes are also produced by iodine excess, often associated with feeding excess seaweed or seaweed products
- Copper – enzootic ataxia in lambs is due either to a primary copper deficiency or to a secondary deficiency where the availability of copper is interfered with by other minerals, e.g. molybdenum and iron
- Manganese – chondrodystrophy and limb deformities in calves[15]
- Vitamin D – neonatal rickets
- Vitamin A – eye defects, harelip and other defects in piglets
- Vitamin E and/or selenium – congenital cardiomyopathy and muscular dystrophy
- Congenital cobalt deficiency is reported to reduce lamb vigor at birth and to increase perinatal mortality because of impaired immune function in the lamb.[16] A similar effect on immune function in neonatal lambs and calves has been proposed with copper deficiency[17]
- Malnutrition of the dam can result in increased neonatal mortality and is suspected in the genesis of limb deformities[17] and in congenital joint laxity and dwarfism in calves[18,19]
- Vitamin A deficiency induced by feeding potato tops or water with high nitrate content has been associated with congenital blindness in calves.

Poisonous plants

Their teratogenic effects have been reviewed in detail.[20] Some examples are given below.

- *Veratrum californicum* fed to ewes at about the 14th day of pregnancy can cause congenital cyclopia and other defects of the cranium and brain in lambs, as well as prolonged gestation.[6] When fed at 27–32 days of pregnancy it can produce limb abnormalities. Tracheal stenosis has been produced by feeding at 31–33 days of gestation. The alkaloid cyclopamine is the teratogenic substance[20]
- 'Crooked calf disease' is associated with the ingestion of *Lupinus* sp. during pregnancy. This is a major problem on some range lands in western North America. There are approximately 100 species of *Lupinus* in Canada and the USA but the disease has been mainly associated with *L. sericeus*, *L. leucophyllus*, *L. caudatus* and *L. laxiflorus*.[21] These are believed to be toxic because of their content of anagyrine, but some piperidine alkaloids may also produce the disease.[22] The disease has been

reproduced by feeding anagyrine-containing lupines to pregnant cattle between 40 and 90 days of gestation but can occur with later feeding in natural grazing. The syndrome is one of arthrogryposis, torticollis, scoliosis and cleft palate[4]

- *Astragalus* and *Oxytropis* spp. locoweeds cause limb contracture in calves and lambs, also fetal death and abortion
- Tobacco plants – ingestion of *Nicotiana tabacum* (burley tobacco) and *N. glauca* (tree tobacco) by sows between 18 and 68 days, with peak susceptibility between 43 and 55 days of gestation, can cause limb deformities in their piglets. The teratogen is the piperidine alkaloid anabasine. Cleft palate and arthrogryposis has also been produced experimentally in the fetuses of cattle and sheep fed *N. glauca* during pregnancy but the plant is not palatable and this is an unlikely cause of natural disease[20]
- *Conium maculatum*, poison hemlock, fed to cows during days 55–75 of pregnancy, to sheep in the period 30–60 days of pregnancy and to sows in the period 30–62 days of pregnancy will cause arthrogryposis, scoliosis, torticollis and cleft palate in the fetuses.[20] Cattle are most susceptible. Piperidine alkaloids coniine and – coniceine are responsible[22,23]
- *Leucaena leucocephala* (or mimosine, its toxic ingredient) causes forelimb polypodia (supernumerary feet) in piglets when fed experimentally to sows
- Fungal toxicosis from the feeding of moldy cereal straw has been epidemiologically linked to outbreaks of congenital spinal stenosis and bone deformities associated with premature closure of growth plates in calves.[24]

Farm chemicals

- Some benzimidazoles (parbendazole, cambendazole, oxfendazole, netobimin) are important teratogens for sheep, producing skeletal, renal and vascular abnormality when administered between 14 and 24 days of pregnancy[25]
- Methallibure, a drug used to control estrus in sows, causes deformities in the limbs and cranium of pigs when fed to sows in early pregnancy
- Apholate, an insect chemosterilant, is suspected of causing congenital defects in sheep
- The administration of trichlorfon to pregnant sows can result in the birth of piglets with cerebellar hypoplasia and congenital trembles[26]
- Organophosphates have been extensively tested and found to be usually nonteratogenic.[27] A supposed teratogenic effect is probably more a reflection of the very common usage of these substances in agriculture (see under poisoning by organophosphates)
- Griseofulvin given to a mare in the second month of pregnancy is suspected of causing microphthalmia and facial bone deformity in a foal.[28]

Physical insults

- Severe exposure to beta or gamma irradiation, e.g. after an atomic explosion, can cause a high incidence of gross malformations in developing fetuses
- Rectal palpation of pregnancy using the amniotic slip method between 35 and 41 days of pregnancy in Holstein Friesian cattle is associated with atresia coli in the calf at birth,[29] but there is also a genetic influence.[30] It is probable that the cause is palpation-induced damage to the developing colonic vasculature
- Hyperthermia applied to the dam experimentally causes congenital deformities, but this appears to have no naturally occurring equivalent. The most severe abnormalities occur after exposure during early pregnancy (18–25 days in ewes). Disturbances of central nervous system development are commonest. Defects of the spinal cord manifest themselves as arthrogryposis and exposure of ewes to high temperatures (42°C, 107.5°F) causes stunting of limbs; the lambs are not true miniatures as they have selective deformities with the metacarpals selectively shortened. The defect occurs whether nutrition is normal or not.[31] Hyperthermia between 30 and 80 days of pregnancy in ewes produces growth retardation in the fetus. Developmental abnormalities have been reproduced experimentally in explanted porcine embryos exposed to environmental temperatures similar to those that may be associated with reproductive failure due to high ambient temperatures in swine herds.[32]

Environmental influences

Currently, there is considerable interest in the possible teratogenic effects of man-made changes in the environment. The concern is understandable because the fetus is a sensitive biological indicator of the presence of some noxious influences in the environment. For example, during an accidental release of polybrominated biphenyls much of the angry commentary related to the probable occurrence of congenital defects. The noxious influences can be physical or chemical. In one examination of the epidemiology of congenital defects in pigs, it was apparent that any environmental causes were from the natural environment; manmade environmental changes, especially husbandry practices, had little effect.[33] A current concern in some regions is an apparent increase in congenital defects believed to be associated with exposure to radio-frequency electromagnetic fields associated with mobile telephone networks,[34,35] but there is little hard data.

EPIDEMIOLOGY

Individual abnormalities differ widely in their spontaneous occurrence. The determination of the cause of congenital defects in a particular case very often defies all methods of examination. Epidemiological considerations offer some of the best clues but are obviously of little advantage when the number of cases is limited. The possibility of inheritance playing a part is fairly easily examined if good breeding records are available. The chances of coming to a finite conclusion are much less probable. Some of the statistical techniques used are discussed in Chapter 34 on inherited diseases. The determination of the currently known teratogens has mainly been arrived at following epidemiological studies suggesting possible causality followed by experimental challenge and reproduction of the defect with the suspected teratogen.

An expression of the **prevalence** of congenital defects is of very little value unless it is related to the size of the population at risk, and almost no records include this vital data. Furthermore, most of the records available are retrospective and based on the number of cases presented at a laboratory or hospital.

Reported prevalence rates of 0.5–3.0% for calves and 2% for lambs are comparable with the human rate of 1–3%.[36] A much higher rate for animals of 5–6% is also quoted.[21] A study of over 3500 cases of abortion, stillbirth and perinatal death in horses found congenital malformations in almost 10%.[37] A very extensive literature on congenital defects in animals exists and a bibliography is available.[38–40]

Some breeds and families have extraordinarily high prevalence rates because of intensive inbreeding. The extensive use, by artificial insemination, of certain genetics can result in a significant increase in the occurrence and nature of congenital defects when the bulls are carriers of genetic disease. The use of bulls that were carriers for the syndrome 'complex vertebral malformation' resulted in an approximately threefold increase in the presence of arthrogryposis, ventricular

septal defect and vertebral malformations in Holstein–Friesian calves submitted to diagnostic laboratories in the Netherlands between 1994 and 2000.[41]

In the USA an extensive registry has been established at the veterinary school at Kansas State University.

Checklists of recorded defects are included in the review literature.

PATHOGENESIS

The pathogenesis of many of the congenital defects of large animals is poorly understood but it is apparent that disease produced by each teratogen is likely to have its own unique pathogenesis. Congenital defects in large animals have examples of defects induced from structural malformations, from deformations, from the destruction of tissue by extraneous agents and from enzyme deficiencies – or from a combination of these.

Structural malformations and deformations

Structural malformations result from a localized error in morphogenesis. The insult leading to the morphogenic error takes place during organogenesis and thus is an influence imposed in early gestation. **Deformations** occur where there is an alteration in the shape of a structure of the body that has previously undergone normal differentiation. Deforming influences apply later in the early gestational period, after organogenesis.

Deformation is the cause of arthrogryposis and cleft palate produced by the piperidine alkaloids from *Conium maculatum* and *Nicotiana* spp. and by anagyrine from *Lupinus* spp., which produce a chemically induced reduction in fetal movements. Ultrasound examination of the normal fetus shows that it has several periods of stretching and vigorous galloping during a 30 minute examination period. In contrast, the fetus that is under the influence of anagyrine has restricted movement and lies quietly, often in a twisted position. Restricted fetal limb movement results in arthrogrypotic fixation of the limbs, and pressure of the tongue on the hard palate when the neck is in a constant flexed position inhibits closure of the palate. In experimental studies there is a strong relation between the degree and duration of reduced fetal movement, as observed by ultrasound, and the subsequent severity of lesions at birth.[21]

Restriction in the movement of the fetus, and deformation, can also result from teratogens that produce damage and malfunction in organ systems, such as the primary neuropathy that occurs in the autosomal recessive syndrome in Charolais cattle and the acquired neuropathy in Akabane infection, both of which result in arthrogryposis through absence of neurogenic influence on muscle activity.

It has been suggested, with some good evidence, that the etiology and pathogenesis of congenital torticollis and head scoliosis in the equine fetus are related to an increased incidence of transverse presentation of the fetus.[42,43] Flexural deformities of the limbs are also believed to be due to errors in fetal positioning and limited uterine accommodation, which may be further complicated by maternal obesity. Abnormal placental shape may also be important in the genesis of skeletal deformations.[44]

Viral teratogenesis

Viral teratogenesis is related to the susceptibility of undifferentiated and differentiated cells to attachment, penetration and virus replication, the pathogenicity of the virus (cytopathogenic versus noncytopathogenic strains of bovine virus diarrhea), the effects that the virus has on the cell and the stage of maturation of immunological function of the fetus at the time of infection. Viral infections can result in prenatal death, the birth of nonviable neonates with severe destructive lesions, or the birth of viable neonates with growth retardation or abnormal function (tremors, blindness). The gestational age at infection is a major influence. In sheep infected with border disease virus between 16 and 90 days of gestation, the occurrence of the syndromes of early embryonic death, abortion and stillbirth or the birth of defective and small weak lambs is related to the fetal age at infection. Certain viruses cause selective destruction of tissue and of organ function late in the gestational period and the abiotrophies are examples of selective enzyme deficiencies. The pathogenesis of the viral diseases is given under their specific headings in later chapters.

Inherited congenital defects

A number of **inherited congenital defects**, some of which are not clinically manifest until later in life, are associated with specific enzyme deficiencies. Examples are maple syrup urine disease (MSUD), citrullinemia, factor XI deficiency in cattle and the lysosomal storage diseases. Inherited lysosomal storage diseases occur when there is excessive accumulation of undigested substrate in cells. In mannosidosis, it is due to an accumulation of saccharides due to a deficiency of either lysosomal α-mannosidase or β-mannosidase. In GM_1 gangliosidosis, disease is due to a deficiency of β-galactosidase and in GM_2 gangliosidosis a deficiency of hexosaminidase.[45]

The age at development of clinical signs and their severity is dependent on the importance of the enzyme that is deficient, the biochemical function and cell type impacted and, in storage disease, the rate of substrate accumulation. Factor XI deficiency is manifest with bleeding tendencies but is not necessarily lethal. In contrast, calves with citrullinemia and MSUD develop neurologic signs and die shortly after birth, whereas the onset of clinical disease can be delayed for several months with α-mannosidosis.

CLINICAL AND NECROPSY FINDINGS

It is not intended to give details of the clinical signs of all the congenital defects here but some general comments are necessary. Approximately 50% of animals with congenital defects are **stillborn**. The defects are usually readily obvious clinically. Diseases of the nervous system and musculoskeletal system rate high in most published records and this may be related to the ease with which abnormalities of these systems can be observed. For example, in one survey of congenital defects in pigs, the percentage occurrence rates in the different body systems were as follows:

- Bones and joints 23%
- Central nervous system 17%
- Special sense organs 12%
- Combined alimentary and respiratory tracts (mostly cleft palate and atresia ani) 27%
- Miscellaneous (mostly monsters) 9%
- Genitourinary and abdominal wall (hernias) each 5%
- Cardiovascular system 3%.

In a survey of congenital defects in calves the percentage occurrence rates were:

- Musculoskeletal system 24%
- Respiratory and alimentary tracts 13%
- Central nervous system 22%
- Abdominal wall 9%
- Urogenital 4%
- Cardiovascular 3%
- Skin 2%
- Others 4%
- (Anomalous-joined twins and hydrops amnii accounted for 20%).

In a survey of foals the approximate percentage occurrence rates were:

- Musculoskeletal system 50%
- Respiratory and alimentary tracts 20%
- Urogenital 9%
- Abdominal wall 6%
- Cardiovascular 5%
- Eye 5%
- Central nervous system 5%.

Contracted foal syndrome and craniofacial abnormalities were the most com-

mon congenital defects in a study of stillbirth and perinatal death in horses.[37,46]

Many animals with congenital defects have more than one anomaly: in pigs, the average is two and considerable care must be taken to avoid missing a second and third defect in the excitement of finding the first. In some instances, the combinations of defects are repeated often enough to become specific entities. Examples are microphthalmia and cleft palate, which often occur together in piglets, and microphthalmia and patent interventricular septum in calves.

There are a number of defects that cannot be readily distinguished at birth and others that disappear subsequently. It is probably wise not to be too dogmatic in predicting the outcome in a patient with only a suspicion of a congenital defect or one in which the defect appears to be causing no apparent harm. A specific instance is the newborn foal with a cardiac murmur.

Sporadic cases of congenital defects are usually impossible to define etiologically but when the number of affected animals increases it becomes necessary and possible to attempt to determine the cause.

CLINICAL PATHOLOGY

The use of clinical pathology as an aid to diagnosis depends upon the disease that is suspected and its differential diagnosis. The approach varies markedly with different causes of congenital defects: **specific tests** and procedures are available for some of the viral teratogens, for congenital defects associated with nutritional deficiencies and for some enzyme deficiencies and storage diseases, and the specific approach for known teratogens is covered in the individual diseases section.

When an unknown viral teratogen is suspected, precolostral blood samples should be collected from the affected neonates and also from normal contemporaries that are subsequently born in the group. Precolostral serum can be used for investigating the possible fetal exposure of the group to an agent and the buffy coat or blood can be used for attempted virus isolation. IgG and IgM concentrations in precolostral serum may give an indication of fetal response to an infecting agent even if the agent is not known and there is no serological titer to known teratogenic agents.

Enzyme-based tests have been used to virtually eradicate carriers of α mannosidosis in cattle breeds in Australia and New Zealand[47] and DNA-based tests are used to detect and eliminate the carriers of diseases such as generalized glycogenosis in cattle.[48]

DIFFERENTIAL DIAGNOSIS

- The diagnostic challenge with congenital defects is to recognize and identify the defect and to determine the cause
- Syndromes of epidemic disease resulting from environmental teratogens are usually sufficiently distinct that they can be diagnosed on the basis of their epidemiology combined with their specific clinical, pathological and laboratory findings and on the availability of exposure
- Congenital defects occurring sporadically in individual animals pose a greater problem. There is usually little difficulty in defining the condition clinically, but it may be impossible to determine what was the cause. With conditions where there is not an obvious clinical diagnosis, an accurate clinical definition may allow placement of the syndrome within a grouping of previously described defects and suggest possible further laboratory testing for further differentiation.

The examination for cause of an unknown congenital defect is usually not undertaken unless more than a few newborn animals in a herd or area are affected in a short period of time with similar abnormalities. A detailed epidemiological investigation will be necessary which will include the following:

- Pedigree analysis. Does the frequency of occurrence of the defect suggest an inherited disease or is it characteristically nonhereditary?
- Nutritional history of dams of affected neonates and alterations in usual sources of feed
- Disease history of dams of affected neonates
- History of drugs used on dams
- Movement of dams during pregnancy to localities where contact with teratogens may have occurred
- Season of the year when insults may have occurred
- Introduction of animals to the herd.

The major difficulty in determining the cause of nonhereditary congenital defects is the long interval of time between when the causative agent was operative and when the animals are presented, often 6–8 months. Detailed clinical and pathological examination of affected animals offers the best opportunity in the initial approach to determine the etiology based on the presence of lesions that are known to be caused by certain teratogens.

INTRAUTERINE GROWTH RETARDATION

This is a special form of congenital defect. It is a failure to grow properly, as apposed to a failure to gain body weight, and occurs when the developmental age is less than the chronological (gestational) age. **Runt** is a common colloquial agricultural term. Normal fetal growth rate is determined by genetic and epigenetic factors and cross-breeding experiments suggest that fetal size is regulated by the embryonic/fetal genotype and also an effect of maternal genotype.[1] Litter size has an effect on birth weight in all species. A **genetic** association with intrauterine growth retardation has been shown in Japanese Black calves.[2]

There is a strong positive association between placental mass and fetal size at birth in all species and the majority of cases of growth retardation result from inadequate placentation, disturbance in utero-placental blood flow or placental pathology.

ETIOLOGY

There are a number of different etiologies.

Heat stress to ewes in the final third of pregnancy will result in intrauterine growth retardation but it is not as severe as when ewes are exposed in the second third of pregnancy – the period of placental growth.[3,4] Hyperthermia results in a redistribution of blood away from the placental vascular bed and a decrease in cotyledon mass with consequent reduction in birth weight. The degree of growth restriction is directly related to the degree of hyperthermia to which the ewe is exposed and her heat tolerance. The growth retardation affects fetal weight more than fetal length and, while there is some reduction in the growth of the brain, it is relatively less than that of the internal organs, resulting in an increased brain:liver weight ratio at birth.[5]

Viral infections, such as border disease and bovine virus diarrhea in ruminants and parvovirus in pigs, produce growth-retarded neonates,[6,7] as do bacterial and other infections that result in placentitis.

Inadequate placentation is the cause of runt piglets. Runts are smaller, thinner and have disproportionately larger, domed heads than normal pigs. A deficiency in specific **trace elements** is suspect in some field cases of growth retardation in ruminants but there is no evidence for deficient trace element nutrition in runt pigs.[8]

Inadequate nutrition can result in in-utero growth retardation. Growth retardation can be produced in fetal pigs, lambs and calves by **maternal caloric undernutrition**. Nutritional restriction in ewes reduces the number of placental lactogen receptors that mediate amino acid transport in fetal liver and glycogen synthesis in fetal tissue, leading to depletion of fetal liver glycogen stores. This has been postulated as a possible cause of the fetal growth retardation that accompanies maternal caloric undernutrition;[9] runt pigs have a reduced metabolic rate and lower skeletal muscle respiratory enzyme activity.[10] This deficiency persists after birth – runt pigs have a lower core temperature and a lessened ability to increase their metabolic rate and heat production in response to cold.[11]

Paradoxically, **overnourishing the adolescent ewe** will also result in placental growth restriction and in in-utero growth retardation.[4,12] This effect is most evident in the second third of pregnancy. This syndrome is accompanied by the birth of lambs with a shorter gestational age, commonly reduced by 3 days. It is thought that the fetal hypoxia and hypoglycemia that accompanies placental insufficiency might stimulate the maturation of the fetal hypothalamic–pituitary–adrenal axis, initiating early parturition. The growth of those lambs that survive initially lags behind that of normal lambs but there is compensatory growth and no difference in weight at 6 months-of age.[13]

Measurements that can be used to determine the presence of growth retardation in a **dead fetus** include crown–rump (anal) length, brain weight, body weight, brain to body weight ratios, long bone weight and appendicular ossification centers. Formulas are available to determine the degree of growth retardation.[14]

In the **live animal** the presence of radiodense lines in long bones and the examination of closure of ossification centers can provide evidence for prior stressors in pregnancy that induce fetal growth retardation, such as malnutrition or infection of the dam, that may not be found by other examinations.[7,15,16]

Intrauterine growth retardation is accompanied by an impaired cellular development of tissues such as the small intestine and skeletal muscle and disproportionately large reductions in the growth of some organs such as the thymus, spleen, liver, kidney, ovary and thyroid. There is an associated impairment of thermogenesis, immune and organ function at birth.[17–19] In lambs there is impaired development of secondary wool follicles.

The **survival** of fetuses with growth retardation requires special nutritional care and the provision of adequate heat, and is discussed in the section on Critical care for the newborn. In large piggeries that practice batch farrowing, the survival of runts can be significantly improved by the simple practice of fostering them together in one litter on one sow so that they do not have to compete with larger-birth-size and more vigorous pigs, by ensuring adequate colostrum intake and adequate environmental warmth and by feeding using a stomach tube in the first few hours of life if indicated.

NEONATAL NEOPLASIA

Congenital neoplasia is rare, occurring at a substantially lower rate than in adults, and accounts for a minor percentage of findings in surveys of neonatal mortality.[1,2] It is probable that genetic rather than environmental factors influence its development.

Clinical signs depend upon the type of neoplasm and its site and they can result

in dystocia or abortion. A variety of tumors have been recorded in all large animal species and are predominantly of mesenchymal origin.[2,3]

In calves, malignant lymphoma is most commonly reported. It is usually multicentric and also affects the skin. Sporadic bovine leukosis of young calves may also be present at birth Other tumors reported predominant in calves include diffuse peritoneal mesothelioma, mixed mesodermal tumor, mast cell tumor, hemangiomas and cutaneous melanoma.[2,4]

Melanomas (both benign and malignant) also occur in foals and piglets. Duroc Jersey, Vietnamese pot-bellied pigs and Sinclair miniature pigs have a high incidence of congenital malignant melanoma, which is fatal in approximately 15% of affected pigs but regresses spontaneously, and without recurrence, in the remainder.[5,6]

A breed predisposition to cardiac rhabdomyoma is recorded in Red Wattle pigs.[7]

Papillomatosis is rare but **lingual papillomatosis** is reported as a cause of enzootic disease of piglets in China.[5]

Physical and environmental causes of perinatal disease

Disease in the neonate can result directly from noxious influences in the postnatal period but it can also be predisposed or produced by noxious influences in the period before and during birth.

PERINATOLOGY

The clinical care of the newborn animal in large animal veterinary medicine has traditionally started at the time of birth but there is a growing recognition of the importance of antenatal and parturient events to the subsequent viability of the neonate. This has been particularly recognized by equine clinicians and has led to the clinical concept of perinatology.[1] One purpose of perinatology is to expand the care of the neonate into the antenatal and parturient period by measurements that reflect fetal health or that can predict risk to fetal viability. Measures that can be used are still being developed and evaluated but the following include those that have apparent value.[2,3]

Heart rate

In the horse, **fetal heart rate** recorded by electrocardiography (ECG) or by ultrasound can be used as a measure of fetal viability, for the detection of twins and as a monitor for fetal distress during parturition. Fetal heart rate decreases logarithmically from approximately 110 beats/min at 150 days before term to 60–80 beats/min near to term.[4] It has been suggested that a base heart rate of 80–92 beats/min with baseline variations of 7–15 beats/min and occasional accelerations above this is normal for the fetal heart rate of equines, and that bradycardia is evidence of abnormality.[2] Continued monitoring traces may be needed to assess fetal distress. Cardiac arrhythmia is common at the time of birth and for the first few minutes following and is believed to result from the transient physiological hypoxemia that occurs during the birth process.[5]

Ultrasound examination

The foal can be examined by **ultrasound** to establish the presentation, the presence of twins, the heart rate, the presence and quality of fetal movement, the presence of placentitis, placental thickness, the presence of echogenic particles in the amniotic fluid and an estimate of body size from the measurement of the aortic and orbit diameters. Measurements of fetal heart rate, fetal aortic diameter, uteroplacental contact, maximal fetal fluid depths, uteroplacental thickness and fetal activity have allowed the development of an objective measurement profile to assess fetal wellbeing.[2,6]

The examination of the **amniotic fluid** for the determination of pulmonary maturity and other measures of foal health may be limited as there is a cosiderable risk for abortion and placentitis, even with ultrasound-guided amniocentesis, and the technique is not recommended for routine clinical use.[7,8]

Prematurity

Foals born at less than 320 days of gestational age are considered premature and those less than 310 days are at significant risk for increased mortality. Traditionally, external signs have been used to predict a premature foaling and the common signs used are the enlargement of the udder, milk flow and the occurrence of vaginal discharge. Causes of early foaling include bacterial or fungal placentitis and twin pregnancy.[9] Several **assays** are used as alternate methods of determining if foaling is imminent and if problems are present.

Plasma **progestogen** concentrations decline in pregnancy to reach a low around 150 days of gestation. In Thoroughbreds, they remain below 10 ng/mL until approximately 20 days prior to foaling when they start to increase but in ponies there is a greater variation.[10,11] Concentrations decline 24 hours before parturition. Plasma progestogen cannot be used to accurately predict the time of foaling and a single sample is not diagnostic.[8] There is a strong correlation between the presence of plasma progestogen concentrations above 10 ng/mL before a gestational age of 310 days and the presence of placental pathology[2] and a rapid drop in concentration to below 2 ng/mL that persists for more than 3 days indicates impending abortion. Current research is examining the profiles of individual progestogens during pregnancy to determine if the profile of any one can be used as a predictor of fetal distress.[12]

During the last week of gestation the concentration of calcium and potassium in **milk** increases and that of sodium decreases. The rise in calcium concentrations are the most reliable predictor of fetal maturity[3] and milk calcium concentrations above 10 mmol/L, in combination with a concentration of potassium that is greater than sodium, are indicative of fetal maturity. Milk calcium concentrations above 10 mmol/L in the earlier stages of pregnancy are suggestive of fetal compromise.[2] Commercial milk test strips are available for estimating mammary secretion electrolyte concentrations; however, it is recommended that testing be done in an accredited laboratory.[13]

PREMATURITY AND DYSMATURITY OF FOALS

Foals that are born before 300 days are unlikely to survive and foals born between 300 and 320 days of gestation are considered premature but may survive with adequate care.[1,2] **Premature foals** are characterized clinically by low birth weight, generalized muscle weakness, poor ability to stand, lax flexor tendons, weak or no suck reflex, lack of righting ability, respiratory distress, short silky haircoat, pliant ears, soft lips, increased passive range of limb motion, and sloping pastern axis. Radiographs may show incomplete ossification of the carpal and tarsal bones and immaturity of the lung and there may be clinical evidence of respiratory distress. **Full term foals** born after 320 days of gestation but exhibiting signs of prematurity are described as **dysmature.**

Premature foals have hypoadrenal corticalism. They are neutropenic and lymphopenic at birth and have a narrow neutrophil to lymphocyte ratio.[3,4] In premature foals older than 35 hours the neutrophil count can be used to predict survival and foals that remain neutropenic after this time have a poor prognosis.[4,5] Premature foals also have low plasma glucose, low plasma cortisol and a blood pH of less than 7.25. An extensive collaborative investigation of equine prematurity has been conducted and information on foal metabolism[6–9] and guidelines for laboratory and clinical assessment of maturity are available.[5,10]

The **placenta** is critical to the fetus in the antenatal period and pregnancies involving placental pathology commonly result in foals that suffer premature-like signs at whatever stage they are delivered.[11] Placental edema, placental villous atrophy and premature separation of the placenta are significant causes.[12,13]

Precocious lactation of the mare can be associated with placentitis. The examination of the placenta for evidence of placentitis and for the presence of larger than normal avillous areas should be part of normal foaling management. A study of the equine placenta showed a high correlation between both allantochorionic weight and area and foal weight in normal placentas. Normal placentas had a low association with subsequent perinatal disease in the foals. In contrast, abnormal placental histology was associated with poor foal outcome (three normal foals from 32 abnormal placentas). Cords longer than 70 cm were often associated with fetal death or malformation. Edema, sacculation and strangulation are other abnormalities and can be associated with microscopic deposits of mineral within the lumen of placental blood vessels.[12]

PARTURIENT INJURY AND INTRAPARTUM DEATH

During parturition extreme mechanical forces are brought to bear upon the fetus and these can result in direct traumatic damage or can impair fetal circulation of blood by entrapment of the umbilical cord between the fetus and the maternal pelvis, which may lead to hypoxemia or anoxia and death of the fetus during the birth process. Neonates that suffer birth trauma and anoxia but survive are at risk for development of the neonatal maladjustment syndrome,[1] have reduced vigor, are slower to suck and are at increased risk for postnatal mortality.

In all species, but in ruminants in particular, the **condition of the dam** can have a marked influence on the prevalence of birth injury and its consequences. The effect is well illustrated in sheep, where the two extremes of condition can cause problems. Ewes on a high plane of nutrition produce a large fetus and also deposit fat in the pelvic girdle, which constricts the birth canal, predisposing to dystocia. Conversely, thin ewes may be too weak to give birth rapidly.[2] **Pelvic size** can influence the risk of birth injury and ewe lambs and heifers mated before they reach 65% of mature weight are at risk. **Pelvimetry** is used to select heifers with adequate pelvic size for breeding but the accuracy and validity is seriously questioned.[3,4] **Breed** is also a determinant of length and ease of labor and the subsequent quickness to time to first suckle.[5]

TRAUMA AT PARTURITION

Traumatic injuries can occur in apparently normal births, with prolonged birth and as a result of dystocia, which may or may not be assisted by the owner. Incompatibility in the sizes of the fetus and the dam's pelvis is the single most important cause of dystocia, and birth weight is the most important contributing factor. In cattle, expected progeny difference (EPD) estimates for calf birth weight are good predictors of calving ease.[3] In foals, calves and lambs the chest is most vulnerable to traumatic injury but there is the chance of vertebral fracture and physical trauma to limbs with excessive external traction.

Fractured ribs are common in foals and can lead to laceration of the lungs and heart and internal hemorrhage.[6] **Rupture of the liver** is common in some breeds of sheep[7,8] and can also occur in calves and foals. A retrospective study of rib and vertebral fractures in calves suggests that most result from excessive traction and that as a result smaller dystocial calves are more at risk.[9] **Vertebral fractures** occur as the result of traction in calves with posterior presentations and in calves with hip lock. Trauma is a major cause of neonatal mortality in piglets but it occurs in the postparturient phase and is associated with being overlain or stepped on by the sow. It is possible that the underlying cause of crushing mortality in piglets is hypothermia.[10]

Intracranial hemorrhage can result in damage to the brain. A high proportion (70%) of nonsurviving neonatal lambs at, or within 7 days of birth have been shown to have single or multiple intracranial hemorrhages, the highest incidence being in lambs of high birth weight. Similar lesions have been identified in foals and calves. Experimentally controlled parturition in ewes showed that duration and vigor of the birth process affected the severity of intracranial hemorrhages and further studies indicated that these birth-injured lambs had depressed feeding activity and that they were particularly susceptible to death from hypothermia and starvation.[11,12]

Birth anoxia associated with severe dystocia in cattle can result in calves with lower rectal temperatures in the perinatal period than normal calves and a decreased ability to withstand cold stress.[13]

Intracranial hemorrhage, especially subarachnoid hemorrhage, occurs in normal full-term deliveries as the result of physical or asphyxial trauma during or immediately following delivery.[14] The forceful uterine contractions associated with parturition can result in surges of cerebral vascular pressure resulting in subarachnoid hemorrhage. It is also of common occurrence in foals born before full term.[15] In one study, the highest incidence occurred in pony foals in which parturition was induced prior to 301 days of gestation. Similar hemorrhage occurred in pony foals born by cesarean section at 270 and 280 days of gestation and appeared associated with anoxic damage.

In a prolonged birth, **edema** of parts of the body, such as the head and particularly the tongue, may also occur. This occurs particularly in the calf and the lamb, possibly because of less close supervision at parturition and also because the young of these species can sustain a prolonged birthing process for longer periods than the foal without their own death or death of the dam. The edema can interfere with subsequent sucking but the principal problem relative to neonatal disease is the effect of the often prolonged hypoxia to which the fetus is subjected. There is interference with the placental circulation and failure of the fetus to reach the external environment. The hypoxia may be sufficient to produce a stillborn neonate, or the neonate may be alive at birth but not survive because of irreparable brain damage. Intrapartum deaths due to prolonged parturition occur in piglets.

FETAL HYPOXIA

Hypoxemia and hypoxia can occur as a result of influences during the birth process or because of pulmonary immaturity in premature births.[1,2]

Transient tachypnea occurs following birth and is believed to be due to transient hypoxemia associated with the birth process and the absorption of pulmonary fluid.

Prolonged tachypnea, with flaring of the nostrils, open-mouth breathing, exaggerated rib retraction and paradoxical breathing patterns, is highly suggestive of primary pulmonary abnormality. Failure of respiration can occur at this stage and creates an urgent need for resuscitation measures. In the foal, **body position** can have a major effect on arterial oxygen tension.[3] A foal that is unable to stand or to right itself from lateral recumbency is at risk from atelectasis[4] and should be moved frequently. Hypoxia and hypercapnia resulting from mismatching of ventilation and perfusion are accentuated by prolonged recumbency.

Placental dysfunction or occlusion of the umbilicus in the second stage of labor can result in a much more serious situation so that the neonate is born in a state of terminal, as distinct from primary, apnea. It will be stillborn unless urgent and vigorous resuscitation is initiated immediately. Resuscitation includes:

- Establishing a patent airway by extending the head and clearing the nostrils of mucus and, if necessary, by postural drainage to clear excess fluids from the airways
- Artificial ventilation. This is easier if the foal is intubated but can also be achieved by sealing one nostril by hand and breathing forcibly into the other (or inflating with a rubber tube from an oxygen cylinder, delivering at a rate of 5 L/min). The chest wall should be moved only slightly with each positive breath. Continue at 25 ventilations/min until respiration is spontaneous
- Administering 200 mL 5% sodium bicarbonate solution intravenously to counter acidosis. However, respiratory acidosis with hypoxemia and hypercapnia should be primarily treated by assisted ventilation.

In general, the response of the neonate to hypoxemia is an increase in blood pressure and a redistribution of cardiac output with increased blood flow to the brain, heart and adrenal gland and a reduction in flow to the lungs, kidney, gastrointestinal tract and carcass.[5,6] These regulatory changes fail with developing hypoxia and metabolic acidosis and failure leads eventually to cerebral anoxia. The avoidance of acidemia and the maintenance of an adequate oxygen supply are essential in the care of hypoxemic and premature foals.

A special cause of hypoxia, due usually to hypovolemia in addition to inadequate oxygenation of blood, occurs in the foal as a result of an inadequate **placental blood transfusion**, when the umbilical cord is severed too early after birth. This is one cause of the neonatal maladjustment syndrome, which is detailed in another section of this text.

Intrapartum hypoxemia due to **prolonged parturition** is common,[7] particularly in calves born to first-calf beef heifers, and is considered to be one cause of the 'weak calf syndrome' described in Chapter 36.

A similar syndrome has been produced experimentally by clamping the umbilical cord of the bovine fetus in utero for 6–8 minutes, followed by a cesarean section 30–40 minutes later. Calves born following this procedure may die in 10–15 minutes after birth or survive for only up to 2 days.[8] During the experimental clamping of the umbilical cord, there is a decline in the blood pH, P_{O_2} and standard bicarbonate levels and an increase in P_{CO_2} and lactate levels.[8] There is also increased fetal movement during clamping and a release of meconium, which stains the calf and the amniotic fluid. Those that survive for a few hours or days are dull, depressed, cannot stand, have poor sucking and swallowing reflexes and their temperature is usually subnormal. They respond poorly to supportive therapy. A slight body tremor may be present and occasionally tetany and opisthotonus occur before death. Calves that are barely able to stand cannot find the teats of the dam because of uncontrolled head movements. At necropsy of these experimental cases, there are petechial and ecchymotic hemorrhages on the myocardium and endocardium, an excess of pericardial fluid, and the lungs are inflated. When the experimental clamping lasts only 4 minutes, the calves usually survive.

Meconium staining (brown discoloration) of the coat of the newborn at birth is an important indicator that it has suffered hypoxia during or preceding the birth process; such neonates require close supervision in the early postnatal period. In lambs, severe hypoxia during birth results in death shortly following birth and there is an increased risk in those that survive for metabolic acidosis and depressed heat production capacity, which causes hypothermia.[9]

Fetal anoxia associated with **premature expulsion** of the **placenta** occurs in all species but may be of greatest importance in cattle.[10] It occurs in all parities of cow and with little relation to calving difficulty, although malpresentation is a predisposing factor. Prepartum diagnosis in cattle is hindered by the low prevalence of prepartum vaginal hemorrhage, and the majority of fetuses die during the birth process. The placenta is expelled with the

fetus. **Premature separation** of the placenta ('red bag') occurs in foals when foals experience difficulty in breaking through the cervical star region of an edematous thickened placenta. This is an emergency and requires immediate attention.

In all species the prevention of intrapartum hypoxia depends on the provision of surveillance. Universal surveillance is usually not practical for species other than the horse, and in cattle, for example, it tends to concentrate on the group at most risk so that surveillance, and assistance if necessary, is provided for first-calf heifers at the time of calving. Heifers that do not continue to show progress during the second stage of parturition should be examined for evidence of dystocia, and obstetrical assistance should be provided if necessary.

The treatment and care of foals with this syndrome is described under Critical care of the newborn later in the chapter. The monitoring, treatment and care of agricultural animals with this syndrome should follow the same principles but is usually limited by the value of the animal and the immediate access to a laboratory. Measures such as the time from birth to sternal recumbency, time from birth to standing and time from birth to first suckle have been used to grade calves and identify those that might require intervention and treatment, but the best method of evaluation is an assessment of muscle tone.[11] There is no effective practical treatment for calves affected with intrapartum hypoxia other than the provision of ventilation as for the foal and the correction of the acidosis. The airway should be cleared and, if physical stimulation of ventilation gives no response, then mechanical ventilation should be attempted. The practice of direct mouth-to-mouth ventilation assistance should be strongly discouraged, especially in lambs, because of the risk from zoonotic disease agents. Doxapram hydrochloride has been used in calves to stimulate respiration.[11]

The provision of warmth, force-feeding of colostrum and fluid therapy are logical support approaches.

HYPOTHERMIA

The environment of the neonate can have a profound effect on its survival. This is especially true for lambs and piglets, in which hypothermia and hypoglycemia are common causes of death. Hypothermia can also predispose to infectious disease and can adversely affect the response of neonates in coping with an exogenous endotoxin challenge. Endotoxin exposure of hypothermic pigs results in an even greater reduction in body temperature.[1]

LAMBS

Lambs are very susceptible to cold and hypothermia is an important cause of mortality in the early postnatal period. **Cold stress** to neonatal lambs exists in three forms, ambient temperature, wind and evaporative cooling. The healthy newborn lamb has a good ability to increase its metabolic rate in response to a cold stress by shivering and non-shivering thermogenesis (brown adipose tissue). The energy sources in the neonatal lamb are liver and muscle glycogen, brown adipose tissue and, if it sucks, the energy obtained from colostrum and milk. The ingestion of colostrum can be essential for early thermogenesis in lambs, especially twin lambs.[2]

The **critical temperature** (the ambient temperature below which a lamb must increase metabolic heat production to maintain body temperature) for light birth-weight lambs is 31–37°C in the first days of life.

The risk for mortality from hypothermia is highest in lambs of small birth size. **Heat production** is a function of body mass while **heat loss** is a function of body surface area. Large-birth-size lambs have a greater body mass in relation to their surface areas and are thus more resistant to environmental cold stress. In contrast, small-birth-size lambs, with a smaller body mass relative to surface area, are more susceptible. The dramatic nature of this relationship was shown in early studies on cold stress and survival in lambs many years ago. Birth weight is lower in twins and triplets and in the progeny of maiden ewes. Susceptibility is also influenced by maternal nutrition in pregnancy (see next section), as this can both influence placental mass, birth weight and the energy reserves of the neonate, and also affect the activity of the ewe at parturition, and the resultant poor mothering behavior and mismothering can result in starvation in the lamb.

Lambs are particularly susceptible to cold stress during the first 5 days of life. During this period hypothermia can result from heat loss in excess of summit metabolism or from depressed heat production caused by intrapartum hypoxia, immaturity and starvation.[3]

Heat loss in excess of summit metabolism

Low-birth-weight lambs born into a cool environment where there is wind are especially susceptible because of the evaporative cooling of fetal fluids on the fleece.[4] To a small newborn lamb the evaporative cooling effect of a breeze of 19 km/h (12 mph) at an ambient temperature of 13°C (55°F), common in lambing seasons in many countries, can be the equivalent of a cold stress equivalent to 25°C. The heat loss in these circumstances can exceed their ability to produce heat (summit metabolism) and progressive hypothermia and death results. Hypothermia due to heat loss in excess of summit metabolism can also occur when there is rain or just with cold and wind. This mortality occurs primarily in the first 12 hours of life.

Hypothermia from depleted energy reserves

Hypothermia occurring in lambs after 12 hours of age is usually due to depletion of energy reserves in periods of cold stress. There are three major causes. Milk is the sustaining energy source.

One of the early manifestations of developing hypothermia is the **loss of sucking drive**; severe cold stress and developing hypothermia can result in low milk intake and depletion of energy reserves.

The second important cause is **mismothering**; the third is related to **birth injury**. Dystocia-related hypoxia results in acidemia, a reduction in summit metabolism and disturbance in thermoregulation and can result in hypothermia.[5] Birth-injured lambs, usually large single-born lambs, have depressed sucking and feeding activity.[6,7] Systems are available for the categorization of deaths based on postmortem examination.[7–9]

In lambs that have hypothermia associated with heat loss in excess of summit metabolism, heat is required for **therapy**, but in lambs with starvation hypothermia the administration of glucose is also necessary. Glucose is administered intraperitoneally at a dose of 2 g/kg body weight using a 20% solution. Following the administration of the glucose, the lambs should be dried with a towel if wet and rewarmed in air at 40°C (104°F). This can be done in a warming box using a radiant heater as the heat supply. Care should be taken to avoid the occurrence

of hyperthermia. Careful attention must be given to the nutrition of the lambs after rewarming otherwise relapse will occur. A feeding of 100–200 mL of colostrum will also be beneficial but lambs should not be fed before they are normothermic, as aspiration pneumonia is a risk. Experimental hypothermia in lambs has shown little direct long-term pathological effect.[10]

In most countries the selection of time of lambing is dictated by nutritional considerations and the seasonality of the ewes' sexual behavior and lambing occurs at a time of year when cold stress is likely. The **control** of loss from hypothermia in newborn lambs requires supervision at lambing and protection from cold. Shed lambing will reduce cold stress loss. The provision of shelter in lambing paddocks may be effective but site is important as birth sites in lambing paddocks are not randomly distributed and there is variation in the preferred sites between breeds.[5] Some ewes will seek shelter at lambing but many ewes in wool will not. In some flocks, sheep are shorn before lambing in an attempt to force this shelter-seeking trait.

Experimentally, there is a strong relationship between breed and the degree of hypothermia produced.[10] There is also convincing evidence that rearing ability is heritable in sheep, that some of this relates to traits within the newborn lamb, and that a significant reduction in neonatal mortality associated with susceptibility to hyperthermia could be achieved with a genetic approach.[6,7,10–12]

Lambs are also susceptible to hyperthermia and thermoregulation is not efficient at high environmental temperatures. Heat prostration and some deaths can occur in range lambs when the environmental temperature is high, especially if lambs have to perform prolonged physical exercise and if there is an absence of shade.

CALVES

Hypothermia as a result of environmental influence is less common in full-term healthy calves than in lambs but mortality rates have been shown to increase with decreasing ambient temperature and increasing precipitation on the day of birth.[13] The **critical temperature** for neonatal calves is much lower than for lambs, approximately 13°C, and *Bos taurus* calves are more resistant to cold stress than *Bos indicus*.[14]

Experimentally produced hypothermia in calves has also been shown to cause little overt injury except for peripheral damage to exterior tissues.[15,16] During cooling, there can be significant peripheral hypothermia prior to any marked reduction in core body temperature. Calves have a remarkable ability to resist and overcome the effects of severe cold temperatures.[14,16] However, there is a relationship between the occurrence of cold weather and calf deaths, including those due to the 'weak calf syndrome', and deficiencies in thermoregulation occur in animals born prematurely and in dystocial calves. As in lambs, dystocia will reduce teat-seeking activity and sucking drive and dystocial calves have lower intakes of colostrum[17] and lower body temperatures and decreased ability to withstand cold stress.[18]

Rewarming of hypothermic calves can be by radiant heat but immersion in warm water produces a more rapid response and with minimal metabolic effort. The prevention of hypothermia requires the provision of shelter from wet and wind for the first few days of life. Cows can be calved in a shed, or alternately sheds for calves can be provided in the fields. Beef calves will use shelters in inclement weather; these may not improve their health status, although they are in common use.[19]

PIGLETS

Hypothermia from heat loss and hypothermia/hypoglycemia from starvation are major causes of loss in neonatal pigs.[20] Newborn piglets have a reasonably good ability to increase their metabolic rate in response to cold stress but they have limited energy reserves, especially limited brown adipose tissue, and they consequently rely on a continual intake of milk for their major energy source, sucking approximately every hour. Young pigs have a good ability for peripheral vasoconstriction at birth but surface insulation is deficient because at this age there is no subcutaneous layer of fat. The **critical temperature** for young pigs is 34°C.

Thermoregulation is inefficient during the first 9 days of life and is not fully functional until the 20th day. Newborn piglets must be provided with an external heat source in the first few weeks of life. The body temperature of the sow cannot be relied upon for this and the preferred air temperature for neonatal pigs is 32°C (89.5°F) during the first day and 30°C (86°F) for the first week. In contrast, the preferred temperature for the sow is about 18°C. A **separate environment** (creep area) must be provided for the piglets. Providing there is an adequate ambient temperature to meet the requirements of the piglets, and good floor insulation, hypothermia will not occur in healthy piglets of viable size unless there is a failure of milk intake.

Birth anoxia, with resultant reduced vigor, reduced teat-seeking activity and **risk for hypothermia**, occurs particularly in later-birth-order pigs in large litters from older sows. Failure of milk intake can also occur with small-birth-size piglets and is influenced by litter size, low number of functional teats relative to litter size and teat sucking order.

FOALS

There have been few studies on thermoregulation in foals but the large body mass in relation to surface area renders healthy newborn foals, like healthy calves, relatively resistant to cold. Also, foals are less likely to be born in a hostile environment than other farm animals. Significant foal mortality from hypothermia as a result of starvation and exposure can occur in extensively managed herds and dystocia, low birth weight and poor mothering are contributing factors.[21]

Sick and **premature foals** may have difficulty in maintaining body temperature in normal environments and the metabolic rates of sick foals and premature foals are approximately 25% lower than healthy foals.[22,23]

The relatively larger surface area to mass ratio, lower energy reserves and lower insulation of the coat of premature foals, coupled with the lower metabolic rate, places them at particular risk for hypothermia. **Dystocial foals** also have lower metabolic rates but dysmature foals appear to thermoregulate normally.[22,24] Methods of investigation that allow postmortem differentiation of placental insufficiency, acute intrapartum hypoxemia, inadequate thermogenesis and starvation as causes of mortality in foals are described.[8]

Hypothermia should be suspected in premature foals when the rectal temperature falls below 37.2°C (99°F) and should be corrected with external warmth, rugging or moving to a heated environment. If fluids are being administered they should be heated to normal body temperature.

MATERNAL NUTRITION AND THE NEWBORN

Effects on both the dam and the fetus can occur from overfeeding or underfeeding of the dam, and there can be effects from the influences of trace element deficiencies or toxic substances. Severe **undernutrition** of the dam can affect fetal size, and its thermogenic rate, with consequences mentioned earlier. Prepartum protein restriction has most effect.[1] Severe undernutrition of the dam can also lead to weak labor, increased rates of dystocia and can limit the development of the udder. Colostrogenesis may be impaired, with a greater risk of infectious disease in the neonate, and milk production may be significantly reduced or delayed, with a risk of starvation.

Most information is available for the effects of nutrition of the pregnant ewe on fetal growth rate, udder development, the availability of energy in the body reserves of fetuses at term, and the amount and energy content of colostrum.[2–4] In sheep, maternal nutrition can have a significant influence on fetal growth rate and on placental size. The underfeeding of hill sheep in late pregnancy markedly reduces the term weight of the udder and the prenatal accumulation and subsequent rates of secretion of colostrum.[4] A low plane of nutrition in late pregnancy results in a marked decrease in fetal body lipid and brown fat reserves, and marked reductions in the total production of colostrum and in the concentration in colostrum during the first 18 hours after parturition.[4] However, exposure of late pregnant ewes to cold by shearing increases lamb birth weight and lamb brown fat reserves.[5,6]

Inadequate nutrition can also result in in-utero growth retardation. Growth retardation can be produced in fetal pigs, lambs and calves by **maternal caloric undernutrition**. Nutritional restriction in ewes reduces the number of placental lactogen receptors that mediate amino acid transport in fetal liver and glycogen synthesis in fetal tissue, leading to depletion of fetal liver glycogen stores. This has been postulated as a possible cause of the fetal growth retardation that accompanies maternal caloric undernutrition. Runt pigs have a reduced metabolic rate and lower skeletal muscle respiratory enzyme activity. This deficiency persists after birth – runt pigs have a lower core temperature and a lessened ability to increase their metabolic rate and heat production in response to cold. Paradoxically, **overnourishing the adolescent ewe** will also result placental growth restriction and in in-utero growth retardation.[7,8] This effect is most evident in the second third of pregnancy. This syndrome is accompanied by the birth of lambs with a shorter gestational age, commonly reduced by 3 days. It is thought that the fetal hypoxia and hypoglycemia that accompanies placental insufficiency might stimulate the maturation of the fetal hypothalamic–pituitary–adrenal axis initiating early parturition.

Maximum lamb survival is achieved at intermediate lamb birth weights and the **nutritional management** of the pregnant ewe in fecund flocks is very important.[9] Ewes with multiple lambs can be selected using ultrasound and fed separately from those with singles. Pregnant maiden ewes should also be fed to their separate requirements. The recommendation is for a body condition score of 3.0–3.5 at mating, with a fall of 0.5 in score during the second and third months of pregnancy and a subsequent rise in score to 3.55 to the point of lambing, and with a distinct weight gain in late pregnancy. Equivalent condition scores are also appropriate for other species.

Toxic substances and trace element deficiencies can result in increased risk for fetal and neonatal mortality and are discussed under those headings. One of particular significance is agalactia, prolonged gestation and fetal distress at birth seen in mares fed grain contaminated with ergot (*Claviceps purpurea*) and in mares grazing tall fescue (*Festuca arundinacea*) containing the endophyte fungus *Acremonium coenophialum*.

POOR MOTHER–YOUNG RELATIONSHIP

Any examination of neonatal mortality suspected of being caused by hypothermia, starvation or infection due to failure of transfer of passive immunity, and even trauma by crushing in piglets, must take into account the possibility that poor mothering and a poor mother–young bond may be the primary cause. Inadequate maternal care leads to rapid death of the newborn under extensive conditions where there is no human intervention to correct the problem. The defect is most likely to be on the side of the dam but may originate with the offspring. A poor relationship may be genetic or nutritional and, on the part of the offspring, may be the result of birth trauma.

For both the dam and the young there is a much greater chance of establishing a good bond if the animal has been reared in a group rather than as an individual. Because sight, smell, taste and hearing are all important in the establishment of a seeking and posturing to suckle activity by the dam and a seeking, nuzzling and sucking activity by the offspring, any husbandry factor that interferes with the use of these senses predisposes to mortality. Weakness of the offspring due to poor nutrition of the dam, harassment at parturition by overzealous attendants and high growth of pasture are obvious examples. This can be a problem in cattle, pigs and sheep, and occasionally in horses, especially with extensive foaling practices.[1] In pigs it may be developed to an intense degree in the form of farrowing hysteria, and is dealt with under that heading. In sheep it can be a significant contributor to neonatal death from starvation, especially in highly strung breeds like the Merino.[2]

Bonding occurs rapidly after birth, although there is some minor variation between species with bonding starting within a few minutes of birth in sheep but taking up to 2–3 hours in some horses.[3] The strength of bonding also appears to vary between species.[4] The bonding of the dam to the neonate is usually quite specific, although this can be modulated by management systems, and the neonate

may be less selective and will often attempt to suck other dams. With sheep lambed under intensive lambing practices, this can lead to high rates of mismothering and subsequent abandonment, when preparturient 'robber' ewes adopt lambs from multiple births. A high degree of shepherding is required to minimize loss in these management systems, whereas in extensive systems a strong bonding is established providing the ewe and lamb are allowed to remain relatively undisturbed on the lambing site for 6 hours.[2]

Vaginal cervical stimulation and the central release of oxytocin are believed to be important in initiating maternal behavior[5,6] though caudal epidural anesthesia for delivery does not effect mothering or bonding.[7] Sucking is also a major determinant. Recognition is olfactory and auditory and mediated by the release of neurotransmitters.[8]

Bonding is often slower with primiparous dams and is also delayed where there is postpartum pain. A failure of bonding leads to rejection and abandonment of the neonate.

Maternal care is also important to neonatal survival and there is significant difference in litter mortality from crushing and injury between sows related to sow behavior and their response to piglet distress calls.[9] A description of normal and abnormal behavioral patterns of the mare and foal is available[10] and techniques for fostering are described.[3,11]

INDUCTION OF PREMATURE PARTURITION

CALVES

The medical induction of parturition by the parenteral injection of corticosteroid into pregnant cows during the last 6 weeks of pregnancy has raised the question of animal welfare and of the possible effects of prematurity on the disease resistance of the newborn calf. The induction of premature parturition in cattle has found application in five main areas:

- With pastoral-based dairy production, synchronization of the calving period has allowed maximal utilization of seasonally available pastures by the synchronization of peak demand for dry matter intake with spring flush in pasture growth. In pastoral-based herds with breeding for seasonal calving, late-calving cows will be induced and these average approximately 8% of the herd[1]
- Ensuring that calving coincides with the availability of labor to facilitate observations and management of calving and to overcome the inconvenience caused by late-calving cows
- Minimizing dystocia in small heifers
- The therapeutic termination of pregnancy for various clinical reasons, including potential problems such are associated with pregnancy in feedlot heifers
- As an aid in the control of milk fever using vitamin D analogs [2]

A variety of short-acting and long-acting corticosteroids have been used. A single injection of a short-acting formulation is used when it is desirable to induce calving in the last 2–3 weeks of gestation. Earlier in pregnancy the long-acting formulations are more reliable. Sometimes this is followed in 5–8 days by treatment with a short-acting glucocorticoid. Parturition occurs 30–60 hours (mean 48 h) after injection.

Some reports have indicated that the **mortality rate** of induced calves was higher than expected, and that the level of serum immunoglobulins was lower because of interference with absorption by the corticosteroid. Mortality in calves born as a result of induced parturition is primarily as a result of prematurity and calf mortality is generally low when calving is induced within 12 days of parturition, although there are welfare concerns.[3] The calves are usually lighter in weight. The health of calves that survive is generally good, provided they receive adequate quantities of colostrum. When short-acting corticosteroids are used to induce calving close to term, the ability of the calves to absorb immunoglobulins from colostrum is not impaired. However, calves born earlier in pregnancy after using long-acting corticosteroid are lethargic, slow to stand and to suck properly and their ability to absorb immunoglobulins is impaired.[2] Up to 60% of calves born following induction with long-acting corticosteroids are at risk for failure of transfer of immunoglobulins. The colostrum available to such calves also has a reduced content of immunoglobulins, and there may also be a reduction in the total volume of colostrum available from the induced-calving cows.

Artificial induction of parturition is an important risk factor for retention of the placenta and the incidence is reported to vary from 20% to 100%[1,4,5] Subsequent reproductive performance of induced cows can be impaired.[1] A risk for acute Gram-negative bacterial infections is reported in a low (0.3%) proportion of cows following induction with dexamethasone.[6]

When parturition is induced in large herds of beef cattle, particularly with a high percentage of heifers, increased surveillance will be necessary after the calves are born to avoid mismothering. Every attempt must be made to establish the cow–calf pair (neonatal bond) and move them out of the main calving area. Heifers that disown their calves must be confined in a small pen and be encouraged to accept the calf and let it suck – sometimes a very unrewarding chore for the cowman. Calf mortality can be very high where calving is induced earlier than 35 weeks of pregnancy.[3]

FOALS

The induction of parturition in mares for reasons of economy, management convenience, concern at prolonged gestation or clinical conditions such as prepubic tendon rupture, or research and teaching is now being practiced.[7,8]

Foaling is induced with oxytocin and occurs within 15–90 minutes of its administration.[9] High doses of oxytocin are potentially dangerous to the foal and low doses (10–20 IU) are preferred. Glucocorticoids, antiprogestagens and prostaglandins that are effective in inducing pregnancy in other species are either ineffective in the mare or capricious in their efficacy, and can also be associated with adverse effects on the foal.[8]

Induction of parturition in the mare it is not without risk and has been associated with the birth of foals that are weak, injured or susceptible to perinatal infections. The period of fetal maturation is relatively short in the horse and is considered to be the last 2–3 days of gestation. Because spontaneous parturition in healthy mares can occur between 320 and 360 days there is the risk of delivering a foal that is premature and nonviable. Fetal maturity is the major prerequisite for successful induced parturition and the three essential criteria are:[8]

- A gestational length of more than 330 days
- Substantial mammary development and the presence of colostrum in the mammary gland with a calcium concentration greater than 10 mmol/L
- Softening of the cervix.

The rise in calcium concentration is the most reliable predictor of fetal maturity

and milk calcium concentrations above 10 mmol/L, in combination with a concentration of potassium that is greater than sodium, are indicative of fetal maturity. Commercial milk test strips are available for estimating mammary secretion electrolyte concentrations, however, it is recommended that testing be done in an accredited laboratory.[8,10–12]

In mature foals, head lifting, sternal recumbency and evidence of suck reflex occurs within 5 minutes of spontaneous full-term deliveries. The foal can stand within 1 hour and suck the mare within 2 hours. The behavior and viability of the premature foal after induced parturition have been described.[13] The overall survival rate of foals delivered from induced parturition before 320 days of gestation was 5%.[13] Four patterns of neonatal adaptation were observed on the basis of righting, sucking and standing ability. If the suck reflex was weak or absent and the foals were unable to establish righting reflexes, the prognosis of survival was poor. Foals born before 300 days of gestation did not survive for more than 90 minutes; foals born closer to 320 days of gestation had a better chance of survival and exhibited behavioral patterns of adaptation.

In addition to the potential delivery of a premature or weak foal, other adverse effects of induction can be dystocia, premature placental separation and retained placenta.

PIGLETS

The induction of parturition of gilts and sows on days 112, 113 or 114 of gestation is highly reliable and can be achieved by a single intramuscular injection of 175 mg of cloprostenol or 5–10 mg of prostaglandin $F_{2\alpha}$.[14] The sows farrow approximately 20–24 hours later. The interval to onset can be decreased by the use of oxytocin.[15]

Induction of parturition has been used on large-scale farms to allow a concentration of labor and improve supervision and care at the time of farrowing, and to reduce the incidence of the mastitis/metritis/agalactia syndrome[16] and reduce the percentage of stillborn piglets. The end-day of a batch farrowing system can be fixed and weekend farrowing avoided. The subsequent fertility of the sows is not impaired. Induction on day 110 may be associated with a slight increase in perinatal mortality.

LAMBS

The induction of parturition in sheep is not commonly practiced but it can be used to synchronize lambing in flocks where there are accurate dates of mating for individual ewes. Unless accurate dates are available there is risk of prematurity. Also, ewes that are more than 10 days from their normal parturition date are unlikely to respond.[17]

Induction of parturition is also used as a therapeutic ploy to terminate pregnancies in sheep with pregnancy toxemia.

Induction is usually with dexamethasone, betamethasone or flumethazone.[18,19] Lambing occurs 36–48 hours later and there may be breed differences in response. Variability in lambing time can be reduced by the use of clenbuterol and oxytocin.[20]

Diseases of cloned offspring

The successful cloning of domestic animals using somatic-cell nuclear transfer has resulted in birth of offspring with a high frequency of clinical abnormalities. Cloning of livestock and horses is achieved by transfer of nuclear material from the cell of an adult animal to the enucleated egg of an animal of the same species (somatic-cell nuclear transfer) with subsequent implantation of the resulting embryo in a surrogate dam and birth of a live, viable offspring.[1] However, the use of nuclear material from somatic cells of adult animals, and from fetal cells, does not result in normal development of the embryo and placenta. The abnormal development is a consequence of altered methylation of the genome in transferred nuclear material.[2] In normal reproduction, the paternal genome is demethylated during passage through the oocyte and fusion with the maternal genome. Consequently, the methylation marks of the two genomes (paternal and maternal) are different at the end of the cleavage process. Transfer of somatic nuclear material into an enucleated oocyte results in exposure of both genomes to the active demethylating process in the cytoplasm of the oocyte and uniform demethylation of both genomes.[2,3] The loss of these parent-specific epigenetic markers results in widespread dysregulation of imprinted genes and subsequent abnormalities in the placenta, fetus and newborn.

A small proportion of transferred blastocysts develop in viable animals. For cattle, of 134 recipients that received blastocysts, 50 were pregnant 40 days after blastocyst transfer and 23 had full-term pregnancies.[4] For all species studied, fewer than 3% of cloned embryos result in birth of viable animals.[1] Abnormalities in placenta and newborn cloned animals are reported for cattle and sheep but not for pigs and equids (horses and mules).[1,5] Factors influencing the risks of abnormalities in newborns have not been well defined, but include the source of the nuclear material, with frequency of birth of live animals born after somatic cell nuclear transfer from well-differentiated tissue (e.g. fibroblasts) or fetal somatic cells being lower than after nuclear transfer from embryonic cells (7%, 15% and 34%, respectively).[6]

The cause of placental, fetal and neonatal abnormalities is abnormal expression of imprinted genes as a consequence of transfer of nuclear material from differentiated somatic cells, conditions and media used for maintenance and culture of cytoplasts and blastocysts, and techniques used for handling cells.[1,7] Candidate genes for large offspring syndrome include *IGF-2* and *IGFBP-2*, insulin-like growth factor (IGF) concentrations in plasma of cloned calves being higher than that of normal calves[7,8] although others, such as genes related to endothelin-1 production, might well be involved.[9]

Clinical findings in cloned calves and lambs include abortion, placental

abnormalities, large birth size, poor extrauterine viability, respiratory disease, cardiovascular abnormalities and neurologic disease compatible with neonatal encephalopathy. Abortion occurs after day 90 of gestation in 30–50% of pregnancies in cattle resulting from transfer blastocysts containing transferred nuclear material.[6] Abnormalities, including hydroallantois, are present in approximately 25% of advanced pregnancies.[6] **Placental abnormalities** include hydroallantois, a reduction in the number of placentomes (from a normal of approximately 100 to as few as 26–70 in cloned calves),[7,10] abnormally large placentomes (140 g in cloned calves vs 33 g in conventional calves) and edema of the placenta.[6,7,11] Maternal retention of the placenta is common and occurs in most cows.[11] Duration of gestation is probably longer in cloned calves, although the frequent delivery of cloned calves by cesarian section makes assessment of gestational duration difficult. Cloned calves are heavier than conventional calves, often by as much as 25%, a well-recognized part of the '**large offspring syndrome**' that affects calves born as a result of reproductive manipulation, including in-vitro fertilization.[6,12] Viability of cloned calves that are born alive (commonly by cesarian section) is less than that of conventional calves – only approximately two-thirds of cloned calves born alive survive more than 1 month,[10] although others report better survival.[11] Similar results are reported for horses.[13]

A high proportion of cloned calves have **clinically detectable abnormalities** at or soon after birth, including sepsis, neonatal encephalopathy, respiratory failure, umbilical abnormalities, anemia, flexure contracture, abdominal distension and renal dysfunction. Respiratory failure is a common finding and might reflect persistent fetal circulation or inadequate surfactant production, as evidenced by the high pulmonary artery pressures and signs consistent with patent ductus arteriosus. Left heart failure, which can also cause pulmonary hypertension, is reported in cloned calves.[11] Umbilical abnormalities are evident as abnormal umbilical cord structure (multiple arteries and veins) and large size, with a high risk of hemorrhage from the umbilical cord after birth. Cloned calves have higher body temperatures than do conventional calves.[7]

Hematological abnormalities include anemia and decreased mean corpuscular volume. Biochemical abnormalities include hypoxemia, azotemia and hypoglycemia. Plasma leptin and IGF-2 concentrations are higher, and thyroxine lower, in cloned calves.[7] Serum cortisol and ACTH stimulation tests do not differ between cloned and conventional calves.[7]

Necropsy examination reveals placentomegaly, presence of excess pleural and peritoneal fluid, hepatomegaly, interstitial pneumonia or pulmonary consolidation and alveolar proteinosis, right ventricular dilation and hepatocellular vacuolation.[11]

Treatment is supportive and directed toward correcting hypoxemia and providing nutritional, fluid and environmental support (see above).

There are currently no recognized methods for preventing these abnormalities, but presumably improvements in methodology and culture techniques will result in fewer cloned offspring with these abnormalities.

Neonatal infection

Synopsis

Etiology Common infections for each animal species are listed under etiology below. Most are bacterial.
Epidemiology Commonly predisposed by management and environmental factors that increase the exposure risk and load and decrease the resistance of the neonate.
Clinical findings Septicemia or bacteremia with localization is most common but signs can be specific for the infecting agent.
Clinical pathology White blood cell and differential counts, toxic change, serum immunoglobulin concentrations, arterial oxygen concentrations, metabolic acidosis, fibrinogen levels, blood culture.
Necropsy findings Specific to disease.
Diagnostic confirmation Specific to disease.
Treatment General therapy may include antibacterial therapy, blood or plasma transfusion, correction of acid–base disturbance, fluid and electrolyte therapy, and supportive treatment.

Infection is a common cause of morbidity and mortality in neonates. There are a number of specific infectious pathogens that can cause disease. Other infectious agents, normally considered to have low virulence, can also cause disease if the immunological status of the neonate is not at an optimum level. Maternal immunoglobulins are not transferred transplacentally in ungulates and the newborns are at particular risk for infectious disease during the neonatal period because they rely on the acquisition of immunoglobulins from colostrum for passive antibody protection.

ETIOLOGY

In domestic farm animals the common infections that can produce disease during the neonatal period are as follows. (Relative importance and prevalence statistics are not given, as these vary from area to area and with differing management systems.)

Calves

- Bacteremia and septicemia associated with *Escherichia coli, Listeria monocytogenes, Pasteurella* spp., streptococci or *Salmonella* spp.
- Enteritis associated with enterotoxigenic *E. coli, Salmonella* spp., rotavirus and coronavirus, *Cryptosporidium parvum* and *Clostridium perfringens* types A, B and C; and occasionally by the virus of infectious bovine rhinotracheitis and bovine virus diarrhea.

Pigs

- Septicemia with or without localization in joints, endocardium and meninges associated with *Streptococcus suis, Streptococcus equisimilis, Streptococcus zooepidemicus* and *L. monocytogenes*
- Bacteremia, septicemia and enteritis associated with *E. coli*
- Transmissible gastroenteritis, Aujeszky's disease, swine pox, enterovirus infections, and vomiting and wasting disease are associated with viruses
- Enteritis associated with *C. perfringens, Campylobacter* spp., rotavirus and *Coccidia* spp.
- Arthritis and septicemia associated with *Erysipelothrix rhusiopathiae.*

Foals

- Septicemia with localization associated with *E. coli, Actinobacillus equuli, Klebsiella pneumoniae,* α-hemolytic streptococci, *S. zooepidemicus, L. monocytogenes, Rhodococcus equi* and *Salmonella typhimurium*
- Enteritis associated with *C. perfringens* types A, B, and C., *Clostridium difficile, R. equi, Salmonella* spp., *Strongyloides westeri, C. parvum* and rotavirus.

Lambs
- Septicemia or bacteremia with localization in joints and/or synovia and/or leptomeninges associated with *E. coli*, *L. monocytogenes*, streptococci, micrococci, *E. rhusiopathiae* and *Chlamyodophila* spp.
- Enteritis associated with enterotoxigenic *E. coli*, *Salmonella* spp., rotavirus and coronavirus and *C. parvum*
- Lamb dysentery associated with *C. perfringens* type B and C
- Gas gangrene of the navel associated with *Clostridium septicum*, *Clostridium novyi* and *Clostridium chauvoei*
- Pyemia associated with *Staphylococcus aureus*, *Fusobacterium necrophorum* and *Arcanobacterium pyogenes*
- Pneumonia, polyserositis and peritonitis associated with *Pasteurella multocida* and *Mannheimia haemolytica*.

The following agents are recorded as causing neonatal infections but are less common than those listed above and not of as great importance.

Calves

Pseudomonas aeruginosa, *Streptococcus pyogenes*, *Streptococcus faecalis*, *S. zooepidemicus*, *Pneumococcus* spp.; enteritis due to *Providencia stuartii*, *Chlamydophila* spp., *A. equuli*.

Lambs

S. aureus (tick pyemia); enteritis due to *E. coli*, rotavirus; pneumonia due to *Salmonella abortus–ovis*.

Foals

Enterobacter cloacae, *S. aureus*, *Pasteurella multocida*, *P. aeruginosa*, *A. pyogenes*, *Serratia marcescens*.

All species

Nonspecific infections are associated with pyogenic organisms, including *Arcanobacterium pyogenes* and *Fusobacterium necrophorus*; *S. faecalis*, *S. zooepidemicus*, *Micrococcus* spp. and *Pasteurella* spp. occur in all species.

EPIDEMIOLOGY

The occurrence of neonatal disease is broadly influenced by two main factors: the exposure or infection pressure of the infectious agent to the neonate and the ability of the neonate to modulate the infection so that disease does not occur. With some agents the organism is sufficiently virulent in its own right that an exposure can lead to disease. With others, the majority, the defenses of the host must be compromised or the infection challenge must be very high before clinical disease occurs. Management of the neonate has a great influence on both these factors and the recognition and correction of these risks is the key to the prevention of neonatal disease in both the individual and the group.

Sources of infection

Postnatal infection

The vast majority of infections are acquired by the neonate after birth from the enteric or respiratory tract flora of the dam, from the environment or from close contact with other infected neonates. Depending upon the specific agent, the reservoir of infection may be in a carrier animal or in the environment. Details for the common neonatal diseases are given under the individual disease headings in the chapters on special medicine.

Prenatal infection

Some bacterial infections that manifest with neonatal disease are acquired in utero. The majority of these are agents that cause abortion, and neonatal septicemia is only part of the spectrum of abortion and perinatal death associated with these agents. Examples would be many of the agents producing abortion in sheep.

Some septicemic infections in **foals**, particularly those associated with *A. equuli*, *S. zooepidemicus*, *Salmonella abortivoequina* and possibly some *E. coli* septicemic infections, are acquired by prenatal infection. If the disease is intrauterine in origin it must gain entrance via the placenta, and probably by means of a placentitis due to a blood-borne infection or an existing endometritis. In the latter case, disinfecting the uterus before mating becomes an important hygienic precaution; disinfecting the environment may have little effect on the incidence of the disease.

Viral infections that are acquired in utero are listed in the section on congenital disease.

Routes of transmission

The **portal of infection** is commonly by ingestion but may occur via aerosol infection of the respiratory tract. Organisms capable of invading to produce a bacteremia and septicemia invade through the nasopharynx or through the intestinal epithelium. An alternate route of infection and invasion is via the umbilicus. Routes of **excretion** are via the feces in enteric disease and the nasal secretions, urine and sometimes the feces in septicemic disease to result in contamination of the neonatal environment.

Where neonates are in groups or in close contact, direct transmission by fecal, respiratory secretion and urine aerosols can also occur. Neonatal bull calves that are group-housed and that suck each other's navels can transmit infection by this activity.

Risk factors and modulation of infection

Immunity

All newborn farm animals are more susceptible to infection than their adult counterparts. The calf, lamb, piglet and foal are born without significant levels of immunoglobulins and possess almost no resistance to certain diseases until after they have ingested colostrum and absorbed sufficient quantities of immunoglobulins from the colostrum. **Failure of transfer** of colostral immunoglobulins is a major determinant and is discussed under that heading later in this chapter.

Immune responsiveness

All components of the immune system are present in foals and calves at birth but the immune system of the newborn animal is less mature than its adult counterpart, at least for the first 30 days of life, and does not respond as effectively to many antigens.

Immune responsiveness is age-dependent but also varies with the antigen.[1] In colostrum-fed animals part of the inefficiency of the newborn to produce humoral antibody following infection of antigen is the interference from circulating colostral antibody and the downregulation by colostrum of endogenous immunoglobulin production.[2–4]

Colostrum-deprived calves respond actively to injected antigens and are believed to be immunologically competent at birth with respect to most antigens. Immune competence begins during fetal life and the age of gestation at which this occurs varies according to the nature of the antigen. The bovine fetus will produce antibody to some viruses, beginning at 90–120 days, and by the third trimester of gestation it will respond to a variety of viruses and bacteria.[5] The lamb will respond to some antigens beginning as early as 41 days and not until 120 days for others. The piglet at 55 days and the fetal foal also respond to injected antigens.

The presence of high levels of antibody in the precolostral serum of newborn animals suggests that an in-utero infection was present, which is useful for diagnostic purposes. The detection of immunoglobulins and specific antibodies in aborted fetuses is a useful aid in the diagnosis of abortion in cattle.

Exposure pressure

The exposure pressure is a factor of the cleanliness of the environment of the neonate. The phenomenon of a 'buildup of infection' in continual-throughput housing for neonatal animals has been recognized for decades and has been translated to many observations of risk for neonatal disease associated with suboptimal hygiene and stocking density in

both pen and paddock birthing areas. Details for the individual species are provided in the section on perinatal disease.

Age at exposure

With several agents that produce neonatal disease, the age of the neonate at infection and the infecting dose have a significant influence on the outcome. Examples are the importance of age with respect to susceptibility to disease associated with some enteric infections. Disease associated with enteropathogenic *E. coli* and with *C. perfringens* type B and C occurs only in young animals and if infection can be avoided by hygiene in this critical period disease will not occur regardless of subsequent exposure. Colostrum-deprived calves show significant resistance to challenge at 7 days of age with strains of *E. coli* that invariably produce septicemic disease if challenged at the time of birth and isolation of an immunocompromised neonate is an important factor in its survival. Thus the management of the neonate and its environment is a critical determinant of its health. Age at exposure also varies with the epidemiology of the pathogen and segregated early weaning is used to reduce transmission of and infection with certain pathogens in pigs.

Animal risk factors

Animal risk factors that predispose infection include those that interfere with sucking drive and colostral intake, such as cold stress and dystocia. These are detailed in the preceding section on perinatal disease.

PATHOGENESIS

The pathogenesis varies with the neonatal infectious disease under consideration and is given for each of these in the special medicine section.

Following invasion via the nasopharynx and the gastrointestinal tract, the usual pattern of development is a bacteremia followed by **septicemia** with severe systemic signs; or a **bacteremia** with few or no systemic signs, followed by **localization** in various organs. If the portal of entry is the navel, local inflammation occurs –'**navel ill**'– which can be easily overlooked if clinical examination is not thorough. From the local infection at the navel, extension may occur to the liver or via the urachus to the bladder and result in chronic ill-health. Extension systemically may produce septicemia.[6]

Localization is most common in the joints, producing a suppurative or nonsuppurative arthritis. Less commonly there is localization in the eye to produce a panophthalmitis, in the heart valves to cause valvular endocarditis, or in the meninges to produce a meningitis.

In some cases these secondary lesions take time to develop and signs usually appear at 1–2 weeks of age. This is especially true with some of the streptococcal infections, where bacteremia may be present for several days before localization in the joints and meninges produces clinical signs. Bacterial meningitis in newborn ungulates is preceded by a bacteremia followed by a fibrinopurulent inflammation of the leptomeninges, choroid plexuses and ventricle walls but does not affect the neuraxial parenchyma. It is proposed that the bacteria are transported in monocytes, which do not normally invade the neuraxial parenchyma.

Dehydration, acid–base and electrolyte imbalance can occur very quickly in newborn animals, whether diarrhea and vomiting (pigs) are present or not, but obviously are more severe where there is fluid loss into the gastrointestinal tract. In Gram-negative sepsis the prominent signs are those of endotoxemia.

CLINICAL FINDINGS

The clinical findings depend on the rapidity of growth of the organism, its propensity to localize and its potential to produce toxemia. With organisms that have a low propensity for toxemia there is fever, depression, anorexia and signs referable to localization. These include endocarditis with a heart murmur; panophthalmitis with pus in the anterior chamber of the eye; meningitis with rigidity, pain and convulsions; and polyarthritis with lameness and swollen joints. With more virulent organisms there are clinical signs of toxemia as well as bacteremia, including fever, severe depression, prostration, coma, petechiation of mucosae, dehydration, acidosis and rapid death.[7,8]

The clinical and clinicopathological characteristics of the septicemic foal have been detailed in an outbreak of septicemia in colostrum-deprived foals[9] and on the clinical records of 38 septicemic foals admitted to a referral clinic,[10] where the survival rate of septicemic foals, 26%, was markedly less than the rate for all other foal admissions. The major clinical findings included lethargy, unwillingness to suck, inability to stand without assistance but remaining conscious, unawareness of environment and thrashing or convulsing, diarrhea, respiratory distress, joint distension, central nervous system abnormalities, uveitis and colic. Fever was not a consistent finding.

A **sepsis score** has been developed for foals based on 14 measures related to historical, clinical and laboratory data (Table 3.6). The score derived from the collective differential scoring of these data has been found to be more sensitive and specific for infection than any parameter taken individually.[7] However, a subsequent study of 168 foals presented to a university hospital found that the sepsis score correctly predicted sepsis in 58 out of 86 foals and nonsepsis in 24 out of 45 foals resulting in a sensitivity of 67%, a specificity of 75%, a positive predictive value of 84% and a negative predictive value of 55%, and it was suggested that the score system should be used with care as the low negative predictive value limited its clinical utility.[11]

A sepsis score, based on fecal consistency, hydration, behavior, ability to stand, state of the umbilicus and degree of injection of scleral vessels, is described for calves and has reasonable predictive value.[12]

The clinical findings specific to individual etiological agents are given under their specific headings in the special medicine section of this book.

CLINICAL PATHOLOGY

Clinical pathology is used as an integral part of the evaluation of a sick neonate and to help formulate a treatment plan. A major evaluation is to attempt to confirm the presence or absence of sepsis and this type of evaluation has been developed most successfully in the foal. **Blood culture** is part of this examination but the time for a positive result limits its value in the acutely ill neonate. Laboratory findings in foals with neonatal sepsis are variable and depend upon the severity, stage and site of infection.[8] **Serial examinations** are commonly used. In examinations relating to the possible presence of septicemia, particular emphasis is placed on the results of the white blood cell and differential counts, the presence of toxic change, serum immunoglobulin concentrations, arterial oxygen concentrations, presence of metabolic acidosis and fibrinogen levels.[7,8,12]

DIFFERENTIAL DIAGNOSIS

- The principles of diagnosis of infectious disease in newborn animals are the same as for older animals. However, in outbreaks of suspected infectious disease in young animals there is usually a need for more diagnostic microbiology and pathology
- With outbreaks, owners should be encouraged to submit all dead neonates as soon as possible for a meaningful necropsy examination
- In addition to postmortem examination it is necessary to identify the factors that may have contributed to an outbreak of disease in newborn calves, piglets or lambs and only detailed epidemiological investigation will reveal these

TREATMENT

The first principle is to obtain an etiological diagnosis if possible. Ideally a drug sensitivity of the causative bacteria should be obtained before treatment is given, but this is not always possible. It may be necessary to choose an **antibacterial** based on the tentative diagnosis and previous experience with treatment of similar cases.

Outbreaks of infectious disease are common in litters of piglets and groups of calves and lambs, and individual treatment is often necessary to maximize survival rate. There is usually no simple method of mass-medicating the feed and water supply of sucking animals and each animal should be dosed individually as necessary. Supportive fluid and electrolyte therapy and correction of acid–base disturbances are described in detail in Chapter 2.

The provision of **antibodies** to sick and weak newborn animals through the use of blood transfusions or serum is often practiced, especially in newborn calves in which the immunoglobulin status is unknown. Whole blood given at the rate of 10–20 mL/kg body weight, preferably by the intravenous route, will often save a calf that appears to be in shock associated with neonatal diarrhea. The blood is usually followed by fluid therapy. Serum or plasma can also be given at half the dose rate. The blood should not be taken from a cow near parturition as the circulating immunoglobulins will be low from the transfer into the mammary gland.

Plasma is often incorporated into the therapeutic regimen in foals, both for its immunoglobulin content and for its effect on blood volume and osmotic pressure. Stored plasma can be used. A dose of 20 mL plasma/kg body weight given slowly intravenously is often used, but significantly higher doses are required to elevate circulating immunoglobulins by an appreciable amount.[8] Blood may be collected, the red blood cells allowed to settle and the plasma removed and stored frozen. The donor plasma should be prescreened for compatibility. Lyophilized hyperimmune equine serum as a source of antibodies may also be fed to foals within 4 hours after birth. Good nursing care is also essential.

Further information on treatment is given in the section on critical care for the newborn later in this chapter.

CONTROL

Methods for avoidance of failure of transfer of passive immunity and the principles for prevention of infectious disease in newborn farm animals follow in this chapter. The control of individual diseases is given under specific disease headings elsewhere in this book.

FAILURE OF TRANSFER OF COLOSTRAL IMMUNOGLOBULINS

The acquisition and absorption of adequate amounts of colostral immunoglobulins is essential to the health of the neonate as it is born virtually devoid of circulating immunoglobulin and relies on antibody acquired from colostrum for protection against common environmental pathogens. Adequate antibody transfer is the cornerstone of all neonatal preventive health programs. This has been recognized for many years and it is discouraging that a study conducted in 2002 in the USA by the National Animal Health Monitoring System found that over 40% of dairy heifer calves sampled by the National Dairy Heifer Evaluation Project had failure of transfer of colostral immunoglobulins.[1]

Much of the description that follows refers to the calf because more studies on transfer of passive immunity have been conducted in calves. However, most of the information is applicable to the other species; where there are differences these are mentioned.

NORMAL TRANSFER OF IMMUNOGLOBULINS

The major **immunoglobulin in colostrum** is IgG, but there are also significant amounts of IgM and IgA. IgG_1 is present in highest concentration and is concentrated in colostrum by an active, selective, receptor-mediated transfer of IgG_1 from the blood of the dam across the mammary secretory epithelium. This **transfer to colostrum** begins approximately 4–6 weeks before parturition and results in colostral IgG_1 concentrations in first milking colostrum that are several-fold higher than maternal serum concentrations. The transfer of the other immunoglobulin classes is believed to be nonselective and lesser concentrations in colostrum are achieved.

Following **ingestion by the newborn**, a significant proportion of these immunoglobulins in ingested colostrum is transferred across the epithelial cells of the small intestine during the first few hours of life and transported via the lymphatic system to the blood. Immunoglobulins in the blood are further varyingly distributed to extravascular fluids and to body secretions depending upon the immunoglobulin class.

These absorbed immunoglobulins protect against systemic invasion by microorganisms and septicemic disease during the neonatal period. Unabsorbed immunoglobulins and immunoglobulins resecreted back into the gut play an important role in protection against intestinal disease for several weeks following birth. In calves, passive immunity also influences the occurrence of respiratory disease during the first months of life and may be a determinant of lifetime productivity. In foals, failure of transfer of passive immunity presents a significant risk for the development of an illness during the first 3 months of life.

Lactogenic immunity

The IgG concentration in milk falls rapidly following parturition in all species and immunoglobulin concentrations in milk are low. In the sow, the concentration of IgA falls only slightly during the same period and it becomes a major immunoglobulin of sows' milk. IgA is synthesized by the mammary gland of the sow throughout lactation and serves as an important defense mechanism against enteric disease in the nursing piglet. In the piglet, IgA in milk is an important mucosal defense mechanism whereas in the calf there is little IgA in milk but some enteric protection is provided by colostral and milk IgG, and IgG derived from serum that is resecreted into the intestine.[2,3]

FAILURE OF TRANSFER OF PASSIVE IMMUNITY

Failure of transfer of colostral immunoglobulins is the major determinant of septicemic disease in all species.[4,5] It also modulates the occurrence of mortality and severity of enteric and respiratory disease in early life[6] and, in some studies, performance at later ages.[7–9] While an important determinant for neonatal disease and subsequent performance, it is not the sole determinant and it is not surprising that some studies have found only a minor relationship.

In terms of the modulation of disease, there can be **no set cut-point** for circulating immunoglobulins as the cut-point will vary according to the farm, its environment, infection pressure and also the type of disease. Figures are given as a guide. With dairy **calves** serum IgG_1 concentrations of 500 mg/dL are

associated with protection against septicemic disease and concentrations of 1000 mg/dL or more are sufficient to reduce the risk of infectious disease in most environments. With **foals**, the equivalent IgG_1 concentrations for protection are given as 400 mg/dL and 800 mg/dL.[10,11]

Rates of failure of transfer of passive immunity are high in both sucking and artificially fed dairy calves but are less in beef calves.[12,13] Failure rates in foals are lower and approximate 13–16%.[11,14] Rates in lambs are also comparatively low.

In animals that are **fed colostrum artificially,** risk for failure of transfer of passive immunity is primarily dependent upon the amount or mass of immunoglobulin present in a feeding of colostrum, the time after birth that this is fed, and the efficiency of its absorption by the calf. The mass of immunoglobulin fed is determined by the concentration of immunoglobulin in the colostrum and the volume that is fed. Feeding trials with calves suggest that a **mass of at least 100 g** of IgG_1 is required in colostrum fed to a 45 kg calf to obtain adequate (≥ 1000 mg/dL IgG_1) passive blood immunoglobulin concentrations.[15]

In animals that **suck colostrum naturally** such as foals, risk for failure of transfer of passive immunity is primarily dependent upon the concentration of immunoglobulin in the colostrum, the amount that is ingested and the time of first suckling. Inadequate colostral immunoglobulin concentration and delay in ingestion of colostrum are the two important factors in failure of transfer of passive immunity in foals.[16]

Determinants of transfer of colostral immunoglobulins

1. Amount of immunoglobulin in colostrum fed:
   a. *Volume* of colostrum fed
   b. *Concentration* of immunoglobulins in colostrum
2. The amount of colostrum actually suckled or fed
3. Efficiency of absorption of immunoglobulins by neonate
4. Time after birth of suckling or feeding

Determinants of immunoglobulin concentration in colostrum

Nominal concentrations of immunoglobulin in the first milking colostrum of cows are shown in Table 3.1. There can be **substantial variation** in the concentration of immunoglobulin in colostrum in all species and the ingestion of a 'normal' amount of colostrum that has low immunoglobulin concentration may provide an insufficient amount of immunoglobulin for protection. In a study of over 900 first-milkings colostrum from American Holstein cows, only 29% of the colostrum samples contained a sufficiently high concentration of immunoglobulin to provide 100 g IgG in a 2 L volume.[17] The equivalent percentages for 3 and 4 L volume feedings were 71% and 87%.

A similar situation exists with **horses**. The mean concentrations of IgG in colostrum of mares 3–28 days before foaling is greater than 1000 mg IgG/dL, while at parturition the mean concentrations may vary from 4000–9000 mg/dL. The concentrations decrease markedly to 1000 mg/dL in 8–19 hours after parturition.[18]

It is apparent that variation in colostral immunoglobulin concentration can be a cause of failure of transfer of passive immunity.

Some causes of this variation are:

- The concentrations of immunoglobulin in colostrum fall dramatically following parturition. Only the **first milking** of colostrum after calving should be considered for feeding to calves for immunoglobulin transfer. The concentrations in second-milking colostrum are approximately half those in the first milking and by the fifth postcalving milking, concentrations approach those found during the remainder of lactation
- The immunoglobulin concentration of colostrum decreases after calving even when the cow is not milked. In order to facilitate early feeding of colostrum to a calf, herd policy may be to feed stored colostrum taken from a previously calved cow rather than the newborn calf's dam. It is important that this colostrum be milked as soon as possible after parturition. Colostrum that is collected 6 hours or later after calving has a significantly lower concentration than that collected 2 hours after calving[17,19]
- Colostrum from cows or mares that have been **premilked** to reduce udder edema or from dams that **leak colostrum** prior to parturition will have low immunoglobulin concentrations and alternate colostrum should be fed for immunoglobulin transfer as there is a higher rate of failure in their foals and calves
- In cattle, **dry periods** of less than 30 days may result in colostrum of lower immunoglobulin concentration
- **Premature foaling** or the **induction of parturition** can result in colostrum with low immunoglobulin concentration and/or low volume
- In cattle, average colostral immunoglobulin concentrations are higher in cows in third or higher **lactation groups** compared to younger cows. However, colostrum from all lactation numbers can produce adequate immunoglobulin mass. There is no scientific basis for not feeding first-milking colostrum from first-lactation cows
- Larger-volume first-milking colostrum tends to have lower immunoglobulin concentrations than smaller-volume colostrum, and **colostrum weight** can be used to select colostrum of higher immunoglobulin concentration for calf feeding (Table 3.2)
- A recent study has shown that immunoglobulin concentrations are higher in the early temporal fractions of a single milking of first-milking colostrum.[20] This might suggest that segregation of the first portion of the first-milking colostrum could provide colostrums with higher immunoglobulin concentration for feeding

Table 3.1 Concentrations and relative percentage of immunoglobulins in serum and mammary secretions of cattle and pigs

Animal	Immunoglobulin	Concentration (mg/mL)			Total immunoglobulin (%)		
		Serum	Colostrum	Milk	Serum	Colostrum	Milk
Cow	IgG_1	11.0	47.6	0.59	50	81	73
	IgG_2	7.9	2.9	0.02	36	5	2.5
	IgM	2.6	4.2	0.05	12	7	6.5
	IgA	0.5	3.9	0.14	2	7	18
Sow	IgG	21.5	58.7	3.0	89	80	29
	IgM	1.1	3.2	0.3	4	6	1
	IgA	1.8	10.7	7.7	7	14	70

Table 3.2 Immunoglobulin concentrations in the first milking of colostrum of Holstein cattle by weight of colostrum produced

Weight (lb)	% of colostrums	IgG_1 concentration (mg/mL) Mean	Range
< 10	20	67	24–136
11–20	38	58	17–136
21–30	26	46	15–93
> 30	16	39	19–76

- There are **breed differences** in the concentration of immunoglobulins in first milking colostrum. In **cattle**, beef breeds have higher concentrations. Many dairy breeds, including American Holsteins, produce colostrum of relatively low immunoglobulin concentration, and a significant proportion of calves that suckle cows of these breeds ingest an inadequate mass of immunoglobulin. Channel Island breeds have a greater concentration of immunoglobulin in colostrum that Holsteins. **Breed differences** are also seen in **horses**, with Arabian mares having higher colostral immunoglobulin concentrations than Standardbreds, which in turn are higher than those of Thoroughbreds. Breed differences also occur in **sheep**, with higher concentrations in meat and wool breeds than dairy breeds[21]
- Heat **stress** to cattle in the latter part of pregnancy results in lower colostral immunoglobulin concentrations[22]
- One study found that calves from cows with **mastitis** have lower serum immunoglobulins.[23] Colostral volume but not colostral immunoglobulin concentration is reduced in mastitic quarters and it is unlikely that mastitis is a major determinant of the high rate of failure of transfer of passive immunity in dairy calves[24]
- There is a significant positive but weak correlation between total lactational milk and immunoglobulin concentration in that cow's colostrum.[17] Selection for **production** does not appear to be a negative influence on colostral immunoglobulin concentration, although dilution by high volume production in first-milking colostrum is a factor in low colostral immunoglobulin concentration[25]
- The **pooling of colostrum** in theory could avoid the variation in immunoglobulin concentration of individually fed colostrum and could provide a colostrum that reflects the antigenic experience of several cattle. In practice, colostrum pools from Holsteins invariably have low immunoglobulin concentrations because high-volume, low-concentration colostrum dilutes the concentration of the other samples in the pool. If pools are used, the diluting influence of low-immunoglobulin-concentration, high-volume colostrum should be limited by restricting any individual cow's contribution to the pool to 9 kg (20 lb) or less. However, pooling increases the risk of disease transmission, as multiple cows are represented in a pool and the pool is fed to multiple calves. This can be important in the control of Johne's disease, bovine leukosis and *Mycoplasma bovis*
- **Bacterial contamination** of colostrum can have a negative effect on transfer of passive immunity and one study[26] found high bacterial counts in 85% of colostrums sampled from 40 farms in the USA. Colostrum that is to be fed or stored should be collected with appropriate preparation and sanitation of the cow and of the milking equipment used on fresh cows
- **Pasteurization of colostrum** (both pasteurization at 63°C for 30 min and HTST 72°C for 15 s) reduces colostrum IgG concentration. A recent study[27] of batch pasteurization at 63°C for 30 minutes showed that the percentage reduction in colostral IgG concentration varied with the batch size, with a 24% reduction in 57 L batch size and a 58% reduction in a larger batch size. Calves fed 2 L of pasteurized colostrum had twofold lower serum concentrations of IgG than controls
- **Old mares** (older than 15 years) may have poor colostral immunoglobulin concentration.

Volume of colostrum ingested

Holstein cows

The volume of colostrum that is fed has a direct influence on the mass of immunoglobulin ingested at first feeding. The average volume of colostrum ingested by nursing Holstein calves in the first 24 hours of life is reported as 2.4 L but there is wide variation around this mean[28] and a significant proportion of dairy calves fail to ingest an adequate mass of immunoglobulin in management systems that provide colostrum solely by allowing the calf to suck the dam.[6,29]

In **natural suckling** situations, calves may fail to ingest adequate colostrum volumes before onset of the closure process, and therefore absorb insufficient colostral immunoglobulin. Early assisted suckling may help avoid this. In dairy calves the volume of colostrum that is ingested can be controlled in **artificial feeding systems** using nipple bottle feeders or esophageal tube feeders. **Bucket feeding** of colostrum is not recommended, as training to feed from a bucket can be associated with erratic intakes.

The **traditional recommendation** for the volume of colostrum to feed at first feeding to calves is 2 L (2 quarts). However, only a small proportion of first-milking colostrum from Holsteins contains a sufficiently high concentration of immunoglobulin to provide 100 g IgG in a 2 L volume and higher volumes of colostrum are required to achieve this mass intake.[17] Possibly the major cause of failure of transfer of passive immunity rests with the fact that commercial feeding bottles are made in a 2 L size and this is consequently the amount of colostrum that is fed. Some calves fed with a **nipple bottle** will drink volumes greater than 2 L but others will refuse to ingest even 2 L of colostrum in a reasonable period of time, and calf rearers may lack the time or patience to persist with nipple bottle feeding until the required volume has been ingested by all calves.

Larger volumes of colostrum can be fed by an **esophageal feeder** and single feedings of large volumes of colostrum (3.5–4.0 L per 45 kg body weight) result in the lowest percentage of calves with failure of transfer of passive immunity by allowing calves fed colostrum with relatively low immunoglobulin concentrations to receive an adequate immunoglobulin mass prior to closure.[12,13,30] Feeding this volume by an esophageal feeder causes no apparent discomfort to a minimally restrained calf.

Channel Island breeds

Jersey cows produce colostrum with a higher immunoglobulin content than Holsteins and the feeding of nipple bottle 2.0 L of first milking at birth and again at 12 hours of life results in excellent circulating concentrations of immunoglobulin.[31] Three L at each feeding is recommended where feeding is with an esophageal feeder.

Beef cows

With beef breeds very effective colostral immunoglobulin transfer is achieved with

natural sucking. This is believed to be due to the greater vigor at birth exhibited by these calves and the higher immunoglobulin concentrations in beef colostrum, requiring a smaller volume intake to acquire an adequate mass. **Natural sucking** will give an adequate volume intake and there is no need to artificially feed colostrum unless the dam is observed to refuse nursing or the calf's viability and sucking drive are compromised.[32,33] The **yield of colostrum** and colostral immunoglobulins in beef cows can vary widely[32] and range beef heifers may produce critically low volumes of colostrum. Differences in yield can be due to breed or to nutritional status, although undernutrition is not an effect unless it is very severe.[34]

Ewes

Colostrum yield is high in ewes in good condition at lambing but may be low in ewes with condition scores of 1.5–2.0.[35]

Sows

In sows there is also very effective colostral immunoglobulin transfer with natural sucking and piglets average an intake of 5–7% of body weight in the first hour of life.[36] There is between-sow variation in the amount of colostrum and there can be a large **variation** in colostrum supply from teat to teat, which may explain variable health and performance. During farrowing and for a short period following, colostrum is available freely from the udder but thereafter it is released in ejections during mass suckling. A strong coordinated sucking stimulus is required by the piglet for maximum release of colostrum and this requires that the ambient temperature and other environmental factors be conducive to optimum vigor of the piglets. Small-birth-weight piglets, late-**birth-order** piglets and piglets sucking posterior teats obtain less colostrum.

All species

In all species a low-volume intake may also occur because of:

- Poor **mothering behavior**, which may prevent the newborn from sucking, occurrence of disease or milk fever
- Poor **udder and/or teat conformation** so the newborn cannot suck normally or teat seeking is more prolonged. Udder to floor distance is most critical and low-slung udders can account for significant delays in intake. Bottle-shaped teats (35 mm diameter) also significantly reduce intake[37]
- Delayed and **inadequate colostral intake** frequently accompanies perinatal asphyxia or acidosis due to the greatly decreased vigor of the calf in the first few hours of life. Perinatal asphyxia can occur in any breed and is greatly increased by matings resulting in fetal–maternal disproportion and dystocia
- The newborn may be weak, traumatized, or unable to suck for other reasons – **a weak sucking drive** can be a result of congenital iodine deficiency, cold stress or other factors
- Failure to allow newborn animals to ingest colostrum may occur under some management systems.

Efficiency of absorption

After ingestion of colostrum by the newborn, colostral immunoglobulins are absorbed by the small intestine, by a process of pinocytosis, into the columnar cells of the epithelium. In the newborn calf this is a very rapid process and immunoglobulin can be detected in the thoracic duct lymph within 80–120 minutes of its being introduced into the duodenum. The **period of absorption** varies between species and with immunoglobulin class and the mechanism by which absorption ceases is not well understood but may be related to replacement of the fetal enterocyte. The region of maximum absorption is in the lower small intestine and peak serum concentrations are reached by 12–24 hours in all species. Absorption is not limited to immunoglobulins and there is a **proteinuria** during the first 24 hours of life associated with the renal excretion of low-molecular-weight proteins such as β-lactoglobulin.

Feeding methods, closure and immunoglobulin absorption

Under normal conditions complete loss of the ability to absorb immunoglobulin (closure) occurs by 24–36 hours after birth in all species and there is a significant reduction in absorptive ability (as much as 50% in some studies but minimal in others) by 8–12 hours following birth. **The time from birth to feeding** is a crucial factor affecting the absorption of colostral immunoglobulins by all species, and any delay beyond the first few hours of life, particularly after 8 hours, significantly reduces the amount of immunoglobulin absorbed.

The recommendation is that all neonates be fed colostrum within the first 2 hours of life.

Natural sucking

Natural sucking is the desired method of intake of colostrum and is the most efficient, but it is influenced by the sucking drive and **vigor** of the calf at birth. Calves that suck colostrum can achieve very high concentrations of colostral immunoglobulin and the efficiency of absorption is best with this feeding method. However, natural sucking of dairy calves is commonly associated with a high rate of passive transfer failure due to **delays in sucking** coupled with low intakes. In one study 25–34% of calves failed to suck by 6–8 hours of age and 18% of calves did not suck by 18 hours of age. There may be **breed differences** in sucking ability: Jersey calves have better rates of successful transfer of passive immunity with natural sucking than do Holsteins.[38] Many factors influence the occurrence of delayed sucking but calf vigor and birth anoxia are the most important. Conformation of the udder is significant and the importance of this increases with parity.

Artificial feeding

In contrast, when calves are **fed colostrum artificially**, minimal delays from birth to the time of colostrum feeding occur and maximal colostrum immunoglobulin absorption results. In breeds like American Holsteins, where colostral immunoglobulin concentrations tend to be quite low and maximal efficiency of absorption is necessary, the logical way to minimize the effects of closure is to feed the maximum well-tolerated colostrum volume at the first feeding within the first few hours of life. The published literature consistently reports higher calf serum IgG_1 concentrations and a lower rate of failures in response to larger colostrum feeding volumes.[12,13]

Other influences

Even with the best available on-farm colostrum selection methods, **large colostrum-feeding volumes are essential** to minimize failure of transfer of colostral immunoglobulins in breeds with relatively low colostral immunoglobulin concentrations. The method is particularly advantageous where time constraints of other farm activities limit the time available for calf feeding. The major detrimental influence on absorptive efficiency of immunoglobulins is **delayed feeding after birth**. Other factors that affect absorptive efficiency include:

- Perinatal asphyxia or acidosis may have both direct and indirect effects on colostral immunoglobulin transfer. **Asphyxia** has a major effect on subsequent sucking drive and **acidemic** calves ingest far less colostrum than calves with more normal acid–base status at birth. In carefully controlled colostrum feeding studies, there was also significant negative correlation between the degree of hypercapnia and efficiency of absorption of colostral

immunoglobulins, even in calves within the 'normal' newborn blood pH and P_{CO_2} ranges.[39] Direct oxygen deprivation of newborn calves did not cause a similar effect.[40] Treatment of calves with an alkalinizing agent and a respiratory stimulant altered pH and P_{CO_2} values towards adult normal values but did not influence immunoglobulin absorption efficiency[39]

- In one early study, a **mothering effect** was reported where calves remaining with their dams absorbed colostral immunoglobulin much more efficiently than calves removed immediately to individual box stalls. However, other studies have shown much smaller or no effects of mothering using similar experimental designs. The different results of these studies have not been reconciled
- There can be **seasonal** and **geographical** variations in transfer of immunoglobulins in calves although these are not always present on farms in the same area and their cause is unknown. Where seasonal variation occurs in temperate climates the mean monthly serum IgG_1 concentrations are lowest in the winter and increase during the spring and early summer to reach their peak in September, after which they decrease. The cause is not known but an decrease in sucking drive is observed in colder months and may contribute. In subtropical climates, peak levels occur in the winter months, while low levels are associated with elevated temperatures during the summer months.[41] Heat stress in late pregnancy will reduce colostral immunoglobulin concentration but high ambient temperature is a strong depressant of absorption and the provision of shade will help to obviate the problem
- The efficiency of absorption may be decreased in **premature calves** that are born following induced parturition[42] but the medical **induction of parturition** with short-acting corticosteroids in cattle does not interfere with the efficiency of absorption of immunoglobulins in calves
- The absorption of small volumes (1–2 L) fed by an esophageal feeder is usually suboptimal, probably due to retention of some colostrum in the immature forestomachs for several hours. The calf will feel satiated and not inclined to suck naturally for the next few hours
- A **trypsin inhibitor** in colostrum may serve to protect colostral IgG from intestinal degradation. It varies in concentration between colostrums. The addition of a trypsin inhibitor to colostrum improves immunoglobulin absorption[43]
- In a study of **mare-associated determinants of failure of transfer of passive immunity** in foals (based on serum Ig measurements), there was a trend to increase rates of failure in foals from mares aged over 12 years but no real association with age, parity or gestational age of foals over 325 days. There was an association with season with a lower incidence in the late spring compared with foals born earlier in the year and with a foal score based on a veterinary score of foal health and 'fitness'.[44]

Traditionally it has been considered that the **movement** of animals, either the dam just **before parturition** or the newborn animal during the first few days of life, is a special hazard for the health of the calf. The postulated reason is that the dam may not have been exposed to pathogens present in the new environment and thus not have circulating antibodies against these pathogens. The newborn animal may be in the same position with regard to both deficiency of antibodies and exposure to new infections. While this may obtain in some situations, the developing practice of contract-rearing of dairy heifers away from the farm to be brought back as close-up springers, and the practice of purchase of close-up heifers on to the farm, are not associated with appreciable increase in mortality in their calves.

Decline of passive immunity

Passive antibody levels fall quickly after birth and have usually disappeared by 6 months of age. In the **foal**, they have fallen to less than 50% of peak level by 1 month of age, and to a minimum level between 30 and 60 days. This is the point at which naturally immunodeficient foals are highly susceptible to fatal infection.

In **calves**, the level of IgG declines slowly and reaches minimum values by 60 days, in contrast to IgM and IgA, which decline more rapidly and reach minimum values by approximately 21 days of age. The half-lives for IgG, IgM and IgA in calves are approximately 20, 4 and 2 days respectively and half lives of IgGa, IgGb, IgG(T) and IgA in foals are approximately 18, 32, 21 and 3.5 days respectively.[45]

Immunological competence is present at birth but endogenous antibody production does not usually reach protective levels until 1 month, and maximum levels not until 2–3 months of age. The endogenous production of intestinal IgA in the piglet begins at about 2 weeks of age and does not reach significant levels until 5 weeks of age.

Foals that acquire low concentrations of immunoglobulins from colostrum may experience a transitory hypogammaglobulinemia at several weeks of age as the levels fall and before autogenous antibodies develop. They are, as expected, more subject to infection than normal.

OTHER BENEFITS OF COLOSTRUM

In addition to its immunoglobulin content, colostrum contains considerably more protein, fat, vitamins and minerals than milk and is especially important in the transfer of fat-soluble vitamins. It has **anabolic effects** and lambs that ingest colostrum have a higher summit metabolism than colostrum-deprived lambs. Colostrum also contains growth-promoting factors that stimulate DNA synthesis and cell division including high concentrations of insulin-like growth factor (IGF)-1.[46,47]

Colostrum contains approximately 106 leukocytes/mL and several hundred million are ingested with the first feeding of colostrum. In calves 20–30% of these are lymphocytes and cross the intestine into the circulation of the calf.[48] It is postulated that they have importance in the development of neonatal resistance to disease but there is little tangible evidence. Calves fed colostrum depleted of leukocytes are claimed to be more poorly protected against neonatal disease than those fed normal colostrum.[49]

ASSESSMENT OF TRANSFER OF PASSIVE IMMUNITY

Because of the importance of transfer of colostral antibodies to the health of the neonate, it is common to quantitatively estimate the levels of immunoglobulins, or their surrogates, in colostrum and in serum in order to predict risk of disease and to take preventive measures in the individual or to make corrective management changes where groups of animals are at risk.

Assessment in the individual animal

Where samples are taken from an individual animal to determine the risk for infection, sampling is undertaken early so that replacement therapy can be given promptly if there has been inadequate transfer. IgG is detectable in serum 2 hours following a colostrum feeding and **sampling at 8–12 hours** after birth will give a good indication of whether early sucking has occurred and has been effective in transfer.[50] This type of monitoring is commonly performed in foals. There are a number of different tests that can be used, some of which are quantitative and others semi-quantitative. For foals, these include commercially available

tests such as the latex agglutination, concentration immunoassay and hemagglutination inhibition tests. These are semi-quantitative and the relative value of these tests for this type of analysis has been evaluated.[51,52] A glutaraldehyde test for serum is available commercially for use in the horse and is reported to correlate well with radial immunodiffusion (RID) values.[53] In calves, sampling may be undertaken for similar reasons but the cost of replacement therapy is limiting.

Monitoring assessment tests on serum

Sampling to **monitor** the efficacy of a farm policy for feeding colostrum, to evaluate levels in **calves to be purchased** or to determine the **rates of failure of transfer of passive immunity** in investigations of neonatal disease can be conducted at any time in the first week of life after 48 hours with most tests. This is possible because of the relatively long half-life of IgG.

Radial immunodiffusion

This test is usually used in research studies and is the gold standard. It is available commercially but is expensive and takes longer to perform than is desirable for most clinical purposes. An enzyme-linked immunosorbent assay (ELISA) for measurement of IgG concentration in horses and in porcine plasma and colostrum suffers from the same problems.

Quantitative zinc sulfate test

This is a good predictor of mortality but requires instrumentation. It has been used for many years in calves and lambs and has been validated in horses.[54] Hemolyzed blood samples will give artificially high readings, and the reagent must be kept free of dissolved carbon dioxide. The suggested cut-point is 20 ZST units. Increased test solution concentrations to those traditionally used have been suggested to improve sensitivity.[55]

Serum γ-glutamyltransferase activity

Serum γ-glutamyltransferase (GGT) activity has been used as a surrogate for determining the efficacy of transfer of passive immunity in calves and lambs. GGT concentrations are high in the colostrum of ruminants (but not horses) and serum GGT activity in calves and lambs that have sucked or been fed colostrum are 60–160 times greater than normal adult serum activity and correlate moderately well with serum IgG concentrations.[56,57] The half-life of GGT from colostrum is short and serum GGT activity falls significantly in the first week of life. Serum GGT values equivalent to a serum IgG concentration of 10 mg/mL are 200 IU/L on day 1 of life and 100 IU/L on day 4. Serum GGT concentrations less than 50 IU/L indicate failure of transfer of passive immunity.[56,58]

Serum total protein

Total protein, as measured by a refractometer, gives an indirect measure of the amount of immunoglobulin. Despite the indirect nature of the test, there is a reliable correlation between the refractometer reading and total immunoglobulin concentration (IgG and IgM) measured by RID. In healthy calves a serum total protein of 5.2 g/dL or greater is associated with adequate transfer of passive immunity.

Serum total protein has good predictive value for fate of the newborn, and the facile and practical nature of the test and its predictive ability commends it for survey studies in calves and lambs but not foals. Cut-points will vary with the environment[59,60] and the infection pressure to the calves. The sensitivity of the test is maximal using a cut point of 5.5 g/dL and the specificity is maximal at a cut point of 5.0 g/dL.[61] The refractometer can give false high values in dehydrated calves but these can be clinically identified and a cut point of 5.5 g/dL can be used.

Sodium sulfite precipitation and glutaraldehyde test

Both of these were developed as rapid field tests to evaluate the immune status of neonatal calves. An 18% test solution is used and the development of turbidity is the determinant of adequate transfer of passive immunity. The glutaraldehyde coagulation test is also available for the detection of hypogammaglobulinemia in neonatal calves but is less accurate.[61] Neither test is widely used.

ELISA test

An ELISA test is commercially available and used for calf-side testing.

Monitoring colostrum

There has long been the desire for a method to select colostrums with high immunoglobulin concentration for feeding neonates.

Specific gravity

Specific gravity can be used as a measure of immunoglobulin content of colostrum. In **mares** the concentration of immunoglobulins in colostrum is highly correlated with the specific gravity of the colostrum, which in turn is highly correlated with the serum immunoglobulin levels achieved in foals.[50,62] Temperature-corrected measurements are most accurate.[63] Measurement of colostrum specific gravity provides a rapid and easy method of identifying foals likely to be at a high risk for failure of transfer of passive immunity and the need to provide them with colostrum of a higher Ig content. It is recommended that, to prevent failure of transfer of passive immunity, the colostral specific gravity should be equal to or greater than 1.060 and the colostral IgG concentration be a minimum of 3000 mg/dL.[62]

In **cattle** the relation of specific gravity of colostrum to colostral immunoglobulin concentration is linear but is better in Holsteins than in Jerseys.[58] The measurement is simple but there is a correction for temperature, and air trapped in colostrum taken by a milking machine can give a false reading if the measurement is taken too quickly after milking. The cut-point recommended to distinguish moderate from excellent colostrum has been set at 1.048 and is based on the amount of immunoglobulin required for a 2 quart feeding. Specific gravity is not a perfect surrogate for immunoglobulin concentration with cattle colostrum. It has good negative prediction but it will falsely pass many Holstein colostrums that have low immunoglobulin concentration and is not accurate with Jersey colostrum.[64,65] An analysis of first-milking colostrum in midwest USA dairies found that specific gravity differed among breeds and was influenced by month of calving, year of calving, lactation number and protein yield in previous lactation and that it was more closely associated with colostrum protein concentration ($r = 0.76$) than IgG_1 concentration ($r = 0.53$).[66]

Glutaraldehyde test

This test for mare colostrum is available commercially and is reported to have a high predictive value for colostrums that contain more than 38 mg/mL of IgG and have a specific gravity greater than 1.060.[67,68]

ELISA

Recently, a cow-side immunoassay kit has become available commercially in the US. The kit provided a positive or a negative response with the cut point being a concentration of 50 g/L of IgG in colostrum and has accuracy sufficient to recommend its use for rejection of colostrums with low immunoglobulin concentration.[69]

CORRECTION OF FAILURE OF TRANSFER OF PASSIVE IMMUNITY

Parenteral immunoglobulins

Blood transfusion is commonly used and the method is described elsewhere in this text. Purified immunoglobulin preparations are an alternative and are available commercially in some countries. Large amounts are required to obtain the required high serum concentrations of immunoglobulins and intravenous infusion can be accompanied by transfusion-type reactions.

AVOIDANCE OF FAILURE OF TRANSFER OF PASSIVE IMMUNITY

With all species, with the exception of dairy calves, the common practice is to allow the newborn to suck naturally. The policy for avoidance of failure of transfer of passive immunity with naturally sucking herds should be to provide supplemental colostrum by artificial feeding of those neonates with a high risk for failure, based on the risk factors detailed above. In the dairy calf, rates of failure with natural sucking are so high that many farms opt to remove that calf at birth and feed colostrum by hand to ensure adequate intakes.

Colostrum

Colostrum can be stripped from the dam and fed fresh or the neonate can be fed stored (banked) colostrum.

Colostrum for banking

With **dairy cows**, first-milking colostrum from a cow with a first-milking yield of less than 10 kg should be used. The temptation for the farmer is to store the leftover from the feeding of large-volume colostrum. This should not be used as it has a high probability of containing a low immunoglobulin concentration.

Colostrum from **mares** should have a specific gravity of 1.060 or more and 200 mL can be milked from a mare before the foal begins sucking.

Storage of colostrum

Colostrum can be kept at **refrigerator temperature** for approximately 1 week without significant deterioration in immunoglobulins. Storage in plastic containers also maintains the viability of cellular components.[26] The addition of formaldehyde to 0.05% (wt/vol) allows maintenance at 28°C for 4 weeks without loss of immunoglobulins as detected by RID[70] but information on such colostrum's protection efficacy, when fed, is not available. The addition of 5 g of propionic or lactic acid per liter extends the storage life to 6 weeks[30] but, more commonly, colostrum is frozen for storage. **Frozen colostrum**, at –20°C, can be stored virtually indefinitely and there is no impairment to the subsequent absorption of immunoglobulins. Frozen colostrum should be stored in flat plastic bags in the amount required for a feeding, which facilitates thawing. **Thawing** should be at temperatures below 55°C. Higher temperatures and microwave thawing results in the deterioration of immunoglobulins and antibody in frozen colostrum and frozen plasma.[71]

Cross-species colostrum

Colostrum from another species can be used to provide immunological protection where same-species colostrum is not available. Bovine colostrum can be fed to a number of different species. While absorption of immunoglobulins occurs and significant protection can be achieved,[72] the use of cross-species colostrum is not without some risk and the absorbed immunoglobulins have a short half-life. Bovine colostrum has been successfully used for many years to improve the survival rate of hysterectomy-produced artificially reared pigs. It has also been used as an alternate source of colostral antibody for rearing goats free of caprine arthritis–encephalitis. Colostrum from some cows can result in the development of a hemolytic anemia, occurring at around 5–12 days of age, in lambs and kids because the IgG of some cows attaches to the red cells and their precursors in bone marrow, resulting in red cell destruction by the reticuloendothelial system.[73,74] Treatment of the anemia consists of a blood transfusion. Bovine colostrum can be tested for 'anti-sheep' factors by a gel precipitation test on colostral whey but this test is not generally available. Bovine colostrum can provide some protection to newborn foals against neonatal infections and protection appears to be due to factors in addition to the immunoglobulins, which have a short half-life in foals.

Colostrum supplements

In recent years there has been a move to develop supplements or even replacements for colostrum to feed calves. These have been attempted using IgG concentrated from bovine colostrum, milk whey, eggs or bovine serum. The search for colostrum substitutes or colostrum replacers has been prompted by the problem of the variability of IgG concentration in natural colostrum. It has also been prompted by possible limitations of availability of high-quality colostrum on dairy farms as the result of discarding colostrum from cows that test positive to disease that can transmit through colostrum, such as Johne's disease, bovine leukosis, *Mycoplasma bovis*. This problem is confounded by reports that pasteurization of colostrum can have a deleterious effect on IgG concentration in colostrum and its subsequent absorption by calves.[27]

Lacteal-secretion-based preparations

Colostrum supplements prepared from whey or colostrum are available commercially in many countries. Depending upon the manufacturer, they contain varying amounts of immunoglobulin but significantly less than first-milking colostrum. The amount of immunoglobulin contained varies, but the recommendations for feeding that accompany these products indicate that they will supply approximately 25% or less of the immunoglobulin required to elevate calf serum IgG concentrations above 1000 mg/dL. There is a further problem in that the immunoglobulins in products made from colostrum or whey are poorly absorbed and trials assessing their ability to increase circulating immunoglobulins when fed with colostrum have generally shown little improvement and no improvement in health-related parameters.[75–80]

There is evidence that their inclusion with colostrum can impair the efficiency of colostral immunoglobulin[77] and if they are fed they should be fed after normal colostrum. While these milk-protein-derived products are advertised for supplementing normal colostrum feeding, they are unfortunately often promoted as replacements and used by farmers as total substitutes for colostrum. When fed as the sole source of immunoglobulin to colostrum-deprived calves, they achieve circulating concentrations of immunoglobulin that are lower than those achieved by natural colostrum containing equivalent amounts of immunoglobulin.[76]

Bovine-serum-based preparations

Colostrum supplements prepared from bovine serum are also available commercially but regulations governing the feeding of blood or blood products to calves (risk reduction for bovine spongiform encephalopathy) may limit their availability in some countries. The absorption of immunoglobulin from these bovine-serum-derived commercial products appears better than from milk-protein-derived products[80] and consequently they are also marketed as colostrum replacers. It has been proposed that the distinction between a colostrum supplement and a colostrum replacer should be the immunoglobulin mass contained in the product, with a colostrum supplement having less than 100 g IgG per dose and a colostrum replacer having sufficient immunoglobulin mass in a dose to result in a serum IgG concentration greater than 10 mg/mL following a feeding.[80]

A large mass of immunoglobulin is required for acquisition of adequate circulating immunoglobulin. Calves fed a colostrum replacement containing a high mass (250 g for Holsteins) of an IgG derived from bovine serum and fed at 1.5 and again at 13.5 hours after birth, achieved equivalent serum IgG concentrations to calves fed normal colostrum and showed no difference in gain or health parameters during the first 4 weeks of life.[81]

The IgG in a commercially available bovine serum colostrum replacer has been shown to be effectively absorbed when fed to newborn lambs. The feeding

of 200 g of IgG in the first 24 hours of life resulted in a mean plasma concentration of 18 mg/mL [82]

The published literature suggests that there is little advantage to be gained from the use of milk-protein-derived colostrum *supplements* and their use as colostrum *replacers* or *substitutes* is not recommended, except where there is no source of natural colostrum due to factors such as the death of the dam. The feeding of colostrum-derived supplements can result in a modest elevation of circulating IgG, sufficient to protect against experimental colisepticemia. If available, the bovine-serum-derived products would be more suitable.

The use of colostrum replacers should be confined to this type of emergency and there can be little justification for more widespread use, particularly as there are limited independent health-related publications of their efficacy. Also, as mentioned above, in addition to immunoglobulins, natural colostrum contains various substances important to neonatal physiology.

Administration of colostrum

Foals

Foals should be allowed to suck naturally. The specific gravity of the mare's colostrum can be checked at foaling and, where this is less than 1.060, supplemental colostrum may be indicated. Foals that do not suck, or that have serum IgG concentrations less than 400 mg/mL at 12 hours of age, or that require supplementation for other reasons, should be fed colostrum with a specific gravity of 1.060 or more at an amount of 200 mL at hourly feedings.[50,60]

Dairy calves

Assisted natural sucking

Leaving the newborn dairy calf with the cow is no guarantee that the calf will obtain sufficient colostrum and a high proportion fail either to suck early or to absorb sufficient immunoglobulins from ingested colostrum. This problem can be alleviated to some extent by **assisted natural sucking** but this can fail because not all calves requiring assistance are detected. An alternate approach is to milk 2 L of colostrum from the dam, bottle-feed each calf as soon after birth as possible, then leave the calf with the cow for 24 hours and allow it to suck voluntarily. While this will not be as effective as a system based entirely on artificial feeding of selected colostrum, it is an approach that is suitable for the **smaller dairy farm**.

Artificial feeding systems

With **artificial feeding systems**, the calf is removed from the dam at birth and fed colostrum by hand throughout the whole absorptive period. Nipple bottle-feeding can be used with 2 L of colostrum given every 12 hours (Holstein calves) for the first 48 hours of life. The first feeding is usually milked from the cow by hand and the remaining feedings are from the colostrum obtained from the cow after the first machine milking. If care and patience is taken with feeding, this system can result in good transfer of passive immunity in all calves except those born to dams that have very low concentrations of immunoglobulin in their colostrum. Unfortunately, with American Holsteins this can be a significant percentage. An extension from this system is to nipple bottle-feed at the same frequency but to feed stored colostrum selected for its superior immunoglobulin content. Nipple bottle-feeding of newborn calves requires considerable **patience** and its success is very much dependent on the calf feeder and on the availability of the feeder's time when faced with a calf that has a slow intake.

Where the diligence of the calf feeders is poor, or where there is a time constraint on their availability, the feeding of a large volume of colostrum (4 L to a 45 kg calf) by **esophageal feeder** at the initial feeding immediately after birth can be a successful practice. The **large-volume feeding** also allows the delivery of an adequate mass of immunoglobulin with colostrum that has low immunoglobulin concentrations and the delivery of colostrum to the gut in its early absorptive period. The practice usually uses stored colostrum and the feeding can be achieved within a few minutes. It can be supplemented by bottle-feeding of a second feeding at 12 hours of life.

The practice of feeding stored colostrum as the sole source of colostrum is limited to **larger dairy herds** but it does allow the selection of superior colostrum for feeding with selection based on weight and specific gravity as detailed above.

Beef calves

Beef calves should be allowed to suck naturally and force-feeding of colostrum to beef breeds should not be practiced unless there is obvious failure of sucking. Where colostrum is required, as with weak beef calves, calves with edematous tongues and calves that have been subjected to a difficult birth, it can be administered with an esophageal feeder or a stomach tube.

Lambs

Lambs are allowed to suck naturally but there can be competition between siblings for colostrum and one large single lamb is capable of ingesting, within a short period of birth, all the available colostrum in the ewe's udder. Lambs require a total of 180–210 mL colostrum/kg body weight during the first 18 hours after birth to provide sufficient energy for heat production.[35] This amount will usually provide enough immunoglobulins for protection against infections. **Supplemental feeding** of colostrum may be advisable for lambs from multiple birth litters, lambs that lack vigor and those that have not nursed by 2 hours following birth. This can be done with a nipple bottle or an esophageal feeder.

Piglets

Colostral supplementation is not commonly practiced with piglets. An immunoglobulin dose of 10 g/kg body weight on day 1 followed by 2 g/kg on succeeding days for 10 days is sufficient to confer passive immunity on the colostrum-deprived pig.

PRINCIPLES OF CONTROL AND PREVENTION OF INFECTIOUS DISEASES OF NEWBORN FARM ANIMALS

The four principles are:

- Reduction of risk of acquisition of infection from the environment
- Removal of the newborn from the infectious environment if necessary
- Increasing and maintaining the nonspecific resistance of the newborn
- Increasing the specific resistance of the newborn through the use of vaccines.

The application of each of these principles will vary depending on the species, the spectrum of diseases that are common on that farm, the management system and the success achieved with any particular preventive method used previously.

REDUCTION OF RISK OF ACQUISITION OF INFECTION FROM THE ENVIRONMENT

The animal should be born in an **environment** that is clean, dry, sheltered and conducive for the animal to get up after birth, suck the dam and establish bonding.[1,2] Calving and lambing stalls or grounds, farrowing crates and foaling stalls should be prepared in advance for parturition. No conventional animal area can be sterilized but it can be made reasonably clean to minimize the infection rate before colostrum is ingested and during the first few weeks of life when the newborn animal is very susceptible to infectious disease.

With seasonal calving or lambing there can be buildup of infection in the birth area and animals born later in the season are at greater risk of disease. In these circumstances it may be necessary to move to secondary lambing or calving areas. In northern climates snow may constrict the effective calving area and result in a significant buildup of infection. Buildup of infection pressure must be minimized by a change to a fresh calving/lambing area and by the frequent movement of feed bunks or feed areas. Any system that concentrates large numbers of cattle in a small area increases environmental contamination and close confinement of heifers and cows around calving time is a known risk factor for calf mortality.[3,4] With large herds both the cow herd and heifer herd should be broken into as many subgroups as is practical. Extensive systems where cows calve out over large paddocks are optimal and with more intense systems a group size no larger than 50 has been suggested.[5]

Lambing sheds and calving areas for beef cattle should be kept free of animal traffic during the months preceding the period of parturition. In dairy herds, maternity pens separate from other housing functions should be provided and cleaned and freshly bedded between calvings. Certainly **they should not also be used as hospital pens**.

In swine herds, the practice of batch farrowing, with all-in all-out systems of management and disinfection of the farrowing rooms, is essential. Sows should be washed prior to entry to the farrowing area and the floor of the farrowing crate should be of the type that minimizes exposure of the piglet to fecal material at birth.

The swabbing of the **navel** with tincture of iodine to prevent entry of infection is commonly practiced by some producers and seldom by others. In a heavily contaminated environment it is recommended; ligation of umbilical vessels at the level of the abdomen using plastic clamps available for this purpose may however be more effective. The efficiency of the disinfection of the umbilicus after birth is uncertain. It is often surprising how many cases of

omphalophlebitis occur in calves in herds where swabbing or 'dunking' of the navel in a solution of tincture of iodine is a routine practice. Severance of the umbilical cord too quickly during the birth of foals can deprive the animal of large quantities of blood, which can lead to the neonatal maladjustment syndrome.

When deemed necessary, some **surveillance** should be provided for pregnant animals that are expected to give birth, and assistance provided if necessary. In large herds this attention is concentrated on the heifers and because these are more susceptible to dystocia and to neonatal disease they are preferably calved in a separate group that can be easily supervised. The major objective is to avoid or minimize the adverse effects of a difficult or slow parturition on the newborn. Physical injuries, hypoxia and edema of parts of the newborn will reduce the vigor and viability of the newborn and, depending on the circumstances and the environment in which it is born, may lead to death soon after birth.

When possible, every effort should be made to minimize exposure of the neonate to extremes of temperature (heat, cold, snow). Shelter sheds should be built if necessary. Restricting feeding to between 4 pm and 6 am can reduce the number of calves born at night.

In beef herds, the practice of purchasing dairy bulls to foster on to cows whose calves have died should be discouraged. If calves are purchased they should be from a herd whose health status is known to the veterinarian and certainly never through a market. Similarly, colostrum should be obtained from cows within the herd and stored frozen for future use. Colostrum from a dairy herd is a break in herd biosecurity and may transmit the agents of leukosis and Johne's disease. Furthermore, purchased dairy colostrum is commonly second- or third-milking colostrum and of limited immunological value. The use of a commercial colostrum supplement or replacer is possible, although they have significant limitations (see Colostrum substitutes, above).

REMOVAL OF THE NEWBORN FROM THE INFECTIOUS ENVIRONMENT

In some cases of high animal population density (e.g. a crowded dairy barn) and in the presence of known disease it may be necessary to transfer the newborn to a noninfectious environment temporarily or permanently. Adult cows shedding enteric pathogens are a risk for calf infection. Thus dairy calves are often removed from the dam at birth and placed in individual pens inside or outdoors in hutches and reared in these pens separately from the main herd. This reduces the severity of neonatal diarrhea and pneumonia and risk for mortality compared to calves allowed to remain with the dam.[6,7] **Individual housing** in hutches is preferred because this avoids navel sucking and other methods of direct-contact transmission of disease. Humans entering these hutches should also practice interhutch hygiene. The prevalence of disease is higher in enclosed artificially heated barns than in hutches. However, despite the well-established value of individual rearing of calves, animal welfare regulations in several countries require that there be visual and tactile contact between calves. The removal of the cow–calf pair from the main calving grounds to a '**nursery pasture**' after the cow–calf relationship (neonatal bond) is well established at 2–3 days of age, has proved to be a successful management practice in beef herds.[8] This system moves the newborn calf away from the main calving ground, which may be heavily contaminated because of limited space. It necessitates that the producer plan the location of the calving grounds and nursery pastures well in advance of calving time. Calves that develop diarrhea in the calving grounds or nursery pasture are removed with their dams to a '**hospital pasture**' during treatment and convalescence. The all-in all-out principle of successive population and depopulation of farrowing quarters and calf barns is an effective method of maintaining a low level of contamination pressure for the neonate.[9]

INCREASING THE NONSPECIFIC RESISTANCE OF THE NEWBORN

Following a successful birth, the next important method of preventing neonatal disease is to ensure that the newborn ingests colostrum as soon as possible. As detailed above, with natural sucking the amount which the calf ingests will depend on the amount available, the vigor of the calf, the acceptance of the calf by the dam and the management system used, which may encourage or discourage the ingestion of liberal quantities of colostrum. Beef cows that calve at a condition score lower than 4 (out of 10) are at higher risk of having calves that develop failure of transfer of passive immunity and the ideal condition score at calving is 5 to 6.[4]

The method of colostrum delivery that is needed to optimize transfer of passive immunity to the dairy calf will vary with the breed of cow, the management level of the farm and the priority given to calf health. Owner acceptance of alternate feeding systems to natural sucking also is a consideration. The success of the farm policy for the feeding of colostrum is easily monitored by one of the tests listed above, as is the effect of an intervention strategy.

Newborn male dairy calves are commonly assembled and transported to market or to **calf-rearing units** within a few days of birth. Studies have repeatedly shown high rates of failure of transfer of passive immunity in this class of calf. The high rates occur either because the original owner does not bother to feed colostrum to the calf, knowing it is to be sold, or because calves are purchased off the farm before colostrum feeding is completed. The effects of the transportation can have a further deleterious effect on the defense mechanism of the calves and they are at high risk of disease.

Calf-rearing units should preferably purchase calves directly from a farm with an established policy of feeding colostrum before the calf leaves the farm, and every effort should be made to reduce the stress of transportation by providing adequate bedding, avoiding long distances without a break and attempting to transport only calves that are healthy. In some countries there is now legislation requiring the feeding of colostrum and limiting the transport of newborn calves.

The honesty of the stated farm colostrum feeding policy can be monitored by testing the calves for immunoglobulins. Where this is not possible and **market calves** must be used, the entry immunoglobulin value should be tested; the incidence of infectious disease in low-testing calves will be high unless hygiene, housing, ventilation, management and nutrition are excellent. Low-testing calves should probably be culled. The entry immunoglobulin of calves entering veal or other calf-rearing units is a prime determinant of subsequent health and performance. The cull cut-point can be established for an individual farm by monitoring of individual immunoglobulin levels and subsequent calf fate.

Following the successful ingestion of colostrum and establishment of the neonatal bond, emphasis can then be given to provision, if necessary, of any special nutritional and housing requirements. Newborn piglets need supplemental heat, their eye teeth should be clipped and attention must be given to the special problems of intensive pig husbandry. Orphan and weak piglets can now be reared successfully under normal farm conditions with the use of milk replacers containing added porcine immunoglobulins. Heat is often provided to lambs for the first day in pen lambing systems.

Milk replacers for the newborn must contain high-quality ingredients. Human-grade milk products are preferred to

animal-grade products because there is less heat denaturation. Calves younger than 3 weeks are less able to digest nonmilk proteins, and the fats best used by the calf are high-quality animal source fats and slightly unsaturated vegetable oils.[10,11] A 22% crude protein is recommended for milk replacers comprised only of milk proteins and 24–26% in replacers that contain nonmilk protein sources. The level of fat should be at least 15%; higher fat concentration will provide additional energy which may be required in colder climates. Feeding utensils must be cleaned and disinfected between each feeding if disease transmission is to be minimized.[12]

With animals at pasture, the mustering and close contact associated with management procedures such as castration and docking pose a risk for disease transmission. These procedures should be performed in yards prepared for the purpose – preferably temporary yards erected for this sole purpose in a clean area.

INCREASING THE SPECIFIC RESISTANCE OF THE NEWBORN

The specific resistance of the newborn to infectious disease may be enhanced by vaccination of the dam during pregnancy to stimulate the production of specific antibodies which are concentrated in the colostrum and transferred to the newborn after birth. Vaccination of the dam can provide protection for the neonate against enteric and respiratory disease. Details are given under the specific disease headings in this text. The vaccination of the late fetus in utero stimulates the production of antibody but its practical application has yet to be determined.

OMPHALITIS, OMPHALOPHLEBITIS AND URACHITIS IN NEWBORN FARM ANIMALS (NAVEL-ILL)

Infection of the umbilicus and its associated structures occurs commonly in newborn farm animals and appears to be particularly common in calves. The umbilical cord consists of the amniotic membrane, the umbilical veins, the umbilical arteries and the urachus. The amniotic membrane of the umbilical cord is torn at birth and gradually the umbilical vein and the urachus close, but they remain temporarily outside the umbilicus. The umbilical arteries retract as far back as the top of the bladder.

In many countries regulations govern the minimal age at which neonatal calves can be shipped or sent to market and slaughter. Commonly this can not legally be done until the calf is in its fifth day of life. The wetness or dryness of the umbilicus is used as a surrogate measure of age in welfare regulations and the requirement is that the umbilical cord at the junction with the abdominal skin should be dry and shriveled. The drying time varies from 1 to 8 days, with variation between breeds and a longer drying period in bull calves. As might be expected, this measure is only an approximate surrogate for age but approximately 90% of calves have dry navels by 4 days of age.[1]

Infection of the umbilicus occurs **soon after birth** and may result in omphalitis, omphalophlebitis, omphaloarteritis or infection of the urachus, with possible extension to the bladder, causing cystitis. The majority of infections progress to sites beyond the umbilicus.[1] There is usually a **mixed bacterial flora** including *E. coli*, *Proteus* spp., *Staphylococcus* spp., *A. pyogenes*, *Bacteroides* spp, *F. necrophorum* and *Klebsiella* spp.[2,3]

Bacteremia and localization with infection may occur in joints, bone, meninges, eyes, endocardium and end-arteries of the feet, ears and tail. The navel can also be the source of infection leading to septicemia, arthritis and fever of unknown origin in neonates with failure of transfer of passive immunity.[4]

Omphalitis

Omphalitis is inflammation of the external aspects of the umbilicus and occurs commonly in calves and other species within 2–5 days of birth and often persists for several weeks.[5] The umbilicus is enlarged, painful on palpation and may be closed or draining purulent material through a small fistula. The affected umbilicus may become very large and cause subacute toxemia. The calf is moderately depressed, does not suck normally and is febrile. Treatment consists of surgical exploration and excision. A temporary drainage channel may be necessary.

Omphalophlebitis

Omphalophlebitis is inflammation of the umbilical veins. It may involve only the distal parts or extend from the umbilicus to the liver. Large abscesses may develop along the course of the umbilical vein and spread to the liver, with the development of a hepatic abscess that may occupy up to one-half of the liver. Affected calves are usually 1–3 months of age and are unthrifty because of chronic toxemia. The umbilicus is usually enlarged with purulent material; however, in some cases the external portion of the umbilicus appears normal-sized. Placing the animal in dorsal recumbency and deep palpation of the abdomen dorsal to the umbilicus in the direction of the liver may reveal a space-occupying mass.

Ultrasonography may assist in the diagnosis and can help in formulating a surgical approach.[6,7] Affected calves and foals are inactive, inappetent, unthrifty and may have a mild fever. Parenteral therapy with antibiotics is usually unsuccessful. Exploratory laparotomy and **surgical removal** of the abscess is necessary.[8,9] Large hepatic abscesses are usually incurable unless surgically removed, but the provision of a drain to the exterior and daily irrigation may be attempted if resection is not feasible.

Omphaloarteritis

In omphaloarteritis, which is less common, the abscesses occur along the course of the umbilical arteries from the umbilicus to the internal iliac arteries. The clinical findings are similar to those in omphalophlebitis: chronic toxemia, unthriftiness and failure to respond to antibiotic therapy. Treatment consists of surgical removal of the abscesses.

Urachitis

Infection of the urachus may occur anywhere along the urachus from the umbilicus to the bladder. The umbilicus is usually enlarged and draining purulent material, but can appear normal. Deep palpation of the abdomen in a dorsocaudal direction from the umbilicus may reveal a space-occupying mass. Extension of the infection to the bladder can result in cystitis and pyuria. **Contrast radiography** of the fistulous tract and the bladder will

reveal the presence of the lesion. The treatment of choice is exploratory laparotomy and surgical removal of the abscesses. Recovery is usually uneventful.

CONTROL

The control of umbilical infection depends primarily on **good sanitation and hygiene** at the time of birth. The application of drying agents and residual disinfectants such as tincture of iodine is widely practiced. However, there is limited evidence that chemical disinfecting is of significant value. Chlorhexidine is more efficient in reducing the number of organisms than 2% iodine or 1% povidone iodine. High concentrations of iodine (7%) are most effective but are damaging to tissue.[10]

Clinical assessment and care of critically ill newborns

The following discussion focuses on care and treatment of critically ill foals, although the principles are applicable to any species. The increasing availability of secondary and tertiary care for ill newborns has allowed the development of sophisticated care for newborns of sufficient emotional or financial value. This level of care, at its most intensive, requires appropriately trained individuals (both veterinarians and support staff) and dedicated facilities. True intensive care of newborns requires 24-hour monitoring. The following discussion is not a comprehensive guide to intensive care of newborns but is rather an introduction to the general aspects of advanced primary or secondary care. Sophisticated interventions, such as mechanical ventilation and cardiovascular support, are mentioned but not discussed in detail.

CLINICAL EXAMINATION

Initial assessment of an ill newborn should begin with collection of a detailed history including the length of gestation, health of the dam, parturition and behavior of the newborn after birth, including the time to stand and to commence nursing activity. Physical examination should be thorough, with particular attention to those body systems most commonly affected. A form similar to that in Figure 3.1 is useful in ensuring that all pertinent questions are addressed and that the physical examination is comprehensive.

Examination of ill neonates should focus on detection of the common causes of disease in this age group: sepsis, either focal or systemic; prematurity or dysmaturity; metabolic abnormalities (such as hypoglycemia or hypothermia); birth trauma; diseases associated with hypoxia; and congenital abnormalities. Detailed descriptions of these conditions are provided elsewhere in this chapter.

Sepsis

Sepsis is an important cause of illness in neonates that can manifest as localized infections without apparent systemic signs, localized infections with signs of systemic illness, or systemic illness without signs of localized infection.

Localized infections without signs of systemic illness include septic synovitis or osteomyelitis, or omphalitis. Signs of these diseases are evident on examination of the area affected and include lameness, distension of the joint and pain on palpation of the affected joint in animals with synovitis or osteomyelitis, and an enlarged external umbilicus with or without purulent discharge in animals with infections of the umbilical structures. Specialized imaging, hematological and serum biochemical examinations (see below) are useful in confirming the infection.

Systemic signs of sepsis include depression, failure to nurse or reduced frequency of nursing, somnolence, recumbency, fever or hypothermia, tachypnea, tachycardia, diarrhea and colic, in addition to any signs of localized disease. Fever is a specific, but not sensitive, sign of sepsis in foals. The presence of petechia in oral, nasal, ocular or vaginal mucous membranes, the pinna or coronary bands is considered a specific indicator of sepsis, although this has not been documented by appropriate studies. A similar comment applies for injection of the scleral vessels. A scoring system ('the sepsis score') has been developed to aid in the identification of foals with sepsis.[1]

The '**sepsis score**' was developed with the intention of aiding identification of foals with sepsis, and thereby facilitating appropriate treatment. A table for calculation of sepsis score is provided in Table 3.3. Foals with a score of 12 or greater are considered to be septic, with a sensitivity of 94%.[1] However, the sepsis score, which was widely used for over a decade, was not appropriately evaluated in other clinics until very recently. These recent studies demonstrate that the sepsis score has limited sensitivity (67%, 95% confidence interval (CI) 59–75%) and specificity (76%, 95% CI 68–83%) in foals less than 10 days of age.[2] The associated positive and negative likelihood ratios were 2.76 and 0.43, respectively.[2] Similarly, 49% of 101 foals with positive blood cultures had a sepsis score of 11 or less.[3] The low sensitivity of the sepsis score for detection of sepsis or bacteremia means that many foals with sepsis are incorrectly diagnosed. This is an important shortcoming of the test, as accurate and prompt identification of foals with sepsis is assumed to be important for both prognostication and selection of treatment. The sepsis score might be useful in some situations, but its shortcomings should be recognized when using it to guide treatment or determine prognosis.

Prematurity and dysmaturity

Detection of **prematurity** is important because it is a strong risk factor for development of other diseases during the immediate postpartum period. The detection of prematurity is often based on the length of gestation. However, the duration of gestation in Thoroughbred horses varies considerably, with 95% of mares foaling after a gestation of 327–357 days[4] – the generally accepted 'average' gestation is 340 days. Ponies have a shorter gestation (333 days, range 315–350 days).[5] Therefore, a diagnosis of prematurity should be based not just on gestational age but also on the results of physical, hematological and serum biochemical examination of the newborn. Factors helping in the determination of prematurity are listed in Table 3.4. Foals that are immature (premature) at birth typically have low birth weight and small body size, a short and silky hair coat and laxity of the flexor and extensor tendons. The cranium is rounded and the pinnae lack tone (droopy ears). The foals are typically weak and have trouble standing, which is exacerbated by laxity of the flexor tendons and periarticular ligaments. **Dysmature** (postmature) foals are typically large, although they can be thin, and have a long hair coat and flexure tendon contracture. These signs are consistent with prolonged gestation combined with inadequate intrauterine nutrition. Examination of the placenta, either by ultrasonographic examination before birth or by direct examination, including histologic and microbiologic testing, after birth is useful in identifying abnormalities that have significance for the newborn.[5–7]

Table 3.3 Worksheet for calculating a sepsis score for foals less than 12 days of age[1]

Variable	Number of points to assign 4	3	2	1	0	Score for this case
1. Historical data						
a. Placentitis, vulvar discharge before delivery, dystocia, sick dam, induced parturition		Present			Absent	
b. Gestation length (days)		< 300	300–310	311–330	> 330	
2 Clinical examination						
a. Petechiation or scleral injection (nontraumatic)		Marked	Moderate	Mild	None	
b. Rectal temperature (°C)			> 38.9	< 37.8	37.9–38.7	
c. Hypotonia, convulsions, coma, depression			Marked	Moderate	Mild	
d. Anterior uveitis, diarrhea, respiratory distress, swollen joints or open wounds		Present			Absent	
3. Hemogram						
a. Neutrophil count (cells × 10^9/L)		< 2.0	2.0–4.0 or 8.0–12.0 > 12		4.0–8.0	
b. Band neutrophils (cells × 10^9/L)		> 0.2	0.05–0.2		< 0.05	
c. Toxic changes in neutrophils	Marked	Moderate	Slight		None	
d. Fibrinogen concentration (g/L)			> 6.0	4.1–6.0	4.0	
4. Laboratory data						
a. Blood glucose (mmol/L)			< 2.7	2.7–4.4	> 4.4	
b. IgG concentration (g/L)	< 2.0	2.0–4.0	4.1–8.0		> 8.0	
c. Arterial oxygen tension (Torr)		< 40	40–50	51–70	> 70	
d. Metabolic acidosis (base excess < 0)				Present	Absent	
Total points for this foal						

To calculate the sepsis score, assign foal a score corresponding to the historical, physical examination and laboratory data included in the above table. A score of 11 or less predicts the absence of sepsis correctly on 88% of cases whereas a score of 12 or higher predicts sepsis correctly in 93% of cases. For foals less than 12 hours of age that have nursed or received colostrum, assign a value of 2 for the serum immunoglobulin score. If the foal has not nursed, assign a value of 4.

Table 3.4 Criteria to assess stage of maturity of the newborn foal[1]

Criterion	Premature	Full term
Physical		
Gestational age	320 d	Normally > 330 d
Size	Small	Normal or large
Coat	Short and silky	Long
Fetlock	Overextended	Normal extension
Behavior		
First stand	> 120 min	< 120 min
First suck	> 3 h	< 3 h
Suck reflex	Poor	Good
Righting reflexes	Poor	Good
Adrenal activity		
Plasma cortisol values over first 2 h postpartum	Low levels (< 30 ng/mL)	Increasing levels (120–140 ng/mL) at 30–60 min postpartum
Plasma ACTH values over first 2 h postpartum	Peak values (≈ 650 pg/mL) at 30 min postpartum and declining subsequently	Declining values from peak (300 pg/mL at birth)
Response to synthetic ACTH1-24 (short-acting Synacthen), dose 0.125 mg IM	Poor response shown by a 28% increase in plasma cortisol and no changes in neutrophil:lymphocyte ratio	Good response shown by a 208% increase in plasma cortisol and widening of neutrophil:lymphocyte ratio
Hematology		
Mean cell volume (fl)	> 39	< 39
White blood cell count (× 10^9/L)	6.0	8.0
Neutrophil:lymphocyte ratio	< 1.0	> 2.0
Carbohydrate metabolism		
Plasma glucose levels over first 2 h postpartum	Low levels at birth (2–3 mmol/L), subsequently declining	Higher levels at birth (4.1 mmol/L), maintained
Plasma insulin levels over first 2 h postpartum	Low levels at birth (8.6 μU/mL), declining	Higher levels at birth (16.1 μU/mL), maintained
Glucose tolerance test (0.5 mg/kg body weight IV)	Slight response demonstrated by a 100% increase in plasma insulin at 15 min post-administration	Clear response demonstrated by a 250% increase in plasma insulin at 5 min post-administration
Renin–angiotensin–aldosterone system		
Plasma renin substrate	Higher and/or increasing levels during 15–60 min postpartum	Low (< 0.6 μg/mL) and declining levels during 15–30 min postpartum
Acid–base status (pH)	< 7.25 and declining	> 7.3 and maintaining or rising

IM, intramuscularly; IV, intravenously.

Foal Examination Protocol

Fig. 3.1 (*Cont'd*) Examples of forms used to document and record historical aspects and findings on physical examination of foals less than 1 month of age.

(See Prematurity, immaturity and dysmaturity of foals for a complete discussion of this topic.)

Hypoxia

Hypoxia during late gestation, birth or the immediate postpartum period has a variety of clinical manifestations depending on the tissue or organ most affected. Signs of central nervous system dysfunction, the so-called 'dummy foals' or 'barkers and wanderers' are often assumed to be a result of cerebral hypoxia during birth. Other signs suggestive of peripartum hypoxia include colic and anuria.

Hypoglycemia

Foals that are hypoglycemic because of inadequate intake, such as through mismothering, congenital abnormalities

or concurrent illness, are initially weak with rapid progression to somnolence and coma.

DIAGNOSTIC IMAGING

Radiographic and ultrasonographic examination of neonates can be useful in determining maturity and the presence of abnormalities. Prematurity is evident as failure or inadequate ossification of cuboidal bones in the carpus and tarsus. Radiographs of the thorax should be obtained if there is any suspicion of sepsis or pneumonia, because thoracic auscultation has poor sensitivity in detecting pulmonary disease in newborns (see Table 10.2 for definition of radiographic abnormalities in foals). Severity of abnormalities in lungs of foals detected by radiographic examination is related to prognosis, with foals with more severe disease having a worse prognosis for recovery.[8] Abdominal radiographs may be useful in determining the site of gastrointestinal disease (see Foal colic).

Ultrasonography is a particularly useful tool for examination of neonates, in large part because their small size permits thorough examination of all major body cavities. Ultrasonography of the umbilical structures can identify omphalitis and abscesses of umbilical remnants[9] and, when available, is indicated as part of the physical examination of every sick neonate.

Examination of the **umbilical structures** can reveal evidence of infection, congenital abnormalities and urachal tears. Examination of the umbilicus can be achieved using a 7.5 mHz linear probe (such as that commonly used for reproductive examination of mares) although sector scanners provide a superior image. Examination of the umbilical structures should include examination of the navel and structures external to the body wall, the body wall, the umbilical stump as it enters the body wall and separates into the two umbilical arteries, the urachus and apex of the bladder, and the umbilical vein. The size and echogenicity of each of these structures should be determined. For foals less than 7 days of age the intra-abdominal umbilical stump should be less than 2.4 cm in diameter, the umbilical vein less than 1 cm and the umbilical arteries less than 1.4 cm (usually < 1 cm). Examination of these structures should be complete: the umbilical vein should be visualized in the umbilical stump and then followed as it courses along the ventral abdominal wall and into the liver; the umbilical arteries should be visualized in the umbilical stump and then as they separate from that structure and course over the lateral aspects of the bladder; the urachus should be visualized from the external umbilical stump through the body wall and as it enters the bladder.

Abnormalities observed frequently in the umbilical structures include overall swelling, consistent with omphalitis, gas shadows in the urachus or umbilical stump, which are indicative of either a patent urachus allowing entry of air or growth of gas-producing bacteria, and the presence of flocculent fluid in the urachus, vein or artery, which is consistent with pus. Urachal tears can be observed, especially in foals with uroperitoneum.

Ultrasonographic examination of the **abdomen** is useful in identifying abnormalities of gastrointestinal function and structure, including intestinal distension or thickening of intestinal wall. Intussusceptions are evident as 'donut' lesions in the small intestine. Gastric outflow obstruction should be suspected in foals with a distended stomach evident on ultrasonographic examination of the abdomen. Uroperitoneum is readily apparent as excessive accumulation of clear fluid in the abdomen. Hemorrhage into the peritoneum can be detected as accumulation of echogenic, swirling fluid. Accumulation of inflammatory fluid, such as in foals with ischemic intestine, is detected by the presence of flocculent fluid.

Ultrasonographic examination of the **chest** can reveal the presence of pleural abnormalities, consolidation of lung (provided that the consolidated lung is confluent with the pleura), accumulation of fluid in the pleural space (hemorrhage secondary to birth trauma and fractured ribs, inflammatory fluid in foals with pleuritis), pneumothorax (usually secondary to lung laceration by a fractured rib[10]) or congenital abnormalities of the heart.

Advanced imaging modalities, such as **computed tomography (CT) and magnetic resonance imaging (MRI)**, are available at referral centers and are practical in foals and other neonates because of the small size of the animals. These modalities are useful in detection of intrathoracic and intra-abdominal abnormalities, including abscessation, gastrointestinal disease and congenital abnormalities.[11,12] MRI is particularly useful for diagnosis of diseases of the brain and spinal cord.[13]

CLINICAL PATHOLOGY

Serum immunoglobulin concentration

Serum immunoglobulin G (IgG) concentration, or its equivalent, must be measured in every ill or at-risk newborn and should be repeated every 48–96 hours in critically ill neonates. A variety of tests are available for rapid detection of failure of transfer of passive immunity in foals[14–17] and calves.[18] While measurement of serum IgG concentration is ideally performed by the gold standard test, a radial immunodiffusion, this test requires at least 24 hours to run, whereas the stall side or chemistry analyzer tests can be run in a few minutes. The sensitivity and specificity of a number of these rapid tests has been determined. Overall, most tests have high sensitivity (> 80%), meaning that the few foals that have low concentrations of IgG are missed, but poor specificity (50–70%), meaning that many foals that have adequate concentrations of immunoglobulin are diagnosed as having inadequate concentrations.[15–17] The exact sensitivity and specificity depends on the test used and the concentration of immunoglobulin considered adequate. The high sensitivity and low specificity of most of the available rapid tests result in a number of foals that do not need a transfusion receiving one. However, this error is of less importance than that of foals that should receive a transfusion not receiving one.

Serum or plasma concentrations of IgG should be measured after approximately 18 hours of age, and preferably before 48 hours of age – the earlier failure of transfer of passive immunity is recognized the better the prognosis for the foal. Foals that ingest colostrum within the first few hours of birth have minimal increases in serum IgG concentration over that achieved at 12 hours of age,[19] suggesting that measurement of serum IgG concentration as early as 12–18 hours after birth is appropriate. This early measurement of serum IgG concentration could be especially important in high-risk foals. The oldest age at which measurement of serum IgG is useful in foals is uncertain, but depends on the clinical condition of the foal. Typically, immunoglobulin concentrations of foals that have adequate concentrations of IgG within the first 24 hours reach a nadir at about 6 weeks of age and then rise to concentrations similar to adults over the next 2–3 months.

Hematology

It is important to recognize that the hemogram of neonates differs from that of older animals (Table 3.5), as these differences can impact on the clinical assessment of the animal. The hematologic and serum biochemical values of foals and calves can vary markedly during the first days and weeks of life and it is important that these maturational changes are taken into account when assessing results of hematological or serum biochemical examination of foals. Hematological examination can reveal evidence of hemolytic

disease, bacterial or viral infection, or prematurity/dysmaturity (Table 3.4). Repeated hemograms are often necessary to monitor for development of sepsis and responses to treatment.

Foals with **sepsis** can have a leukocyte count in the blood that is low, within the reference range or high.[20] Approximately 40% of foals with sepsis have blood leukocyte counts that are below the reference range. Most foals with sepsis (approximately 70%) have segmented neutrophil counts that are below the reference range, with fewer than 15% of foals having elevated blood neutrophil counts. Concentrations of band cells in blood are above the reference range in almost all foals with sepsis. Some foals born of mares with placentitis have a very pronounced mature neutrophilia without other signs of sepsis – these foals typically have a good prognosis. Lymphopenia is present in foals with equine herpervirus-1 septicemia or Arabian foals with severe combined immunodeficiency. Thrombocytopenia occurs in some foals with sepsis.[21] Hyperfibrinogenemia is common in foals that have sepsis, although the concentration might not be above the reference range in foals examined early in the disease. Hyperfibrinogenemia is common in foals born of mares with placentitis, and reflects systemic activation of the inflammatory cascade even in foals that have no other evidence of sepsis. Serum amyloid A concentrations are above 100 mg/L in foals with sepsis.[22] Septic foals also have blood concentrations of proinflammatory cytokines that are higher than those in healthy foals.[23] Indices of coagulation are prolonged in foals with sepsis, and concentrations of antithrombin and protein C antigen in plasma are lower than in healthy foals.[23] These abnormalities indicate that coagulopathies are common in septic foals.

Prematurity is associated with a low neutrophil:lymphocyte ratio (< 1.5:1) in blood and a red cell macrocytosis (Table 3.4).[24] A neutrophil:lymphocyte ratio above 2:1 is considered normal. Premature foals that are not septic can have low blood neutrophil counts but rarely have immature neutrophils (band cells) or toxic changes in neutrophils.

Serum biochemistry

Care should be taken in the interpretation of the results of serum biochemical examinations because normal values for newborns are often markedly different to those of adults, and can change rapidly during the first days to weeks of life (Table 3.6). Serum biochemical examination can reveal electrolyte abnormalities associated with renal failure, diarrhea and sepsis. Elevations in serum bilirubin concentration or serum enzyme activities may be detected. As a minimum, blood glucose concentrations should be estimated using a chemical strip in depressed or recumbent newborns.

Markedly elevated serum **creatinine** concentrations are not uncommonly observed in foals with no other evidence of renal disease. The elevated serum creatinine in these cases is a consequence of impaired placental function during late gestation, with the consequent accumulation of creatinine (and probably other compounds). In foals with normal renal function, which most have, the serum creatinine concentration should decrease to 50% of the initial high value within 24 hours. Other causes of high serum creatinine concentration that should be ruled out are renal failure (dysplasia, hypoxic renal failure) and postrenal azotemia (uroperitoneum).

Sepsis is usually associated with hypoglycemia, although septic foals can have normal or elevated blood glucose concentrations. Hypoglycemia is attributable

to failure to nurse whereas hyperglycemia indicates loss of normal sensitivity to insulin. Indicators of renal, hepatic or cardiac (troponin) damage can increase in foals with sepsis causing organ damage or failure.[25] Foals with sepsis tend to have elevated concentrations of cortisol in serum.

Prematurity is associated with low concentrations of cortisol in plasma or serum and minimal increase in response to intramuscular administration of 0.125 mg of exogenous ACTH (corticotropin).[26] Plasma cortisol concentration of normal, full-term, foals during the first 24 hours of life increases from a baseline value of approximately 40 ng/mL to over 100 ng/mL 60 minutes after ACTH administration, whereas plasma cortisol concentrations in premature foals do not increase from values of slightly less than 40 ng/mL.[26] At 2 and 3 days of age, plasma cortisol concentrations of full-term foals increase twofold after ACTH administration, albeit from a lower resting value, but do not increase in premature foals. Blood glucose concentrations of premature foals are often low, probably because of inability to nurse.

Blood gas

Arterial blood pH, P_{CO_2} and P_{O_2} should be measured to determine the newborn's acid–base status and the adequacy of respiratory function. Foals with hypoxemia are five times more likely to have pulmonary radiographic abnormalities.[27] Prolonged lateral recumbency of foals compromises respiratory function, and arterial blood samples should be collected with the foal in sternal recumbency. Repeated sampling may be necessary to detect changes in respiratory function and to monitor the adequacy of oxygen supplementation or assisted ventilation.

Blood culture

Identification of causative organisms of sepsis in foals can aid in prognostication and potentially in selection of therapy, although there does not appear to be a relation between antimicrobial sensitivity of organisms isolated from blood, as determined by Kirby–Bauer testing, and survival of foals. Anaerobic and aerobic blood cultures should be performed as early in the disease process as possible, and preferably before initiation of antibiotic treatment, although antimicrobials should not be withheld from a newborn with confirmed or suspected sepsis in order to obtain a result from blood culture. Strict aseptic technique should be used when collecting blood for culture. Blood cultures should also be collected if there is a sudden deterioration in the newborn's condition.

Gram-negative enteric bacteria are the most common isolates from blood of newborn foals, with *E. coli* the most common isolate.[3] *A. equuli* is also a common isolate from foals. There are important differences in diseases produced by the various organisms, with foals with *A. equuli* septicemia being twice as likely to die, seven times more likely to have been sick since birth, six times more likely to have diarrhea, five times more likely to have a sepsis score of more than 11 and three times more likely to have pneumonia than foals with sepsis associated with other bacteria.[3]

Other body fluids

Synovial fluid should be submitted for aerobic and anaerobic culture, Gram stain and cytological examination when signs of synovitis, such as lameness, joint effusion or joint pain are present.

Analysis of cerebrospinal fluid (CSF) is indicated in newborns with signs of neurologic disease. Samples of CSF should be submitted for cytological examination, measurement of total protein concentration, Gram stain and bacterial culture.

Urinalysis may provide evidence of renal failure (casts) or urinary tract infection (white blood cells).

Abdominal fluid should be collected in foals with abdominal pain or distension

and should be submitted for cytological examination and, if uroperitoneum is suspected, measurement of creatinine concentration.

TREATMENT

The principles of care of the critically ill newborn farm animal are that:

- The newborn should be kept in a sanitary environment to minimize the risk of nosocomial infections
- Systemic supportive care should be provided to maintain homeostasis until the newborn is capable of separate and independent existence
- There should be frequent and comprehensive re-evaluations of all body systems in order to detect signs of deterioration and allow early correction
- Provision should be made to ensure adequate passive immunity to reduce the risk of secondary infections or to treat existing infections. Transfer of passive immunity should be evaluated using laboratory methods that measure serum or plasma immunoglobulin G concentration.

The level of care provided depends upon the value of the animal and the available facilities, personnel and expertise. Newborns of limited financial worth are usually treated on the farm whereas valuable foals and calves can be referred for specialist care. Referral of sick neonates to institutions and practices with expertise in provision of critical care to newborns should be timely and prompt and, when necessary, should be recommended on the first visit.

Nursing care

The sophistication of care for critically ill newborns depends on the facilities and personnel available, with intensive management requiring dedicated facilities and trained personnel available 24 hours a day. The minimum requirement for providing basic care of ill newborns is a sanitary area in which the newborns can be protected from environmental stress. Often this means separating the newborn from its dam.

Excellent nursing care is essential for maximizing the likelihood of a good outcome. Critically ill animals might benefit from constant nursing care. Strict attention must be paid to maintaining the sanitary environment in order to minimize the risk of nosocomial infections. The newborn should be kept clean and dry and at an ambient temperature in its thermoneutral zone. Bedding should prevent development of decubital ulcers. Foals should be maintained in sternal recumbency, or at least turned every 2 hours, to optimize their respiratory function.

Correction of failure of transfer of passive immunity

Colostral immunoglobulin

Ideally, adequate transfer of passive immunity is achieved by the newborn nursing its dam and ingesting an adequate amount of colostrum containing optimal concentrations of immunoglobulins, principally IgG (IgGb) in foals. Foals need approximately 2 g of IgG per kilogram of body weight to achieve a plasma concentration of 2000 mg/dL (20 g/L), therefore a 45 kg foal needs approximately 90 g of IgG to attain a normal serum IgG concentration (or approximately 40 g to achieve a serum IgG concentration of 800 mg/dL (8 g/L)). Assuming that colostrum contains on average 10 000 mg/dL (100 g/L), foals must ingest at least 1 L of colostrum to obtain sufficient immunoglobulin. Because colostral IgG concentration varies considerably (from 2000–30 000 mg/dL), specific recommendations regarding the quantity of colostrum to be fed to neonatal foals cannot be made with certainty. However, colostrum with a specific gravity of more than 1.060 has an IgG concentration of more than 3000 mg/dL (30 g/L),[28] suggesting that foals should ingest at least 1.5 L to achieve serum IgG concentrations above 800 mg/dL (8 g/L).

Critical plasma IgG concentrations in foals

There is some debate as to what constitutes a critical serum or plasma IgG concentration. Foals that ingest an adequate amount of colostrum typically have serum immunoglobulin concentrations during the first week of life greater than approximately 2000 mg/dL (20 g/L).[29–31] Both 400 mg/dL (4 g/L) and 800 mg/dL (8 g/L) have been recommended as concentrations below which foals should be considered to have increased likelihood of contracting infectious disease. However, on a well-managed farm the serum IgG concentration was not predictive of morbidity or mortality amongst foals, suggesting that serum immunoglobulin concentration in some populations of foals is not an important risk factor for infectious disease.[32] The foals in this study were from an exceptionally well-managed farm. Other researchers have found that foals with serum IgG concentration below 800 mg/dL (8 g/L) are at markedly increased risk of subsequent development of infectious disease, including sepsis, pneumonia and septic arthritis.[33,34] It is likely that there is no single concentration of IgG in serum that is protective in all situations and the concentration of IgG in serum that is desirable in an individual foal depends on the risk factors for infectious disease of that foal. Our opinion is that a minimum serum IgG in foals free of disease and housed in closed bands on well-managed farms is 400 mg/dL (4 g/L). For foals at increased risk of disease, for instance those on large farms with frequent introduction of animals and foals that are transported or housed with foals with infectious disease, the minimum advisable serum IgG concentration is 800 mg/dL (8 g/L). Foals that have infectious disease should have serum IgG concentrations of at least 800 mg/dL and it might be advantageous for these foals to have even higher values, as indicated by the enhanced survival of foals with septic disease administered equine plasma regardless of their serum IgG concentration.[35] This therapeutic advantage could be because of the additional IgG, or because of other factors included in the plasma. Transfusion of plasma to sick foals improves neutrophil function, an important advantage given that oxidative burst activity of neutrophils from septic foals is reduced compared to that in healthy foals.[36]

Plasma transfusion

The ability of foals to absorb macromolecules, including immunoglobulins, declines rapidly after birth, being 22% of that at birth by 3 hours of age, and 1% of that at birth by 24 hours of age.[37] Consequently, by the time that failure of transfer of passive immunity is recognized it is no longer feasible to increase serum IgG concentrations by feeding colostrum or oral serum products. Foals should then be administered plasma or serum intravenously. The **amount of plasma** or serum to be administered depends on the target value for serum IgG concentration and the initial serum IgG concentration in the foal. For each gram of IgG administered per kilogram of body weight of the foal, serum IgG concentration increases by approximately 8.7 mg/dL (0.87 g/L) in healthy foals and 6.2 mg/dL (0.62 g/L) in sick foals.[38] To achieve serum IgG concentrations above 800 mg/dL (8 g/L) in foals with serum IgG concentrations below 400 mg/dL (4 g/L), they should be administered 40 mL/kg of plasma containing at least 20 g/L of IgG. Similarly foals with serum IgG concentrations above 400 mg/dL (4 g/L) but below 800 mg/dL (8 g/L) should be administered 20 mL/kg of plasma. For 45 kg foals, these recommendations translate to administration of 1 or 2 L of plasma, respectively.

The ideal product for transfusion into foals with failure of transfer of passive immunity is **fresh frozen plasma** harvested from horses that are Aa and Qa

antigen-negative and that do not have antibodies against either or both of these red blood cell antigens (see Neonatal isoerythrolysi). The donor horses should have been vaccinated against the common diseases of horses and have tested negative for equine infectious anemia. Good-quality commercial products specify the minimum concentration of IgG in the plasma. Concentrated serum products that do not need to be frozen until use are available. These are much more convenient for field use than are plasma products that must be frozen until immediately before transfusion. However, the IgG concentration of these products is often not specified, and the manufacturer's recommendations for dosing often result in administration of inadequate amounts of immunoglobulin. Serum products can produce adequate concentrations of IgG in foals, but the dose is usually two to three times that recommended by the manufacturer. An adequate dose of concentrated serum products is approximately 1 L for some products.[39] The crucial point is that it is not the volume of plasma or serum that is administered that is important, but rather the quantity of immunoglobulin delivered to the foal. A total of 20–25 g of IgG is required to raise the serum IgG concentration of a 50 kg foal by 400 mg/dL (4 g/L).[39]

Plasma should be administered intravenously – oral administration is likely to be wasteful, especially in foals more than a few hours old. Frozen plasma should be thawed at room temperature or by immersion in warm (< 100°F, 37°C) water. Thawing by immersion in water at temperatures higher than body temperature can cause denaturation and coagulation of proteins with loss of efficacy of transfused immunoglobulins. Plasma should never be thawed or warmed using a microwave, as this denatures the proteins.

Administration of plasma should be intravenous – intraperitoneal administration, such as used in pigs or small ruminants, has not been investigated in foals. The thawed plasma should be administered through a jugular catheter using a blood administration set containing a filter (160–270 μm mesh) to prevent infusion of particulate material. Strict asepsis should be used. The foal should be adequately restrained for the procedure, with some active foals needing moderate tranquillization. Premedication with antihistamines or nonsteroidal anti-inflammatory drugs is usually not necessary. The plasma should be infused slowly at first, with the first 20–40 mL administered over 10 minutes. During this period the foal should be carefully observed for signs of transfusion reaction, which is usually evident as restlessness, tachycardia, tachypnea, respiratory distress, sweating or urticaria. If these signs are observed the transfusion should be stopped and the foal should be re-evaluated and treated if necessary. If no transfusion reactions are noted during the first 10 minutes, the infusion can then be delivered at 0.25–1.0 mL/kg/min (i.e. about 1 L/h for a 50 kg foal). Rapid infusion can result in acute excessive plasma volume expansion with the potential for cardiovascular and respiratory distress.

Serum IgG concentration should be measured after the infusion to ensure that an adequate concentration of IgG has been achieved. Serum IgG can be measured as early as 20 minutes after the end of the transfusion.[39]

Nutritional support

Provision of adequate nutrition is essential to the recovery of ill newborns. Newborn foals have estimated energy requirements of 500–625 (kJ/kg)/d (120–150 (kcal/kg)/d) and consume approximately 20% of their body weight as milk per day. The best food for newborns is the dam's milk and newborns that are able to do so should be encouraged to nurse the dam. However, if the foal is unable to nurse or the dam is not available, then good-quality milk substitutes should be used. Soy and other plant-protein-based milk replacers are not suitable for newborns. Commercial products formulated for foals, calves and lambs are available. Human enteral nutrition products supplying 0.7–1 kcal/mL (2.8–4.1 kJ/mL) can also be used for short-term (several days to a week) support of foals.

It is preferable to provide enteral, rather than parenteral, nutrition to ill newborns with normal or relatively normal gastrointestinal function. Sick neonatal foals should initially be fed 10% of their body weight as mare's milk, or a suitable replacer, every 24 hours, divided into hourly or 2-hourly feedings. If the foal does not develop diarrhea or abdominal distension, then the amount fed can be increased over a 24–48-hour period to 20–25% of the foal's body weight (or 150 (kcal/kg)/day; 620 (kJ/kg)/day). Newborns can be fed by nursing a bottle or bucket or via an indwelling nasogastric tube such as a foal feeding tube, stallion catheter, human feeding tube or enema tube. Every attempt should be made to encourage the newborn to nurse its dam as soon as the newborn can stand. Adequacy of nutrition can be monitored by measuring blood glucose concentrations and body weight.

Parenteral nutrition (PN) can be provided to newborns that are unable to be fed by the enteral route. This can be achieved by administration of various combinations of solutions containing glucose (dextrose), amino acids and fat. A commercial product that does not include lipid has been used successfully for up to 12 days in foals. One product that has been used successfully for foals is a solution of amino acids (5%), dextrose (25%) and electrolytes (Clinimix E, Baxter Healthcare Corporation, Deerfield, IL). Lipid emulsion is not added to the preparation. Additional multivitamin supplements including calcium gluconate (provided 2.5 mmol/L), magnesium sulfate (6 mEq/L), B vitamin complex (thiamine 12.5 mg/L; riboflavin 2 mg/L; niacin 12.5 mg/L; pantothenic acid 5 mg/L; pyridoxine 5 mg/L; cyanocobalamin 5 μg/L), and trace elements (zinc 2 mg/L; copper 0.8 mg/L; manganese 0.2 mg/L; chromium 8 μg/L) are added.[40] Administration is through a catheter, a single-lumen 14-gauge over-the-wire catheter (Milacath), inserted in the jugular vein with its tip placed in the cranial vena cava. A double-T extension set is used to allow concurrent constant rate infusion of isotonic crystalloid fluids and intravenous administration of medication in one line and PN solution in the other. An infusion pump is used for continuous-rate infusion of the solutions. The PN solution should be prepared under aseptic conditions just prior to administration and used for only a period of 24 hours after preparation. A 0.22 μm filter is included in the administration line to remove all bacteria, glass, rubber, cellulose fibers and other extraneous material in the PN solution. The filters and administration sets are changed with each new bag of PN solution.

The rate of PN infusion is determined based on the weight and physical and metabolic condition of the foal. The general protocol is based on the assumption that sick foals expend approximately 50 kcal/kg body weight per day (basal rate).[41] The PN is started at half the basal rate for 12 hours, increasing to the basal rate over 24–48 hours, and then in some foals increased slowly to 75 (kcal/kg)/d if tolerated by the foal. The clinical condition of the foal is assessed frequently. Blood glucose concentrations should be measured every 6–8 hours during the introduction and weaning of PN until the blood glucose concentration is stabilized. Insulin can be administered during hyperglycemic crises (>>250 mg/dL) at a dose of 0.1–0.4 U/kg regular insulin intramuscularly, but this is rarely needed. When a constant rate of PN is achieved glucose concentrations should be measured every 8–12 hours, depending on the clinical condition of the foal. Foals

are weaned off the PN as their clinical condition improves and enteral feeding is gradually increased. The rate of PN is halved every 4–12 hours if blood glucose concentration is stable until half the basal rate was obtained, at which time the infusion is discontinued if the foal is bright, alert and nursing well.

PN is supplemented with isotonic fluid therapy administered intravenously. The fluid rate and composition are determined based on clinical condition, packed cell volume, total protein and serum electrolyte concentrations (Na, Cl, Ca, K and HCO^-). The composition and rate are adjusted to maintain normal hydration, and electrolyte and acid–base status. During the period that foals receive PN, enteral feeding is initially withdrawn and the foals are muzzled or separated from the mare. Beginning 24 hours after the institution of PN, 20–40 mL of mare's milk ('trophic' feeding) is administered enterally every 4 hours. The trophic feeding provides nutrition to enterocytes and stimulates production of lactase in the small intestine in preparation for resumption of enteral feeding. As the foals are weaned off the PN, enteral feedings are gradually increased from small trophic feeding every 4 hours to allowing the foal to nurse from the mare for 2–5 minutes every 2 hours and eventually unrestricted nursing from the mare.

Antimicrobial treatment

Normal newborns are at risk of acquiring life-threatening bacterial infections, and the risk increases when they do not ingest adequate colostrum in a timely fashion or are subjected to environmental stresses (see Neonatal infection). Newborns in which bacterial infection is suspected and those at high risk of developing an infection, such as sick newborns with failure of transfer of passive immunity, should be administered antimicrobials. Antimicrobial therapy should not be delayed pending the results of bacterial culture and antimicrobial sensitivity testing.

The choice of antimicrobial is determined by the likely infecting agent and clinical experience with antimicrobial susceptibility of local strains of pathogens. In general, broad-spectrum antimicrobials are chosen because it is almost impossible to predict, based on clinical signs, the nature of the infecting agent and its antimicrobial susceptibility. Although *Streptococcus* spp. were historically reported to be the cause of most infections in neonatal foals, currently infections of neonatal foals are usually due to Gram-negative organisms including *E. coli*, *Klebsiella* spp. and *Salmonella* spp.[3] Because of the wide variety of infecting agents and their varying antimicrobial susceptibility, it is possible to make only general recommendations for antimicrobial therapy of neonates. A frequently used antimicrobial regimen is an aminoglycoside (gentamicin or, more commonly, amikacin) and penicillin.[42] Some commonly used drugs and their doses are listed in Table 3.7. Dosage of antimicrobials in foals differs somewhat from that of adults, and the pharmacokinetics of drugs in normal foals are often different from those of the same drug in sick foals.[43,44] Consequently, higher dosages administered at prolonged intervals are often indicated in sick foals, especially when concentration-dependent drugs such as the aminoglycosides are used.[43,44]

The response to antimicrobial therapy should be monitored, using physical examination and clinical pathology data, on at least a daily basis. Failure to improve should prompt a reconsideration of the therapy within 48–72 hours, and a

Table 3.7 Antimicrobials used in neonatal foals

Antimicrobial	Dose and route	Frequency	Comments
Amikacin sulfate	25 mg/kg, IM or IV	24 h	Excellent Gram-negative activity, potentially nephrotoxic. Use with a penicillin
Amoxicillin trihydrate	25 mg/kg, PO	6–8 h	Variable absorption decreasing with age. Limited Gram-negative spectrum
Amoxicillin–clavulanate	15–25 mg/kg, IV	6–8 h	Enhanced Gram-negative spectrum
Amoxicillin sodium	15–30 mg/kg, IV or IM	6–8 h	Limited Gram-negative spectrum. Use with an aminoglycoside. Safe
Ampicillin sodium	10–20 mg/kg, IV or IM	6–8 h	Limited Gram-negative spectrum. Use with an aminoglycoside. Safe
Ampicillin trihydrate	20 mg/kg, PO	6–8 h	Limited Gram-negative spectrum. Variable absorption decreasing with age
Cefotaxime sodium	15–25 mg/kg, IV	6–8 h	Use for bacterial meningitis. Expensive
Cefoperazone sodium	20–30 mg/kg, IV	6–8 h	Use for *Pseudomonas* sp. infections
Cefpodoxime proxetil	10 mg/kg PO	8–12 h	Broad spectrum and well absorbed by foals after oral administration
Ceftazidime sodium	20–50 mg/kg	6–8 h	Third-generation cephalosporin. Save for refractory infections
Ceftiofur sodium	10 mg/kg, IV over 15 min	6 h	Broad spectrum. Note higher dose than used in adults
Chloramphenicol palmitate	50 mg/kg, PO	6–8 h	Broad spectrum, bacteriostatic. Human health risk. Restricted use
Chloramphenicol sodium succinate	50 mg/kg, IV	6–8 h	Broad spectrum, bacteriostatic. Human health risk. Restricted use
Ciprofloxacin	5 mg/kg, IV	12 h	Broad spectrum. Potentially toxic to developing cartilage
Enrofloxacin	5–7.5 mg/kg, PO or IV	12–24 h	Broad spectrum. Potentially toxic to developing cartilage
Gentamicin sulfate	7 mg/kg, IV or IM	24 h	Good Gram-negative spectrum. Nephrotoxic. Use with a penicillin
Metronidazole	15–25 mg/kg, IV or PO	8–12 h	Active against obligate anaerobes and protozoa only
Oxytetracycline	5 mg/kg, IV	12 h	Variable Gram-negative activity. Safe. Cheap
Procaine penicillin G	20 000–40 000 IU/kg, IM	12 h	Very limited Gram-negative activity. Muscle soreness. Cheap
Sodium or potassium penicillin G	20 000–40 000 IU/kg, IV or IM	6 h	Limited Gram-negative activity. Use with an aminoglycoside
Pivampicillin	15–30 mg/kg, IV or IM	8 h	Ampicillin prodrug
Ticarcillin sodium	50 mg/kg, IV	6 h	Active against Gram-negative organisms. Expensive
Ticarcillin-clavulanate	50 mg ticarcillin/kg, IV	6 h	Extended activity. Expensive
Trimethoprim-sulfonamide	15–30 mg/kg, PO, IV	12 h	Cheap. Broad spectrum. Limited efficacy in treating septicemia in foals

worsening of the newborn's condition may necessitate changing the antimicrobial sooner than that. The decision to change antimicrobial therapy should be guided, but not determined, by the results of antimicrobial sensitivity testing of isolates from the affected newborn. These antimicrobial susceptibility patterns should be determined locally, as the results can vary geographically, although results of studies are published.[45] The utility of antimicrobial sensitivity testing in determining optimal antimicrobial therapy for foals has not been determined, although it is likely that, as with mastitis in cows, sensitivity to antimicrobials determined by the Kirby–Bauer method will not be useful in predicting efficacy.

Fluid therapy

Fluid therapy of newborns differs from that of adult animals because of important differences in fluid and electrolyte metabolism in newborns.[46,47] The following guidelines are suggested:[47]

- **Septic shock** – sequential boluses of 20 mL/kg delivered over 5–20 minutes with re-evaluation after each bolus. Usually, 60–80 mL/kg is the maximum dose before use of pharmacological support of blood pressure is considered. Care should be taken to avoid fluid overload and the foal should be re-evaluated after each bolus and the need for continued fluid therapy determined. Continuous infusion of fluid is not indicated
- **Maintenance support** – this should be determined based on the ongoing losses and the clinical status of the animal. However general recommendations are:
  - First 10 kg body weight – 100 (mL/kg)/d
  - Second 10 kg body weight – 50 (mL/kg)/d
  - Weight in excess of 20 kg – 25 (mL/kg)/d

  Neonates with high ongoing losses, such as those with diarrhea or gastric reflux, can have higher fluid requirements.

Care should be taken to prevent administration of **excess sodium** to foals as they have a limited ability to excrete sodium.[48] The recommended intake is 2–3 (mEq/kg)/d, and this includes sodium administered in parenteral fluids. One L of isotonic sodium chloride provides a 50 kg foal's sodium requirements for one day.[47]

A suitable maintenance fluid for foals is isotonic dextrose (5%) with supplemental potassium (10–40 mEq/L).

Respiratory support

Respiratory failure, evidenced by elevated arterial P_{CO_2} and decreased P_{O_2}, may be due to depressed central activity, weakness of respiratory muscles or lung disease. Regardless of the cause, should the hypoxemia become sufficiently severe then oxygenation must be improved by increasing respiratory drive, increasing the inspired oxygen tension, or employing mechanical ventilation. Foals should always be maintained in sternal recumbency to allow optimal respiratory function.

Provision of respiratory support should be considered when the arterial P_{O_2} is less than 60 mmHg (8 kPa) and the arterial P_{CO_2} is more than 60 mmHg (8 kPa) in a foal in sternal recumbency. Pharmacological respiratory stimulants have only a very short duration of action and are of limited use. Nasal insufflation of oxygen is achieved by placing a nasopharyngeal tube and providing oxygen at a rate of 5 L/min.

Mechanical ventilation is useful for maintaining oxygenation in foals with botulism, with more than 80% of foals surviving in one small study.[49] However, this intervention requires considerable expertise and sophisticated equipment. The prognosis is much worse for foals with diseases of the lungs that require mechanical ventilation.

Gastroduodenal ulcer prophylaxis

Ill neonatal foals are often treated with antacid drugs in an attempt to prevent the development or progression of gastroduodenal ulcers, although the efficacy of this approach is unproven. There is a trend toward not administering antiulcer medications to foals except for those with demonstrated gastric ulceration, in part because of the recognition that critically ill foals often have gastric pH above 7.0 and administration of ranitidine does not affect this pH.[50] (See Gastric ulcers in foals for further discussion.)

COMMON COMPLICATIONS

Complications of the neonate's disease or its treatment occur frequently:

- Entropion is common in critically ill foals and, although readily treated, can cause corneal ulceration if undetected
- Aspiration pneumonia occurs in weak foals, often as a result of aggressive bottle feeding or regurgitation of milk around a nasogastric tube
- Nosocomial infections can be severe and life-threatening and are best prevented by strict hygiene and asepsis
- Septic synovitis/arthritis occurs as a consequence of bacteremia and should be treated aggressively
- Omphalitis and omphalophlebitis occur and can be an undetected cause of fever and relapse. These are best detected by ultrasonographic examination of the abdomen
- Patent urachus, evident as urine at the navel, usually resolves with time and local treatment
- Uroperitoneum as a result of urachal rupture occurs in critically ill foals and should be suspected in any ill foal that develops abdominal distension
- Angular limb deformities and excessive flexor tendon laxity occur frequently in ill neonatal foals but usually resolve with minimal symptomatic treatment as the foal recovers its strength.

PROGNOSIS

The prognosis for critically ill neonates depends on many factors, including the nature and severity of the disease, facilities available for care and the expertise of the personnel caring for the neonate. There is a consensus that the recovery rate for severely ill foals has improved over the last decade because of provision of better care. There are reports of survival rates of around 80% for foals treated at a specialized intensive care unit.[51] However, the high cost of providing care for these animals has prompted studies to determine outcome, as a means of deciding whether, financially, treatment is warranted.

The increased number of foals being treated intensively has resulted in prospective studies of outcome. The prognosis for athletic activity for foals with septic arthritis is poor. Thoroughbred foals with **septic arthritis** have odds of 0.28 (95% CI of 0.12–0.62) (roughly one-quarter of the likelihood) for racing as compared with a cohort of healthy foals.[52] Multisystemic disease, in addition to the presence of septic arthritis, decreased the likelihood of racing to 1/10th that of healthy foals (odds ratio 0.12, 95% CI 0.02–0.90).[27] Affected foals that survive take almost 40% longer to race for the first time. Approximately 30–48% of affected Thoroughbred foals eventually race, compared to approximately 65% of normal foals.[52,53]

Attempts to determine prognostic indicators for survival of foals have been partially successful but tend to be most applicable to the intensive care unit in which they were developed.[3,23,25,35,54–56] The results of these studies are summarized in Table 3.8. The common theme is that sicker foals are less likely to be discharged from hospital alive. Characteristics of foals that are more likely to survive include ability to stand when first examined, normal birth, white cell count in blood that is within or above the reference range, lack of dyspnea, normal plasma fibrinogen concentration, and short duration of disease.

Table 3.8 Variables associated with survival in sick foals

Variable	Odds ratio for survival	Comments	No. foals (reference)
Dystocia	0.2	Dystocial foals have a decreased chance of survival	109 (25)
Standing at admission	12.1	Foals that are standing when first examined are much more likely to survive than recumbent foals	65(53)
Duration of clinical signs (days)	0.17	Foals with disease of longer duration are less likely to survive	65 (53)
Sepsis score	0.63	Increased sepsis score is associated with greater risk of death	68 (33)
≤ 7 days of age	8.8	Younger foals are more likely to survive	65 (53)
Respiratory rate (≥ 60 bpm)	18.8	Foals with high respiratory rates are more likely to survive	65 (53)
Dyspnea	0.25	Foals in respiratory distress are less likely to survive	109 (25)
Rectal temperature subnormal	0.19	Foals with rectal temperature below normal are less likely to survive	90 (52)
Rectal temperature above normal	0.86	Foals with rectal temperature above normal are less likely to survive	90 (52)
Heart rate below normal	0.1	Foals with heart rate below normal are less likely to survive	90 (52)
Heart rate above normal	0.49	Foals with heart rate above normal are less likely to survive	90 (52)
Radiographic evidence of diffuse lung disease	0.28	Foals with radiographic evidence of lung disease in multiple areas of the lung are less likely to survive	75 (6)
Segmented neutrophil count in blood	1.7	Increased neutrophil count in blood is associated with lower risk of death	68 (33)
Neutrophil count > 4000 μL (4.0×10^9/L)	37.5	Foals with neutrophil counts in lolood > 4000 μL (4.0×10^9/L) are much more likely to survive are foals with counts < 4000 μL (4.0×10^9/L)	65 (53)
Neutrophil count below normal	0.28	Low neutrophil count in blood is associated with greater risk of death	90 (52)
Neutrophil count above normal	1.5	Increased neutrophil count in blood is associated with lower risk of death	90 (52)
IgG (mg/dL)	1.003	Foals with higher serum IgG on admission are more likely to survive	68 (33)
Plasma fibrinogen (mg/dL)	0.99	Foals with high fibrinogen concentration are less likely to survive	68 (33)
Red blood cell count	1.8	Foals with higher red cell counts are more likely to survive	68 (33)
Venous Po_2 (mmHg)	1.1	Foals with higher venous oxygen tension are more likely t o survive	56 (51)
Anion gap (mEq/L)	0.81	Foals with higher anion gap are less likely to survive	56 (51)
Serum creatinine (mg/dL)	0.20	Foals with higher creatinine concentration are less likely to survive	109 (25)

Odds ratios > 1 are indicative of an increased probability of survival. All variables reported above were statistically significantly associated with survival in the reporting publication.

Practical antimicrobial therapeutics

4

This chapter is not intended as a treatise on pharmacology, pharmacodynamics and antibacterial activity of antimicrobial agents. Other textbooks are available that deal with those subjects. However, antimicrobials are the most commonly employed group of drugs in large animal practice and their use is recommended on many occasions in the following chapters. To avoid repetition, the principles of usage and considerations for dose schedules and for the selection of antibacterial agents for certain circumstances are given here and in the formulary.

Some of the information or opinions presented are based on clinical use rather than experimental evidence. However, this is often unavoidable, because unfortunately many antimicrobial agents have in the past been released for use in large animals with minimal pharmacological or clinical evaluation in the species concerned. As a result it has been assumed, often erroneously, that information obtained from studies in laboratory animals, dogs and humans can be directly applied to the ruminant, horse and pig.

Principles of antimicrobial therapy

The success of antimicrobial therapy depends upon maintaining, at the site of infection, a drug concentration that will result, directly or indirectly, in the death or control of the infectious organism with minimal deleterious effect to the host. In order to achieve this aim the antimicrobial agent must have activity against the organism at its **site of infection** and it must be administered in such a way as to maintain an **effective inhibitory or lethal concentration**. These principles apply to therapy in all species and dictate the choice of antimicrobial agent to be used. However, in farm animal veterinary practice there are also other important considerations

- **Cost** is critical. This consideration includes not only the primary cost of the drug but also related factors such as the ease and frequency of administration and the duration of treatment
- **Tissue residue problems** and **withdrawal periods** must also be taken into consideration and are a primary determinant of treatment strategy
- **Animal welfare** becomes a consideration when a decision is made not to treat an animal because of concerns about cost or the occurrence of residues that would preclude marketing of the animal or its products in the future
- **Antimicrobial resistance** and the risk of contributing to the emergence and problem of antimicrobial resistance is a concern that has increasing attention, not so much with the therapeutic use of antimicrobials but certainly with the prolonged administration of antimicrobials in animal feeds for disease prevention.

In the theoretically ideal situation, the following steps would be taken before selecting an antimicrobial agent for therapy.

- First, the site of infection would be located and the identity of the infecting organism established by culture
- Second, the minimal inhibitory concentration (MIC) of each antimicrobial agent for the infecting organism would be identified
- Third, an initial selection would be made based on the sensitivity of the organism and the knowledge of the capacity of the individual antimicrobial agents to penetrate to the site of infection and to achieve and exceed these concentrations at nontoxic dose rates
- Fourth, the dose rates, route of administration and frequency of administration required to achieve these concentrations for each of the selected antibiotics, in the particular animal species being treated, would then be considered
- Finally, selection of a particular drug would be based on a consideration of the potential toxicity to the host, on the likely relative efficiency of each drug, on the cost and ease of administration and, in food animals, on costs associated with the relative withholding periods.

It is obvious that for many clinical situations all these steps cannot be followed before therapy is instituted. It may take several days to establish the identity of the infectious agent unless it can be ascertained by clinical diagnosis. The identification of the organism helps in determining its potential sensitivity but even without identification the establishment of exact MICs by tube dilution for each antimicrobial agent also takes several days, and the results would frequently be historical by the time that they were received. Also, a knowledge, for each antimicrobial agent, of the varying tissue and organ levels achieved following varying doses given by different routes of administration is not easily remembered and therefore not easily available in large-animal field situations. Nor, unfortunately, is complete information of this type available for each antimicrobial agent in all large-animal species.

Because of this uncertainty, some expedients are adopted in clinical antimicrobial therapy. One of them is the concept of the **recommended dose** and another is the use of disk sensitivity testing, both of which are discussed later in this chapter. Regardless of these expedients, it should be recognized that rational antimicrobial therapy is based upon the principles outlined above. These important principles in antimicrobial therapy are discussed in greater detail individually.

IDENTIFICATION OF THE INFECTION BY CLINICAL EXAMINATION

In infectious disease, clinical examination aims to identify the nature and site of the

infection and its cause. The importance of making an accurate clinical diagnosis cannot be overemphasized as the first prerequisite for successful antimicrobial therapy. The establishment of a diagnosis in many instances immediately identifies the pathogen and previous clinical experience may suggest the specific antibiotic to be used and allow a confident prediction of success of the therapy. Equally, it may indicate the likelihood of unsuccessful or prolonged therapy. For example, the diagnosis of erysipelas or Glasser's disease in pigs or strangles in horses immediately identifies the etiological cause of the infection and the type of antimicrobial agent that will be required. It also gives some indication of the likely ease or difficulty of successful therapy and of the duration of therapy that might be required.

The establishment of an accurate diagnosis is also important in animals where chemotherapeutic control of further disease may be required. Thus, in pigs, an accurate differentiation between the diarrhea of swine dysentery and that associated with coliform gastroenteritis is essential for effective prophylactic medication.

It is often not possible to establish an exact diagnosis at the first examination and yet in almost every instance it is essential that treatment be instituted at that time, not only for the wellbeing of the patient but also for the maintenance of good client relationships. The lack of a definitive etiological diagnosis should never preclude the initiation of therapy during the period when further tests are being carried out. Rational therapy in these circumstances depends very much on clinical acumen. A detailed examination leading to a determination of the site and nature of the infection can frequently allow an educated guess at the likely pathogen and allow rational therapy during the period that specific diagnosis is being determined by culture.

This approach is frequently used initially in field situations in large animal medicine but it requires good clinical knowledge. Clinicians should be familiar not only with the individual diseases of large animals but also with their **differential diagnosis** and with the **relative prevalence** of each condition in their area. They should also be familiar with the types of organism that may produce infections in various body areas with similar clinical manifestations and the relative prevalence of each of these. Thus peracute mastitis in recently calved cows is most commonly associated with infection by staphylococci but can also be associated with coliform organisms or, more rarely, *Actinomyces (Corynebacterium) pyogenes* or *Pasteurella multocida*. Treatment must be initiated immediately if the gland or even the cow is to be saved. There are subtle clinical and epidemiological differences that may allow some clinical differentiation between these agents but frequently treatment must begin with no sure knowledge of which agent is involved. There are **two approaches** in this type of situation:

- Therapy may be directed at the most prevalent or likely agent and, in situations where one particular infectious agent is the most prevalent cause of the condition, this is a rational approach
- In other situations, where a disease could be associated with any one of several different organisms, each with a different sensitivity, and where clinical experience suggests that no one organism is the predominant infectious agent, it is more common to initiate therapy with a broad-spectrum antimicrobial agent or a combination that will have activity against all the possibilities. If indicated, the antibacterial agent being used for therapy may have to be changed to a more specific one once the actual pathogen and its sensitivity have been determined.

There are also clinical situations where therapy must begin when there is little knowledge of the site of infection and consequently **no knowledge of the identity** of the infecting agent. This occurs where infection, such as abscessation, occurs in deep-seated and clinically inaccessible organs such as the liver or spleen. Also in these situations it may not be possible to determine the nature and cause of the disease by laboratory examination although biochemical examinations and ultrasound may give some indication of the site. In these cases therapy is generally started with a broad-spectrum antimicrobial agent or a combination of lesser ones, and the accuracy of the selection is determined by subsequent clinical response.

TAKING SAMPLES FOR DIAGNOSIS

In teaching hospitals, there is ready access to bacteriology laboratories, which frequently contain automated and rapid systems for sensitivity testing. However, in practice the taking of samples for this purpose is generally restricted and limited by such factors as the availability of a diagnostic laboratory, and by cost. Furthermore, in many cases the results of culture and sensitivity are historical by the time they are received. Nevertheless, information of this type is of value for future similar cases and it provides prevalence data and data of antimicrobial sensitivity that can be used for background clinical knowledge and justification for extralabel drug use in food-producing animals.

The recognition of when samples should be taken for microbiological examination and sensitivity testing comes with clinical experience. In general, the approach is different when dealing with individual sick animals from when dealing with groups of animals and a contagious disease. In individual animals, cost and the time for processing usually limit the taking of samples to valuable stud animals and to horses. They should be taken from **individual sick animals** with life-threatening conditions so that, if a response is not obtained to initial therapy, the subsequent choice of antimicrobial agent can be based on laboratory data. They should also be taken from animals with disease syndromes that may be caused by one of several agents or by an organism that may show **variable resistance patterns**. Examples would be infective arthritis in foals or Gram-negative sepsis.[1] The increasing emergence of variable resistance patterns in veterinary pathogens places an increasing importance on sampling and sensitivity testing and many practices have now established their own laboratories for this purpose.

Samples are also frequently taken from chronic, **poorly responsive conditions** to determine the best course of treatment. In groups of animals where there is **contagious** disease, the taking of samples to establish or confirm the etiological diagnosis and to determine the best drug for chemotherapy is most important. Where there are **a large number of animals at risk** it is important to confirm the initial choice of therapy as soon as possible so that remedial steps can be taken if this was incorrect. It is also important in these situations to have a confirmed accurate etiological diagnosis so that control measures can be instigated to prevent future problems. Thus an outbreak of diarrhea in postweaned pigs may be due to coliform gastroenteritis, salmonellosis or swine dysentery. Clinical and pathological examination may eliminate swine dysentery but not allow complete differentiation between salmonellosis and coliform gastroenteritis. An aminoglycoside could be used for the initial therapy of the outbreak but, at the same time, samples are taken for culture and sensitivity to determine the exact antimicrobial sensitivity of the infectious agent in case there is resistance to this antibiotic. Also, by this procedure the exact etiological diagnosis will be

determined, which will then determine recommendations for future control of the disease.

Consideration should be given to the **nature of the sample** for examination. In outbreaks of diarrhea there is little point in taking fecal samples from chronically scouring and runted animals. Samples should be taken from animals at the onset of diarrhea. The site of sampling can also have an influence that may affect the relevance of the results. In animals with pneumonia, the nasal flora may not reflect that in the lung and cultures are best taken as transtracheal aspirates of the lower respiratory system.[2,3]

Similarly, fecal *Escherichia coli* strains are not always representative of small-intestinal strains in scouring calves.[4]

ANTIMICROBIAL SENSITIVITY TESTS

RATIONALE

Antimicrobial sensitivity testing is not required with all infections because many organisms are invariably sensitive to one or more antimicrobial agents and in most cases these can be used for therapy. The clinician should be familiar not only with the spectrum of each antimicrobial drug but also with the spectrum of sensitivity for the common organisms involved in diseases of large animals. **Sensitivity testing** is generally reserved for members of those groups of organisms that show considerable variation in sensitivity to individual antimicrobial agents.

There can be considerable area-to-area variation and spatial and temporal clustering in the sensitivity patterns of individual organisms.[5–7] It is wise to establish the broad patterns of general sensitivity or resistance for these groups in any practice area and to monitor any change periodically so that therapy can be guided by this information. This also can provide information justifying the extralabel use of antimicrobials in food-producing animals.

The **purpose of sensitivity testing** is to attempt to determine if the organism under consideration is likely to be susceptible to the action of an antimicrobial agent at the drug levels that can be achieved using the usual therapeutic dose rates. In clinical terms, organisms are considered to be either **sensitive** or **resistant** to the action of an antimicrobial. However, with many organism–antimicrobial associations, resistance or susceptibility is **not an all-or-none phenomenon** but is dependent upon drug concentration. Organisms that may be resistant to low levels of an antimicrobial agent are frequently susceptible to its action at higher concentrations. Thus an organism that is susceptible to the action of benzylpenicillin at a concentration of 0.1 μg/mL would be considered sensitive because equivalent levels of benzylpenicillin can be easily achieved in the blood and tissues. One that was susceptible only at a concentration above 5 μg/mL might be considered resistant, even though it is possible to achieve and maintain this concentration of benzylpenicillin in the tissues with high and frequent dosing.

SENSITIVITY TEST METHODS

Tube sensitivity tests

Sensitivity tests may be quantitative or qualitative. **Tube sensitivity tests**, using serial dilutions of the antimicrobial drug against a standard dose of the test organism, provide quantitative information in terms of an exact MIC of the drug being tested. The MIC is the lowest antibiotic concentration that prevents the growth of bacteria within a defined period of time and under the conditions of the test. Tube sensitivity testing is the gold standard. With most antibiotics, a mean plasma level 2–5 times the MIC needs to be sustained through the dosing interval for effective therapy. These tests are laborious and time-consuming and are seldom used in practice situations for these reasons.

Disk sensitivity tests

Disk sensitivity tests provide more limited qualitative information. They are generally a valuable adjunct in the choice of an antimicrobial agent for therapy, particularly for systemic diseases. However, the limitations of the usual method of testing, and the limitations of interpretation should be recognized by the clinician.

The **Kirby–Bauer** technique is the most commonly used method of disk diffusion sensitivity testing. With this technique, disks are impregnated with a standard amount of antibiotic that diffuses into the media to produce a zone of inhibition of growth. With a standard concentration of antibiotic in the disk and standard antibiotic sensitivity test media and test conditions, the concentration of the diffused antibiotic at any given distance from the disk is relatively predictable and constant. There is a linear relationship between the diameter of the zone of inhibition and the $\log^2$ of the MIC. For each antibiotic MIC, breakpoints have been established and corresponding zone size breakpoints established above or below which an organism is classified as resistant, susceptible or of intermediate sensitivity.

Although the Kirby–Bauer disk sensitivity testing system has a quantitative genesis the results are qualitative – especially as used in most practice laboratories. MIC breakpoints are specific values used to assign bacteria to one of three classifications – susceptible, intermediate and resistant.

The MIC breakpoints and thus the published reference zone sizes for resistance and susceptibility are often based on the pharmacokinetic properties of each antimicrobial in humans. These frequently have limited relationship to their pharmacokinetic properties in animals, particularly ruminants.[8]

Also, a single antimicrobial considered to be representative of its class is used to test sensitivity to that class of antimicrobials, but commonly this representative is not the antibiotic agent present in commercially available antibiotic treatments for livestock.[8] Further, the use of specific zone diameters to establish resistance and susceptibility assumes a standard test with standard media and under standard conditions. These conditions are frequently not met in veterinary practice laboratories.

Despite these limitations, disk sensitivity tests can be used as a guide to the selection of antimicrobials for therapy in large-animal veterinary practice. They are of particular value in selecting a choice of antibiotic with organisms that exhibit variable patterns of resistance and where this pattern for any one antibiotic is essentially bimodal in distribution.[9] They may have limited value in the testing of organisms where the sensitivities are clustered around the MIC breakpoint. However, there is a lack of validation for susceptibility testing being predictive for treatment outcome in almost all large-animal diseases as the breakpoints have not been validated.[8,10]

There should not be over-reliance on the results of testing for sulfonamide sensitivity, as these are frequently misleading and a good clinical response can be achieved with therapy even though the sensitivity test suggests resistance.

Frequently, with disk sensitivity tests, the organism proves sensitive to a number of different antimicrobial agents. The selection of one of these for therapy is based on such factors as **ease of administration** and **cost**. The relative efficacy of any one of the agents cannot be determined by comparison of the size of the zones of inhibition.

Microtiter techniques

The development of semiautomated microtiter methodology for direct MIC determinations allows many reference diagnostic laboratories and teaching hospitals to determine MIC concentrations directly in bacterial sensitivity testing. The results are more directly

applicable to rational therapy and, in particular, have more relevance than disk diffusion tests for determining the sensitivity of organisms that cluster around the MIC breakpoint for a given antibiotic.[9,11]

OTHER CONSIDERATIONS

The antimicrobial sensitivity of an organism can **vary** considerably depending upon the **species of animal** from which it is isolated. *E. coli* isolates from pigs generally show a greater degree of antibiotic resistance than those isolated from adult cattle. Similarly, *Campylobacter* spp. isolates from pigs show substantially different antibiotic sensitivity patterns from those isolated from sheep. Isolates from the same species may also vary significantly in sensitivity, so that *E. coli* isolated from mastitis in cattle generally have a broader sensitivity pattern than those isolated from enteric disease in calves. In addition, there are area differences and changes with time. Low levels of antibiotic fed for growth-promoting purposes may influence sensitivity patterns, and in herds where growth promoters are being used it is generally wise not to use the same drug or members of the same group for therapeutic purposes without prior testing.

ANTIBIOTIC RESISTANCE

Antimicrobial resistance is a natural biological phenomenon and the introduction of antibiotics into clinical use has almost invariably been followed by the emergence of resistance to these drugs in bacterial populations.[1] When a microbial population is exposed to an antibiotic, the more susceptible organisms will succumb, and antimicrobial use in human medicine and in agriculture naturally must result in the selection of antimicrobial-resistant phenotypes. This occurs in nonpathogens as well as pathogens.[2] Resistance is generally slow to reverse or is irreversible.

There are a number of mechanisms whereby resistance is engendered. Resistance that results from spontaneous mutation of chromosomal genes encoding a target site is probably of limited importance in clinical settings. It occurs more frequently with certain antibacterials, i.e. rifampin, and may be combated by the inclusion of a second antibacterial in the treatment regimen. Plasmid- and transposon-determined drug resistance is of much more importance in clinical situations and has led to widespread multiresistance patterns in certain bacterial populations.

Plasmids are extrachromosomal genetic elements that replicate independently of the chromosome. They can be transferred within, and in some cases between, bacterial species and may also act as vectors for transposons. They may encode for single or multiple patterns of antibiotic resistance and, increasingly, multiple patterns of resistance are emerging. With veterinary pathogens, plasmid-determined resistance is particularly important in the Enterobacteriaceae, *Staphylococcus aureus* and to some extent in *Pasteurella* spp.[3–5]

Virtually all antibiotics given in therapeutic doses cause marked changes in the microflora of sites in the host normally colonized by bacteria. There is suppression of the sensitive flora with subsequent selection and colonization by resistant bacteria. In pigs, there is some evidence that therapeutic use of antibiotics in individual animals does not greatly influence herd flora resistance patterns but in-feed medication of postweaned pigs selects for antibiotic resistance that maintains in finisher pigs.[6] The feeding of antibiotics for growth promotion and the feeding of antibiotic-treated milk to calves will select for resistance among organisms within the alimentary tract. These resistant organisms can persist in the animal and in the environment and subsequently form part of the normal colonizing flora of other animals, so that it is not unusual to isolate organisms, *E. coli* for example, that are resistant to one or more antibiotics even though the animal from which they were isolated had never received antibiotic medication.[7,8]

There is a higher prevalence of antibiotic-resistant *E. coli* in the normal intestinal flora of young animals than adults.[9] The prevalence is higher in young animals reared intensively, such as veal calves and pigs, and in environments where antibiotic usage has exerted selection pressure. The prevalence falls with increasing age and the intestinal flora of adults generally shows a broader sensitivity pattern. Although many of these resistant organisms are not pathogens, they contribute a pool of R plasmids that can be transmitted to pathogens, and therapy decisions should take into account what antibiotics are in routine use on the farm as growth-promoting additives. Tetracyclines and neomycin are commonly incorporated in calf milk replacers with the label claim that they are growth promoters and aid in the control of calf diarrhea. However, there are no published studies that support health benefits.[10] There are studies that show improved growth of calves on medicated milk replacers compared with control calves but this difference is lost after weaning and not of any production benefit.

Feeding antimicrobials to livestock and poultry to reduce disease and promote weight gain has been standard practice in developed countries for several decades but is engendering increasing concern and the occurrence of antimicrobial resistance is beginning to be considered to be a societal issue. The concern is that antimicrobial use in food-producing animals may affect human health by the presence of drug residues in foods, and by promoting the presence of antibiotic-resistant strains in animals that can subsequently infect humans through food or from effluent contamination of the environment.[11–13] The consequences of this also include an increased risk for resistant pathogens to be transferred to humans by direct contact with animals. Although many of the growth-promoting antibiotics used in animals are not the same as those used for human therapy, antimicrobial exposure can initiate bacterial resistance to compounds of dissimilar structures.[14]

There is a particular risk to farmers, farm workers and veterinarians from exposure to contamination in the farm environment.[13,15–17] and a risk from transfer of resistant bacteria through farm food and via environmental contamination from farm effluents.[18]

Public and medical concern about the ways in which antimicrobials are used in

agriculture has particularly been aroused by the development of vancomycin-resistant enterococci in humans associated with the use of the related drug avoparcin as a growth-promoter in animal feeds.[19] In response to concerns about the emergence of antimicrobial resistance, Sweden banned all growth-promoting antibiotics in 1986. This was followed by a ban on avoparcin and virginiamycin in Denmark in 1995 and 1998. Finally, the European Union (EU) banned the use of avoparcin in 1997 and bacitracin, spiramycin, tylosin and virginiamycin for growth promotion in 1999. The effects of these bans on the antibiotic resistance of flora in animals and humans will take some time to determine. There has been an apparent reduction in vancomycin resistance in fecal enterococci isolated from humans and animals.[20,21] There has also been an apparent increase in morbidity and mortality among pigs, associated with enteric infections, diarrhea and chronic infections due to *Lawsonia intracellularis*. This increase in animal disease since the ban has resulted in a substantial increase in the use of therapeutic antibiotics for food animals in Europe, primarily tetracyclines, trimethoprim/sulfonamides and macrolides.[21]

With respect to the emergence of antibiotic resistance in zoonotic organisms, a particular concern has been plasmid-determined multiple antibiotic-resistant strains of salmonella that have emerged and caused rapidly spreading epidemics of disease in young calves in England and Europe.[22] These multiple resistance patterns have been associated with particular phage types and biotypes of *Salmonella typhimurium* and *Salmonella dublin*.

Preventing the spread of multiresistant organisms is not easily achieved and there are examples of spread involving virtually every major pathogenic bacterial group.[23] An example is the emergence and spread of *S. typhimurium* DT 104, in which multiple antibiotic resistance is chromosomally determined. A pathogen of a variety of different animal species, including humans, this organism spread globally in the 1990s. Because of the advanced salmonella surveillance system in the UK, this organism was first recognized as causing outbreaks of disease in cattle and humans in the UK and its emergence was initially attributed to the use of antimicrobials in cattle. There is however no evidence in support of this[24] and its spread was due to its colonizing ability, not to selection by the feeding of antimicrobials. The history of the emergence and spread of this organism, which was unrelated to the use of antimicrobials in livestock and related more to the colonizing ability of DT104, should act as a brake on proposals to use changing patterns of antimicrobial resistance as a measure of the risk of the use of antimicrobials in livestock.

Plasmid-determined multiple patterns of resistance are likely to increase in organisms in environments where selection pressure is high as a result of frequent antibiotic usage. The use of antibiotics in agriculture is an obvious target to reduce this selection, and is frequently blamed for the problem of developing antibiotic resistance in human pathogens. Nosocomial infection with antibiotic-resistant animal pathogens is an emerging problem in veterinary hospitals and procedures for limiting their spread are available.[25]

Whereas the major concern has been directed at antibiotic use for growth promotion there are also moves, in some countries, to restrict the use of certain antimicrobials, e.g. fluoroquinolones, from therapeutic use in farm animals. However, a European survey of antimicrobial susceptibility among zoonotic and commensal bacteria from food-producing animals found that, although there was variation among European countries in the resistance of enteric organisms, this largely involved the older antimicrobials, and that resistance to the newer compounds used to treat humans was low.[26] Equally, a study of mastitis pathogens over a 7-year period in the USA showed no trend towards increased resistance and reported a reduction of resistance to beta-lactam antimicrobials for several Gram-positive mastitis pathogens.[27]

Practical usage of antimicrobial drugs

ANTIBIOTIC DOSAGE: THE RECOMMENDED DOSE

Theoretically, there is no set dose for any antimicrobial agent. The concentration of an antimicrobial drug required for effective activity against different microorganisms varies and these requirements could be met by varying the dose rate of the drug. However, this is an impractical situation and in practice one works from the **recommended dose**. The recommended dose is one that will give blood and tissue levels that will be effective against very susceptible organisms, with minimal side effects to the host. In this respect the recommended dose should be considered as a minimum dose.

If one is dealing with organisms that require higher concentrations of the drug for therapeutic effectiveness, the recommended dose can be exceeded. With low-toxicity antibacterials this dose may be exceeded severalfold and with drugs such as benzyl penicillin this is a frequent therapeutic ploy. However, with antibacterials that have toxic potential the recommended dose should only be exceeded with caution and frequently it is wise to search for a different antimicrobial agent to which the organism is more sensitive.

Similarly, the recommended dose may be exceeded in an attempt to increase the concentration gradient in sensitive infections where necrotic tissue produces long diffusion paths. The recommended dose may also be exceeded for management reasons, as in the case of the treatment of sheep with footrot or mycotic dermatitis, where only a single treatment is administered for practical purposes.

The **label dose** is the dose stated on the label of the drug and is the legal dose that can be used for that product. The label states the required **withdrawal periods** for avoidance of tissue or milk residues. The recommended doses given in the sections on individual diseases are based on our expectations of therapeutic efficiency, and may exceed the label dose recommendations for certain drugs. The problem of persisting tissue residues should be recognized when label recommendations are exceeded and withdrawal periods should be adjusted accordingly.

Label dose levels and dose intervals for many of the antimicrobial agents used in large animals are frequently too low and too long. In many cases, there are no obvious pharmacological reasons for these dosing regimes. Unfortunately, pharmacokinetic studies of the earlier antimicrobial agents released for use in large animal species were limited at the time of their release and it would appear that in many instances the label dose established at that time was inadequate. Some estimate of the dose required for an antimicrobial drug can be obtained by a comparison of the MICs required for activity against various organisms with the blood and tissue levels of the drug obtained at various dose levels. Usually, levels 3–5 times the MIC are considered necessary for effective therapy, and it is generally considered desirable to maintain these levels over the treatment period, especially with bacteriostatic antimicrobials, although this is probably not essential.

The ultimate proof for dose levels and dose intervals of an antimicrobial is by clinical trials of its efficacy in the treatment of infectious disease. It is apparent that antimicrobial drugs are effective in many diseases in large animals at the dose rates and intervals currently in use. Nevertheless, as the results of pharmacokinetic studies in farm animals become available it is quite probable that they will suggest changes in the dose levels and intervals for several of the antimicrobial drugs in use, which may result in more efficacious therapy and lead to label doses that have a broader spectrum of activity against disease.

ROUTES OF ADMINISTRATION

INTRAVENOUS INJECTION

Intravenously administered antibiotics attain high and immediate blood and tissue levels. This route should be used in the treatment of **septicemia** and other life-threatening diseases. The concentrations obtained are much higher than those obtained with equivalent doses of the same drug given intramuscularly or orally, and consequently greater **diffusion concentrations** are achieved at sites of infection. For this reason this route of administration may also be used in an attempt to increase the drug concentration in areas where the antibiotic normally achieves only low concentrations, and where areas of necrosis increase the length of the diffusion pathway. Intravenous administration may also be indicated in **chronic infections** such as corynebacterial pneumonia in foals, where high diffusion concentrations are required in order to penetrate the abscess areas and the capsular material of the organism.

An initial intravenous loading dose may combat the development of **stepwise resistant mutants**. Because of the initial higher blood and tissue levels, the intravenous route may also be used for the treatment of infections that are only moderately sensitive to the antibacterial drug being used. This is because effective concentrations may be achieved by repeated intravenous dosing which would not be achieved by equivalent doses given intramuscularly or orally.

For practical reasons the intravenous route of administration is used for **low-concentration**, high-volume antimicrobial agents such as sulfamethazine and oxytetracycline. It is also preferred to the intramuscular route in racehorses where there is a need to avoid muscular soreness. The need to avoid **muscle damage** in beef cattle close to marketing may also dictate intravenous administration.

Administration by this route is not without its dangers. Acute **toxic reactions** either to the drug or to its vehicle are more common when intravenous administration is used. Drugs specifically formulated for intravenous use should be used, or the manufacturer's recommendations on the advisability of the use of this route for any preparation should be followed. Severely toxemic terminal cases may die immediately following injection, and in the owner's mind death may be attributed to the therapy.

Injections should be given **slowly** and not as a bolus. Therapy by repeated intravenous administration is generally restricted to hospital situations and can be expensive because of the added **cost** of the intravenous preparations. In field situations an initial **intravenous loading dose** followed by sustaining intramuscularly administered doses is frequently indicated in the treatment of infectious diseases and is sound therapeutic policy.

The jugular vein is used in all species except the pig, where the inaccessibility of superficial veins other than the ear veins makes the jugular route of administration generally impractical. **Perivascular reactions** and intravascular thrombosis are a hazard with this route, especially following the administration of irritant drugs such as sulfonamides and tetracyclines.

INTRAMUSCULAR INJECTION

Intramuscular injection is the most commonly used method for antimicrobial administration in large animals. Where possible this route should be **avoided in meat-producing animals**, especially with irritant preparations. Lesions can be detected at slaughter 12 months after the intramuscular injection of long-acting tetracyclines.[1] If the drug must be given intramuscularly in a meat-producing animal it should be given in the **muscles of the neck**, as scar tissue and blemish are more likely to be detected at this site in the cutting process after slaughter and they can be trimmed. With certain antibiotics, drug residues may persist at these sites for long periods, and the label recommendation for withdrawal or withholding time should be followed.[2]

Irritant drugs should be used with care in **horses**, or avoided, as this species more commonly develops severe reactions at the site of injection. The development of such reactions is usually an indication to change to alternative therapy. Oil-based vehicles frequently produce severe reactions at the site of injection in horses and should not be used.

There is evidence, for some antibiotics at least, that the site of intramuscular administration can influence the rate of absorption, the **bioavailability** and the subsequent pharmacokinetics of the administered antibiotic. In both cattle and horses, injection in the neck gives more favorable pharmacokinetic parameters

than does injection into the gluteal or shoulder muscles.[3–5] Injection into the dewlap gives the poorest bioavailability. These differences presumably result from differences in the spread of the injected drug within and between the muscles and differences in blood supply. With intermuscular spread there is a greater absorption area and less compromise of capillary and lymphatic structures.[5] Injection into the side of the neck of horses is considered to be malpractice in some countries. When irritant preparations must be given to horses it is wise to inject them into the muscle of the chest between the forelegs, as reactions in this area have less tendency to spread and are more accessible to drainage and treatment.

At all sites, care should be taken to ensure that the injection is not inadvertently given intravascularly, by applying negative pressure to the syringe prior to injection. In adult animals no more than 10 mL should be given at any injection site. Large injection volumes can result in the formation of encapsulated antibiotic-filled cysts in muscle.[2] Label directions of the maximum amount to be given at any one site should not be exceeded.

With most antimicrobial drugs, excepting the repository forms and drugs of an irritant nature, peak blood concentrations are obtained within 30–120 minutes of injection. However, the bioavailability of drugs given by intramuscular injection is markedly influenced by their formulation and irritant nature. This is especially marked with oxytetracycline preparations.

INTRAPERITONEAL INJECTION

Intraperitoneal injection is occasionally used for antimicrobial administration, especially in cattle close to market size, and where intravenous administration for various reasons may be impractical. It is also occasionally used in pigs with diarrhea, where the antibacterial drug is combined with fluids for rehydration. In cattle the injection is given in the right flank midway between the last rib and the tuber coxae and at least 10 cm ventral to the lateral processes of the lumbar vertebrae so as to avoid retroperitoneal and perirenal deposition of the drug. An aseptic injection technique should be used. Animals with peritonitis are also occasionally additionally treated by this route of injection. In horses with peritonitis the peritoneal cavity can be drained through a cannula inserted in the ventral midline as used for abdominal paracentesis, and the antimicrobial agent is injected via this route. Intraperitoneal injection may also be used for the parenteral administration of the tetracycline group in acutely toxemic animals or in animals with severe respiratory distress where intravenous injection may result in collapse and even death.

SUBCUTANEOUS INJECTION

Subcutaneous injection has not been commonly used in large-animal practice but concerns regarding lesions in meat following intramuscular injections is leading to a greater use of this route. Providing the drug is not deposited in a fat depot, this route provides a reasonable alternative to intramuscular injection.[6] With irritant preparations there is a danger of excessive reaction and the occurrence of sterile abscesses. Very small animals (piglets) are often treated by this route.

ORAL ADMINISTRATION

Oral administration of antimicrobial agents is generally restricted to **preruminant animals**, **young foals** and **pigs**. The blood and tissue levels achieved following oral administration are considerably less than those achieved by an equivalent dose of the same antimicrobial agent given parenterally, and for this reason the oral dose rate is generally 2–5 times greater than the parenteral dose. Oral drugs are less reliable because **absorption characteristics** may vary with the volume of ingesta, the presence or absence of gastric and intestinal stasis or hypermotility and the nature of the ingesta, which variably bind the orally administered drug. For example, oxytetracycline and trimethoprim have a much lower **bioavailability** to calves when administered in milk, rather than in water, because of the high degree of binding to milk.[7] There is some evidence that the oral administration of antibiotics to calves in glucose–glycine–electrolyte solutions is associated with more favorable absorption characteristics. The aminoglycoside and polymyxin groups of antimicrobial agents are not absorbed from the alimentary tract and benzylpenicillin is largely destroyed within the stomach.

The oral route is the easiest method for administration, and where the cost of revisits is a significant consideration this route is often chosen for **continuing medication**, as it is within the capability of any owner. In general, however, systemic infections are better treated by parenteral injection and certainly treatment should be initiated by this route. The oral route is the one of choice for the treatment of enteric infections. Experimental studies have shown that the oral administration of antibiotics to healthy neonatal calves may induce villous atrophy within the intestine and a malabsorption diarrhea.[8] This occurred particularly with neomycin and to a lesser extent with tetracycline and ampicillin. Although this does not negate the use of antibiotics for specific therapy of enteritis in young calves (when this is indicated), it does suggest that prophylactic use of oral antibiotics has a risk in young calves.

Prolonged oral medication at therapeutic levels may result in **superinfection** in all animal species. Commonly a yeast, staphylococcus or *Pseudomonas aeruginosa* is involved. It occurs most commonly in calves given courses of differing antimicrobial agents. It is more common following medication involving tetracyclines and usually a treatment period of at least 2 weeks is required for its development.

Antimicrobial drugs are seldom given orally to ruminant animals. Exceptions are the use of sulfonamides, especially as sustaining medication following initial parenteral treatment, and low-level antibiotic therapy to feedlot animals to reduce the incidence of liver abscess and respiratory disease. Blood levels following oral administration in ruminants are variable and frequently not achieved until 12–18 hours after dosing. Also, many antibacterials are destroyed or inactivated within the rumen. Orally administered antimicrobials cause a significant disruption of the ruminal flora and by itself this may result in a syndrome of ruminal stasis, anorexia and depression. If antibacterial agents are given orally to ruminants, the course should be followed by re-establishment of the ruminal flora by cud transfer.

Contamination of feedstuffs

Antibiotic contamination of rations is a potential problem in feed mills that process medicated and nonmedicated feeds consecutively. The inadvertent feeding of antibiotics to cattle and horses can result in **clinical disease** and the cause may not be immediately apparent to the investigating clinician. This can occur when cattle and horses are fed medicated pig feed, but may also occur when regular rations become contaminated with antibiotics. Residual carryover of medicated material into other feedstuffs can occur with feed-mixers of various types and also via residues in conveyors, hoppers and trucks. The risk for feedstuffs being contaminated can be quite high and the most common contaminating drugs are chlortetracycline, sulfonamides, penicillin and ionophores.[9]

Within 24 hours of being fed medicated feed, dairy cattle show anorexia, rumen stasis and subsequently pass custard-consistency feces containing undigested fiber. There is a precipitous fall in milk production. Dullness, muscle fasciculation, ketosis, hypocalcemia and recumbency have also been observed. Affected cattle usually recover when placed on non-

medicated feed, but milk production may be adversely affected for the remainder of the lactation. Feeds contaminated with dimetridazole, lincomycin and tylosin have been incriminated,[10,11] although there is debate as to the role of tylosin in this syndrome.[12] The **carryover** of medicated material into other feeds can also create violative **tissue residues** at slaughter.[9] Sulfonamide contamination of swine rations is a particular problem.[13]

The use of orally administered antimicrobial agents in horses over 3 months of age should be approached with great care. Their use can be followed by diarrhea, which is often intractable and results in chronic debilitation or death. Clindamycin and lincomycin carry a high risk and are probably totally contraindicated but macrolides, tetracyclines, tylosin and metronidazole are also associated with risk in stressed horses.

Water medication of pigs

The oral route is the most common and convenient one for group medication of pigs. The antibacterial agent may be incorporated in the water or in the feed. For the treatment of disease in pigs, water medication is preferred as **sick pigs may drink**, whereas they frequently will not eat. Also, water medication can usually be **started immediately**, whereas the mixing of an antibacterial agent with the diet for piggeries purchasing prepared diets may take 1–2 days. Antibiotic bioavailability is also less in pelleted feeds.[14]

In outbreaks of contagious disease in pigs, the sick pigs within the group are usually initially treated individually by parenteral injection followed by mass medication of the water supply. Large swine units usually have facilities for in-line medication; small swine units may not. With pigs using troughs, water medication is no problem. However, with automatic watering systems, medication must be through the header tank, if this can be isolated, or more commonly the water is turned off and medicated water is provided for the pigs via portable 200 L drums with a drinking bowl or nipple drinker inserted in the side.

In determining the **concentration of antibiotic** required in the water, the total daily dose of the drug is computed by multiplying the total weight of the group of pigs in kilograms by the daily dose of the drug in milligrams per kilogram. This dose must then be added to the amount of water that will be consumed in one day. It is obvious that this amount will vary according to climatic conditions and to the nature of the disease in the pigs. For example, diarrheic pigs may drink more than normal quantities. In practice, a rule of thumb of 10% body weight water consumption of pigs between weaning and market age has been found to be satisfactory, with estimates of 15% for situations in which high water consumption can be expected. The total daily dose is thus added to the number of liters of water equivalent to 10–15% of the estimated total body weight of the group. In pregnant sows, water consumption is usually 5–8 L/d, but lactating sows may drink 15–20 L/d. When there is doubt as to the exact water consumption the medication can be added to the lower estimate and, when consumed, fresh water provided for the remainder of the day. Water medication is generally continued for a period of at least 5 days. Antibiotics may deteriorate rapidly in water and a fresh mix should be prepared each day. Most drugs for water medication have label directions.

Water medication in cattle

There are some major limitations in the mass medication of water supplies of cattle. The daily amount of water consumed is usually directly proportional to the amount of dry matter intake. Anorexia or inappetence will result in a marked decrease in water intake to mere maintenance requirements. Depending on the drug used, the palatability of the medicated water may affect intake. With large drinking water tanks that are replenished on a continuous basis, or even two or three times daily, it is difficult to determine how much drug should be added on a daily basis in order to maintain a reasonably steady concentration. On a theoretical basis, automatic in-line water medicators should provide a uniform concentration of drug in the water supply. However, some medicators are extremely unreliable and regular surveillance and servicing may be necessary. In countries where below-freezing temperatures occur during the winter months, the medication of water supplies may be difficult and impractical under certain management conditions.

Dietary medication

This is generally used for long-term disease control. In many countries, the amount of an antimicrobial that can be added to a feed is restricted to the **approved label level** and the veterinarian has no legal right to alter this concentration. The drug is usually added at the feed mill.

OTHER ROUTES

Other routes of administration may be used to increase the level of antibacterial drug in areas where diffusion following parenteral administration of the drug may be limited and when high local levels are required. These include intra-articular, intrapleural and subconjunctival injection. Non-irritant preparations should be used with strict aseptic technique. In most cases these treatments should be supported by parenteral treatment. The indications are described in the special medicine section.

Intramammary infusion of drugs is dealt with under mastitis.

Intratracheal administration of antibiotics has its advocates for the treatment of pneumonia in cattle. In theory, this could result in higher levels of antibiotics at the site of infection, although with many pneumonias diffusion through the affected lung must be minimal. The antibiotics are administered in sterile physiological saline equivalent to 2.0 mL/kg body weight. An extensive study has shown variation in absorption and persistence between antibiotics administered by this route, when compared to parenteral administration, but has concluded that there is no potentially useful advantage to its use.[15]

The local administration of antibiotics may not always be the preferred route despite historical precedence. For example, in the treatment of the **genital tract**, it has been shown that parenteral administration of antibiotics achieves tissue concentrations of drug in all areas of the genital tract, whereas intrauterine infusion results in comparable concentrations only in the endometrium and uterine secretions. Local and/or parenteral administration may be indicated in different cases of genital tract infection.[16]

DRUG DISTRIBUTION

ABSORPTION

Antibiotics of the aminoglycoside group and polymyxins are not absorbed from the alimentary tract and if circulating levels of these antibiotics are required they must be given by parenteral injection. Where both intestinal and systemic levels are required, as may be the case in neonatal colibacillosis, these drugs should be given both orally and parenterally. Benzylpenicillin and methicillin are destroyed by acid pH and significant blood levels are not achieved following oral administration but blood levels are achieved with ampicillin and amoxicillin. Certain sulfonamides (phthalylsulfathiazole, phthalylsulfacetamide, sulfaguanidine and succinyl sulfathiazole) are not absorbed from the alimentary tract. The remaining antibiotics and sulfonamides are absorbed following oral administration in preruminant calves and lambs and in pigs and horses. However, in general, blood and tissue levels obtained are considerably lower than those achieved with equivalent doses given parenterally. Whey feeding (calcium) will inhibit the absorption of tetracylines in pigs.

DISTRIBUTION

Factors governing the distribution of antimicrobial agents in the body fluids are complex, and distribution should be considered as involving a multicompartmental system with all body compartments being in contact directly or indirectly with the blood. The occurrence of exchange, and its rate, between the blood and the various tissue compartments is governed by the factors that influence the diffusion of solutes, such as the concentration of the drug and the volume of blood flow through the tissues and the volume of the tissue. It is also considerably influenced by the extent of protein binding of the drug in blood and in the tissues, the ionization constant of the drug, pH differences in the compartments, and the lipid solubility of the drug. Drug distribution is also influenced by age and the disease state of the animal.

In most diseases infection occurs in the extravascular tissue compartments and it is the concentration of the unbound drug at these sites that determines the efficacy of therapy. The majority of antibiotics diffuse relatively freely in extracellular fluids but sulfonamides, the chloramphenicol group, tetracyclines, fluoroquinolones and macrolides have a distribution that more closely approximates total body water, and they can enter cells.

There are several so-called **barriers** to antimicrobial diffusion and these include the brain and cerebrospinal fluid, serous cavities, joints and synovial fluid, the eye and the placenta and fetus. In general sulfonamides, the tetracyclines and chloramphenicol have some ability to penetrate these barriers in the normal state, whereas penicillin may not. Erythromycin has the ability to penetrate intracellularly and across most barriers but will not produce effective levels in the brain or cerebrospinal fluid. Members of the aminoglycoside group of antibiotics generally achieve effective levels in synovial fluid and the pleural and peritoneal fluid but not in the brain or eye. The importance of these barriers, especially those of serous cavities and synovia, in the presence of inflammation is open to doubt and effective therapy can often be achieved by the use of antibiotics that do not in normal situations reach these areas unless they are inflamed. An exception to this rule is infections involving the eyes where, in order to achieve effective levels, high circulating levels of the antimicrobial agent are required and intravenous injection to achieve this is usually necessary. Lipophilic drugs diffuse into tears and parenterally administered erythromycin, oxytetracycline and gentamicin, for example, may achieve bacteriostatic concentrations in tears. In many areas, especially joints and the peritoneal, pleural and pericardial cavities, high levels of the required antimicrobial agent can be achieved by local administration.

Almost all antimicrobial agents are **excreted** via the kidney, and the urine usually contains high levels of them. This feature is not of great significance in large animals, where urinary tract infections are comparatively rare, but violative residue levels can persist in the kidney for long periods with drugs such as the aminoglycosides. Penicillins and tetracyclines have a significant enterohepatic cycle, and erythromycin also may obtain significant levels in bile.

DURATION OF TREATMENT

For certain infectious diseases there is an established regimen of therapy that is known from clinical experience to be therapeutically effective. Where such regimens are known they are stated in the treatment section for the individual diseases in the Special Medicine section. As a rule of thumb in undifferentiated diseases, therapy should be continued for at least a 3–5-day period, or longer if there is evidence of chronic infectious disease with localization. An alternative rule of thumb is that treatment should be continued for at least 1 day beyond the return of body temperature to normal, especially if bacteriostatic antibiotics are being used. Chronic pyogenic processes may require treatment for a 2–4-week period or even longer.

DRUG COMBINATIONS

Combinations of antimicrobial drugs are frequently used in veterinary practice. Combinations of antimicrobial agents are used either to achieve a **synergistic effect** in the case of a single infection, or to achieve a **broad spectrum of activity** in the case of infections involving more than one agent. Combinations may also be of value in combating the **emergence of resistant** mutants during therapy.

The combination of two drugs may result in **indifference**, where the effect is either that of the single most effective drug or is equal to the sum of the effects of the two individual drugs, or it may result in **synergism** or **antagonism**. There are, however, no hard and fast rules for combinations that will result in any of these effects. Knowledge of these effects results largely from laboratory animal studies and from some human therapeutic trials. From these trials it is evident that the occurrence of **synergism** is very much dependent on the type of infectious organism, and to some extent the site of infection, and, whereas two drugs may show a synergistic effect with one type of infection, the effect may be indifferent or even occasionally antagonistic with other infective agents. **Antagonism** is equally not easily predictable but the drugs that most commonly result in antagonistic effect when combined with others are the tetracycline group, chloramphenicol and the macrolide groups.

A traditional approach has been that combinations of bactericidal drugs will generally result in an indifferent effect or in synergism; combinations of bacteriostatic drugs generally give an indifferent effect,

Table 4.1 Mode of action of antimicrobial drugs

Bactericidal antimicrobials	Bacteriostatic antimicrobials
Beta-lactams	Sulfonamides – all
Penicillins	Trimethoprim
Cephalosporins	Methotrexate
Semisynthetic penicillins	Pyrimethamine
Ampicillin	Tetracyclines
Amoxicillin	Macrolides
Cloxacillin	Erythromycin
Methicillin	Oleandomycin
Carbenicillin	Spiramycin
Aminoglycosides	Tylosin
Streptomycin	Carbomycin
Neomycin	Lincomycin
Gentamicin	Chloramphenicol
Paromomycin	Florphenicol
Tobramycin	
Glycopeptides	
Vancomycin	
Rifampin	
Bacitracin	
Polymyxins	
Fluoroquinolones	

whereas combinations of a bactericidal with a bacteriostatic drug may result in antagonism (Table 4.1). This approach is, however, too general for validity as interactions are specific to individual infections and are dose-dependent.

In farm animals, **synergistic activity** between penicillin and streptomycin has been demonstrated in the therapy of mycotic dermatitis and footrot in sheep.

The synergism between aminoglycoside and beta-lactam antimicrobials is widely used in the approach to the therapy of sepsis in neonates. Carbenicillin and gentamicin in combination can be of value in therapy against *P. aeruginosa, Klebsiella* and *Proteus* spp., and tylosin and oxytetracycline can be of value in treating infection with *Mannheimia* and *Pasteurella* spp. Trimethoprim and sulfonamide combinations are of special value in treating several infectious diseases in large animals. Rifampin and erythromycin show in-vitro synergism against *Rhodococcus equi*, as does a combination of gentamicin and penicillin. Tiamutilin and tetracycline show in-vitro synergism against several swine respiratory pathogens and herd studies show a measured response in the control of respiratory disease greater than that achieved by chlortetracycline alone.

Drug combinations are also used for **broad-spectrum therapy**. An accurate diagnosis with consequent recognition of the likely infectious organism allows specific antibacterial therapy and obviates the need for broad-spectrum antibacterial therapy. However, there are clinical situations where broad-spectrum therapy, including the possibility of combined drug therapy, is indicated. These include such problems as the acute septicemia, where a number of different organisms, with differing antibacterial sensitivities, can produce identical clinical disease, and those infections associated with organisms that have a varying sensitivity depending upon the isolate. The requirement for immediate treatment without knowledge of the bacterial sensitivity dictates the use of antimicrobial drugs designed to obtain a broad spectrum of activity.

The availability of **broad-spectrum drugs** such as ampicillin or amoxicillin and trimethoprim-potentiated sulfonamides has lessened the need to use drug combinations but the latter may still be necessary in certain situations and are fully indicated. Although antagonism has not been demonstrated in clinical veterinary situations it is wise to avoid bacteriostatic and bactericidal drug combinations.

Fixed-dose combinations are available commercially for some antibiotics but they **are not recommended** for use and are gradually being withdrawn from the market or being declared not legal for use in food-producing animals. Fixed-dose combinations suffer from the deficiency that the dose level of any one of the drugs in the combination is dictated by the level of the other. Also, the excretion rates of the two drugs may be markedly different. The most common of these, fixed-dose penicillin/streptomycin combinations, suffer from this deficiency.

Where combinations of antibacterial drugs are used they should be given individually and at their respective recommended doses and repeats. Some antibiotics are **physically incompatible** when mixed together. The incompatibility may rest with the drugs or their vehicles and may be visible, as with crystalline benzylpenicillin and neomycin, or it may be inapparent, as with gentamicin and carbenicillin. The two drugs should be given separately at separate sites. Incompatibilities can also occur with antibiotics and intravenous fluid solutions – especially those containing protein hydrolysates.

Antibiotics may influence the **activity of other drugs**. In particular, chloramphenicol and tetracyclines inhibit liver microsomal metabolism and may significantly increase the half-life of drugs metabolized by this mechanism, such as digitalis or barbiturates, with resultant potential toxicity.

ADDITIONAL FACTORS DETERMINING SELECTION OF AGENTS

In addition to the considerations of bacterial sensitivity to the antimicrobial agent, there are other important factors that dictate the selection of the antimicrobial agent to be used in a particular case. In most clinical situations several agents would be effective and a choice needs to be made amongst them.

COST

This is a major factor and includes not only the primary cost of the drug but also the ancillary costs that may be associated with its administration. This is a most important factor in agricultural animals but of less importance with pleasure horses. The importance of the primary cost of the drug is obvious. For example, in most countries a 5-day course of treatment with procaine benzylpenicillin will cost considerably less than one with, for example, oxytetracycline. If there is no specific indication for the use of the more expensive drug then the less expensive one should be used. The **ancillary costs** associated with repeat visits to administer the drug may also be important. The practice of dispensing drugs for continuing intramuscular therapy varies between countries and veterinary practices and has an influence on this consideration.

EASE OF ADMINISTRATION

This is a further factor that influences the nature of the drug and treatment used. In general, one avoids starting a course of therapy with an antibacterial such as tetracycline, which may require daily intravenous administration, in favor of one that can be administered more simply – unless there are good therapeutic reasons for choosing the former. In situations where facilities are poor, where **mustering or yarding** is difficult, or where mass medication is required, long-acting repository preparations may be indicated. Irritant preparations are avoided where possible.

TOXICITY

This is always a consideration when dealing with infections that may require high dose rates of antimicrobial drugs, or in chronic infections that require a prolonged course of therapy. Where a choice is available, antimicrobial agents with a low incidence of toxic side effects at high doses are chosen. As in all clinical situations involving large animals it is

essential to make an assessment of the case and to attempt a **prognosis**. The possible cost and duration of treatment should be estimated and the owner advised of this. When examined in this light the decision may be against treatment and for salvage slaughter.

BACTERICIDAL OR BACTERIOSTATIC ANTIMICROBIALS

Antibiotics are either primarily bactericidal or primarily bacteriostatic in their activity (Table 4.1). Some of the bactericidal group are bacteriostatic at low concentration. Both classes rely on intact and **effective body defense mechanisms** for full effect. Although in terms of clinical response little if any difference can be detected between the two groups in most diseases, in certain situations it is probably advisable to choose a bactericidal antibiotic for therapy. This is especially true when dealing with acute septicemic infection where there is frequently a significant leukopenia, and quick maximal bactericidal effect is required. There is also the need to prevent subsequent localization.

Bactericidal antimicrobials are also indicated for antibacterial treatment of secondary infection in **granulocytopenic syndromes** such as bracken fern poisoning or chronic furazolidone poisoning in calves. Bactericidal antibiotics are also preferable in the treatment of heavily **capsulated organisms**, such as *Klebsiella* spp. and *R. equi*, which show antiphagocytic activity. Infections in which significant **intracellular parasitism** occurs are a problem. The majority of antimicrobials that diffuse relatively freely into cells are bacteriostatic in activity and, although the disease may be controlled by their use, infection may still persist in a latent carrier state.

Antimicrobials prohibited from use in animals intended for food in the USA

- Chloramphenicol
- Dimetridazole
- Ipronidazole
- Other nitroimidazoles
- Furazolidone, nitrofurazone, other nitrofurans
- Sulfonamide drugs in lactating dairy cattle (except approved use of sulfadimethoxine, sulfabromomethazine and sulfamethoxypyridazine)
- Fluoroquinolones
- Glycopeptides (example: vancomycin)

DRUG DETERIORATION

Many antibacterials lose their activity rapidly when kept under adverse conditions. **Quality control** in terms of purity, efficacy and freedom from toxicity costs money but for these reasons it is preferable to purchase from known reputable companies and follow their recommendations with respect to storage and expiration periods. The use of cheap antibacterial preparations, often purchased in bulk and simply packaged, and distributed with little consideration for factors influencing drug stability, often results in poor therapeutic results. **Crystalline** or dry preparations that require reconstitution to a solution before parenteral administration are frequently presented this way because their activity degenerates rapidly once they are in solution. Therefore, once they have been prepared they should be used immediately, or the manufacturer's recommendations should be followed regarding storage. Attention should be paid to the length of activity expected following reconstitution.[1] **Temperature** and exposure to **sunlight** can be important factors in antibiotic stability and become especially important in farm ambulatory practice: car cold boxes should be used to store antibiotic preparations and other sensitive drugs.

UNFAVORABLE RESPONSE TO THERAPY

In clinical cases that do not respond to antimicrobial therapy the initial consideration should be that the wrong antimicrobial agent has been chosen for therapy. This is especially true of infectious conditions of undetermined etiology where the drug has been chosen on the basis of an educated guess. In these circumstances adequate time should be given for an evaluation of the efficacy of the treatment before a change is made. In general a **3-day period of treatment** is allowed for this evaluation provided there is no marked deterioration in the clinical state or further elevation of temperature during this period. If there is no response to initial therapy then, in the case of conditions of undetermined etiology, it is generally best to change to an entirely different class of antimicrobial agent. However, the possibility of viral or noninfectious etiology should always be considered in these cases and the case and diagnosis should be reviewed before any change is made.

In any situation where there is a poor response to therapy the usual causes of this failure should be considered in any further adjustments to therapy or future therapy of similar cases. The first and most obvious of these is that the organism is either **insensitive to the drug** or that it is **not susceptible to the level of the drug** that is being used for therapy. There are two possible approaches. The first is to increase the dose rate and dose frequency and/or to change the route of administration so that higher and possibly effective levels will be achieved, bearing in mind the possible toxic consequences. The second, and safer, approach is to change the antimicrobial agent being used. This problem can be avoided if the organism and its potential **sensitivity** can be identified, either by clinical examination or by appropriate sampling with culture and sensitivity testing. The development of resistance during antimicrobial treatment of an individual animal is not a recognized problem in large-animal medicine.

Another common cause of poor response is that the infection is situated in an area to which the drug is **poorly accessible**. If this is associated with an area behind a barrier to the entry of the antibiotic, such as the joints or the eye, it may be necessary to resort to **higher dose rates** and frequency, or intravenous administration of the drug, or to ancillary local treatment into this area. Alternatively, another drug with **superior penetrability** may be used.

Organisms must be actively metabolizing in order for antimicrobial agents to exert their effect. This feature can result in poor response to therapy or relapse following discontinuation of therapy in **chronic infections** such as endocarditis or where there is excessive necrotic or fibrotic tissue associated with the infection. In these instances, dormant organisms and the long diffusion tracks make effective cure difficult and high antimicrobial levels sustained over longer periods are required. In **purulent conditions** surgical drainage, where possible, is an essential adjunct to antimicrobial therapy.

The importance of ancillary and **supportive therapy** to counteract the effects of shock, toxemia and dehydration that may be associated with infection cannot be overemphasized and frequently such therapy may markedly influence the outcome of a case. It is obvious, for example, that 3 mL of antibiotic will do little to counter the effects of a 4 L fluid deficit in a scouring calf.

DRUG WITHDRAWAL REQUIREMENTS AND RESIDUE AVOIDANCE

In most countries there are requirements for the withdrawal of antimicrobial agents from the feed for specified periods prior to slaughter, and animals or their milk cannot be marketed for certain periods following antimicrobial therapy.

Antibiotic contamination of food products can be a **public health risk**,

although proven risk for toxicity or allergy from antibiotics in humans is minuscule. An example would be allergic reactions to antibiotic residues – particularly penicillin. There are also **commercial considerations** where residues of antibiotics in milk can cause considerable problems in the manufacture of milk products. Effects on starter cultures for cheese and yoghurt can be particularly deleterious and can result in downgrading or total loss of large quantities of manufacturing milk.

The purpose of withdrawal requirements is to ensure that meat and milk for human consumption is wholesome and does not contain violative residues of drugs. The public's concern for the wholesomeness of the food that it consumes will determine the food that it buys. Cooperative quality assurance programs involving both the producer and the veterinarian are a major answer to this concern.

A **withdrawal period** is the time during which the animal must be held free of the drug before it can be marketed. In the case of milk, the term **withholding period** is commonly used and defines the period during which milk cannot be sent for human consumption following the treatment of the animal with a drug. A **tolerance** for the pharmacologically active ingredient in tissues is set by regulatory authorities for each drug. The **tolerance level** is the level below which tissue concentrations must fall before they are considered safe for human consumption, and there is a large margin of safety.[2]

The required withdrawal and withholding periods will vary between antimicrobial agents and also with the same antimicrobial agent depending upon the amount of drug given; factors such as age and the disease state of the animal are also important. Unfortunately, the required withdrawal and withholding periods to ensure freedom of food products from violative drug residues are not known for the variety of dose concentrations and dose intervals of the various antimicrobials that could be used in clinical practice – nor are they likely to be known in the near future. In many countries this has led to regulations that limit the quantity of antibiotics in drug products. **Label instructions explaining product usage and drug withdrawal times are required.** These label instructions include what is generally called the **label dose**.

The label dose and extralabel use

The label dose (and dose interval) is a dose of an antimicrobial for which the specific withdrawal and withholding periods have been established, and these are stated in conjunction with the label dose. The label dose is the officially approved or legal dose rate for that drug.

When an antimicrobial is used, it is incumbent upon the practitioner to notify the owner that the animal cannot be marketed (or milk sent for human consumption) before the accompanying withdrawal (or withholding) period has expired. The practitioner may be legally liable if a violation occurs and this notification has not been given.

In the **USA** the **label dose** of a drug also includes use only in the species of animal for which the drug is labeled, the class of animal (lactating versus nonlactating dairy cow), the disease conditions indicated by the label, the route of injection, the amount of drug to be injected at one site and the number of repeat treatments that can be given. These **label directions**, and the need to follow them, are directed primarily at lay users of these drugs and lay users may not use the drug in a nonlabel fashion. The label directions should also be followed by the veterinarian whenever possible.

Requirements for extralabel use of drugs in the USA

- Extralabel use of drugs (ELDU) is permitted only by or under the supervision of a veterinarian
- ELDU is allowed only for US Food and Drug Administration (FDA)-approved animal and human drugs
- A valid veterinarian–client–patient relationship is a prerequisite for all ELDU
- ELDU must be for therapeutic purposes only (animal's health is suffering or threatened), not drugs for production use
- Rules apply to dosage form drugs and drugs administered in water – ELDU in feed is prohibited
- ELDU is not permitted if it results in a violative food residue, or any residue that may present a risk to public health
- FDA prohibition of a specific ELDU precludes such use

Extralabel use

There are times where **extralabel use** of drugs is necessary and veterinarians can do this where they have established a proper veterinarian–client–patient relationship.[3] It is the intention that the label dose should be one that is therapeutically effective for that drug. However, this is not always the case, and the label dose should not be confused with the term 'recommended dose' as used elsewhere in this book. There are also circumstances where, although the label dose may be therapeutically efficient in many cases, it is not for the particular case in hand. In fact, optimal therapeutic dose regimes often require extralabel use of the drug.[4,5] In these situations, antimicrobial drugs may need to be used at dose concentrations and dose intervals different from the label dose. Extralabel use of the drug may be therapeutically necessary for the successful treatment of the problem, but it is not officially approved and the establishment of the required withdrawal period is entirely incumbent upon the veterinarian. The withdrawal period in these circumstances cannot always be extrapolated from that for the label dose.[2]

Definition of valid veterinarian–client–patient relationship (American Veterinary Medical Association)

An appropriate veterinarian–client–patient relationship will exist when:

1. The veterinarian has assumed the responsibility for making medical judgments regarding the health of the animal(s) and the need for medical treatment, and the client (owner or other caretaker) has agreed to follow the instructions of the veterinarian
2. There is sufficient knowledge of the animal(s) by the veterinarian to initiate at least a general or preliminary diagnosis of the medical condition of the animal(s). This means that the veterinarian has recently seen and is personally acquainted with the keeping and care of the animal(s) by virtue of an examination of the animal(s) and/or by medically appropriate and timely visits to the premises where the animal(s) are kept, and
3. The practicing veterinarian is readily available for followup in case of adverse reactions or failure of the regimen of therapy

WITHDRAWAL PERIODS

Label dose withdrawal periods are determined from pharmacokinetic studies of excretion following administration of the label dose. However, the rate of drug elimination from the body can be influenced by drug dose and dose frequency. For example, the metabolism and excretion half-life of sulfonamides in cattle is dose-dependent. With repeated dosing of antibiotics such as tetracycline and the aminoglycosides, there is deposition of the antibiotic in certain tissues and following cessation of drug administration there is a slow release from these tissues and a long **washout period**.[6,7] During this washout period there are decreasing concentrations of the drug in tissues and in milk, which, although not of therapeutic importance, are sufficiently high to be violative. This presents a dilemma to the veterinarian trying to establish withdrawal periods.

The occurrence of significant washout periods following prolonged therapy with antibiotics has only recently been recognized and there are few data on their duration at different dose concentrations and dose frequencies. A further problem is that most pharmokinetic parameters have been determined in healthy animals and altered physiology in diseased animals can markedly alter elimination half-lives; there is also considerable animal-to-animal variation.[2] Rather than try to guess the possible withdrawal period for an extralabel use, computer-based data information banks with easy access are established to provide this information.[8] One of these is the Food Animal Residue Avoidance Databank (FARAD), which provides recommendations for withdrawal intervals for extralabel drug use based on analysis of published pharmacokinetic data, foreign and domestic label drug withdrawal intervals and established maximum residue limits. Another, the Veterinary Antimicrobial Support System (VADS), aims to provide information on optimal therapeutic regimens against pathogens in cattle and swine using approved drugs and treatment regimens but also providing information on extralabel regimens that might be required in the face of a refractory pathogen.

RESIDUE TESTING

Currently, the only way to attempt to ensure nonviolation with extralabel use of antimicrobials is to test for residues.[9,10] There are a very large number of testing systems becoming available, which vary in their method of detection of the presence of antibiotics.[11–14] Tests such as the Swab Test on Premises (STOP), Calf Antibiotic and Sulfa Test (CAST), Live Animal Swab Test (LAST), Fast Antimicrobial Screen Test (FAST) (which has a higher sensitivity and shorter analytical time and has largely replaced the use of STOP and CAST), the Delvotest-P, the Charm Inhibition Assay and the Charm Farm and Disk Assays are based on the inhibition of growth of *Bacillus stearothermophilus* var. *calidolactes* or *Bacillus stearothermophilus*. While relatively cheap and easy to perform, they have a risk for false-positive results due to inhibition of growth by inhibitory substances other than antibiotics in milk, particularly substances in milk from inflamed mammary glands.[12,13,15–17] They are sensitive for detecting penicillin and its derivative compounds but less sensitive to other classes of antibiotic. Other commercially available tests use a variety of different immunological detection methods and test for a single antibiotic or class of antibiotics.

TESTING FOR COMPLIANCE

Most countries have a monitoring program to detect the occurrence of residues in meat. In the USA, sampling is such as to provide a 95% probability of finding a violative residue when 1% of the population is violative. The occurrence of violative residues in red meat is very low as the prevalence of infectious disease is low in the period before slaughter. Feedlot cattle can have a high prevalence of disease in the early feeding period but there is a substantial subsequent period on-feed before the animals are slaughtered, which exceeds the withholding period of most drugs used for treatment of disease occurring during the early feeding period. Violative drug residues occur predominantly in cull dairy cows and in bob veal calves.

The concentrations for the various antibiotics that are violative are not stated in this chapter for two reasons. First, they vary from country to country. Secondly, the violative concentrations tend to be set by the sensitivity of the detection assay used by the regulatory authority and, as assay technology improves, legally acceptable minimal concentrations will be lowered. Local regulatory publications should be consulted for current requirements.

Assay techniques can be remarkably sensitive. An example is the occurrence of violative residues of chloramphenicol in the milk, blood and urine of cows that had teat or skin lesions sprayed with a 5% chloramphenicol solution[18] – an illegal drug for use in animals for food in most countries.

CAUSES OF RESIDUE VIOLATIONS IN MILK

In a retrospective study of reasons for the presence of violative antibiotic residues in milk[19] **failure to withhold milk** for the full withdrawal period and **accidental inclusion of treated milk** in the shipment were the most common. Accidental inclusion of treated milk can occur when there is **inadequate identification** of treated cows. The veterinarian should work with the producer to establish a system that easily identifies cows whose milk is subject to a withholding period. Colored leg markers are one system and are immediately visible to the milker.

Contamination of recorder jars and milking equipment with the high concentration of antibiotic secreted in milk in the first milking after treatment is a further reason for residue violations. Treated cows should be **milked last** in large dairies, or milked with separate equipment, and are preferably kept separate as a hospital string.

Common causes of antibiotic residues in milk

- Extended usage or excessive dosage
- Failure to observe withdrawal times
- Poor records of treatment
- Prolonged drug clearance
- Failure to identify treated animals
- Contaminated milking equipment
- Milker or producer mistakes
- Products not used according to label directions
- Lack of advice on withdrawal period
- Withholding milk from treated quarters only
- Early calving or short dry periods
- Purchase of treated cows
- Use of dry cow therapy for lactating cows
- Milking dry cows

Other reasons for residue violations include **short dry periods**, where dry cow therapy has been used but the cow has calved earlier than expected. The infusion of **dry cow treatments** into the udder of heifers prior to calving for the prevention of summer mastitis has also been followed by the presence of violative residues for as long as 26 days.[9] A less common cause is the **accidental milking of dry cows**, where the latter are not kept as a separate group, and the withholding of milk from only treated quarters.[19] The use of dry cow infusion preparations for treatments during lactation can occur by mistake if drugs intended for the treatment of lactating cows are not kept in a **separate storage area** from other drugs.

The **risk** for residues is higher for farms that have higher frequency of antibiotic usage and for those that use part time labor.[10] The use of **records** to document treatments and the day of exit from the withholding period is an important preventive measure. Sulfonamides, tetracyclines, penicillins, aminoglycosides, cephalosporin and chloramphenicol have been found in milk in the USA.[20]

CAUSES OF RESIDUE VIOLATIONS IN BEEF CATTLE

Violative drug residues occur predominantly in cull dairy cows and in bob veal calves.[21] In one study[22] the primary reasons for violations in this group were:

- Failure to observe the withdrawal periods (61%)
- Use of an unapproved drug (10%)
- The feeding to calves of milk or colostrum from a treated cow (9%). A greater risk for residues occurs in herds that feed larger volumes of colostrum, possibly reflecting contamination from dry cow therapy; waste milk, discarded from treated cows and fed to calves, is also a

risk[23,24] especially if extralabel doses of antimicrobials are used for udder infusions[25]
- Exceeding the label dose (6%).

The major drugs involved with residues in meat are neomycin, streptomycin, penicillin, oxytetracycline, gentamicin and sulfamethazine, with intramuscular injection being the route of administration in 60% of the residue cases, oral administration in 28% and intramammary infusion in 9%.[21,22] The use of orally administered antimicrobial boluses in calves that were subsequently slaughtered as bob veal calves is also a problem.

CAUSES OF RESIDUE VIOLATIONS IN SWINE

Similar causes are recorded for the occurrence of violative residues in pigs but an additional problem in pigs is tissue residues resulting from **antibiotic inclusions in feeds** for growth promotion and disease control purposes. Sulfonamides are a particular problem. Nonobservance of the required withdrawal period can result in the rejection of market batches of animals with a substantial financial loss to producers. If feed inclusions have been for the purposes of medication, the prescribing veterinarian may be liable if adequate information on withdrawal periods has not been given.

There is also a problem with **sulfonamide residues** resulting from carryover of sulfonamides from medicated to nonmedicated feeds at the feed mill or on the farm.[26] Mistakes in feed **delivery**, feed **mixing** sequences, ingredient **contamination** and contamination within the bulk feed **distribution system**, and **delivery augers** can cause residual contamination.[26,27] **Carryover concentrations** of sulfamethazine (sulfadimidine) of greater than 2 g per tonne in the finisher ration can result in violative residues in the liver at slaughter.[28] The use of granular forms of sulfamethazine markedly reduces the potential for carryover.[29]

A further source of contamination in the piggery is **environmental contamination**. Manure and pooled urine from swine fed 100 g per tonne of sulfamethazine contains sufficient drug to contaminate swine to violative levels when contact with the material is maintained and this can continue for 6–7 weeks when pens are not cleaned after a drug is withdrawn from the feed.[27] **Dried urine** has the potential for airborne contamination of pigs. Sulfamethazine is stable in manure and flush water for long periods and **coprophagy** by pigs can lead to significant intake of the drug. In order to avoid the risk of this occurring, it is recommended that, 3 days after the medicated feed has been withdrawn, the pens should be thoroughly cleaned or the pigs moved to new housing. Water medication can also lead to buildup of residues in the water delivery system, so the watering systems should be flushed. Pigs destined for slaughter can be tested on the farm prior to shipping using commercially available testing systems, which can also be used for detection of the occurrence of sulfonamides in feed and water.[27]

TYPE OF THERAPY

In the USA veterinarians are responsible for a very minor proportion of detected residue violations.[30] Possible causes of violations resulting from veterinary therapy include the selection of an inadequate withdrawal period following extralabel use of an antimicrobial and treatment modalities that may not be considered a risk. The local infusion of antibiotic solutions into the uterus of cows may result in circulating concentrations of antibiotic and residues in body tissues and in milk. This results from the absorption of the antibiotic through the endometrium and from the peritoneal cavity following passage through the fallopian tubes.[31] Similarly, following infusion of antibiotic solutions into one quarter of the udder, low concentrations of the antibiotic can occur in milk secreted from the remaining quarters. Gentamicin is generally considered not to be absorbed from the mammary gland but more than 87% of an intramammary dose of gentamicin is absorbed from the *inflamed* udder.[32]

APPROVED DRUGS

Whenever possible, approved antimicrobials should be used for therapy at label dose and a known withdrawal time in order to comply with regulatory requirements and to minimize the possibility of antibiotic residues in meat and milk. It may be necessary to use nonapproved antimicrobial drugs in certain circumstances and in minor species. The use of an approved antibiotic in a minor species for which it is not approved constitutes an extralabel use of the drug. The legality of the use of unapproved drugs, or of approved drugs in minor species for which they are not approved, is questionable. If such use is contemplated it is probably wise to have culture and sensitivity data indicating that the use of the unapproved drug is therapeutically necessary. Certain nonapproved antibiotics are **totally banned** for use in food-producing animals in some countries (e.g. in the USA: chloramphenicol, the nitroimidazoles, sulfamethazine in dairy cattle over 20 months of age, furazolidone and the use of fluoroquinolones in an extralabel fashion) and local regulations should be followed. The use of sulfamethazine in food-producing animals may be banned in some countries. The American Association of Bovine Practitioners has passed a voluntary moratorium on the use of aminoglycosides in cattle.

Diseases of the alimentary tract – I

5

Principles of alimentary tract dysfunction

The primary functions of the alimentary tract are the **prehension, digestion** and **absorption of food and water** and the **maintenance of the internal environment** by modification of the amount and nature of the materials absorbed.

The primary functions can be divided into four major modes and, correspondingly, there are four major modes of alimentary dysfunction. There may be abnormality of **motility, secretion, digestion** or **absorption.** The procedure in diagnosis should be to determine which mode or modes of function are disturbed before proceeding to the determination of the site and nature of the lesion and ultimately of the specific cause.

MOTOR FUNCTION

NORMAL GASTROINTESTINAL MOTILITY

The form and function of the small intestine of farm animals is similar between species but the stomachs and large intestines vary considerably.[1] The motility patterns in both the small and large intestine are similar among the species. In the small intestine, the fundamental unit of electrical activity is the slow wave, which is a subthreshold fluctuation in membrane potential. Slow waves are constantly propagated from the stomach to the rectum. When an additional stimulus causes the membrane potential to exceed the excitation threshold, a spike or electrical response activity occurs, which is usually accompanied by contraction. Almost all spike activity in the intestine is superimposed on slow waves, which are important in controlling frequency and velocity at which spiking events occur. The spiking activity, also known as the migrating myoelectric

complex, is the myoelectric pattern in the stomach and small intestine of fasted nonruminants, fed and fasted ruminants, and pigs and horses fed ad libitum.[2] There are three phases of the migrating myoelectric complex:

- The **quiescent phase**, in which very little spike activity occurs
- The **irregular phase**, characterized by intermittent spike activity
- The **activity front**, characterized by intense, continuous spike activity.[2]

There is very little muscle contraction or transit of gut contents during the quiescent phase. During the irregular phase, contractions mix the intestinal contents and propel them in an aboral direction. The activity front is accompanied by intense muscular contraction that obliterates the lumen, preventing backflow of content as it propagates, or migrates, down the intestine. In nonruminants, and pigs and horses fed periodically, feeding abolishes the migrating myoelectric complex for several hours. It is replaced by the fed pattern, characterized by intermittent spike activity resembling the irregular phase.

Normal cecal and colonic myoelectric activities, like those of the small intestine, are characterized by slow waves and spikes. However, unlike the small intestine, the patterns of spikes vary greatly with the species and the area of the large intestine.[2]

Abnormalities of stomach and intestinal motility represent the most common consequence of gastrointestinal tract disease. Disruption in gastrointestinal tract motility can result in:

- **Hypermotility or hypomotility**
- **Distension of segments of the tract**
- **Abdominal pain**
- **Dehydration and shock.**

HYPERMOTILITY AND HYPOMOTILITY

The most important functions of alimentary tract motility are the peristaltic movements that move ingesta from the esophagus to the rectum, the segmentation movements that churn and mix the ingesta, and the tone of the sphincters. In ruminants these movements are of major importance in the forestomach. Prehension, mastication and swallowing are other functions of alimentary tract motility that are essential for normal function. Eructation of ruminal gases is an additional crucial function of motility in ruminants.

Abnormal motor function may take the form of **increased or decreased motility.** Peristalsis and segmenting movements are usually affected equally and in the same manner. Motility depends upon stimulation via the sympathetic and parasympathetic nervous systems and is thus dependent upon the activity of the central and peripheral parts of these systems, and upon the intestinal musculature and its intrinsic nervous plexuses. Autonomic imbalance, resulting in a relative dominance of one or other system, is manifested by hypermotility or hypomotility, and can arise as a result of stimulation or destruction of hypothalamic centers, the ganglia, or the efferent or afferent peripheral branches of the system. Debility, accompanied by weakness of the musculature, or severe inflammation, such as occurs in acute peritonitis or after trauma, or infarction, results in atony of the intestinal wall. Less severe inflammation, such as occurs in mild gastritis and enteritis, may result in an increase in muscular activity and increased propulsive activity. Increased motility causes diarrhea, decreased motility causes constipation, and both have deleterious effects on digestion and absorption.

Increased irritability at a particular intestinal segment increases its activity and disturbs the normal downward gradient of activity that insures that the ingesta is passed from the esophagus to the rectum. Not only is the gradient towards the rectum made steeper, thus increasing the rate of passage of ingesta in that direction, but the increased potential activity of an irritated segment may be sufficiently high to produce a reverse gradient to the oral segments so that the direction of the peristaltic waves is reversed orally to the irritated segments.

DISTENSION

One of the major results of abnormality of motility is distension of the tract. This occurs in a number of disturbances, including the rapid accumulation or inefficient expulsion of gas, complete occlusion of the lumen by intestinal accident or pyloric or ileocecal valve obstruction, and engorgement on solid or liquid feeds. Fluids, and to a lesser extent gas, accumulate because of their failure to pass along the tract. Much of the accumulated fluid represents saliva and gastric and intestinal juices secreted during normal digestion. Distension causes pain and, reflexly, increased spasm and motility of adjoining gut segments. Distension also stimulates further secretion of fluid into the lumen of the intestine and this exaggerates the distension. When the distension passes a critical point, the ability of the musculature of the wall to respond diminishes, the initial pain disappears, and a state of paralytic ileus develops in which all muscle tone is lost.

ABDOMINAL PAIN

Visceral pain may arise in any abdominal viscus or organ but the mode of its development is always the same and alimentary tract disease is the major cause of visceral and, more specifically, of abdominal pain. The **most important mechanism is stretching of the wall of the viscus**, which stimulates free pain endings of the autonomic nerves in the wall. Contraction does not of itself cause pain but does so by causing direct and reflex distension of neighboring segments. Thus spasm, an exaggerated segmenting contraction of one section of intestine, will result in distension of the immediately oral segment of intestine when a peristaltic wave arrives. When there is increased motility for any reason, excessive segmentation and peristalsis cause abdominal pain, and the frequent occurrence of intermittent bouts of pain depends upon the periodic increases in muscle tone that are typical of alimentary tract wall. Other factors that have some stimulating effect on the pain end organs are edema and failure of local blood supply, such as occurs in local embolism or in intestinal accidents accompanied by twisting of the mesentery. A secondary mechanism in the production of abdominal pain is the stretching and inflammation of serous membranes.

Clinically, abdominal pain can be detected by palpation and the eliciting of pain responses. However, it is unknown if the response elicited is due to involvement of underlying organs or to referred pain. It is difficult to decide if referred pain occurs in animals. In humans it is largely a subjective sensation, although often accompanied by local hyperalgesia. There are no known examples of referred pain that are of diagnostic importance in animals and a local pain response on palpation of the abdomen is accepted as evidence of pain in the serous membranes or viscera that underlie the point of palpation.

DEHYDRATION AND SHOCK

An immediate effect of distension of the stomach or small intestine by the accumulation of saliva and normal gastric and intestinal secretions is the stimulation of further secretion of fluid and electrolytes in the oral segments. The stimulation is self-perpetuating and creates a vicious cycle resulting in loss of fluid and electrolytes to the point where fatal dehydration can occur. The dehydration is accompanied by acidosis or alkalosis depending on whether the obstruction is in the intestine and accompanied by loss of alkali, or in the stomach and accompanied by a large loss of acid radicals. The net effect is the same whether the fluid is lost by vomiting or is retained in the gut.

The same cycle of events occurs in ruminants that gorge on grain but here

the precipitating mechanism is not distension but a gross increase in osmotic pressure of the ingesta due to the accumulation of lactic acid. Dehydration is also of major importance in diarrhea, irrespective of the cause. An important additional factor in the production of shock, when there is distension of alimentary segments, is a marked reflex depression of vasomotor, cardiovascular and respiratory functions. In diarrhea in calves in which there is no septicemia nor toxemia associated with bacteria, the endpoint in the phase of dehydration can be cardiac failure due to severe metabolic acidosis. Renal ischemia leading to uremia may result from decreased circulating blood volume and also contribute to a fatal outcome. These matters are discussed in detail in the section in Chapter 2 on disturbances of body fluids, electrolytes and acid–base balance.

SECRETORY FUNCTION

Diseases in which abnormalities of secretion occur are not generally recognized in farm animals. In humans, and to a lesser extent in small animals, defects of gastric and pancreatic secretion produce syndromes that are readily recognized, but they depend upon clinical pathological examination for diagnosis. If they do occur in farm animals, they have so far only been recognized as aberrations of motility caused by the defects of secretion. However, it is reasonable to assume that some neonates may be deficient in lactase activity, which results in dietetic diarrhea. Undigested lactose causes diarrhea by its hyperosmotic effect, and some of the lactose may be fermented in the large intestine, the products of which fermentation may exaggerate the diarrhea. A deficiency of lactase activity has been suspected in foals affected with diarrhea of undetermined origin but the definitive diagnosis has not been made. The intestinal lactase activity of foals is at its highest level at birth and gradually declines until the fourth month of age, and then disappears from adults before their fourth year.

DIGESTIVE FUNCTION

The ability of the alimentary tract to digest food depends on its motor and secretory functions and, in herbivores, on the activity of the microflora that inhabits the forestomachs of ruminants or cecum and colon of Equidae. The flora of the forestomachs of ruminants is capable of digesting cellulose, of fermenting the end-products of other carbohydrates to volatile fatty acids and converting nitrogenous substances to ammonia and protein. In a number of circumstances, the activity of the flora can be modified so that digestion is abnormal or ceases. Failure to provide the correct diet, prolonged starvation or inappetence, and hyperacidity as occurs in engorgement on grain all result in impairment of microbial digestion. The bacteria, yeasts and protozoa may also be adversely affected by the oral administration of antibiotic and sulfonamide drugs, or drugs that drastically alter the pH of the rumen content.

Diseases of the stomach of ruminants are presented in Chapter 6. Information about the digestive and absorptive capacities of the equine gut is not exhaustive but some basic data are available.[1,3] The rate of passage of ingesta through the stomach and intestines is rapid but varies widely depending on the physical characteristics of the ingesta, dissolved material passaging more rapidly than particulate material; 75% of a liquid marker can be emptied from the stomach in 30 minutes and be in the cecum at 2 hours. Passage through the large bowel is much slower, especially in the latter part of the colon where much of the fluid is absorbed. There is an obvious relationship between the great activity of the small intestine and the effect of a complete obstruction of it: the pain is very severe and often uncontrollable with standard analgesics, fluid loss into the obstructed parts is rapid, and dehydration, loss of electrolytes and disturbances of acid–base balance are acute, severe and life-threatening.

ABSORPTIVE FUNCTION

Absorption of fluids and the dissolved end-products of digestion may be adversely affected by increased motility or by disease of the intestinal mucosa. In most instances, the two occur together but, occasionally, as with some helminth infestations, lesions occur in the intestinal wall without accompanying changes in motility.

Manifestations of alimentary tract dysfunction

Inanition is the major physiological effect of alimentary dysfunction when the disease is a chronic one, dehydration is the major effect in acute diseases, and shock is the important physiological disturbance in hyperacute diseases. Some degree of abdominal pain is usual in most diseases of the alimentary tract, the severity varying with the nature of the lesion. Other manifestations include abnormalities of prehension, mastication and swallowing, and vomiting, diarrhea, hemorrhage, constipation and scant feces.

ABNORMALITIES OF PREHENSION, MASTICATION AND SWALLOWING

Prehension is the act of grasping for food with the mouth (lips, tongue, teeth). It includes the ability to drink. Causes of faulty prehension include:

- Paralysis of the muscles of the jaw or tongue
- Malapposition of incisor teeth due to:
  - inherited skeletal defect (inherited displaced molar teeth, inherited mandibular prognathism, inherited congenital osteopetrosis)
  - rickets
- Absence of some incisor teeth
- Pain in the mouth due to:
  - stomatitis, glossitis
  - foreign body in mouth
  - decayed teeth, e.g. fluorosis
- Congenital abnormalities of tongue and lips:
  - inherited harelip
  - inherited smooth tongue of cattle.

A simple examination of the mouth usually reveals the causative lesion. Paralysis is indicated by the behavior of the animal as it attempts to ingest feed without success. In all cases, unless there is anorexia due to systemic disease, the animal is hungry and attempts to feed but cannot do so.

Mastication may be painful and is manifested by slow jaw movements interrupted by pauses and expressions of pain if the cause is a bad tooth, but in a painful stomatitis there is usually complete refusal to chew. Incomplete mastication is evidenced by the dropping of food from the mouth while eating and the passage of large quantities of undigested material in the feces.

Swallowing is a complex act governed by reflexes mediated through the glossopharyngeal, trigeminal, hypoglossal and vagal nerves. It has been described endoscopically and fluoroscopically in the horse. The mechanism of the act includes closure of all exits from the pharynx, the creation of pressure to force the bolus into the esophagus, and involuntary movements of the musculature of the esophageal wall to carry the bolus to the stomach. A defect in nervous control of the reflex or a narrowing of the lumen of the pharynx or esophagus may interfere with swallowing. It is difficult to differentiate clinically between physical and functional causes of dysphagia (difficulty in eating/swallowing).

Dysphagia is manifested by forceful attempts to swallow accompanied initially

by extension of the head, followed by forceful flexion and violent contractions of the muscles of the neck and abdomen. Inability to swallow is usually caused by the same lesions as dysphagia, but in a greater degree. If the animal attempts to swallow, the results depend on the site of the obstruction. Lesions in the pharynx cause regurgitation through the nostrils or coughing up of the material. In the latter instance, there is danger that some of the material may be aspirated into the lungs and cause acute respiratory and cardiac failure or aspiration pneumonia. When the obstruction is at a low level in the esophagus, a large amount of material may be swallowed and then regurgitated. It is necessary to differentiate between material regurgitated from the esophagus and vomitus: the former is usually slightly alkaline, the latter acid.

CAUSES OF DYSPHAGIA AND INABILITY TO SWALLOW

- Foreign body, tumor or inflammatory swelling in pharynx or esophagus
- Painful condition of pharynx or esophagus
- Esophageal dilatation due to paralysis
- Esophageal diverticulum
- Esophageal spasm at site of mucosal erosion (achalasia of cardia not encountered).

DROOLING OF SALIVA AND EXCESSIVE SALIVATION

Drooling saliva from the mouth, distinct from frothing such as occurs during convulsions, may be caused by pain in the mouth and by an inability to swallow. Excessive salivation is caused by stimulation of saliva production by systemic toxins, especially fungal toxins, or by hyperthermia. With systemic poisonings the increased salivation is often accompanied by lacrimation.

LOCAL CAUSES OF DROOLING

- Foreign body in mouth or pharynx
- Ulceration, deep erosion or vesicular eruption of the oral mucosa
- Inability to swallow (esophageal abnormality).

SYSTEMIC CAUSES OF EXCESSIVE SALIVATION

- Poisonous trees – *Oleander* spp., *Andromeda* spp. (rhododendron)
- Other poisonous plants – kikuyu grass (or an attendant fungus)
- Fungal toxins, e.g. slaframine and those causing hyperthermia, e.g. *Claviceps purpurea, Acremonium coenophialum*
- Iodism
- Watery mouth of lambs
- Sweating sickness
- Methiocarb poisoning.

VOMITING AND REGURGITATION

VOMITING

Vomiting is the forceful ejection of contents of the stomach and the proximal small intestine through the mouth and is a complex motor disturbance of the alimentary tract. It is a vigorously active motion signaled by hypersalivation, retching and forceful contractions of the abdominal muscles and diaphragm. Vomiting is essentially a protective mechanism with the function of removing excessive quantities of ingesta or toxic materials from the stomach. It occurs in two forms: **projectile** and **true vomiting**.

Projectile vomiting

This is not accompanied by retching movements and large amounts of fluid material are ejected with little effort. It is almost always as a result of overloading of the stomach or forestomach with feed or fluid.

True vomiting

As it occurs in monogastric animals like the dog and cat, true vomiting is accompanied by retching movements including contraction of the abdominal wall and of the neck muscles and extension of the head. The movements are commonly prolonged and repeated and the vomitus is usually small in amount and of porridge-like or pasty consistency. It is most commonly a result of irritation of the gastric mucosa. Vomiting is commonly designated as being either peripheral or central in origin depending on whether the stimulation arises centrally at the vomiting center or peripherally by overloading of the stomach or inflammation of the gastric mucosa, or by the presence of foreign bodies in the pharynx, esophagus or esophageal groove. Central stimulation of vomiting by apomorphine and in nephritis and hepatitis are typical examples but vomiting occurs rarely, if at all, in these diseases in farm animals.

Vomiting may have serious effects on fluid and electrolyte balance because of the losses of gastric and intestinal contents during vomiting. Aspiration pneumonia or laryngeal obstruction are potential serious consequences of vomiting. Examination of any suspected vomitus to determine its site of origin should always be carried out.

True vomiting is rare in farm animals except in pigs with gastroenteritis and some systemic diseases. True vomiting does not occur in ruminants but abnormal regurgitation does occur (see below under Regurgitation). **True vomiting is not a feature of gastric disease in the horse for two reasons.** First, the strong cardiac sphincter inhibits the release of stomach contents; in horses rupture of the stomach is more likely to occur before vomiting takes place. Secondly, the soft palate and epiglottis combine to effect a seal between the oral and nasal parts of the pharynx so that any vomited stomach contents must be discharged through the nasal cavities and not through the mouth. Spontaneous nasal regurgitation or vomiting does occur occasionally, as manifested by the production of green stomach contents at the nostrils. This suggests extreme gastric distension or a dilated esophagus and cardiac sphincter and perhaps some underlying neurological deficit. Thus vomiting of large quantities of material in the horse is usually a terminal event and suggests gastric rupture.

REGURGITATION

Regurgitation is the expulsion through the mouth or nasal cavities of feed, saliva and other substances that have not yet reached the stomach. In most cases it is due to abnormalities of the esophagus that interfere with swallowing. A common example in large animals is the regurgitation of feed, saliva, and perhaps blood-stained fluid from the esophagus of the horse with esophageal obstruction. Esophagitis is also a common cause of regurgitation.

Ruminants regurgitate rumen contents as part of rumination but the material is not expelled from the mouth nor into the nasal cavities. The regurgitation of rumen contents through the mouth does occur in cattle occasionally, is abnormal, and is a dramatic event. It is most commonly associated with loss of tone of the cardia or inflammation of the cardia (see examples below).

Nasogastric regurgitation or gastric reflux occurs in the horse. Stomach contents flow into the esophagus, and usually into the nasopharynx and nasal cavities, as a result of distension of the stomach with fluid (which usually originates in the small intestine). This involuntary process is usually slow and gradual, unlike true vomiting. Gastric reflux in the horse can be elicited by nasogastric intubation. Spontaneous efflux of stomach contents is indicative of high-volume and high-pressure fluid distension of the stomach. On other occasions the presence of sequestrated gastric fluids can be confirmed only by the creation of a siphon, using the nasogastric tube to infuse a volume of fluid then disconnecting its supply in order to retrieve the **nasogastric reflux.**

Causes of vomiting and regurgitation include:

- Terminal vomiting in horses with acute gastric dilatation
- 'Vomiting' in cattle is really *regurgitation* of large quantities of

rumen contents through the mouth. Causes include:
- third-stage milk fever (loss of tone in the cardia)
- arsenic poisoning (acute inflammation of the cardia)
- poisoning by plants including *Eupatorium rugosum*, *Geigeria* spp., *Hymenoxis* spp., *Andromeda* spp., *Oleander* spp., *Conium maculatum*
- veterinary administration of large quantities of fluids into the rumen (regurgitation occurs while the stomach tube is in place)
- use of a large-bore stomach tube
- cud-dropping: a special case of regurgitation usually associated with abnormality of the cardia

- Vomiting in pigs may be due to:
  - transmissible gastroenteritis
  - acute chemical intoxications
  - poisoning by the fungus *Fusarium* sp., which also causes off-feed effects suspected to be analogous to nausea in humans
- Regurgitation – in all diseases causing dysphagia or paralysis of swallowing.

DIARRHEA, CONSTIPATION AND SCANT FECES

Diarrhea and constipation are the most commonly observed abnormalities in **fecal consistency**, **composition** and **frequency of defecation**.

DIARRHEA

Diarrhea is the increased frequency of defecation accompanied by feces that contain an increased concentration of water and decrease in dry matter content. The consistency of the feces varies from soft to liquid.

Abnormalities of peristalsis and segmentation usually occur together and when there is a general increase in peristaltic activity there is increased caudal flow, resulting in a decrease in intestinal transit time and diarrhea. Because of a lack of absorption of fluid the feces are usually softer than normal, the dry matter content is below the normal range, and the total amount of feces passed per day is increased. The frequency of defecation is usually also increased. Common causes of diarrhea are:

- Enteritis, including secretory enteropathy
- Malabsorption, e.g. due to villous atrophy and in hypocuprosis (due to molybdenum excess)
- Neurogenic diarrhea as in excitement
- Local structural lesions of the stomach or intestine, including:
  - ulcer, e.g. of the abomasum or stomach
  - tumor, e.g. intestinal adenocarcinoma
- Indigestible diet, e.g. lactose intolerance in foals
- Carbohydrate engorgement in cattle
- In some cases of ileal hypertrophy, ileitis, diverticulitis and adenomatosis
- Terminal stages of congestive heart failure (visceral edema)
- Endotoxic mastitis in cattle (splanchnic congestion)
- Chronic and acute undifferentiated diarrhea in horses
- Vagus indigestion in cows causes pasty feces but bulk is reduced. These cases may be mistaken initially for other causes of diarrhea.

Malabsorption syndromes

Malabsorption syndromes are being recognized with increased frequency in monogastric farm animals. For example, in recently weaned pigs, there is villous atrophy with a resulting loss in secretory and absorptive function. Inefficient digestion originating in this way may or may not be manifested by diarrhea, but in malabsorption there is usually diarrhea. There is always failure to grow or maintain body weight, in spite of an apparently normal appetite and an adequate diet. In horses, the lesions associated with malabsorption, which may be with or without diarrhea, include villous atrophy, edema and/or necrosis of the lamina propria of the gut wall, and nodular tracts and aggregations of eosinophils indicating damage by migrating strongyle larvae. It is possible also that some cases are caused by an atypical reaction of tissue to unknown allergens (possibly helminths) and are probably an abnormal immunological response. A common accompaniment in the horse is thin hair coat, patchy alopecia and focal areas of scaling and crusting. The pathogenesis is unknown. Special tests are now detailed for the examination of digestive efficiency in the horse. These are listed in the next section under special tests. Increased venous pressure in the portal circuit caused by congestive heart failure or hepatic fibrosis also causes diarrhea.

The question of whether or not enteritis in animals causes intestinal hypermotility and increased peristalsis, resulting in diarrhea, remains unresolved. If hypermotility and increased peristalsis cause diarrhea, antimotility drugs may be indicated in some causes of acute infectious diarrhea. Current concepts on the pathophysiology of the common diarrheas associated with infectious agents (such as enterotoxigenic *Escherichia coli*) indicate that there is a net increase in the flow of intestinal fluid into the lumen and a decrease in outflow back into the systemic circulation, which causes distension of the intestine with fluid. The hydraulic effect of the distension can cause diarrhea and hypermotility is probably not necessary. In addition, because of the temporary malabsorption that exists in infectious enteritides, and the presence of infectious agents and enterotoxins in the lumen of the intestine, the emphasis should be on evacuation of the intestinal contents and not on the use of anticholinergic drugs to inhibit evacuation. Furthermore, it is unlikely that the anticholinergics will have any significant effect on the secretory-absorptive mechanisms that have been altered by an enteropathogen.

CONSTIPATION

Constipation is the **decreased frequency of defecation** accompanied by feces that contain a decreased concentration of water. The feces vary in consistency from being hard to dry and of small bulk. True constipation as it occurs in humans is usually characterized by failure to defecate and impaction of the rectum with feces. When the motility of the intestine is reduced, the alimentary transit time is prolonged and constipation or scant feces occurs. Because of the increased time afforded for fluid absorption, the feces are dry, hard and of small bulk and are passed at infrequent intervals. Constipation may also occur when defecation is painful, as in cattle with acute traumatic reticuloperitonitis.

SCANT FECES

Scant feces are small quantities of feces, which may be dry or soft. Scant feces occur most commonly in cattle with abnormalities of the forestomach or abomasum resulting in the movement of only small quantities of ingesta into the small and large intestines (**an outflow abnormality**). The details are available in Chapter 6. When there is complete intestinal stasis the rectum may be empty except for blood-tinged, thick, pasty material.

Common causes of constipation or scant feces are:

- Diseases of the forestomach and abomasum causing failure of outflow
- Impaction of the large intestine in the horse and the sow
- Severe debility, as in old age
- Deficient dietary bulk, usually fiber
- Chronic dehydration
- Partial obstruction of large intestine
- Painful conditions of the anus
- Paralytic ileus
- Grass sickness in horses
- Chronic zinc poisoning in cattle
- Terminal stages of pregnancy in cows.

ILEUS (ADYNAMIC AND DYNAMIC ILEUS)

Ileus is a state of **functional obstruction** of the intestines or failure of peristalsis.

It is also known as **paralytic ileus** or **adynamic ileus. Dynamic or mechanical ileus** is a state of physical obstruction. In paralytic ileus there is loss of intestinal tone and motility as a result of reflex inhibition. This can occur in acute peritonitis, excessive handling of viscera during surgery, and prolonged and severe distension of the intestines as in intestinal obstruction or enteritis. Ileus can also be caused by acid–base imbalance, dehydration, electrolyte imbalances such as hypocalcemia and hypokalemia, and toxemia. Ileus can affect the stomach, causing delayed gastric emptying and subsequent dilatation with fluid and gas. The effect of ileus on the intestines is to cause failure of orocaudal movement of fluid, gas and ingesta and accumulation of these substances, which results in intestinal distension and varying degrees of abdominal pain, dehydration and a marked reduction in the amount of feces. Distension of the abdomen, fluid-tinkling, fluid-splashing sounds, and pings on percussion of the abdomen are common clinical findings. Impaction of the large intestine of horses is a form of ileus.

Postoperative ileus of the large intestine is a common complication of surgical treatment for colic in the horse. The clinical findings include gastric reflux because of gastric distension with fluid, absence of or minimal intestinal peristaltic sounds, an absence of feces, abdominal pain, distended loops of intestine palpable per rectum, and varying degrees of shock and dehydration as a result of intestinal fluid sequestration and a decrease in fluid absorption. **Infarction of the intestinal wall** associated with an acute mechanical obstruction of the intestine also results in ileus. In thromboembolic colic due to verminous mesenteric arteritis in the horse, large segments of the large colon and cecum can become infarcted, resulting in irreversible ileus.

The etiology and pathogenesis of ileus in farm animals are not well understood. Sympathetic hyperactivity is thought to be a factor. The gastroileal reflex is one example of the influence of the activity of one part of the digestive tract on that of another; inhibition of gastric motility when the ileum is distended is called ileogastric reflex. Immediate cessation of all intestinal movement (adynamic ileus) follows distension of an intestinal segment, rough handling of the intestine during abdominal surgery or peritoneal irritation. Adynamic ileus operates through three pathways: general sympathetic discharge of the peripheral reflex pathway through the iliac and mesenteric plexuses, and the intramural plexuses. The treatment of ileus depends on the original cause. Physical obstruction of the intestines and torsion of the stomach must be corrected surgically. Postoperative ileus in the horse is difficult to manage and the case fatality rate is high.[2] Fluid therapy and gastric reflux decompression using a nasogastric tube are standard recommendations. Nonsteroidal anti-inflammatory drugs (NSAIDs) are used to control abdominal pain. Xylazine is contraindicated because of its depressant effect on gastric and intestinal motility.

ALIMENTARY TRACT HEMORRHAGE

Hemorrhage into the stomach or intestine is a common occurrence in farm animals. The main causes are:

- Gastric or abomasal (rarely duodenal) ulcers
- Severe hemorrhagic enteritis
- Structural lesions of the intestinal wall, e.g. adenomatosis, neoplasia
- Infestation with blood-sucking nematodes, e.g. bunostomiasis
- Local vascular engorgement or obstruction as in intussusception and verminous thrombosis.

Hemorrhage into the stomach results in the formation of **acid hematin,** which makes vomitus a dark brown color like coffee grounds, and feces have a black or very dark brown, tarry appearance (**melena**). The change in appearance of the feces caused by hemorrhage into the intestine varies with the level at which the hemorrhage occurs. If the blood originates in the **small intestine,** the feces may be **brown-black**, but if it originates in the **colon or cecum**, the blood is unchanged and gives the feces an **even red color**. Hemorrhage into the **lower colon and rectum** may cause the voiding of feces containing or consisting entirely of **clots of whole blood**.

Hemorrhage into the pharynx is unusual, but when it occurs the blood may be swallowed and appear in the feces or vomitus. If there is any doubt about the presence of blood in the feces or vomitus, biochemical tests should be performed. The hemorrhage may be sufficiently severe to cause anemia and, in particularly severe cases, acute peripheral circulatory failure. In cattle the most sensitive test is one using a dilute alcoholic solution of guaiac as the test reagent. It is capable of detecting a daily blood loss into the abomasum of as small a volume as 70 mL. Transit time of blood from abomasum to rectum in normal cows varies from 7–19 hours.

ABDOMINAL PAIN

The pain associated with diseases of the abdominal viscera causes similar signs regardless of the viscus or organ involved and careful clinical examination is necessary to locate the site of the lesion. The manifestations of abdominal pain vary with the species, horses being particularly sensitive, but comprise largely of abnormalities of behavior and posture. Pain as a systemic state is presented in general terms in Chapter 2, including its effects on body systems and methods for its detection.

Readily identifiable syndromes of abdominal pain referable to the alimentary tract include the following.

Horses

- Acute pain: Pawing, flank-watching, rolling
- Subacute pain: Lesser degree of flank-watching, often excessive pawing, lying down frequently without rolling, stretching out as if to urinate, males may extrude the penis, walking backwards, dog-sitting posture, lying on back, impulsive walking
- Peritoneal pain: Rigidity of the abdominal wall, pain on palpation.

Cattle

- Acute pain: Downward arching of back with treading of the hind feet, lying down (rolling is uncommon). Calves will lie down and bellow with severe abdominal pain, as in abomasal torsion
- Subacute pain, including peritoneal pain: Back arched upwards, grunting on walking or lying down, grunting on deep palpation of the abdomen, immobility.

DIFFERENTIAL DIAGNOSIS

The disease states likely to be mistaken for the above categories of alimentary tract pain are:

- Acute pain: Paresthesia, e.g. in photosensitive dermatitis of cows; pleuropneumonia in the horse; uterine torsion in the mare and cow; snakebite in horses; urticaria as in milk allergy in cows; renal and urethral colic; compulsive walking, e.g. in hepatic disease; lead poisoning; dysuria or obstruction of urinary tract generally; laminitis and lactation tetany in mares
- Subacute pain: Encephalopathy, possibly hepatic insufficiency

COMMON CAUSES OF ALIMENTARY TRACT PAIN

Horses

- Acute pain: All causes of intestinal obstruction, gastric dilatation, enteritis generally, colitis X, rarely salmonellosis
- Subacute pain: Thromboembolic colic, impaction of the large intestine, ileal hypertrophy.

Cattle

- Acute pain: Intestinal obstruction, especially by phytobezoars; poisoning by kikuyu grass, *Andromeda* sp., *Oleander* sp., water hemlock (*Cicuta* sp.)
- Subacute pain: Traumatic reticuloperitonitis and peritonitis generally. Abomasal volvulus.

TENESMUS

Tenesmus, or persistent straining, is common in many diseases of the organs of the pelvic cavity; therefore it is not necessarily a diagnostic sign of disease in the lower alimentary tract. It is sometimes associated with frequent defecation caused by neurological stimulation of peristalsis. Common causes of tenesmus are listed by species below.

Cattle

- Lower alimentary tract disease, e.g. colitis and proctitis caused by coccidiosis
- Genital tract disease, e.g. severe vaginitis, retained placenta
- Estrogen toxicity in steers, e.g. estrogen implantation, fusariotoxicosis
- 4-aminopyridine poisoning, methiocarb poisoning
- Lower spinal cord lesions – spinal cord abscess, rabies
- Idiopathic.

Horses

- Tenesmus does not usually occur except during parturition.

Pigs

- Constipation in parturient sows; also dystocia.

SHOCK AND DEHYDRATION

Acute rapid distension of the intestine or stomach causes reflex effects on the heart, lungs and blood vessels. The blood pressure falls abruptly, the temperature falls below normal and there is a marked increase in heart rate. In acute intestinal accidents in horses that terminate fatally in 6–12 hours, shock is the major cause of death. There appears to be some species difference in the susceptibility to shock because similar accidents in cattle rarely cause death in less than 3–4 days; acute ruminal tympany is an exception and may exert its effects rapidly, causing death in a very short time after its onset. Less severe distension, vomiting and diarrhea cause clinically recognizable dehydration and abnormalities of electrolyte concentration and acid–base balance. Determination of the relative importance of shock and dehydration in a particular case at a particular time is one of the challenges in gastroenterology. The subject is considered in detail under the heading of equine colic and under enteritis.

ABDOMINAL DISTENSION

Distension of the abdomen is a common manifestation of disease of the alimentary tract. Generally, abdominal distension associated with the alimentary tract is caused by **distension of viscera** with **gas** or **fluid**. The degree of abdominal distension depends on the viscera that are distended, the species involved and the age of the animal. Abdominal distension is most pronounced when large viscera of adult cattle and horses are distended. Distension of the small intestines in adult cattle and horses may not be detectable clinically. On the other hand, distension of the small intestine with fluid in calves and foals often causes noticeable abdominal distension.

Occasional cases of abdominal distension are due to **pneumoperitoneum**, which usually follows abdominal surgery. In ruminants the most common causes are distension of the rumen, abomasum, cecum and large intestine, the details of which are presented in Chapter 6. Abdominal distension in horses and pigs is usually due to distension of the large intestine. Gastric dilatation of the horse does not cause abdominal distension. Ascites is a cause in all species.

Abdominal distension may be symmetrical, asymmetrical or more pronounced dorsally or ventrally on one or both sides. The severity can vary from mild and barely detectable to so severe that the skin over the abdominal wall has sufficient tension that it cannot be picked up or 'tented'. Determination of the cause of the distension requires careful examination of the abdomen by inspection, palpation, percussion and simultaneous auscultation. Rectal palpation is used to determine the location and nature of distended viscera. Diseases of other body systems that cause abdominal distension and must be considered in the differential diagnosis include advanced pregnancy and hydrops allantois.

The alimentary tract diseases of simple-stomached animals in which abdominal distension may be a manifestation are:

- Intestinal tympany – due to excessive gas production caused by abnormal fermentation in the large intestine of horses and pigs
- Obstruction of the large intestine – in horses and pigs as a result of their torsion or miscellaneous constrictions caused by adhesions, usually as a result of peritonitis
- Retention of the meconium – in foals. This is often accompanied by severe distension of the colon and abdomen.

Obstruction of the small intestine may cause abdominal distension but not to the degree that occurs in distension of the large intestine. In all the above diseases, acute abdominal pain is common.

ABNORMAL NUTRITION

Failure of normal motor, secretory, digestive or absorptive functions causes impairment of nutrient supply to body tissues. Inanition or partial starvation results and the animal fails to grow, loses body weight or shows other signs of specific nutritional deficiencies. Ancillary effects include decreased appetite when gut motility is decreased; in many cases where motility is increased and there is no toxemia, the appetite is increased and may be voracious.

Special examination

The general aspects of the clinical examination of the alimentary tract and abdomen of farm animals are described in Chapter 1 under Clinical examination. Some additional or special examination techniques and procedures are included here.

NASOGASTRIC INTUBATION

RUMEN OF CATTLE

Examination of the rumen contents is often essential to assist in determination of the state of the rumen environment and digesta. Passage of a stomach tube into the rumen will determine the patency of the esophagus and if there is increased intraruminal pressure associated with a frothy or free-gas bloat. In a free-gas bloat, large quantities of gas are usually released within a minute. In a frothy bloat, the ruminal end of the tube may become occluded by the froth and very little if any gas is released. Moving the tube back and forth within the rumen and blowing air into the tube to clear the ruminal end may result in the release of some gas.

When the tube is in the rumen, some **rumen juice** can be siphoned or pumped out and collected in an open beaker for field and laboratory analysis. The **color**, depending on the feed to a limited extent, will be green, olive-green or brown-green. In cattle on **pasture** or being fed good quality hay, the color is **dark green**. When **silage or straw** is the diet the color is **yellow-brown**. In grain overload the color is **milky-gray**, and in rumen stasis of long duration with putrefaction, the color is **greenish-black**. The **consistency of the rumen contents** is normally slightly viscid, and watery rumen content is indicative of inactive bacteria and

protozoa. **Excess froth** is associated with frothy bloat as in primary ruminal tympany or vagus indigestion. The **odor** of the rumen contents is normally aromatic and, although somewhat pungent, not objectionable to the nose. A **moldy, rotting odor** usually indicates protein putrefaction, and an intensely sour odor indicates an excess of lactic acid formation, due to grain or carbohydrate engorgement. The **pH of the rumen juice** varies according to the type of feed and the time interval between the last feeding and taking a sample for pH examination. The normal range, however, is between 6.2 and 7.2. The pH of rumen juice should be examined immediately after the sample is obtained, using a wide range pH (1–11) paper. **High pH values (8–10)** will be observed when putrefaction of protein is occurring in the rumen or if the sample is mixed with saliva. Low pH values (4–5) are found after the feeding of carbohydrates. In general, a **pH below 5** indicates **carbohydrate engorgement;** this pH level will be maintained for between 6–24 hours after the animal has actually consumed the carbohydrate diet. Microscopic examination of a few drops of rumen fluid on a glass slide with a low-power field will reveal the level of protozoon activity. Normally 5–7 protozoons are active per low-power field. In lactic acidosis the protozoa are usually absent or a few dead ones are visible.

DECOMPRESSION OF DISTENDED RUMEN

In adult cattle with severe abdominal distension due to gross distension of the rumen it is difficult, if not impossible, to assess the status of the abdomen. To determine if the rumen is distended and/or to relieve the pressure a large-bore stomach tube should be passed (Colorado Kingman Tube: 2 m long and 3 cm inside diameter). In vagus indigestion, the rumen may be grossly distended with fluid contents, which will gush out through a large-bore tube. In some cases 100–150 L of rumen contents may be released. If no contents are released the contents may be frothy or mushy and the rumen end of the tube will plug almost instantly. Rumen lavage may then be attempted using a water hose to deliver 20–40 L of water at a time followed by back drainage using gravity flow. After the rumen is partially emptied it is usually possible to more accurately assess the rumen and the abdomen.

DECOMPRESSION OF THE HORSE'S STOMACH

Attempts to pass a nasogastric tube in the horse will usually detect complete or partial obstruction of the esophagus. In gross distension of the stomach in the horse, there is an immediate rush of fluid contents as soon as the cardia is passed (**gastric reflux**). The technique of gastric decompression is therapeutic and diagnostic. Gastric distension is a highly distressing feature of some colic cases and the mere pain relief of gastric decompression facilitates the clinical examination. The retrieval of significant volumes (2 L or more) of sequestrated gastric fluid is also an extremely specific indicator of intestinal obstruction, especially small intestinal obstruction, and a reasonably specific indicator that surgical intervention is necessary.

MEDICAL IMAGING

RADIOGRAPHY

Because of their large size, and the presence of substantial amounts of gas in the large intestine, abdominal radiography has not been used routinely as a diagnostic aid in mature horses with abdominal pain. Similarly, in mature cattle the sheer size of the abdomen and the gas in the rumen has not favored abdominal radiography except for identifying the presence of metal objects in the reticulum. **Esophageal radiography** is, however, useful for the diagnosis of disorders of swallowing in horses.

Foals, calves and small horses are too small to be palpated per rectum, and abdominal radiography, with and without contrast media, has been used diagnostically in colic of foals. A standard lateral abdominal radiography is a valuable diagnostic aid in the foal with colic.[4] The site of the lesion, whether gastric, small or large intestinal, or a combination of all three, can be determined from the radiographs. The **sensitivity of radiography** in detecting gastrointestinal lesions in neonatal foals was found to be 96%; the specificity was 71%.[4]

Knowledge of the radiographic appearance of the normal neonatal abdomen is important before lesions can be reliably detected. The standing lateral radiographic of the normal abdomen of the neonatal foal is characterized by:

- A gas cap over fluid and ingesta in the stomach
- Small collections of gas in the small intestine in the cranial and mid-central abdomen
- Gas caps over fluid and ingesta in the cecum and large colon, seen in the caudodorsal abdomen
- Small amounts of gas in the small colon and inconsistent gas in the rectum, seen at the pelvic inlet.

Abdominal radiography has also been used for the diagnosis of enterolithiasis and sand accumulation as causes of colic.[3] The technique provides a high positive-predictive value and is cost-effective in high-prevalence areas.

ABDOMINAL ULTRASONOGRAPHY

Abdominal ultrasonography has been used to identify small intestine intussusceptions, large colon displacements, abdominal viscera and neoplasms. The technique may require only several minutes in the hands of an experienced clinician.

Horse

Abdominal ultrasonography is a diagnostic aid that is used for evaluation of equine colic and to assist in differentiation of medical from surgical colics.

It is accurate in identifying horses with abnormal small intestines.[5] Ultrasonographic findings of edematous small intestine without motility provides an indication of primary small-intestine disease (obstruction or strangulation) and justifies surgical intervention. Detecting increased thickness of the wall of the large intestine during ultrasonography is a reproducible and accurate preoperative test for large-colon torsion in horses with surgical colic localized to the large colon.[6] Strangulating lipomas and epiploic foramen entrapments were diagnosed more often than any other primary small intestine lesion. Detection of distended or edematous small intestine by rectal palpation provided a sensitivity of 50%, a specificity of 98% and a positive predictive value of 89% for small intestine strangulation obstructions.[5] The duodenum of the horse can be evaluated by ultrasonography.[7] Normally it does not contain any gas and the accumulation of fluid and gas associated with colic may be useful. The technique has been used to detect intestinal sand accumulations.[8] Gastrointestinal activity patterns have been evaluated in healthy horses using B mode and Doppler ultrasonography.[9] The anatomy and biometric analysis of the thoracic and abdominal organs in healthy foals from birth to age 6 months have been evaluated with ultrasonography.[10]

Cattle

Abdominal ultrasonography is an ideal diagnostic aid for the investigation of gastrointestinal diseases, the most common of which include traumatic reticuloperitonitis, left and right displacement of the abomasum, ileus of the small intestine, and dilatation and displacement of the cecum.[11,12] The various divisions of the small intestine can be differentiated from one another with the exception that the ileum cannot be differentiated from jejunum.[13] In normal cows, in which the intestine is full of ingesta, all parts of the intestine have a relatively large diameter.

In cows with ileus, the loops of intestine proximal to the ileus are distended and those distal to the ileus are empty.

ENDOSCOPY

GASTROENTEROSCOPY

Fiberoptic gastroduodenoscopy is a practicable procedure in a sedated horse that has had no feed for 12–24 hours. A 275 × 13.5 cm fiberoptic instrument is passed via a nostril to the stomach, which is then distended with air. The control of the objective of the endoscope is quite difficult and entry into the pylorus particularly so, so that examination of the duodenum is not possible in all horses.

LAPAROSCOPY

In this procedure a laparoscope is passed through an incision in the abdominal wall of either the left or right paralumbar fossa.[14] Feed must be withheld for 36 hours, analgesia is provided during the procedure, and abdominal insufflation with carbon dioxide is required in order to separate the viscera for viewing. Laparoscopy in standing horses is a valuable diagnostic aid for examination of the structures in the dorsal regions of the abdomen. In the standing horse, the anatomic structures of importance that can be viewed in the left half of abdomen are the hepatic duct, left lateral and quadrate lobes of the liver, stomach, left kidney with associated nephrosplenic ligament, segments of the jejunum, descending colon and ascending colon, left side of the male and female reproductive tracts, urinary bladder, vaginal ring and mesorchium. The important structures observable in the right side of the abdomen are the common hepatic duct, left lateral, quadrate and right lobes of the liver, caudate process of the liver, stomach, duodenum, right dorsal colon, epiploic foramen, omental bursa, right kidney, base of the cecum, segments of jejunum, descending colon and ascending colon, urinary bladder, right half of the male and female reproductive tracts, and rectum.[14]

In the dorsally recumbent horse under general anesthesia, with laparoscopy the main structures of diagnostic relevance in the caudal region of the abdomen are the urinary bladder, mesorchium, ductus deferens (left and right), left and right vaginal rings, insertion of the prepubic tendon, random segments of jejunum and descending colon, the pelvic flexure of the ascending colon, body of the cecum and cecocolic fold. The main structures observed in the cranial region of the abdomen are the ventral surface of the diaphragm, falciform ligament and round ligaments of the liver, ventral portion of the left lateral, left medial, quadrate and right lateral lobes of the liver, spleen, right and left ventral colons, sternal flexure of the ascending colon, apex of the cecum, and stomach.[15] Alterations in cardiovascular and respiratory functions in response to the pneumoperitoneum and various positional changes indicated a need for continuous and thorough anesthetic monitoring and support.

EXPLORATORY LAPAROTOMY (CELIOTOMY)

An exploratory laparotomy is useful for palpating and inspecting the abdominal viscera as a diagnostic aid in cattle, sheep and horses of all ages. Cost and time are important factors but if abdominal disease is suspected and other diagnostic techniques cannot identify the location and nature of the abnormality, a laparotomy is highly desirable.

TESTS OF DIGESTION AND ABSORPTION

Digestion and absorption of nutrients are complex, interrelated functions of the gastrointestinal tract. Failure in one or more of normal motility, enzymic digestion of food and absorption of simple sugars, fat and protein by the small intestine can result in inadequate assimilation of nutrients from the gastrointestinal tract. Tests of small intestinal digestion, absorption or both have been devised for use in monogastrics. These tests take advantage of the rapid appearance in blood of products of digestion, or of compounds that are readily absorbed without digestion.

Indications for these tests include:

- Weight loss of undetermined cause that is suspected to be due to failure of absorption of food by the small intestine
- Diarrhea of suckling foals that is suspected to be due to failure of the foal to digest lactose (lactase deficiency)
- Suspected protein-losing enteropathy of older foals and adult horses.

Low serum protein and albumin concentrations with small intestinal disease can be due to failure of digestion of proteins and absorption of amino acids or leakage of plasma proteins into the intestine. Regardless of the mechanism, some horses with protein-losing enteropathy have abnormal tests of intestinal digestion and absorption of sugars. **Contraindications** include the presence of obstructive lesions of the gastrointestinal tract, risk of worsening the disease process by the period of fasting required for most of the tests (such as in ponies with hyperlipemia), or known adverse reactions of the animal to any of the test substances.

Interpretation of the test is based on the concentration of the variable of interest (usually glucose or xylose) in blood over a period of time after administration of the test meal (usually by nasogastric intubation). Concentration of the metabolite or marker of interest in blood is plotted against time and the shape of the curve, highest concentration attained, time to attain the highest concentration, and elevation over baseline values (i.e. those measured immediately before administration of the test meal) is compared against values obtained from clinically normal horses or foals. Blood concentrations of glucose or xylose that are lower than expected (so called 'flat curve') can be indicative of alterations in gastrointestinal function that hinder propulsion, digestion or absorption of nutrients. Thus, tests of digestion and absorption alone rarely provided sufficient information to make a definitive diagnosis of the functional disorder. The exception to this rule is the modified lactose tolerance test in foals (see below). Interpretation of the results of oral tests of absorption is often confounded by factors that alter gastrointestinal function, such as feed withholding or enteritis, or conditions that alter removal of the test compound from blood, such as reduced insulin sensitivity. This is particularly the case for tests that depend on measurement of blood glucose concentration. Blood glucose concentrations are determined in the absorptive state by the difference in rates of absorption of glucose from the small intestine into blood and removal of glucose from blood by uptake into muscle, adipose tissue and metabolically active tissues. Conditions that enhance glucose uptake from the blood can result in low peak blood glucose concentrations, and conditions that decrease insulin sensitivity (as is seen in fat horses) can result in high blood glucose concentrations. The use of D-xylose as an indicator of small intestinal absorption is intended to avoid these effects of variable glucose disposal. Therefore, the values obtained with oral tests of absorption and digestion should be interpreted with caution and should be considered in light of all clinical and laboratory data available for the animal.

GLUCOSE ABSORPTION TEST

The oral glucose tolerance test is one of the simplest tests of small intestinal absorptive capacity to perform. However, because of the many factors that affect blood glucose concentration, including factors not related to small-intestinal absorptive capacity, results of the test can on occasion be difficult to interpret.[16] Oral glucose tolerance testing can produce

abnormal results in horses with diseases that do not involve the small intestine, such as lower motor neurone disease or polysaccharide storage myopathy. On the other hand, the oral glucose tolerance test is often used because of the ready availability of glucose for oral administration and routine nature of measurement of blood glucose concentrations.

The main indications for performing oral glucose tolerance testing include unexplained weight loss believed to be associated with gastrointestinal disease, and suspected protein-losing enteropathy. Contraindications are those listed above. In addition, care should be exercised in performing the test in horses at increased risk of laminitis, as rapid passage of unabsorbed glucose into the large colon and cecum can cause laminitis.

Horses for oral glucose tolerance testing are first fasted for 12–18 hours. Access to water should be provided. Glucose is given by stomach tube at 1 g/kg body weight (BW) of anhydrous glucose (or comparable) as a 10–20% solution in water. Blood for measurement of glucose concentration is collected immediately before, and every 30 minutes for 4–6 hours after glucose administration. Some protocols involve less frequent (hourly) collection of blood. One protocol requires collection of blood samples before and 120 minutes after administration of glucose. This last protocol is not recommended as early or delayed peaks in blood concentration are not detected. The blood glucose concentration in the normal horse increases by at least 85% (from 90 up to 180 mg/dL (5.0 to 10.0 mmol/L)) with peak blood concentrations attained 90–150 minutes after administration of glucose. Horses with partial malabsorption have increases in blood glucose concentration of 15–85% of baseline values, and horses with complete malabsorption have no increase or less than 15% increase in blood glucose concentration by 2 hours.[17] Blood concentrations of glucose in normal horses return to resting values in approximately 6 hours. The shape of the curve is affected by the horse's previous diet, the curve being much lower in horses fed on stored feeds such as hay and grain compared to horses eating pasture of clover and grass.

Horses with weight loss and complete failure of absorption of glucose are likely to have extensive infiltrative disease of the small intestine such as lymphosarcoma or granulomatous enteritis.[17] Of 25 horses with partial failure of glucose absorption, 18 (62%) had structural abnormalities of the small intestine. Clearly abnormal results of the oral glucose tolerance test therefore appear to be fairly specific for severe and widespread small-intestinal disease. Care should be taken when interpreting results that deviate only marginally from normal values.

STARCH DIGESTION TEST

A suitable test for the evaluation of gastric, small-intestinal and pancreatic function is the starch digestion test. The test relies on the presence of amylase in the small intestine with subsequent cleavage of starch into glucose, which is then absorbed into the blood. The horse is fasted for 18 hours and then given corn starch (1 kg in 4 L of water or 2 g/kg BW) by stomach tube. A pretreatment blood sample is matched with others taken at 15, 30, 60, 90 and 120 minutes and then hourly to 6 hours.

In the normal horse there is an increase in blood glucose levels of about 30 mg/dL (1.7 mmol/L) (from 90 up to 120 mg/dL (5.0–6.7 mmol/L)), with the peak occurring at 1–2 hours and the curve returned to pretreatment level at 3 hours.[18] The test can be affected by the diet of the horse prior to testing.

LACTOSE DIGESTION TEST

Newborn animals rely on ingestion of milk sugar (lactose) as an important source of energy until weaning. Lactose is digested in the proximal small intestine by lactase, a disaccharidase present in the brush border of intestinal epithelial cells that cleaves lactose into glucose and galactose. Loss of small-intestinal production of lactase, such as occurs in some bacterial and viral enteritides including rotavirus infection, results in failure to cleave lactose and passage of the sugar to the hind gut. Fermentation of lactose in the hind gut causes acute and sometimes severe osmotic diarrhea. A prime indication for the oral lactose tolerance test is therefore acute diarrhea in neonates being fed milk. The test not only has diagnostic usefulness because a positive test (i.e. demonstration of lactose intolerance) provides a clear indication for feeding lactose-free milk or providing supplemental lactase in the animal's diet.

An oral lactose digestion test has been devised for foals. Lactose (1 g/kg BW) is given by stomach tube in a 20% solution to a foal that has been fasted for 2–4 hours. In foals and young horses up to 3 years of age there is a rise in blood glucose levels from 86 ± 11 mg/dL (4.8 ± 0.1 mmol/L) up to 153 ± 24 mg/dL (8.5 ± 1.3 mmol/L), with a peak achieved in 90 minutes, and the level returns to pretreatment levels in 5 hours. In foals of 1–12 weeks of age the plasma glucose concentration should rise by at least 35 mg/dL (1.9 mmol/L) and peak within 40 minutes of the administration of the lactose. With this test no changes in blood sugar levels occur in horses over 4 years of age. Instead there is abdominal discomfort followed by diarrhea, with feces the consistency of cow feces for the next 24 hours. Sucrose and maltose are readily digested by the intestine of the adult horse, but not by newborn foals. Maximum levels of the relevant intestinal disaccharidases (sucrase and maltase) are not achieved until 7 months of age. The oral lactose digestion test is likely to be of value as a monitor of epithelial damage in young horses. In humans the ability to hydrolyze lactose is one of the first functions of the intestinal mucosa to be lost where there is epithelial damage in the gut. It is also one of the last functions to return in the recovering patient. The loss of intestinal lactase may be the pathogenetic basis of the diarrhea that occurs in rotavirus infections in neonates. Lactase digestion is impaired in calves with mild diarrhea.[19] Calves with acute diarrhea are in a catabolic state and respond with a larger increase in plasma glucose concentration to a given amount of glucose than do healthy calves.

A modification of the oral lactose tolerance test in foals includes a second evaluation in foals in which there is failure of blood glucose concentrations to increase by the appropriate amount after oral administration of lactose. At least 8 hours after the first test, foals are fed a meal of lactose-free milk, or of milk to which lactase has been added. Blood glucose concentrations are measured and an increase of at least 35 mg/dL (1.9 mmol/l) is interpreted as evidence of lactase deficiency. Such animals can then be maintained on a diet of lactose-free milk. Diarrhea usually resolves in 24 hours, but returns within hours of feeding milk containing lactose.

XYLOSE ABSORPTION TEST

D-xylose is used to evaluate small intestinal absorptive function because it is not metabolized by tissues, which is an advantage over the oral glucose tolerance test. D-xylose absorbed from the intestinal tract is excreted unchanged in the urine within 15 hours of dosing.[20] Concentrations of D-xylose in blood are therefore dependent only upon the rate of absorption from the intestine and rate of excretion into the urine. However, the compound is more expensive than glucose and measurement of D-xylose in blood requires a particular analysis that might not be readily available. Indications for the test are the same as those for the oral glucose tolerance test described above.

D-xylose, at a dose rate of 0.5 g/kg BW as a 10% solution, is administered by stomach tube after a starve of 18 hours.[21]

A maximum blood xylose level of 30 mg/dL (2.0 mmol/L) at 1.5 hours is a normal result in adult horses. In normal foals the peak blood concentration of xylose is reached in 30–60 minutes and the level attained varies with age, being highest (47 mg/dL (3.14 mmol/L)) at 1 month of age and lowest (19 mg/dL (1.25 mmol/L)) at 3 months (the pretreatment reading should be zero). In abnormal horses the xylose curve is flat (a peak of 7–13 mg/dL (0.5 mmol/L) at 60–210 minutes) contrasted with a peak of 20 mg/dL (1.3 mmol/L) at 60 minutes in normal horses. As an initial checking test, one postdosing sample at 2 hours is recommended.

Interpretation of the test is influenced by the customary diet of tested animals and feed deprivation. Horses receiving a high energy diet have a lower absorption curve than horses on a low energy diet. The test is also affected by the duration of deprivation of feed.[20] In mares deprived of feed for 72 and 96 hours, the rate of D-xylose absorption and the maximum concentrations of D-xylose in plasma were reduced.[22] For example, apparent low absorption can be caused by increased transit time through the gut, due perhaps to excitement.

Low blood concentrations of xylose occur in horses with small intestinal infiltrative disease, such as lymphosarcoma or granulomatous enteritis.[20] The test appears to be quite specific (low false-positive rate) for small intestinal disease, but the sensitivity (false-negative rate) is unknown.

A D-xylose absorption curve has been determined for cattle. The xylose (0.5 g/kg BW) is deposited in the abomasum by abomasocentesis, and a peak of blood glucose is attained in about 90 minutes.

SUCROSE ABSORPTION TEST

The sucrose absorption test differs from the other tests in this section in that abnormal results are associated with detection of sucrose in blood or urine of horses. Sucrose is not normally absorbed intact – it is usually cleaved by disaccharidases in the small intestine into glucose and fructose, which are then absorbed. Intact sucrose is absorbed across compromised gastric mucosa and detection of sucrose in blood or urine indicates the presence of gastric ulceration, as mammals neither synthesize nor metabolize sucrose.[23,24] The sucrose absorption test involves administration of 250 g of sucrose to an adult horse that has been fasted overnight. Blood samples for measurement of serum sucrose concentration are collected at 0, 15, 30, 45, 60 and 90 minutes after dosing. Alternatively, a urine sample is collected 2 hours after dosing (the bladder must be emptied immediately before dosing). Peak serum sucrose concentrations occur 45 minutes after administration and peak values correlate with the severity of gastric ulceration. Horses with minimal lesions have serum sucrose concentrations of 103 pg/μL, whereas horses with the most severe lesions have concentrations of 3400 pg/μL.[24]

RADIOACTIVE ISOTOPES

A technique used for determining whether a protein-losing enteropathy is present is based on the examination of feces for radioactivity after the intravenous administration of a radioactive agent. $^{51}Cr^{13}C$-labeled plasma protein has been used for this purpose. Similarly, administration of radioactively labeled leukocytes reveals the presence of small-intestinal inflammatory disease in horses.[4,25] The test is quite specific, in that false-positive tests are uncommon, but not very sensitive.

ABDOMINOCENTESIS FOR PERITONEAL FLUID

Peritoneal fluid reflects the pathophysiological state of the parietal and visceral mesothelial surfaces of the peritoneum. Collection of a sample of peritoneal fluid is a useful aid in the diagnosis of diseases of the peritoneum and the abdominal segment of the alimentary tract.[22] It is of vital importance in horses in the differential diagnosis and prognosis of colic and in cattle in the diagnosis of peritonitis.

EQUINE AND BOVINE PERITONEAL FLUID

Normal peritoneal fluid is a transudate with properties as summarized in Tables 5.1 and 5.2. It has functions similar to those of other tissue fluids. It contains mesothelial cells, lymphocytes, neutrophils, a few erythrocytes and occasional mono-

Table 5.1 Guidelines for the classification and interpretation of bovine peritoneal fluid

Classification of fluid	Physical appearance	Total protein g/dL	Specific gravity	Total RBC × 10^6/μl	Total WBC × 10^6/μl	Differential WBC count	Bacteria	Particulate matter (plant fiber)	Interpretation
Normal	Amber, crystal clear 1–5 mL per sample	0.1–3.1 (1.6) Does not clot	1.005–1.015	Few from puncture of capillaries during sampling	0.3–5.3	Polymorphonuclear and mononuclear cells, ratio 1:1	None	None	Increased amounts in late gestation, congestive heart failure
Moderate inflammation	Amber to pink, slightly turbid	2.8–7.3 (4.5) May clot	1.016–1.025	0.1–0.2	2.7–40.7 (8.7)	Nontoxic neutrophils, 50–90%. Macrophages may predominate in chronic peritonitis	None	None	Early stages of strangulation, destruction of intestine; traumatic reticuloperitonitis; ruptured bladder; chronic peritonitis
Severe inflammation	Sero-sanguineous, turbid, viscous 10–20 mL per sample	3.1–5.8 (4.2) Commonly clots	1.026–1.040	0.3–0.5	2.0–31.1 (8.0)	Segmented neutrophils, 70–90% Presence of (toxic) degenerate neutrophils containing bacteria	Usually present	May be present	Advanced stages of strangulation obstruction; acute diffuse peritonitis; perforation of abomasal ulcer; rupture of uterus, stomachs or intestine

Table 5.2 Characteristics of equine peritoneal fluid in selected diseases or horses

Disease	Protein concentration	Total nucleated cell count (TNCC)	Cytological comments	Other variables	Coments
Normal horse	< 2.1 g/dL < 21 g/L	< 9×10^9 cells/L < 9×10^3 cells/μL (TNCC is usually substantially lower in clinically normal horses)	Approximately 50% each of nondegenerate neutrophils and mononuclear cells	Lactate < 1 mmol/L (always < plasma (lactate)); Glucose < 2.0 mmol/L different from blood glucose; pH > 7.45; fibrinogen < 300 mg/dL (3 g/L) Creatinine = serum creatinine No red blood cells	Clear and slightly yellow. Not malodorous. Culture does not yield growth
Normal late-gestation mare	< 2.5 g/dL < 25 g/L	< 0.9×10^9 cells/L < 900 cells/μL	< 40% neutrophils. No degenerative changes. < 20% lymphocytes	Fluid usually readily obtained. Clear and slightly yellow	
Normal post-partum (< 7 d) mare	< 2.5 g/dL < 25 g/L	< 5.0×10^9 cells/L < 5.0×10^3 cells/μL	< 50% neutrophils. No degenerative changes. < 10% lymphocytes	Fluid usually readily obtained. Clear and slightly yellow	
Dystocia but clinically normal mare (1 d)	< 2.5 g/dL < 25 g/L	2.7×10^9 (3.9) cells/L* 2.7×10^3 (3.9) cells/μL	50–90% nondegenerate neutrophils, 40% mononuclear cells and 10% lymphocytes	Fluid clear and yellow. Essentially normal fluid with small increases in TNCC and protein concentration	
Dystocia and clinically abnormal mare (uterine rupture, vaginal tear)	4.4 (1.3) g/dL* 44 (13) g/L	27×10^9 (35) cells/L* 27×10^3 (35) cells/μL	70–100% neutrophils, some of which are degenerate, <10% mononuclear cells and <10% lymphocytes	Increased red blood cell count.	Fluid yellow or serosanguinous and cloudy. Can be malodorous. Culture can yield variety of bacteria. Red cell count in mares with middle uterine artery rupture is high with normal TNCC
Peritonitis, septic	5.2 (4.0–6.0) g/dL† 50 (40–60) g/L	131 (7–700) × 10^9 cells/L† 131 (7–700) × 10^3 cells/μL	Almost all neutrophils, many of which have degenerative changes. Some neutrophils contain bacteria in many cases. Plant material with rupture of intestine	pH < that of blood; glucose < blood (difference < 2.0 mmol/L or 50 mg/dL); peritoneal glucose < 30 mg/dL (1.5 mmol/L); fibrinogen > 200 mg/dL (2.0 g/L)	Fluid usually dark yellow, brown, or serosanguinous. Can be green if severe rupture of intestine or stomach. Cloudy. Malodorous. Culture yields bacteria
Peritonitis, nonseptic (e.g. nonstrangulating, nonischemic obstructive lesion of the bowel)	2.7 (0.7–4.9) g/dL† 27 (7–49) g/L	13 (0.4–516) × 10^9 cells/L† 13 (0.4–516) × 10^3 cells/μL	Mostly neutrophils (> 50%). Nondegenerate. No bacteria detected. No plant or foreign material	No abnormalities. pH ≥ that of blood	Fluid yellow and clear. Not malodorous. No bacteria isolated on culture
Strangulating intestinal lesion or ruptured intra-abdominal viscus	5.2 (4.0–6.0) g/dL† 50 (40–60) g/L	131 (7–700) × 10^9 cells/L† 131 (7–700) × 10^3 cells/μL	Almost all neutrophils, many of which have degenerative changes. Some neutrophils contain bacteria in many cases. Plant material with rupture of intestine	Lactate 8.5 ± 5.5 mmol/L	Serosanguinous fluid. Cloudy if ruptured.
Nonstrangulating obstruction				Lactate 2.1 ± 2.1 mmol/L	
Peritonitis due to *Actinobacillus equuli*	2.5–8.4 g/dL 25–84 g/L	46–810 × 10^9 cells/L 46–810 × 10^3 cells/μL	> 80% neutrophils most of which do not have signs of degeneration. Low numbers of Gram-negative pleomorphic rods. both intra- and extracellular		Cream, orange, brown or red fluid. Turbid. Not malodorous. Growth of *Actinobacillus equuli* on culture
Intra-abdominal abscess	> 2.5 g/dL > 25 g/L	> 10×10^9 cells/L > 10×10^3 cells/μL	> 80% nondegenerate neutrophils. Usually no bacteria detected on Gram stain		Yellow to white. Slightly cloudy. Culture will occasionally yield x causative bacteria (usually *Streptococcus equi*)

Table 5.2 (Cont'd) Characteristics of equine peritoneal fluid in selected diseases of horses

Disease	Protein concentration	Total nucleated cell count (TNCC)	Cytological comments	Other variables	Coments
Hemoperitoneum	3.2–6.3 g/dL 32–63 g/L	< 10×10^9 cells/L < 10×10^3 cells/μL	Differential similar to blood. Mostly nondegenerate neutrophils. Erythrophages and hemosiderophages as hemorrhage resolves	High red cell count ($2.4–8.6 \times 10^{12}$ cells/L, $2.4–8.6 \times 10^6$ cells/μL)	Serosanguinous to frankly bloody
Intra-abdominal neoplasia (lymphosarcoma, gastric squamous cell carcinoma)	< 2.5 g/dL < 25 g/L	< 10×10^9 cells/L < 10×10^3 cells/μL	Abnormal cells not detected in most cases. Care should be taken not to mistake reactive lymphocytes for neoplastic lymphocytes		Clear and yellow. Often subjective assessment of increased quantity (increased ease of collection of a large quantity of fluid)
Uroperitoneum	< 2.5 g/dL < 25 g/L	<<< 10×10^9 cells/L <<< 10×10^3 cells/μL	Normal differential. Might see calcium carbonate crystals in adult horses with uroperitoneum	Creatinine > serum creatinine concentration Urea nitrogen > serum urea nitrogen concentration Potassium > serum potassium concentration	Large amount of fluid. Clear to very pale yellow. Uriniferous odor

** mean (SD). † median (range).*
Data from Frazer G. et al. Theriogenology 1997; 48:919; van Hoogmoed L. et al. J Am Vet Med Assoc 1996; 209:1280; van Hoogmoed L. et al. J Am Vet Med Assoc 1999; 214:1032; Pusterla N et al. J Vet Intern Med 2005; 19:344; Latson KM et al. Equine Vet J 2005; 37:342; Matthews S et al. Aust Vet J 2001; 79:536.

cytes and eosinophils. The following general comments apply:

- It can be examined in terms of physical characteristics, especially color, translucence, specific gravity, clotting time, biochemical composition, cell volume, cell morphology and cell type
- Examination of the fluid may help in determining the presence in the peritoneal cavity of:
  - peritonitis (chemical or infectious)
  - infarction of a segment of gut wall
  - perforation of the alimentary tract wall
  - rupture of the urinary bladder
  - leakage from the biliary system
  - intraperitoneal hemorrhage
  - peritoneal neoplasia

  The reaction of the peritoneum varies with time and a single examination can be dangerously misleading. A series of examinations may be necessary, in acute cases at intervals of as short as an hour
- A significant reaction in a peritoneal cavity may be quite localized, so a normal sample of fluid collected at one point in the cavity may not be representative of the entire cavity
- Changes in peritoneal fluid, especially its chemical composition, e.g. lactate level, may be a reflection of a systemic change. The examination of a concurrently collected peripheral blood sample will make it possible to determine whether the changes are in fact restricted to the peritoneal cavity
- As in any clinicopathological examination the results must be interpreted with caution and only in conjunction with the history and clinical findings.

Specific properties of peritoneal fluid (normal and abnormal)

Color

Normal fluid is crystal clear, straw-colored to yellow. Turbidity indicates the presence of increased leukocytes and protein, which may include fine strands of fibrin.

A **green color** suggests food material; intense orange-green indicates rupture of the biliary system. A **pink-red color** indicates presence of hemoglobin, degenerated erythrocytes, entire erythrocytes and damage to vascular system by infarction, perforation or hydrostatic pressure. A **red-brown color** indicates the late stages of necrosis of the gut wall, the presence of degenerated blood and hemoglobin and damage to gut wall with hemorrhage.

Whole blood, clear fluid streaked with blood or heavily bloodstained fluid indicate that the sample has been collected from the spleen or a blood vessel or that there is hemoperitoneum. Rupture of the uterus or bladder or dicoumarol poisoning are also possibilities.

A dark green sample containing motile protozoa with very few leukocytes and no mesothelial cells indicates that the sample has been collected from the gut lumen. Enterocentesis has little apparent clinical affect in normal horses, although an occasional horse will show a transient fever. However, puncture of a devitalized loop of intestine may lead to extensive leakage of gut contents and a fatal peritonitis. The effect of enterocentesis of normal gut on peritoneal fluid is consistently to increase the neutrophilic count, which persists for several days.

Cellular and other properties

Surgical manipulation of the intestinal tract during exploratory laparotomy or intestinal resection and anastomosis in the horse results in a significant and rapid postoperative peritoneal inflammatory reaction.[26] Manipulation of the viscera causes injury to the mesothelial surfaces. Total and differential nucleated cell counts, red blood cell numbers, and total protein and fibrinogen concentrations were all elevated on the first day after the surgery and remained elevated for up to 7 days in a study of this phenomenon.[26]

In cattle, exploratory celiotomy and omentopexy results in an increase in the total nucleated cell count by a factor of 5–8, minor increases in specific gravity and increases in total protein concentration by a factor of up to 2. These changes appear by two days after surgery and continue to increase through to day 6.[27,28]

Particulate matter in peritoneal fluid suggests either fibrin clots/strands or gut contents caused by leakage from a perforated or ruptured gut wall.

High specific gravity and **high protein content** are indicative of vascular damage and leakage of plasma protein, as in peritonitis or mural infarction.

The **volume** and viscosity of fluid varies. A normal flow is 1–5 mL per sample. A continuous flow with 10–20 mL per sample indicates excess fluid due to

ruptured bladder or ascites (clear yellow), acute diffuse peritonitis (yellow, turbid), infarction or necrosis of gut wall (thin, red-tinged). The higher the protein content, as the peritoneal fluid shifts from being a transudate to an inflammatory exudate, the higher the viscosity becomes. Highly viscous fluid may clot.

Cells

A rapid staining method, using a modified Wright's stain, gives a stained slide ready for examination within 5 minutes. The value of the technique is in indicating the number of leukocytes and other cells present, and in differentiating the types of cell.

An **increase in total white cell count** of the fluid including a disproportionate number of polymorphonuclear cells indicates acute inflammation, which may have an infectious origin or else be sterile. An increase in mononuclear phagocytes from the peritoneum is an indication of chronic peritonitis. **Degenerate and toxic neutrophils** suggest the probability of infection being present.

An increase in the number of **mesothelial cells** with the distinctive presence of actively dividing mitotic figures suggests neoplasia.

Bacteria found as **phagocytosed inclusions in leukocytes,** or by culture of fluid, indicate an infective peritonitis, which may arise by hematogenous spread, in which case the infection is likely to be a specific one. If there has been leakage from a peritoneal abscess the same comment applies, but if there is leakage through a segment of devitalized or perforated bowel wall there is likely to be a mixed infection and possibly particulate matter from bowel contents.

Entire erythrocytes, often accompanied by some hemoglobin, indicate either hemoperitoneum, in which case there should be active phagocytosis of erythrocytes, or that the sample has been inadvertently collected from the spleen. The blood is likely to be concentrated if there has been sufficient time for fluid resorption across the peritoneum. Splenic blood has a higher packed cell volume (PCV) also, but there is no erythrophagocytosis evident in the sample. A **PCV of less than 5%** in peritoneal fluid suggests extravasation of blood from an infarcted or inflamed gut wall; one of more than 20% suggests a significant hemorrhage.

Abdominocentesis in horses

In the horse the recommended site for paracentesis is on the ventral midline, 25 cm caudal to the xiphoid (or midway between the xiphoid and the umbilicus). Following surgical preparation and subcutaneous infiltration of an anesthetic, a stab incision is made through the skin and subcutaneous tissues and into the linea alba. A 9 cm long blunt-pointed bovine teat cannula, or similar metal catheter, with the tip wrapped in a sterile swab to avoid blood and skin contamination, is inserted into the wound and manipulated until the incision into the linea alba can be felt. With a quick thrust the cannula is pushed through the linea alba into the peritoneal cavity. A 'pop' is often heard on entry into the peritoneal cavity. Failure to incise into the linea alba first will cause many cannulas to bend and break.

In most horses (about 75%) a sample of fluid is readily obtained. In others it takes a moment or two before the fluid runs out, usually spurting synchronously with the respiratory movements. Applying suction with a syringe may yield some fluid if there is no spontaneous flow. Normal fluid is clear, yellow and flows easily through an 18-gauge needle. Two samples are collected, one in a plain tube and one in a tube with an anticoagulant. In case the fluid clots readily a few drops should be placed and smeared out on a glass slide and allowed to dry for staining purposes.

In peritonitis, the total leukocyte count will increase markedly, but wide variation in the total count can occur between horses with similar conditions, and in the same horse within a period of hours. Variations are due to the nature and stage of the lesion and to the total amount of exudate in the peritoneal cavity, which has a diluting effect on the total count. Total leukocyte counts ranging from 10 000–150 000 μL have been recorded in peritonitis and in infarction of the intestine in horses. Experimentally, the intravenous injection of endotoxin into horses causes marked changes in the peripheral blood cellular components but there are no changes in the total white cell count of the peritoneal fluid.[29]

In **healthy foals** the reference values for peritoneal fluid are different than in adult horses.[30] The maximum peritoneal fluid nucleated cell counts in foals are much lower than in adult horses (1.5×10^9/L versus 5.0×10^9/L. Nucleated cell counts greater than 1.5×10^9/L should be interpreted as elevated.

Peritoneal fluid abnormalities in mares within a week of foaling should be attributed to a systemic or gastrointestinal abnormality not due to the foaling event.[31] The nucleated cell count, protein concentration, fibrinogen concentration and specific gravity of peritoneal fluid from recently foaled mares should be normal; however, differential cell counts may be abnormal for up to 1 week after foaling.

Risks

Abdominocentesis is not without some danger, especially the risk of introducing fecal contents into the peritoneal cavity and causing peritonitis. This appears to be of major importance only if there are loops of distended atonic intestine situated on the ventral abdominal wall. This is a common occurrence in the later stages of intestinal obstruction that is still amenable to surgery. Puncture of a devitalized loop of intestine may cause a leakage of intestinal contents and acute diffuse peritonitis, which is rapidly fatal. Penetration of a normal loop of intestine occurs often enough to lead to the conclusion that it appears to have no ill-effects. If a sample of peritoneal fluid is an important diagnostic need in a particular case and the first attempt at paracentesis causes penetration of the gut, it is recommended that the attempt be repeated, if necessary two or three times, at more posterior sites. Repeated abdominocentesis does not cause alterations in peritoneal fluid constituents and any significant changes are likely due to alterations in the disease state present.[32] The technique most likely to cause bowel penetration is the use of a sharp needle instead of the blunt cannula recommended, and forcibly thrusting the cannula through the linea alba without a prior incision. When the suggested incision is made in the linea alba, the cannula can be pushed gently through whilst rotating it.

Abdominocentesis in cattle

The choice of sites for paracentesis is a problem because the rumen covers such a large portion of the ventral abdominal wall and avoiding penetration of it is difficult. Cattle have a low volume of peritoneal fluid, and failure to obtain a sample is not unusual.[27] The most profitable sites are those that, on an anatomical basis, consist of recesses between the forestomachs, abomasum, diaphragm and liver. These are usually caudal to the xiphoid sternum and 4–10 cm lateral to the midline. Another recommended site is left of the midline, 3–4 cm medial and 5–7 cm cranial to the foramen for the left subcutaneous abdominal vein. A teat cannula similar to the one described for use in the horse is recommended but, with care and caution, a 16-gauge 5 cm hypodermic needle may also be used. The needle or cannula is pushed carefully and slowly through the abdominal wall, which will twitch when the peritoneum is punctured. When this happens the fluid will usually run out into a vial without the aid of a vacuum. However, if it does not, a syringe may be used and the needle may be moved backwards and forwards in a search for fluid, with the piston of the syringe withdrawn. A further site is the right caudoventral abdominal wall medial

to the fold of the flank, using a 3.8 cm, 15-gauge needle.[27]

In calves, a reliable technique includes the use of sedation with intravenous xylazine hydrochloride and diazepam. The animal is placed in left lateral recumbency with the right hind limb pulled dorsally and caudally. One site slightly dorsal and caudal to the umbilicus is prepared together with another site in the center of the inguinal region. The site is prepared with local anesthetic and a 14-gauge needle is introduced and directed slightly caudally and toward the midline while keeping it parallel to the inner abdominal wall once the peritoneal cavity is entered.[33] A 3.5 gauge urinary catheter (1.2 mm × 56 cm sterile feeding tube) is inserted through the needle and a 3 mL sterile syringe is attached to the catheter. Gentle suction is applied. The fluid is placed in a 2 mL tube containing tri-potassium EDTA. A 14-gauge over-the-needle catheter can also be used, followed by insertion of a 3.5 French feeding tube. If fluid cannot be obtained from the first site, the inguinal site is used using the same basic technique and with the catheter directed slightly cranially toward the midline.

Failure to obtain a sample does not preclude the possibility that peritonitis may be present: the exudate may be very thick and contain large masses of fibrin, or the peritonitis may be localized. Also, animals that are dehydrated may have less peritoneal fluid than normal. Most animals from which samples cannot be obtained, however, are in fact normal. In animals in which peritonitis is strongly suspected for clinical reasons, up to four attempts at paracentesis should be made before aborting the procedure. The fluid should be collected into an anticoagulant, preferably EDTA, to avoid clotting.

Abnormal peritoneal fluid in cattle is a highly sensitive indicator of peritoneal disease, but not a good indicator of the *nature* of the disease. The most pronounced abnormalities occur in acute diseases of the peritoneum; chronic peritonitis may be accompanied by peritoneal fluid which is almost normal.

Examination of the fluid should take into account the following characteristics:

- Large amounts (10–20 mL) of serosanguineous fluid suggests infarction or necrosis of the gut wall
- Heavily bloodstained fluid, whole blood or fluid with streaks of blood through it are more likely to result from puncture of a blood vessel or from bleeding into the cavity, as in dicoumarol poisoning or with a neoplasm of the vascular system
- The same sort of bloodstained fluid as above may accompany a ruptured uterus or bladder or severe congestive heart failure
- Large quantities of yellowish-colored turbid fluid suggests acute diffuse peritonitis. The degree of turbidity depends on the number of cells and the amount of fibrin present
- Particulate food material in the sample indicates perforation or rupture of the gut, except that penetration of the gut with the instrument during collection may be misleading. Such samples are usually heavily fecal in appearance and contain no mesothelial cells
- Laboratory examination is necessary to derive full benefit from the sample. This will include assessment of: the number and type of **leukocytes** present – the number is increased in peritonitis, neutrophils predominating in acute peritonitis and monocytes in chronic forms; the number of **erythrocytes** present; whether **bacteria** are present inside or outside the neutrophils; and **total protein** content.

The significant values for these items are included in Table 5.1.

Reference values for peritoneal fluid constituents of normal adult cattle may be inappropriate for interpretation of peritoneal fluid analysis in calves of up to 8 weeks of age.[34] The peritoneal fluid nucleated cell count and mononuclear cell counts are higher in calves, and the eosinophil counts are lower than in adult cows.

INTESTINAL AND LIVER BIOPSY

An intestinal biopsy may be obtained from an exploratory laparotomy but is costly and time-consuming. Rectal biopsy is easily done and of low cost. It is a valuable diagnostic aid for evaluating certain intestinal diseases of the horse.[35] Biopsy specimens are taken using minimal restraint and unaided by proctoscopic visualization in the standing horse. A rectal biopsy forceps is used to obtain the biopsy from the floor of the rectum approximately 30 cm proximal to the anal sphincter.

The technique for liver biopsy is presented in Chapter 7.

Principles of treatment in alimentary tract disease

Removal of the primary cause of the disease is essential but a major part of the treatment of diseases of the alimentary tract is supportive and symptomatic. This is aimed at relieving pain and distension, replacement of fluids and electrolytes, correcting abnormal motility and relieving tenesmus and reconstitution of the digestive flora if necessary. Specific treatment for individual diseases is presented with each disease throughout this book. General principles are outlined here..

RELIEF OF ABDOMINAL PAIN

The relief of abdominal pain is of prime importance from the humane aspect, to prevent the animal from self-injury associated with falling and throwing itself against a wall or other solid objects, and to allay the concerns of the owner. No single analgesic is completely satisfactory for every situation. Non-narcotic and narcotic analgesics are in general use and are discussed under the heading of pain, and under the individual diseases. The analgesics used in the important subject of equine colic are presented under that heading.

RELIEF OF DISTENSION

The relief of distension of the gastrointestinal viscera is a critical principle in order to minimize shock and to prevent rupture of the viscus. **Relief of distension of the stomach of the horse with colic is accomplished by nasogastric intubation.** Distension due tc bloat in cattle can be relieved by stomach tube or trocarization of the rumen. Relief of distension may be possible by medical means alone with the use of laxatives and purgatives when there is accumulation of ingesta without a physical obstruction. Surgical intervention is often necessary when the distension is associated with a physical obstruction. In functional distension (paralytic ileus), relief of the atony or spasm can be effected by the use of drugs such as metoclopramide. Distension due to intestinal or gastric accidents requires surgical correction.

REPLACEMENT OF FLUIDS AND ELECTROLYTES

Replacement of fluid and electrolytes lost in gastrointestinal disease is one of the most important principles of treatment. In gastric or intestinal obstruction, or when diarrhea is severe, it is necessary to replace lost fluids and electrolytes by the parenteral administration of large quantities of isotonic glucose–saline or other physiologically normal electrolyte solutions. The amount of fluid lost may be very large and fluids must be given in quantities to replace losses and to support continuing losses and maintenance requirements. In acute, severe dehydration in horses, such as occurs in acute intestinal obstruction, the amount of fluid required before and

during surgery ranges from 50–100 mL/kg BW per 24 hours. It is critical that administration of fluid be commenced at the earliest possible time because of the need to maintain homeostasis and thus ameliorate the almost impossible task of restoring animals to normal before surgery is to be attempted. Details of fluid therapy are given in the section on disturbances of water, electrolytes and acid–base balance in Chapter 2.

In young animals the need is much greater still and amounts of 100 mL/kg BW, given slowly intravenously, are commonly necessary and not excessive. The treatment of shock is also presented in Chapters 2 and 9 and includes the administration of fluids, plasma or blood and NSAIDs. The use of intravenous hypertonic saline followed by the ingestion of large quantities of water by the animal is another aspect of fluid therapy in gastrointestinal disease (see Chapter 2).

CORRECTION OF ABNORMAL MOTILITY

INCREASED MOTILITY

When motility is increased, the administration of atropine or other spasmolytics such as dipyrone or proquamezine is usually followed by disappearance of the abdominal pain and a diminution of fluid loss. Meperidine, butorphanol and pentazocine inhibit regular cyclic myoelectric activity in the jejunum.[36] There is a need for some scientific clinical investigation into the desirability of treating intestinal hypermotility, if it does exist in enteritis for example, and the efficacy of anticholinergics. Loperamide has an antidiarrheal effect in experimentally induced diarrhea in calves but the mechanism of action does not involve changes in intestinal motility.

DECREASED MOTILITY

When gastrointestinal motility is decreased, the usual practice is to administer parasympathomimetic drugs or purgatives, usually combined with an analgesic. Prokinetic drugs such as metoclopramide hydrochloride and cisapride monohydrate increase the movement of ingesta through the gastrointestinal tract.[37] They are useful because they induce coordinated motility patterns.

Metoclopramide

Metoclopramide, acting in the upper gastrointestinal tract, increases acetylcholine release from neurons and increases cholinergic receptor sensitivity to acetylcholine. It is a dopamine antagonist and stimulates and coordinates esophageal, gastric, pyloric and duodenal motor activity. It increases lower esophageal sphincter tone and stimulates gastric contractions, while relaxing the pylorus and duodenum. This results in accelerated gastric emptying and reduced esophageal reflux. The transit time of ingested material from the duodenum to the ileocecal valve is reduced, due to increased jejunal peristalsis. It has little or no effect on colonic motility. The pharmacokinetics of metoclopramide in cattle have been studied.[38]

Metoclopramide crosses the blood–brain barrier, where its dopamine antagonist activity at the chemoreceptor trigger zone can result in an antiemetic effect. It can also result in involuntary activity including tremors, restlessness and aggressive behavior characterized by charging and jumping walls. This can be reversed by the use of an anticholinergic such as diphenhydramine hydrochloride intravenously at 0.5–2.0 mg/kg BW.

Indications for metoclopramide include reflux esophagitis and gastritis, chronic gastritis associated with delayed emptying, abomasal emptying defects in ruminants, gastric stasis following gastric dilatation and volvulus surgery, and **postoperative ileus**. It is contraindicated in animals with physical obstruction of the gastrointestinal tract.

In horses, the dose is 0.125–0.25 mg/kg BW diluted in multiple electrolyte solution and given intravenously over 60 minutes.[37] It is used for stimulating equine gastric and small intestinal activity at dose rates of 0.25 mg/kg BW per hour when there is intestinal hypomotility.[39] Given as continuous intravenous infusion of 0.04 (mg/kg)/h it can decrease the incidence and severity of persistent postoperative ileus following resection and anastomosis of the small intestine in horses without serious side effects.[40]

In cattle and sheep metoclopramide is used at 0.3 mg/kg BW subcutaneously every 6–8 hours. Metoclopramide did not alter cecocolic myoelectrical activity in cattle.[41]

Cisapride

Cisapride promotes gastrointestinal motility by enhancing the release of acetylcholine from postganglionic nerve endings of the myenteric plexus. Cisapride is more potent and has broader prokinetic activity than metoclopramide by increasing the motility of the colon as well as the esophagus, stomach and small intestine.[37] It is does not have dopaminergic effects and does not have either the antiemetic or the extrapyramidal effects of metoclopramide. Cisapride is useful for the treatment of gastric stasis, gastroesophageal reflux and postoperative ileus. In horses, cisapride increases left dorsal colon motility and improves ileocecal junction coordination. The suggested dose is 0.1 mg/kg BW orally every 8 hours. Cisapride may have some value in the clinical management of cecal dilatation in cattle.[42]

Xylazine and naloxone

While **xylazine** is used for alleviation of visceral pain in horses and cattle, it is not indicated in cecal dilatation in cattle because it reduces the myoelectric activity of the cecum and proximal loop of the ascending colon.[42] **Naloxone**, a widely used opiate antagonist with a high affinity for μ receptors, is also not indicated for medical treatment of cecal dilatation when hypomotility must be reversed.

Bethanechol, neostigmine

Bethanechol is a methyl derivative of carbachol and classified as a direct-acting cholinomimetic drug. Its action is more specific on the gastrointestinal tract and urinary bladder. **Neostigmine**, a cholinesterase inhibitor, is an indirect-acting cholinergic drug with motor-stimulating activities but only on the gastrointestinal tract. Bethanechol at 0.07 mg/kg BW intramuscularly may be useful for medical treatment of cecal dilatation in cattle in which hypomotility of the cecum and proximal loop of the ascending colon must be reversed.[41] Neostigmine at 0.02 mg/kg BW intramuscularly increased the number of propagated spike sequences but they were uncoordinated.[41]

RELIEF OF TENESMUS

Tenesmus can be difficult to treat effectively. Long-acting epidural anesthesia and sedation are in common use. Combinations of xylazine and lidocaine may be used. Irrigation of the rectum with water and the application of topical anesthetic in a jelly-like base are also used.

RECONSTITUTION OF RUMEN FLORA AND CORRECTION OF ACIDITY OR ALKALINITY

When prolonged anorexia or acute indigestion occurs in ruminants, the rumen flora may be seriously reduced. In convalescence, the reconstitution of the flora can be hastened by the oral administration of a suspension of ruminal contents from a normal cow, or of dried ruminal contents, which contain viable bacteria and yeasts and the substances necessary for growth of the organisms.

The pH of the rumen affects the growth of rumen organisms, and hyperacidity, such as occurs on overeating of grain, or hyperalkalinity, such as occurs on overeating of protein-rich feeds, should be corrected by the administration of alkalinizing or acidifying drugs as the case may be.

Diseases of the buccal cavity and associated organs

DISEASES OF THE MUZZLE

The congenital defect of harelip may be contiguous with a cleft palate. Severe dermatitis with scab formation, development of fissures, and sloughing and gangrene of the skin of the muzzle are common lesions in cattle affected with photosensitive dermatitis, bovine malignant catarrh, bovine virus diarrhea and rinderpest.

In sheep severe lesions of the muzzle are less common, but occur in bluetongue and ecthyma.

In pigs, only the vesicular diseases – vesicular exanthema of swine, swine vesicular disease, and foot-and-mouth disease – cause such lesions on the snout and on other sites. The lesions are vesicular initially and confusion has arisen in recent years because of isolated incidents in Australia and New Zealand in which such outbreaks occurred but in which no pathogenic agent was identified.

STOMATITIS

Stomatitis is inflammation of the oral mucosa and includes **glossitis** (inflammation of the tongue), **palatitis** (lampas) (inflammation of the palate) and **gingivitis** (inflammation of the mucosa of the gums). Clinically it is characterized by partial or complete loss of appetite, smacking of the lips and profuse salivation. It is commonly an accompaniment of systemic disease.

ETIOLOGY

Stomatitis may be caused by physical, chemical or infectious agents, the last being the largest group of causes. The agents are listed under these group headings below.

Physical agents

- Trauma while dosing orally with a balling gun
- Laceration of the tongue[1]
- Foreign body injury
- Malocclusion of teeth
- Sharp awns or spines on plants. The commonest lesions are on the gums of cattle and sheep just below the corner incisors where tough grass is pulled around the corner of the incisor arcade. In spear grass country the alveoli are often stuffed full of grass seeds. Very young animals, e.g. 1–6-week-old lambs, are particularly susceptible to traumatic injury from abrasive feed.[2] Among the most dramatic lesions are those in the mouths of horses. They are large (2–3 cm long and 5 mm wide) and linear in shape. They may be caused by eating hairy caterpillars that infest pasture, or by the awns in hay or chaff made from triticale (a hybrid of wheat and rye) and a yellow bristle grass (*Setaria lutescens*). Foxtail awns can cause multiple painful nodules on the lips of horses that have eaten hay contaminated with the awns
- The strength and thickness of the awn in dwarf barley cultivars used to make silage fed to feedlot cattle in some regions is associated with mouth lesions. The incidence of tongue lesions in slaughter cattle in some areas can be about 19% and the incidence is higher in cattle finished on silage from semidwarf rough awn (29.3%) compared to normal-stem rough awn (13.5%) and normal-stem smooth awn barley (11.8%)[3]
- Eating frozen feed and drinking hot water are recorded, but seem highly improbable
- Ulcers of the soft palate of horses may be due to mechanical trauma associated with dorsal displacement of the soft palate.[4]

Chemical agents

- Irritant drugs, e.g. chloral hydrate, administered in overstrong concentrations
- Counterirritants applied to skin, left unprotected and licked by the animal, including mercury and cantharides compounds
- Irritant substances administered by mistake, including acids, alkalis and phenolic compounds
- Manifestation of systemic poisoning, e.g. chronic mercury poisoning. Poisoning with bracken, *Heraclum mantegazzianum*, furazolidone and some fungi (*Stachybotrys*, *Fusarium* spp. and mushrooms) cause a combination of focal hemorrhages and necrotic ulcers or erosions. They are a common cause of confusion with vesicular or erosive disease
- Lesions associated with uremia syndrome in horses.

Infectious agents

Cattle

- Oral necrobacillosis associated with *Fusobacterium necrophorus*
- Actinobacillosis of the bovine tongue is not a stomatitis, but there may be one or two ulcers on the dorsum and sides of the tongue and on the lips. Characteristically, there is initially an acute diffuse myositis of the muscle of the tongue, followed by the development of multiple granulomas and subsequently fibrosis and shrinkage
- Ulcerative, granulomatous lesions may occur on the gums in cases of actinomycosis
- Stomatitis with vesicles occurs in foot-and-mouth disease and in vesicular stomatitis
- Erosive, with some secondary ulcerative, stomatitis occurs in bovine viral diarrhea (mucosal disease), bovine malignant catarrh, rinderpest

and rarely in bluetongue. Cases of infectious bovine rhinotracheitis in young calves may have similar lesions
- Proliferative lesions occur in papular stomatitis, proliferative stomatitis and rare cases of rhinosporidiosis and papillomatosis where the oral mucosa is invaded
- Oral mucosal necrosis in bovine sweating sickness
- Nondescript lesions varying from erosions to ulcers occur late in the stages of many of the above diseases when secondary bacteria have invaded the breaches in the mucosa. In some cases the involvement goes deeper still and a phlegmonous condition or a cellulitis may develop. Thus, lesions that were initially vesicular are converted to what look like bacterial ulcers. Secondary infection with fungi, especially *Monilia* spp., may also occur.

Sheep
- Erosive lesions in bluetongue, rinderpest and peste de petits ruminantes
- Vesicular lesions rarely in foot and mouth disease
- Granulomatous lesions due to ecthyma are not unusual in the mouth, especially in young lambs. Similarly, oral lesions occur in bad cases of sheep pox, ulcerative dermatosis, coital exanthema and mycotic dermatitis.

Horses
- Cheilitis and gingivitis (inflammatory nodules of the lips and gums caused by plant awns)
- Vesicular lesions in vesicular stomatitis
- Herpesvirus infections are commonly accompanied by small (1 mm diameter) vesicles surrounded by a zone of hyperemia. The lesions are in groups and at first glance appear to be hemorrhages
- Lingual abscess associated with *Actinobacillus* spp.

Pigs
- The vesicular diseases: foot and mouth disease, vesicular stomatitis, vesicular exanthema of swine and swine vesicular disease.

Bullous stomatitis
- Bullous stomatitis has been reported in the horse and may be associated with a paraneoplastic pemphigus syndrome.[5]

Many other causes of stomatitis have been suggested but the relationship of these conditions to the specific diseases listed above is unknown. It is common to find stomatitides that cannot be defined as belonging to any of these etiological groups. An example is necrotic glossitis reported in feeder steers in the USA in which the necrotic lesions are confined to the anterior part of the tongue.

PATHOGENESIS

The lesions of stomatitis are produced by the causative agents being applied directly to the mucosa, or gaining entrance to it by way of minor abrasions, or by localization in the mucosa from a viremia. In the first two instances, the stomatitis is designated as primary. In the third, it is usually described as secondary because of the common occurrence of similar lesions in other organs or on other parts of the body, and the presence of a systemic disease. The clinical signs of stomatitis are caused by the inflammation or erosion of the mucosa and the signs vary in severity with the degree of inflammation.

CLINICAL FINDINGS

There is partial or complete anorexia and slow, painful mastication. Chewing movements and smacking of the lips are accompanied by salivation, either frothy and in small amounts, or profuse and drooling if the animal does not swallow normally. The saliva may contain pus or shreds of epithelial tissue. A fetid odor is present on the breath only if bacterial invasion of the lesion has occurred. Enlargement of local lymph nodes may also occur if bacteria invade the lesions. Swelling of the face is observed only in cases where a cellulitis or phlegmon has extended to involve the soft tissues. An increased desire for water is apparent and the animal resents manipulation and examination of the mouth.

Toxemia may be present when the stomatitis is secondary to a systemic disease or where tissue necrosis occurs. This is a feature of oral necrobacillosis and many of the systemic viremias. In some of the specific diseases, lesions may be present on other parts of the body, especially at the coronets and muco-cutaneous junctions.

Several different lesions of the oral cavity may be present and their characteristic appearances are as follows. The importance of vesicular diseases such as foot-and-mouth disease means that the recognition and differentiation of these lesions assumes major importance.

Erosions are shallow, usually discrete, areas of necrosis, which are not readily seen in the early stages. They tend to occur most commonly on the lingual mucosa and at the commissures of the mouth. The necrotic tissue may remain in situ but is usually shed, leaving a very shallow discontinuity of the mucosa with a dark red base that is more readily seen. If recovery occurs, these lesions heal very quickly.

Vesicles are thin-walled swellings 1–2 cm in diameter filled with clear serous fluid. They are very painful and rupture readily to leave sharp-edged, shallow ulcers.

Ulcerative lesions penetrate more deeply to the lamina propria and are painful, as in necrotic stomatitis in calves associated with *F. necrophorus*. In lambs the tongue may be swollen and contain many microabscesses infected with *Actinomyces (Corynebacterium) pyogenes*. There is an accompanying abscessation of the pharyngeal lymph nodes.[2]

Proliferative lesions are characterized by an abnormality raised above the surface of the mucous membrane as in oral papillomatosis. **Traumatic lesions** are usually solitary and characterized by a discontinuity in the mucous membrane often with evidence of healing and the presence of granulation tissue.

Catarrhal stomatitis is manifested by a diffuse inflammation of the buccal mucosa and is commonly the result of direct injury by chemical or physical agents. **Mycotic stomatitis** is characterized by a heavy, white, velvety deposit with little obvious inflammation or damage to the mucosa.

Deformity of or loss of tissue at the tip of the tongue may result in a chronic syndrome of chewing and swallowing food in such a way that food is always oozing from between the lips. In sheep this may cause permanent staining of the hair around the mouth, creating an appearance similar to that of a tobacco-chewer. Loss of the tip is usually the result of predator attack on a newborn or sick lamb.

Laceration of the tongue can result in complete or partial severance of the organ, with the severed portion protruding from the oral cavity. In cattle, glossectomy interferes with prehension and the animal is unable to eat. Excessive loss of saliva is common because of interference with swallowing.

Ulceration of the soft palate of horses may occur in 16% of horses with dorsal displacement of the soft palate and is characterized clinically by reduced exercise tolerance, respiratory noise during light exercise or racing, dysphagia and coughing after exercising.[4] The ulcers can be viewed by upper respiratory airway video-endoscopy. **Bullous stomatitis** in the horse is characterized by intact or ruptured vesicles on the peripheral margin of the tongue, the sublingual region and the mucosa of the oral cavity and lips.

CLINICAL PATHOLOGY

Material collected from lesions of stomatitis should be examined for the presence of

pathogenic bacteria and fungi. Transmission experiments may be undertaken with filtrates of swabs or scrapings if the disease is thought to be due to a viral agent.

NECROPSY FINDINGS

The oral lesions are easily observed but complete necropsy examinations should be carried out on all fatally affected animals to determine whether the oral lesions are primary or are local manifestations of a systemic disease.

DIFFERENTIAL DIAGNOSIS

- Particularly in cattle, and to a less extent in sheep, the diagnosis of stomatitis is most important because of the occurrence of oral lesions in a number of highly infectious viral diseases. The diseases are listed under etiology and their differentiation is described under their specific headings elsewhere in this book
- Careful clinical and necropsy examinations are necessary to define the type and extent of the lesions if any attempt at field diagnosis is to be made
- In cattle, lymphoma of the ramus of the mandible may spread extensively through the submucosal tissues of the mouth causing marked swelling of the gums, spreading of the teeth, inability to close the mouth and profuse salivation. There is no discontinuity or inflammation of the buccal mucosa but gross enlargement of the cranial lymph nodes is usual
- The differentiation of causes of hypersalivation must depend on a careful examination of the mouth (the causative gingivitis is often surprisingly moderate in horses) and an awareness of the volume of increased saliva output caused by toxic hyperthermia, e.g. in fescue and ergot poisonings
- Poisoning by the mycotoxin slaframine also causes hypersalivation

TREATMENT

Affected animals should be isolated and fed and watered from separate utensils if an infectious agent is suspected. Specific treatments are described under the headings of the individual diseases. Nonspecific treatment includes frequent application of a mild antiseptic collutory such as a 2% solution of copper sulfate, a 2% suspension of borax or a 1% suspension of a sulfonamide in glycerin. Indolent ulcers require more vigorous treatment and respond well to curettage or cauterization with a silver nitrate stick or tincture of iodine.

In stomatitis due to trauma, the teeth may need attention. In all cases, soft, appetizing food should be offered and feeding by stomach tube or intravenous alimentation may be resorted to in severe, prolonged cases. If the disease is infectious, care should be exercised to insure that it is not transmitted by the hands or dosing implements.

DISEASES OF THE TEETH

Surgical diseases of the teeth of animals are presented in textbooks of surgery. Some of the medical aspects of diseases of the teeth of farm animals are described here.

ETIOLOGY

The causes may be congenital or acquired.

Congenital defects

- Inherited
- Malocclusion of sufficient degree to interfere with prehension and mastication
- Red-brown staining of inherited porphyrinuria of cattle
- Defective enamel formation on all teeth combined with excessive mobility of joints in inherited defect of collagen metabolism in Holstein/Friesian cattle identified as bovine osteogenesis imperfecta. The teeth are pink and obviously deficient in substance. This defect is also recorded in a foal with severe epitheliogenesis imperfecta.[1]

Dental fluorosis

The teeth are damaged before they erupt and show erosion of the enamel. See the section on fluorosis.

Enamel erosion

The feeding of acidic byproduct feed such as sweet potato cannery waste, which is acidic because of the presence of lactic acid, can cause erosion of the enamel of the incisors of cattle.[2,3] Exposure of incisor teeth in vitro to a supernatant of cannery waste or lactic acid at pH 3.2 results in removal of calcium from the surface enamel of bovine teeth. Neutralizing the cannery waste to a pH of 5.5 does not cause detectable etching of the teeth. Feeding cattle with heavily compacted silage is also associated with loss of incisor enamel and severe incisor wear.[4]

Premature wear and loss of teeth in sheep (periodontal disease)

Premature loss of incisor teeth or 'broken mouth' causes concern because of the early age at which affected sheep have to be culled. Broken mouth is a chronic inflammatory disease of the tissue supports of the tooth.[5] Between 60% and 70% of ewes sold at slaughter in England and Scotland have loose or missing incisor teeth.[6] Broken mouth is geographically specific and it seems that once the disease is established on a particular farm, the animals are permanently susceptible.[7] Many sheep are culled before the end of their useful reproductive life because of broken mouth. The problem is particularly severe in New Zealand and the hill country in Scotland.[8] The cause is uncertain but environmental factors that result in periodontal disease are probably important. *Bacteroides gingivalis*, an organism that is found in plaque from sheep's teeth, has been found with increased frequency in diseased compared to unaffected animals.[8] The depths of the gingival crevice of sheep are heritable and it is possible that deeper crevices may already be harboring greater numbers of periodontally pathogenic bacteria so that when the animals are exposed to a broken-mouth environment they may be more prone to the changes.[9] While nutrition and mineral deficiencies influence dental development and tooth eruption of sheep, there is no significant difference in calcium or phosphorus status between control and affected populations of sheep. Low planes of nutrition have delayed eruption of the permanent dentition and retarded mandibular growth but these changes are not seen in broken mouth in sheep. The occurrence of this periodontal disease is higher on some soil types than on others. The ingestion of irritating materials such as sand and spiny grass seeds[10] has been suggested as causes, but they are considered to be secondary complications in a pre-existing disease.

Another dental disease of sheep is also recorded on an extensive scale in New Zealand.[11] There is excessive wear of deciduous incisors but no change in the rate of wear of the molar teeth. The incisor wear is episodic and is not due to any change in the supportive tissues, nor is there any change in the intrinsic resistance to wear of the incisor teeth.[12] The disease is not related to an inadequate dietary intake of copper or vitamin D and is thought to be caused by the ingestion of soil particles.[13] The two New Zealand diseases do not occur together and have no apparent effect on body condition score.[14]

Dentigerous cysts have been described in ewes in the South Island of New Zealand with a prevalence of 0.91%.[15]

PATHOGENESIS

There are some limitations to the use of number of incisors for determining age in sheep.[16] In mixed-age female sheep flocks, the median age when two, four, six and eight incisors come into wear is 15,

23, 30 and 42 months of age, respectively.[16] Errors will be made by assuming that all sheep gain a pair of permanent incisors at annual intervals between 1.5 and 4.5 years of age.

In periodontal disease or broken-mouth disease of sheep the primary lesion is an acute gingivitis around permanent incisors and premolars at the time of their eruption. This subsides leaving a chronic gingivitis and an accumulation of subgingival plaque. On some farms, for reasons not understood, this gingivitis penetrates down into the alveoli, causing a severe periodontitis and eventual shedding of the teeth.[17] The severity of the gingivitis can vary between farms.[18] The disease is episodic in nature, with discrete acute inflammatory incidents leading to periodontal injury that may resolve by healing.[8] The balance between repair and the various short- and long-term acute episodes probably accounts for the large variation in incidence and age onset of tooth loss both within and between flocks.[4] The inflammatory periodontal disease markedly affects the tooth's mobility.[19] Collagen fibrils supporting the tooth become abnormal. The deepened periodontal pocket resulting from inflammation removes the major area of support for the tooth and abnormal loads are applied to fibers deeper within the tissue.[20] While the incisor teeth are usually most severely affected, the cheek teeth are also involved.[5] In some unusual circumstances the gingivitis appears to arise from heavy deposits of dental calculus.[21] In the Scottish disease there is local alveolar bone loss but no accompanying general skeletal deficiency.[6]

CLINICAL FINDINGS

The most obvious evidence of broken-mouth disease is incisor tooth loss, which usually occurs when sheep are between 3.5 and 6.6 years; normal sheep without broken mouth will retain their teeth beyond 7 years of age. Several dental health indices can assist to assess the amount of gingivitis, tooth movement, gum recession and pocketing.[5] Gingivitis is characterized by redness and edema of the attached gingiva. Bleeding from the gingivae is also a feature. Clinical gingivitis is evident as soon as the permanent teeth erupt. Chronic gingivitis results in a downward retreat of the gum margin, loss of its normal, scalloped shape and fibrosis of the gingiva. Within a year prior to tooth loss, tissue damage around the incisors leads to deepening of the gingival sulcus and the formation of pockets which are readily detected by the use of graduated dental measuring probes. The normal sulcus is 0.5–1.0 mm deep labially and up to 4 mm deep lingually; pockets may be over 1.0 cm in depth prior to tooth loss. Crown lengthening, protrusion, hemorrhages, loosening and lingual periodontitis are characteristic. If sheep affected with broken mouth periodontal disease are examined over a 12-month period, only a few animals undergo clinically significant destruction.[8] The relationship between periodontal disease and body condition score in sheep is variable.[14]

Secondary starvation occurs even with a plentiful feed supply. Inspection of the mouth may reveal the worn or damaged incisor teeth but the molar teeth are not easily inspected in the living animal and tooth lesions can be missed. Since it is common to find that both incisors and molars are all affected, damage to incisors should lead the clinician to suspect that molar disease is also present.

Cattle fed sweetpotato cannery waste develop black, stained teeth with severe enamel erosion.[3]

An abattoir survey of dental defects in cull cows, all over 30 months of age found that 14.6% had one or more missing incisors, most of which were acquired losses.[22] Rotation and overlapping of rostral teeth were common, as was attrition. Congenitally absent first lower premolars, other missing teeth, large and often multiple interdental spaces and a few cases of macrodontia, cavitation, multiple defects and fractures were observed in cheek tooth arcades. There were also some unusual patterns of premolar and molar attrition, often attributable to malocclusion, one result of which was the formation of a hook at the posterior extremity of the third maxillary molar.

CLINICAL PATHOLOGY

On bacteriological examination spirochetes and *Fusobacterium* spp. are present.

TREATMENT AND CONTROL

There is no reliable treatment and control for broken mouth in sheep. The use of dental prosthetics glued to the incisors when the ewe has three pairs of incisors in place is being investigated. The use of antimicrobials has been proposed to control the gingivitis but there is no apparent effect on the periodontal disease. Cutting the incisor teeth of ewes to control premature tooth loss has been explored but the practice has been banned in the UK.[23]

PAROTITIS

Parotitis is inflammation of any of the salivary glands.

ETIOLOGY

Parotitis may be parenchymatous, when the glandular tissue is diffusely inflamed, or it may be a local suppurative process. There are no specific causes in farm animals, cases occurring only sporadically and due usually to localization of a blood-borne infection, invasion up the salivary ducts associated with stomatitis, irritation by grass awns in the duct, or salivary calculi.[1] Avitaminosis A often appears to be a predisposing cause.

Local suppurative lesions are caused usually by penetrating wounds or extension from a retropharyngeal cellulitis or lymph node abscess. Neoplasia of the parotid glands of cattle examined at slaughter has been described.[2]

PATHOGENESIS

In most cases only one gland is involved. There is no loss of salivary function and the signs are restricted to those of inflammation of the gland.

CLINICAL FINDINGS

In the early stages, there is diffuse enlargement of the gland accompanied by warmth and pain on palpation. The pain may interfere with mastication and swallowing and induce abnormal carriage of the head and resentment when attempts are made to move the head. There may be marked local edema in severe cases. Diffuse parenchymatous parotitis usually subsides with systemic and local treatment within a few days, but suppurative lesions may discharge externally and form permanent salivary fistulae.

CLINICAL PATHOLOGY

Bacteriological examination of pus from discharging abscesses may aid the choice of a suitable antibacterial treatment.

NECROPSY FINDINGS

Death occurs rarely and necropsy findings are restricted to local involvement of the gland or to primary lesions elsewhere in the case of secondary parotitis.

DIFFERENTIAL DIAGNOSIS

- Careful palpation is necessary to differentiate the condition from lymphadenitis, abscesses of the throat region and metastases to the parotid lymph node in ocular carcinoma or mandibular lymphoma of cattle
- Acute phlegmonous inflammation of the throat is relatively common in cattle and is accompanied by high fever, severe toxemia and rapid death. It may be mistaken for an acute parotitis but the swelling is more diffuse and causes pronounced obstruction to swallowing and respiration

TREATMENT

Systemic treatment with sulfonamides or antibiotics is required in acute cases, especially if there is a systemic reaction. Abscesses may require draining and, if discharge persists, the administration of enzymes either parenterally or locally. A salivary fistula is a common sequel.

Diseases of the pharynx and esophagus

PHARYNGITIS

Pharyngitis is inflammation of the pharynx and is characterized clinically by coughing, painful swallowing and a variable appetite. Regurgitation through the nostrils and drooling of saliva may occur in severe cases.

ETIOLOGY

Pharyngitis in farm animals is usually traumatic. Infectious pharyngitis is often part of a syndrome with other more obvious signs.

Physical causes

- Injury while giving oral treatment with balling or drenching gun[1] or following endotracheal intubation.[2] The administration of intraruminal anthelmintic coils to calves under a minimum body weight have also been associated with pharyngeal and esophageal perforation[3]
- Improper administration of a reticular magnet, resulting in a retropharyngeal abscess
- Accidental administration or ingestion of irritant or hot or cold substances
- Foreign bodies, including grass and cereal awns, wire, bones, gelatin capsules lodged in the pharynx or suprapharyngeal diverticulum of pigs.

Infectious causes

Cattle

- Oral necrobacillosis, actinobacillosis as a granuloma rather than the more usual lymphadenitis
- Infectious bovine rhinotracheitis
- Pharyngeal phlegmon or intermandibular cellulitis is a severe, often fatal, necrosis of the wall of the pharynx and peripharyngeal tissues without actually causing pharyngitis. *F. necrophorum* is a common isolate from the lesions.

Horses

- As part of strangles or anthrax
- Viral infections of the upper respiratory tract, including equine herpesvirus-1, Hoppengarten cough, parainfluenza virus, adenovirus, rhinovirus, viral arteritis, influenza-1A/E1 and 1A/E2, cause pharyngitis
- Chronic follicular pharyngitis with hyperplasia of lymphoid tissue in pharyngeal mucosa giving it a granular, nodular appearance with whitish tips on the lymphoid follicles. An exaggerated form of the disease is a soft tissue mass hanging from the pharyngeal roof and composed of lymphoid tissue.

Pigs

- As part of anthrax in this species and in some outbreaks of Aujeszky's disease.

PATHOGENESIS

Inflammation of the pharynx is attended by painful swallowing and disinclination to eat. If the swelling of the mucosa and wall is severe, there may be virtual obstruction of the pharynx. This is especially so if the retropharyngeal lymph node is enlarged, as it is likely to be in equine viral infections such as rhinovirus.

In balling-gun-induced trauma of feedlot cattle treated for respiratory disease with boluses of sulfonamides, perforations of the pharynx and esophagus may occur with the development of periesophageal diverticulations with accumulations of ruminal ingesta, and cellulitis.[1] Improper administration of a magnet to a mature cow can result in a retropharyngeal abscess.[4]

Pharyngeal lymphoid hyperplasia in horses can be graded into four grades (I–IV) of severity based on the size of the lymphoid follicles and their distribution over the pharyngeal wall.

CLINICAL FINDINGS

The animal may refuse to eat or drink or it may swallow reluctantly and with evident pain. Opening of the jaws to examine the mouth is resented and manual compression of the throat from the exterior causes paroxysmal coughing. There may be a mucopurulent nasal discharge, sometimes containing blood, spontaneous cough and, in severe cases, regurgitation of fluid and food through the nostrils. Oral medication in such cases may be impossible. Affected animals often stand with the head extended, drool saliva and make frequent, tentative jaw movements. Severe toxemia may accompany the local lesions, especially in oral necrobacillosis and, to a less extent, in strangles. Empyema of the guttural pouches may occur in horses. If the local swelling is severe, there may be obstruction of respiration and visible swelling of the throat. The retropharyngeal and parotid lymph nodes are commonly enlarged. In 'pharyngeal phlegmon'in cattle there is an acute onset with high fever (41–41.5°C, 106–107°F), rapid heart rate, profound depression and severe swelling of the soft tissues within and posterior to the mandible to the point where dyspnea is pronounced. Death usually occurs 36–48 hours after the first signs of illness.

In **traumatic pharyngitis in cattle,** visual examination of the pharynx through the oral cavity reveals hyperemia, lymphoid hyperplasia and erosions covered by diphtheritic membranes. Pharyngeal lacerations are visible, and palpation of these reveals the presence of accumulated ruminal ingesta in diverticulae on either side of the glottis.[1] External palpation of the most proximal aspect of the neck reveals firm swellings, which represent the diverticula containing rumen contents. A retropharyngeal abscess secondary to an improperly administered magnet can result in marked diffuse painful swelling of the cranial cervical region.[4] Ultrasonographic examination of the swelling may reveal the magnet within the abscess.[4]

Palpation of the pharynx may be performed in cattle with the use of a gag if a foreign body is suspected, and endoscopic examination through the nasal cavity is possible in the horse.

Most acute cases recover in several days but chronic cases may persist for many weeks, especially if there is ulceration, a persistent foreign body or abscess formation. Pharyngitis has become one of the most commonly recognized diseases of the upper respiratory tract of the horse. Chronic pharyngitis after viral infections is relatively common and results in a break in training, which is inconvenient and costly. On endoscopic examination there may be edema in early and relatively acute cases. In long-standing cases there is lymphoid infiltration and follicular hyperplasia. This is more common and

more severe in young horses, who also suffer more attacks of upper respiratory tract disease. The condition does not appear to diminish racing performance or respiratory efficiency. If secondary bacterial infection is present a purulent exudate is seen on the pharyngeal mucosa and in the nostrils. Affected horses cough persistently, especially during exercise, are dyspneic and tire easily. Guttural pouch infections may occur secondarily. An occasional sequel is aspiration pneumonia.

CLINICAL PATHOLOGY

Nasal discharge or swabs taken from accompanying oral lesions may assist in the identification of the causative agent. *Moraxella* spp. and *Streptococcus zooepidemicus* can be isolated in large numbers from horses with lymphoid follicular hyperplasia grades III and IV.

NECROPSY FINDINGS

Deaths are rare in primary pharyngitis and necropsy examinations are usually undertaken only in those animals dying of specific diseases. In 'pharyngeal phlegmon' there is edema, hemorrhage and abscessation of the affected area and on incision of the area a foul-smelling liquid and some gas usually escape.

DIFFERENTIAL DIAGNOSIS

- Pharyngitis is manifested by an acute onset and local pain
- In pharyngeal paralysis, the onset is usually slow
- Acute obstruction by a foreign body may occur rapidly and cause severe distress and continuous, expulsive coughing – but there are no systemic signs
- Endoscopic examination of the pharyngeal mucous membranes is often of diagnostic value

TREATMENT

The primary disease must be treated, usually parenterally, by the use of antimicrobials. 'Pharyngeal phlegmon' in cattle is frequently fatal and early treatment, repeated at short intervals, with a broad-spectrum antimicrobial is necessary.

Pharyngeal lymphoid hyperplasia is not generally susceptible to antimicrobials or medical therapy. Surgical therapy including electrical and chemical cautery is indicated and has been successfully applied.

PHARYNGEAL OBSTRUCTION

Obstruction of the pharynx is accompanied by stertorous respiration, coughing and difficult swallowing.

ETIOLOGY

Foreign bodies or tissue swellings are the usual causes.

Foreign bodies

These include bones, corn cobs and pieces of wire. While horses are considered discriminating eaters in comparison to cattle, they will occasionally pick up pieces of metal while eating.[1]

Tissue swellings

Cattle

- Retropharyngeal lymphadenopathy or abscess due to tuberculosis, actinobacillosis or bovine viral leukosis
- Fibrous or mucoid polyps. These are usually pedunculated because of traction during swallowing and may cause intermittent obstruction of air and food intake.

Horses

- Retropharyngeal lymph node hyperplasia and lymphoid granulomas as part of chronic follicular pharyngitis syndrome
- Retropharyngeal abscess and cellulitis
- Retropharyngeal lymphadenitis caused by strangles
- Pharyngeal cysts in the subepiglottic area of the pharynx, probably of thyroglossal duct origin, and fibroma; also similar cysts on the soft palate and pharyngeal dorsum, the latter probably being remnants of the craniopharyngeal ducts
- Dermoid cysts and goitrous thyroids.

Pigs

- Diffuse lymphoid enlargement in the pharyngeal wall and soft palate
- Food and foreign body impaction in the suprapharyngeal diverticulum.

PATHOGENESIS

Reduction in caliber of the pharyngeal lumen interferes with swallowing and respiration.

CLINICAL FINDINGS

There is difficulty in swallowing and animals may be hungry enough to eat but, when they attempt to swallow, cannot do so and the food is coughed up through the mouth. Drinking is usually managed successfully. There is no dilatation of the esophagus and usually little or no regurgitation through the nostrils. An obvious sign is a snoring inspiration, often loud enough to be heard some yards away. The inspiration is prolonged and accompanied by marked abdominal effort. Auscultation over the pharynx reveals loud inspiratory stertor. Manual examination of the pharynx may reveal the nature of the lesion but an examination with a fiberoptic endoscope is likely to be much more informative. When the disease runs a long course, emaciation usually follows. Rupture of abscessed lymph nodes may occur when a nasal tube is passed, and can result in aspiration pneumonia.

In horses with metallic foreign bodies in the oral cavity or pharynx, the clinical findings include purulent nasal discharge, dysphagia, halitosis, changes in phonation, laceration of the tongue and stertorous breathing.[1] In case studies, most horses were affected with clinical signs for more than 2 weeks and had been treated with antimicrobials with only temporary improvement.[1]

CLINICAL PATHOLOGY

A tuberculin test may be advisable in bovine cases. Nasal swabs may contain *S. equi* when there is streptococcal lymphadenitis in horses.

NECROPSY FINDINGS

Death occurs rarely and in fatal cases the physical lesion is apparent.

DIFFERENTIAL DIAGNOSIS

- Signs of the primary disease may aid in the diagnosis in tuberculosis, actinobacillosis and strangles
- Pharyngitis is accompanied by severe pain and commonly by systemic signs and there is usually stertor
- It is of particular importance to differentiate between obstruction and pharyngeal paralysis when rabies occurs in the area. Esophageal obstruction is also accompanied by the rejection of ingested food but there is no respiratory distress. Laryngeal stenosis may cause a comparable stertor but swallowing is not impeded. Nasal obstruction is manifested by noisy breathing but the volume of breath from one or both nostrils is reduced and the respiratory noise is more wheezing than snoring
- Radiography is useful for the identification of metallic foreign bodies[1]

TREATMENT

Removal of a foreign body may be accomplished through the mouth. Treatment of actinobacillary lymphadenitis with iodides is usually successful and some reduction in size often occurs in tuberculous enlargement of the glands but complete recovery is unlikely to occur. Parenteral treatment of strangles abscesses with penicillin may effect a cure. Surgical treatment has been highly successful in cases caused by medial retropharyngeal abscess.

REFERENCE

1. Kiper ML et al. J Am Vet Med Assoc 1992; 200:91.

PHARYNGEAL PARALYSIS

Pharyngeal paralysis is manifested by inability to swallow and an absence of signs of pain and respiratory obstruction.

ETIOLOGY

Pharyngeal paralysis occurs sporadically, due to peripheral nerve injury, and in some encephalitides with central lesions.

Peripheral nerve injury

- Guttural pouch infections in horses
- Trauma to the throat region.

Secondary to specific diseases

- Rabies and other encephalitides
- Botulism
- African horse sickness
- A series of unexplained fatal cases in horses.

PATHOGENESIS

Inability to swallow and regurgitation are the major manifestations of the disease. There may be an associated laryngeal paralysis, accompanied by 'roaring'. The condition known as 'cud-dropping' in cattle may be a partial pharyngeal paralysis as there is difficulty in controlling the regurgitated bolus, which is often dropped from the mouth. In these circumstances, aspiration pneumonia is likely to develop.

CLINICAL FINDINGS

The animal is usually hungry but, on prehension of food or water, attempts at swallowing are followed by dropping of the food from the mouth, coughing and the expulsion of food or regurgitation through the nostrils. Salivation occurs constantly and swallowing cannot be stimulated by external compression of the pharynx. The swallowing reflex is a complex one controlled by a number of nerves and the signs can be expected to vary greatly depending on which nerves are involved and to what degree. There is rapid loss of condition and dehydration. Clinical signs of the primary disease may be evident but, in cases of primary pharyngeal paralysis, there is no systemic reaction. Pneumonia may follow aspiration of food material into the lungs and produces loud gurgling sounds on auscultation.

In 'cud-dropping' in cattle, the animals are normal except that regurgitated boluses are dropped from the mouth, usually in the form of flattened disks of fibrous food material. Affected animals may lose weight but the condition is usually transient, lasting for only a few days. On the other hand, complete pharyngeal paralysis is usually permanent and fatal.

CLINICAL PATHOLOGY

The use of clinicopathological examinations is restricted to the identification of the primary specific diseases.

NECROPSY FINDINGS

If the primary lesion is physical, it may be detected on gross examination.

DIFFERENTIAL DIAGNOSIS

- In all species, often the first clinical impression is the presence of a foreign body in the mouth or pharynx and this can only be determined by physical examination
- Pharyngeal paralysis is a typical sign in rabies and botulism but there are other clinical findings that suggest the presence of these diseases
- Absence of pain and respiratory obstruction are usually sufficient evidence to eliminate the possibility of pharyngitis or pharyngeal obstruction
- Endoscopic examination of the guttural pouch is a useful diagnostic aid in the horse

TREATMENT

Treatment is unlikely to have any effect. The local application of heat may be attempted. Feeding by nasal tube or intravenous alimentation may be tried if disappearance of the paralysis seems probable.

ESOPHAGITIS

Inflammation of the esophagus is accompanied initially by clinical findings of spasm and obstruction, pain on swallowing and palpation, and regurgitation of bloodstained, slimy material.

ETIOLOGY

Primary esophagitis caused by the ingestion of chemical or physical irritants is usually accompanied by stomatitis and pharyngitis. Laceration of the mucosa by a foreign body or complications of nasogastric intubation may occur.[1] Nasogastric intubation is associated with a higher risk of pharyngeal and esophageal injury when performed in horses examined for colic.[1] This may be related to the use of larger-diameter nasogastric tubes to provide more effective gastric decompression, the longer duration of intubation in some horses, or the presence of gastric distension resulting in increased resistance to tube passage at the cardia.[1] In a series of six horses with esophageal trauma the lesions were detected 5 and 20 cm from the cranial esophageal opening.[1]

The administration of sustained-release anthelmintic boluses to young calves that are not large enough for the size of the bolus used may cause esophageal injury and perforation.[2,3] The boluses are 8.5 cm in length and 2.5 cm in diameter and the calves 100–150 kg. The minimum body weight for these boluses is 100 kg but in the study some calves were younger than the recommended age and were also fractious when handled, which may have contributed to the injury.[2] Death of *Hypoderma lineatum* larvae in the submucosa of the esophagus of cattle may cause acute local inflammation and subsequent gangrene.

Inflammation of the esophagus occurs commonly in many specific diseases, particularly those that cause stomatitis, but the other clinical signs of these diseases dominate those of esophagitis.

PATHOGENESIS

Inflammation of the esophagus combined with local edema and swelling results in a functional obstruction and difficulty in swallowing. Traumatic injury to the esophagus results in edema, hemorrhage, laceration of the mucosa and possible perforation of the esophagus, resulting in periesophageal cellulitis, which spreads proximally and distally along the esophagus in fascial planes from the site of perforation. Perforation of the thoracic esophagus can result in severe and fatal pleuritis. There is extensive edema and accumulation of swallowed or regurgitated ingesta along with gas. The extensive cellulitis and the presence of ingesta results in severe toxemia, and dysphagia may cause aspiration pneumonia.

CLINICAL FINDINGS

In the acute injury of the esophagus, there is salivation and attempts to swallow, which cause severe pain, particularly in horses. In some cases, attempts at swallowing are followed by regurgitation and coughing, pain, retching activities and vigorous contractions of the cervical and abdominal muscles. Marked drooling of saliva, grinding of the teeth, coughing and profuse nasal discharge are common in the horse with esophageal trauma with complications following nasogastric intubation.[1] Regurgitation may occur and the regurgitus contains mucus and some fresh blood. If the esophagitis is in the cervical region, palpation in the jugular furrow causes pain and edematous tissues around the esophagus may be palpable. If perforation has occurred, there is local pain and swelling and often crepitus. Local cervical cellulitis may cause rupture to the exterior and development of an esophageal fistula, or infiltration along fascial planes with resulting compression obstruction of the esophagus, and toxemia. Perforation of the thoracic esophagus may lead to fatal pleurisy. Animals that recover from esophageal traumatic injury are commonly affected by chronic esophageal stenosis with distension above the stenosis. Fistulae are usually persistent but spontaneous healing may occur. In [3]specific diseases such as mucosal disease and bovine malignant catarrh, there are

no obvious clinical findings of esophagitis, the lesions being mainly erosive.

Endoscopy of the esophagus will usually reveal the location and severity of the lesion. Lateral cervical radiographs may reveal foreign bodies and extensive soft tissue swelling with pockets of gas.

CLINICAL PATHOLOGY

In severe esophagitis of traumatic origin a marked neutrophilia may occur, suggesting active inflammation.

NECROPSY FINDINGS

Pathological findings are restricted to those pertaining to the various specific diseases in which esophagitis occurs. In traumatic lesions or those caused by irritant substances, there is gross edema, inflammation and, in some cases, perforation.

DIFFERENTIAL DIAGNOSIS

- Esophagitis must be differentiated from pharyngitis, in which attempted swallowing is not as marked and coughing is more likely to occur. Palpation may also help to localize the lesion; however, pharyngitis and esophagitis commonly occur together
- When the injury is caused by a foreign body, it may still be in the esophagus and, if suitable restraint and anesthesia can be arranged, the passage of a nasogastric tube or endoscope may locate it. Complete esophageal obstruction is accompanied by bloat in ruminants, by palpable enlargement of the esophagus and by less pain on swallowing than in esophagitis, although horses may show a great deal of discomfort
- In cattle perforation of the esophagus is not uncommon. There is a persistent, moderate toxemia, a moderate fever and a leukocytosis. Edema and swelling are prominent in surrounding fascial planes, but may cause only slight physical enlargement, which is easily missed on a routine examination

TREATMENT

Feed should be withheld for 2–3 days and fluid and electrolyte therapy may be necessary for several days. Parenteral antimicrobials are indicated, especially if laceration or perforation has occurred. Reintroduction to feed should be monitored carefully and all feed should be moistened to avoid the possible accumulation of dry feed in the esophagus, which may not be fully functional.

ESOPHAGEAL OBSTRUCTION

Esophageal obstruction may be acute or chronic and is characterized clinically by inability to swallow, regurgitation of feed and water, continuous drooling of saliva, and bloat in ruminants. Acute cases are accompanied by distress. Horses with choke commonly regurgitate feed and water and drool saliva through the nostrils because of the anatomical characteristics of the equine soft palate.

ETIOLOGY

Obstruction may be **intraluminal** by swallowed material or **extraluminal** due to pressure on the esophagus by surrounding organs or tissues. Esophageal paralysis may also result in obstruction.

Intraluminal obstructions

These are usually due to ingestion of materials that are of inappropriate size and that then become lodged in the esophagus:

- Solid obstructions, especially in cattle, by turnips, potatoes, peaches, apples, oranges, etc.
- 15 g gelatin capsules in Shetland ponies[1]
- The most common type of esophageal obstruction in horses is simple obstruction due to impaction of ingesta.[2] Feedstuffs are a common cause of obstruction in horses allowed to eat immediately after a race or workout. Improperly soaked sugarbeet pulp, inadvertent access to dry sugarbeet pulp and cubed and pelleted feed are especially risky for horses when eaten quickly. The horse eats ravenously and swallows large boluses without properly insalivating them. The bolus lodges at the base of the neck or the cardia. Similar obstructions occur when horses are turned into stalls containing fresh bedding, including shavings
- Foreign bodies in horses include pieces of wood, antimicrobial boluses and fragments of nasogastric tubes.[3] A nasogastric tube inserted into a horse may break if the animal is startled and jumps, or in some cases the tube becomes weakened from overuse and breaks if left in place over a period of time[3]
- A trichobezoar caused esophageal obstruction in a cow;[4] it may have been regurgitated rather than ingested because of the lack of teeth marks on the trichobezoar.

Extraluminal obstructions

- Tuberculous or neoplastic lymph nodes in the mediastinum or at the base of lung
- Cervical or mediastinal abscess
- Persistent right aortic arch
- Thymoma.

Esophageal paralysis

This may be due to **congenital or acquired abnormalities of the esophagus** and there are many examples of such abnormalities, which interfere with swallowing and cause varying degrees of obstruction, even though it may be possible to pass a stomach tube through the esophagus into the stomach or rumen.

Esophageal paralysis, diverticulum or megaesophagus has been recorded in horses and in cattle.[5] Congenital hypertrophy of esophageal musculature and esophagotracheal fistula has been found in calves. Congenital esophageal ectasia is recognized in foals,[6] caused by degeneration of musculature and reduced ganglion cells in the myenteric plexus. Congenital esophageal dysfunction has also occurred in foals with no detectable histopathological lesion but with prolonged simultaneous contractions throughout the esophagus.

Megaesophagus

Megaesophagus is a dilatation and atony of the body of the esophagus usually associated with asynchronous function of the esophagus and the caudal esophageal sphincter. It occurs sporadically in cattle, and in horses with pre-existing esophageal disease.[2] It is usually a congenital condition, causing regurgitation and aspiration pneumonia. A mild esophagitis has been observed in some cases and congenital stenosis of the esophagus in a foal has been associated with megaesophagus.[7]

Esophageal strictures

These arise as a result of cicatricial or granulation tissue deposition, usually as result of previous laceration of the esophagus. They may occur in the adult horse with a history of previous obstruction. Esophageal strictures resulting in obstruction occur in foals from 1–6 months of age without any history of foreign body.[8] An esophageal stricture has also been described in a goat.[9]

Other causes of obstruction

- **Carcinoma of stomach** causing obstruction of cardia
- Squamous cell carcinoma of the esophagus of a horse[10]
- Esophageal hiatus hernia in cattle
- Paraesophageal cyst in a horse[11]
- Combined esophageal and tracheal duplication cyst in a young horse[12]
- Esophageal duplication in a horse[12]
- Tubular duplication of the cervical portion of the esophagus in a foal[13]
- Cranial esophageal pulsion (pushing outward) diverticulum in a horse[14]
- Esophageal phytobezoar in a horse[15]
- Esophageal mucosal granuloma[11]
- Traumatic rupture of the esophagus from an external injury (e.g. a kick) or during treatment using a nasogastric tube

- Esophageal paralysis may also be associated with lesions of encephalitis, especially in the brain stem.[16]

PATHOGENESIS

An **esophageal obstruction** results in a physical inability to swallow and, in cattle, inability to eructate, with resulting bloat. In acute obstruction, there is initial spasm at the site of obstruction and forceful, painful peristalsis and swallowing movements. Complications of esophageal obstruction include laceration and rupture of the esophagus, esophagitis, stricture and stenosis, and the development of a diverticulum.

Acquired esophageal diverticula may occur in the horse. A traction diverticulum occurs following periesophageal scarring and is of little consequence. An esophageal pulsion diverticulum is a circumscribed sac of mucosa protruding through a defect in the muscular layer of the esophagus. Causes that have been proposed to explain pulsion diverticula include excessive intraluminal pressure from impacted feed, fluctuations in esophageal pressure and external trauma.[15] Complications associated with esophageal diverticula include peridiverticulitis, pulmonary adhesions, abscesses and mediastinitis. Esophageal stricture and subsequent obstruction secondary to impaction of a diverticulum may also occur.

In **megaesophagus**, the esophagus is dysfunctional, dilated and filled with saliva, feed and water. This results in regurgitation and may lead to aspiration pneumonia. It may be congenital or secondary to other lesions and has been associated with gastric ulceration in a foal.[17]

Using esophageal manometry, the normal values for esophageal pressure profiles in healthy horses, cows and sheep have been recorded.[18] The body of the equine and bovine esophagus has two functionally different regions: the caudal portion and the remainder of the esophageal body (cranial portion).

CLINICAL FINDINGS

Acute obstruction or choke

Cattle

The obstruction is usually in the cervical esophagus just above the larynx or at the thoracic inlet. Obstructions may also occur at the base of the heart or the cardia. The animal suddenly stops eating and shows anxiety and restlessness. There are forceful attempts to swallow and regurgitate, salivation, coughing and continuous chewing movements. If obstruction is complete, bloating occurs rapidly and adds to the animal's discomfort. Ruminal movements are continuous and forceful and there may be a systolic murmur audible on auscultation of the heart. However, rarely is the bloat severe enough to seriously affect the cardiovascular system of the animal, as occurs in primary leguminous bloat.

The acute signs, other than bloat, usually disappear within a few hours. This is due to relaxation of the initial esophageal spasm and may or may not be accompanied by onward passage of the obstruction. Many obstructions pass on spontaneously but others may persist for several days and up to a week. In these cases there is **inability to swallow**, **salivation** and **continued bloat**. Passage of a nasogastric tube is impossible. Persistent obstruction causes pressure necrosis of the mucosa and may result in perforation or subsequent stenosis due to fibrous tissue construction.

Horse

In the horse with esophageal obstruction due to feed, the obstruction may occur at any level of the esophagus from the upper cervical region all the way to the thoracic portion. The ingestion of large quantities of grain or pelleted feed can cause obstruction over a long portion of the esophagus.

The clinical findings vary with the location, nature, extent and duration of the obstruction. Typically the major clinical finding is **dysphagia** with **nasal reflux of saliva, feed and water**. Affected horses will usually not attempt further eating but will drink and attempt to swallow water. External palpation of the **cervical esophagus** may reveal a **firm cylindrical swelling** along the course of the neck on the left side when the esophagus is obstructed with feed. In cases of foreign body obstruction such as a piece of wood, there may be no palpable abnormality.

Horses with acute esophageal obstruction are commonly difficult to handle because they are panicky and make forceful attempts to swallow or retch. They may vigorously extend and flex their necks and stamp their front feet. In some horses it may be difficult to pass a nasogastric tube because they resist the procedure. During these episodes of hyperactivity they may sweat profusely, tachycardia may be present and they may appear to be in abdominal pain. Such clinical findings on first examination may resemble colic but attempted passage of a nasogastric tube as part of the examination of a horse with colic reveals the obstruction.

Passage of a nasogastric tube is necessary to make the diagnosis and to assess the level of the obstruction.[19] The level of obstruction can be approximated by the amount of tube that has been passed. Care must be taken not to push the tube more than gently to avoid injury to the esophagus. Occasionally, a foreign body or bolus of feed will move distally into the stomach as the tube is gently advanced.

The nature of the obstruction can be assessed more adequately with a fiberoptic endoscope but visualization of the entire esophagus of an adult horse requires an endoscope of 2.5 m length. The endoscope allows determination of the rostral but not the distal limit of the obstruction. If radiographic equipment is available, standing lateral radiographs of the cervical and thoracic esophagus along with contrast media may be required to determine the extent and nature of an obstruction.

Persistent obstruction may occur in the horse and death may occur in either species from subsequent aspiration pneumonia or, when the obstruction persists, from dehydration. In **foals** with esophageal obstruction the clinical findings include **nasal reflux of saliva**, feed and milk, reluctance to eat solid feed and dyspnea if aspiration pneumonia has occurred.[8] Unthriftiness occurs if the obstruction has been present for a few weeks. Affected foals may have had several episodes of choke within the previous few weeks from which they appeared to recover spontaneously.[8] Passage of a nasogastric tube may be possible in some and not in others.

Chronic obstruction

No acute signs of obstruction are evident and in cattle the earliest sign is chronic bloat, which is usually of moderate severity and may persist for several days without the appearance of other signs. Rumen contractions may be within the normal range. In horses and in cattle in which the obstruction is sufficiently severe to interfere with swallowing, a characteristic syndrome develops. Swallowing movements are usually normal until the bolus reaches the obstruction, when they are replaced by more forceful movements. Dilatation of the esophagus may cause a pronounced swelling at the base of the neck. The swallowed material either passes slowly through the stenotic area or accumulates and is then regurgitated. Projectile expulsion of ingested material occurs with esophageal diverticula, but water is retained and there is no impedance to the passage of the stomach tube. In the later stages, there may be no attempt made to eat solid food but fluids may be taken and swallowed satisfactorily.

When there is **paralysis of the esophagus**, as in megaesophagus, regurgitation does not occur but the esophagus fills and overflows, and saliva drools from the mouth and nostrils. Aspiration into

the lungs may follow. Passage of a stomach tube or probang is obstructed by stenosis but may be unimpeded by paralysis.

Complications following esophageal obstruction

Complications following an esophageal obstruction are most common in the horse and include esophagitis, mucosal ulceration in long-standing cases, esophageal perforation and aspiration pneumonia. Mild cases of esophagitis heal spontaneously. Circumferential full-thickness mucosal ulceration may result in a stricture, which will be clinically evident in 2–5 weeks and may require surgical correction. Esophageal perforation may occur and is characterized by diffuse cellulitis of the periesophageal tissues, often with subcutaneous emphysema. A fistula may develop.

CLINICAL PATHOLOGY

Laboratory tests are not used in diagnosis although radiographic examination is helpful to outline the site of stenosis, diverticulum or dilatation, even in animals as large as the horse. Radiological examination after a barium swallow is a practicable procedure if the obstruction is in the cervical esophagus. Viewing of the internal lumen of the esophagus with a fiberoptic endoscope has completely revolutionized the diagnosis of esophageal malfunction. Biopsy samples of lesions and tumor masses can be taken using the endoscope.[10] Electromyography has been used to localize the area of paralysis of the esophagus in a cow with functional megaesophagus.[20]

TREATMENT

Conservative approach

Many obstructions will resolve spontaneously and a careful conservative approach is recommended. If there is a history of prolonged choke with considerable nasal reflux having occurred, the animal should be examined carefully for evidence of foreign material in the upper respiratory tract and the risk of aspiration pneumonia. It may require several hours of monitoring, re-examination and repeated sedation before the obstruction is resolved. During this time, the animal should not have access to feed and water.

Sedation

In acute obstruction, if there is marked anxiety and distress, the animal should be sedated before proceeding with specific treatment. Administration of a sedative may also help to relax the esophageal spasm and allow passage of the impacted material. For sedation and esophageal relaxation in the horse, one of the following is recommended:

- Acepromazine 0.05 mg/kg BW intravenously
- Xylazine 0.5–1.0 mg/kg BW intravenously
- Detomidine 0.01–0.02 mg/kg BW intravenously
- Romifidine 0.04–0.12 mg/kg intravenously.[19]

For esophageal relaxation, analgesia and anti-inflammatory effect hyoscine: dipyrone 0.5:0.22 mg/kg BW intravenously can be used and for analgesia and anti-inflammatory effect flunixin meglumine 1.1 mg/kg BW intravenously or phenylbutazone 2–4 mg/kg intravenously are suggested. For analgesia butorphanol 0.02–0.1 mg/kg intravenously may be administered.

DIFFERENTIAL DIAGNOSIS

- The clinical findings of acute esophageal obstruction in cattle and horses are usually typical but may be similar to those of esophagitis, in which local pain is more apparent and there is often an accompanying stomatitis and pharyngitis
- The excitement, sweating, and tachycardia observed in acute choke in the horse often suggests colic. Passage of the nasogastric tube reveals the obstruction. The use of a fiberoptic endoscope will usually locate the obstruction for visualization and obstructions are easiest to see when the endoscope is being withdrawn rather than advanced

Chronic obstruction

- Differentiation of the causes of chronic obstruction may be difficult. A history of previous esophagitis or acute obstruction suggests cicatricial stenosis. Contrast radiography of the esophagus is valuable in the investigation of horses with dysphagia, choke and nasogastric reflux.[21] The use of the sedative detomidine can affect the function of the esophagus and make interpretation of barium swallowing studies difficult[22]
- Persistent right aortic arch is rare and confined to young animals
- Mediastinal lymph node enlargement is usually accompanied by other signs of tuberculosis or lymphomatosis
- Chronic ruminal tympany in cattle may be caused by ruminal atony, in which case there is an absence of normal ruminal movements
- Diaphragmatic hernia may also be a cause of chronic ruminal tympany in cattle and is sometimes accompanied by obstruction of the esophagus with incompletely regurgitated ingesta. This condition and vagus indigestion, another cause of chronic tympany, are usually accompanied by a systolic cardiac murmur but passage of a stomach tube is unimpeded. Dysphagia may also result from purely neurogenic defects. Thus, an early paralytic rabies 'choke' is often suspected, with dire results for the examining veterinarian
- Equine encephalomyelitis and botulism are other diseases in which difficulty is experienced with swallowing
- Cleft palate is a common cause of nasal regurgitation in foals

Pass a stomach tube and allow object to move into stomach

The passage of the nasogastric tube is always necessary to locate the obstruction. Gentle attempts may be made to push the obstruction caudad but care must be taken to avoid damage to the esophageal mucosa. A fiberoptic endoscope can be used to determine the presence of an obstruction, its nature and the extent of any injury to the esophageal mucosa.

If the above simple procedures are unsuccessful it is then necessary to proceed to more vigorous methods. In cattle, it is usual to attempt further measures immediately, partly because of the animal's distress and the risk of self-injury and partly because of the bloat. However, rarely is the bloat associated with esophageal obstruction life-threatening. The important decision is whether to proceed and risk damaging the esophagus or wait and allow the esophageal spasm to relax and the obstruction to pass spontaneously. This problem is most important in the horse. Attempts to push the obstruction too vigorously may injure the mucosa, causing esophagitis and even esophageal perforation. Alternatively, leaving a large obstruction in place may restrict the circulation to the local area of mucosa and result in ischemic necrosis. Complications such as strictures and diverticula may occur but are uncommon. As a guide in the horse it is suggested that conservative measures, principally sedation, waiting and lavaging the esophagus, be continued for several hours before attempting radical procedures such as general anesthesia and manipulation or esophagotomy.

Removal by endoscope

If a specific foreign body, such as a piece of wood, is the cause of the obstruction, it may be removed by endoscopy. The foreign body must be visible endoscopically and suitable forceps or a snare through the scope are required. In some cases, impacted feed anterior to the foreign object must be lavaged out before the object is retrieved.

Manual removal through oral cavity in cattle

Solid obstructions in the upper esophagus of cattle may be reached by passing the hand into the pharynx with the aid of a speculum and having an assistant press the foreign body up towards the mouth. Because of slippery saliva, it is often difficult to grasp the obstruction sufficiently strongly to be able to extricate it from the

esophagus. A long piece of strong wire bent into a loop may be passed over the object and an attempt made to pull it up into the pharynx. The use of Thygesen's probang with a cutting loop is a simple and effective method of relieving choke in cattle that have attempted to swallow beets and other similar-sized vegetables and fruits. If both methods fail, it is advisable to leave the object in situ and use treatments aimed at relaxing the esophagus. In such cases in cattle it may be necessary to trocarize the rumen and leave the cannula in place until the obstruction is relieved. However, this should not be undertaken unless specifically required.

General anesthesia in the horse

In horses, attempts to manually remove solid obstructions from the cranial portion of the esophagus require a general anesthetic, a speculum in the mouth and a manipulator with a small hand. The fauces are much narrower in the horse than in the cow and it is only with difficulty that the hand can be advanced through the pharynx to the beginning of the esophagus. Fragments of nasogastric tubes have been retrieved from the esophagus of horses using sedation with xylazine and butorphanol intravenously and the use of a fiberoptic endoscope.[23]

Esophageal lavage in the horse

Accumulations of feedstuffs, which occur most commonly in the horse, can be removed by careful lavage or flushing of the obstructed esophagus. Lavage may be performed in the **standing horse** or in **lateral recumbency under general anesthesia.** Small quantities of warm water, 0.5–1 L each time, are pumped through a nasogastric tube passed to the point of obstruction, and then the tube is disconnected from the pump and the liquid material is allowed to siphon out through the tube by gravity flow. Return of the fluid through the oral cavity and nostrils is minimized by ensuring that the tube is not plugged by returning material and by using only small quantities of fluid for each input of the lavage. Throughout the procedure, the tube is gently manipulated against the impaction. The use of a transparent tube assists in helping to see the amount and nature of the material coming through the tube. This is repeated many times until the fluid becomes clear. This procedure may require a few hours but perseverance will be successful. After each lavage the tube can be advanced caudad a few centimeters and eventually all the way to the stomach. Following relief of the obstruction the horse will become relaxed and phonate its pleasure. Care must be taken to avoid overflowing the esophagus and causing aspiration into the lungs. This is a constant hazard whenever irrigative removal is attempted and the animal's head must always be kept as low as possible to avoid aspiration. Following relief of obstruction the horse can be offered water to drink, and a wet mash of feed for a few days.

In the recumbent horse under general anesthesia, lavage is similar. A cuffed endotracheal tube is used to maintain an airway and to prevent aspiration of foreign material. Lavage under general anesthesia provides relaxation of the esophagus, which may enhance the procedure and allow a greater volume of water to be used.

Surgical removal of foreign bodies

Surgical removal by esophagostomy may be necessary if other measures fail. Gastrotomy may be necessary to relieve obstructions of the caudal portion of the esophagus adjacent to the cardia.[24] Although stricture or fistula formation is often associated with esophageal surgery, complications do not occur in every case; healing by secondary intention is common.[6]

Repeated siphonage in chronic cases

In chronic cases, especially those due to paralysis, repeated siphonage may be necessary to remove fluid accumulations. Successful results are reported in foals using resection and anastomosis of the esophagus and in a horse using esophagomyotomy, but the treatment of chronic obstruction is usually unsuccessful.

Cervical esophagostomy alimentation

Alimentation of horses with esophageal ruptures can be attempted by various means. Maintenance of nasogastric tubes through the nostrils is difficult but possible. Tube feeding through a **cervical esophagostomy** has some disadvantages, but it is a reasonably satisfactory procedure in any situation where continued extraoral alimentation is required in the horse. However, the death rate is higher than with nasogastric tube feeding. When the obstruction is due to circumferential esophageal ulceration, the lumen is smallest at about 50 days and begins to dilate at that point so that it is normal again at about 60 days.

Diseases of the nonruminant stomach and intestines

Only those diseases that are accompanied by physical lesions, such as displacement or strangulation, or disturbances of motility, such as ileus, are presented. Diseases associated with functional disturbances of secretion are not recognized in animals. Deficiencies of biliary and pancreatic secretion are dealt with in the chapter on diseases of the liver. Those diseases of the stomach and intestines peculiar to ruminants are dealt with separately in Chapter 6.

EQUINE COLIC (ADULT HORSES)

GENERAL PRINCIPLES

Gastrointestinal disease causing signs of abdominal pain in horses is commonly referred to as colic. Colic is a frequent and important cause of death and is considered the most important disease of horses encountered by practicing veterinarians. It is estimated to cost the horse industry in the USA approximately $115 000 000 annually.[1–3]

ETIOLOGY

Several classification systems of equine colic have been described including a disease-based system (Table 5.3) classifying the cause of colic as:

- **Obstructive**
- **Obstructive and strangulating**
- **Nonstrangulating infarctive**
- **Inflammatory** (peritonitis, enteritis).

Colic cases can also be classified on the basis of the duration of the disease: **acute** (< 24–36 h), **chronic** (> 24–36 h) and **recurrent** (multiple episodes separated

Synopsis

Etiology See Tables 5.4, 5.5, 5.6 and 5.7
Epidemiology Incidence of 2–30 cases per 100 horse years, mortality of 0.5–0.7 cases per 100 horse years and case fatality rate of 7–13%. Any age predisposition is weak, although certain diseases (e.g. meconium impaction, strangulation by pedunculated lipoma) have specific age distributions. Consumption of a diet high in concentrate increases the risk of colic, as does a poor parasite control program
Clinical signs Signs of abdominal pain include agitation, flank watching, flank biting, pawing, frequent lying down, kicking at the abdomen, frequent attempts to urinate or defecate, and rolling. Tachycardia is common. Normal gut sounds are absent and replaced by tympanitic sounds. Abdominal distension may develop. Reflux through a nasogastric tube may occur. Rectal examination may reveal abnormalities
Clinical pathology Few changes have diagnostic significance but many are used to monitor the severity of the disease. Hemoconcentration, azotemia and metabolic acidosis are frequent findings. Peritoneal fluid may have increased protein and leukocyte concentration
Lesions Consistent with the particular disease
Diagnostic confirmation Physical examination, exploratory laparotomy, necropsy
Treatment Analgesia (Table 5.7), correction of fluid, acid–base and electrolyte abnormalities (Ch. 2), gastric decompression via nasogastric intubation, administration of fecal softeners or lubricants (Table 5.8), surgical correction of the lesion
Control Parasite control. Ensure adequate roughage in the diet

by periods of > 2 days of normality). Another classification system is anatomically based and is listed in Table 5.4. Regardless of the classification system used, some estimates are that fewer than 20% of colic cases seen in the field have a definitive diagnosis.[2,4] Horses with acute transient colic relieved by analgesics are often referred to as having 'spasmodic colic'.[5] Spasmodic or gas colic was the cause of 35% of horses with colic examined in the field by veterinarians.[6] Large-colon impaction (20%) and undiagnosed (13%) were the other largest diagnostic categories.[6]

EPIDEMIOLOGY

Most studies of the epidemiology of colic do not provide details of specific diseases but rather consider colic as one disease. This inclusion of many diseases into one category, while maximizing the statistical power of the studies, is unfortunate because it can obscure important details regarding the occurrence and risk factors of individual diseases. Furthermore, much of the information related to incidence, treatments and outcome of horses with colic is derived from studies of horses examined at referral centers. Horses examined at these centers are in all likelihood not representative of horses with colic that are not referred for examination by specialists, this being the majority of horses with colic. Details of the epidemiology of specific etiological entities are included under those headings. Only general principles are included here.

Occurrence

Equine colic occurs worldwide, although there are regional differences in the types of colic, and is a common and important disease of horses. For cases of equine colic recognized in the field, as distinct from those referred for specialized treatment, the **incidence** rate ranges between 3.5 and 10.6 cases per 100 horse years, although individual farms may experience rates as high as 30 or more cases per 100 horse years.[2,3,7,8] **Mortality** due to colic ranges between 0.5 and 0.7 deaths per 100 horse years, representing 28% of overall horse deaths (2.5 deaths per 100 horse years).[2,4,8] The **case fatality rate** is 6–13% of field cases.[2–4,8] Approximately 1–2% of colic events in the USA and the British Isles result in surgery.[3,8] It should be borne in mind that these estimates of incidence and mortality are highly influenced by the population of horses studied and may be biased or unduly influenced by inclusion of farms or groups of horses with an extremely high, or low, incidence of colic.

Risk factors

Risk factors for colic can be categorized as: 1) intrinsic horse characteristics; 2) those associated with feeding practices; 3) management; 4) medical history, and; 5) parasite control.[9]

Horse characteristics

Age

There are conflicting results of studies that examine the association of colic and age. The conflicting results might be the result of varying study populations, study design, presence of varying confounding

Type of colic	Etiology	Lesion	Typical clinical signs	Diagnosis
Simple obstruction (not infarctive)	Luminal obstruction	Impaction of stomach, ileum or large intestine with dry ingesta	Mild to moderate pain, heart rate mildly increased initially, moderate dehydration	Usually subacute course. Diagnosis on rectal exam or Imaging. Exploratory celiotomy
		Concretion-type body, e.g. fecalith, meconium, phytobezoar, enterolith, foreign body, sand colic, congenital atresia	Mild to moderate pain, moderate dehydration	Subacute to acute course. Diagnosis on rectal exam or imaging. Exploratory celiotomy
	Mural blockage	Hematoma, neoplasm, idiopathic muscular hypertrophy	Pain, moderate dehydration	Rectal exam, reflux through nasogastric tube. Exploratory celiotomy
	Extramural blockage	Large colon displacement	Mild to moderate pain, mild dehydration, abdominal distension	Rectal exam. Exploratory celiotomy
	Functional	Spasm (spasmodic colic) Paralytic ileus Gastric reflux (acute gastric dilatation, gastric ulcer, anterior enteritis)	Moderate to severe pain, moderate to severe signs of hypovolemia	Rectal exam, gut sounds, nasogastric intubation, ultrasonographic examination
Inflammation (irritation of peritoneal pain receptors)	Infectious (e.g. *Salmonella* spp., *Actinobacillus equuli*), chemical irritation (urine, ingesta)	Peritonitis Enteritis	Mild pain, fever, toxemia, tachycardia, hypovolemia	Leukocytosis, abdominal paracentesis, diarrhea

Table 5.3 (*Cont'd*) Etiological classification of equine colic

Type of colic	Etiology	Lesion	Typical clinical signs	Diagnosis
Simple infarction (no obstruction)	Infarction. Ischemia	Thromboembolic colic (verminous arteritis), arterial occlusion (pedunculated lipoma around mesentery), detachment of mesentery (traumatic or congenital)	Mild to severe pain, toxemia. Possibly blood loss	Abdominal paracentesis, total white cell count. Exploratory celiotomy
Obstruction plus infarction	Intestinal accidents	Intussusception Torsion Strangulation (epiploic foramen, diaphragmatic, inguinal hernias, mesenteric tear or congenital defect, pedunculated lipoma)	Intractable pain followed by profound depression, toxemia, severe tachycardia, hypovolemia	Rectal exam. Abdominal paracentesis, PCV, total white cell count, nasogastric intubation, ultrasonographic examination

Table 5.4 Disorders of the equine gastrointestinal tract causing colic, by anatomical site

Site	Disorder
Stomach	Gastric dilatation
	Primary
	Secondary to outflow obstruction, pyloric stenosis, ileus or anterior enteritis
	Gastric impaction
	Gastroduodenal ulceration
Small intestine	Volvulus
	Intussusception
	Ileocecal
	Jejunojejunal
	Infarction or ischemia
	Thromboembolic disease
	Disruption of blood supply by mesenteric tear
	Strangulation, including entrapment through the epiploic foramen, mesenteric rents (including cecocolic fold, splenic ligament, uterine ligaments, spermatic cord), Merkel's diverticulum and hernias (diaphragmatic, inguinal/scrotal, umbilical).
	Strangulation by pedunculated lipoma
	Luminal obstruction
	Foreign bodies
	Ascarids
	Luminal compression
	Lipomas
	Intramural masses such as *Pythium* spp. and neoplasms (adenocarcinoma, lymphoma, eosinophilic enteritis)
	Adhesions
	Enteritis
Cecum	Impaction
	Rupture and perforation
	Intussusception
	Cecocolic
	Cecocecal
	Cecal torsion
	Infarction (thromboembolic disease, necrotizing enterocolitis)
	Typhilitis
	Tympany
Ascending (large) colon	Impaction
	Intestinal tympany
	Volvulus
	Displacement, including left dorsal (reno- or nephrosplenic), right dorsal, cranial displacement of pelvic flexure
	Infarction (verminous mesenteric arteritis, necrotizing enterocolitis)
	Luminal obstruction
	Sand accumulation
	Enterolith
	Right dorsal ulcerative colitis
	Colitis
	Necrotizing enterocolitis
Descending (small) colon	Impaction
	Luminal obstruction
	Fecalith
	Enterolith
	Luminal compression
	Pedunculated lipoma
	Intramural hematoma
	Perirectal abscess
	Perirectal tumor (melanoma)
	Avulsion of mesocolon and rectal prolapse in mares at parturition
	Strangulation

factors, and interpretation of data. Confounding factors are those that alter with the age of the horse, such as use, feeding and management of horses, and mask an effect of age or give the impression of an effect of age when in fact such an effect is not present.[9,10] Horses 2–10 years of age are 2.8 times more likely to develop colic that horses less than 2 years.[11] One large-scale study reported that foals less than 6 months of age had an incidence of 0.2 cases of colic per 100 horses per year, while horses more than 6 months of age had incidence of approximately 4–6 colic-affected horses per 100 horse years, with the incidence varying to a limited extent among older age groups.[3] Other studies have not found a similar effect of age.[4] However, each age group has a particular set of diseases unique or common to it. Newborn foals may have congenital colon or anal atresia, or meconium impaction (see Colic in foals), diseases that do not affect older horses, whereas strangulating or obstructive lesions caused by pedunculated lipomas are found only in older horses.[12]

Sex

There is no overall effect of sex on risk of colic[4,11] but certain diseases are restricted by sex. For instance, inguinal hernias occur only in males, whereas entrapment of intestine in the mesometrium is restricted to mares, for obvious reasons.

Breed

There is a consistent finding that Arabian horses are at increased risk of colic, but the reason for this apparently greater risk has not been determined.[4,6,9,10] Thoroughbreds are reported to be at increased risk of colic, independent of their use.[3,11]

Diet and feeding practices

Horses at pasture are at a lower risk of developing colic than are **stabled horses** fed concentrate feeds.[11,13,14] The risk of colic increases with the amount of concentrate fed, such that a horse fed 5 kg of concentrated feed per day has 6 times as great a risk of developing colic as a horse not fed concentrate.[11] However, another report did not detect an effect of diet composition on risk of colic.[6] Changes to the horse's diet through changes in quantity and quality of feed, feeding frequency, or time of feeding increase the risk of colic by 2–5 times.[6,11,13,15]

Management

Watering

Horses without constant **access to water** are at increased risk of developing colic,[14] whereas horses with access to ponds or dams have a reduced risk of colic compared to horses provided with water from buckets or troughs.[11,14] This might represent a confounding effect of pasturing, in that horses with access to dams are probably at pasture and benefit from the lower risk of colic associated with that management practice. Alternatively, horses provided with water from buckets may be at greater risk of having periods when water is not available.[14]

Housing

Increased duration of stabling per day is associated with an increased risk of colic.[6,13] Horses cared for by their owner and horses in stables with large numbers of horses are less likely to develop colic.[8]

Exercise

Overall, there appears to be an increased risk of colic among horses that are undertaking physical activity or that have a recent change in the amount of physical activity. However, the finding of this association should be considered in the context of other differences that exist between active and inactive horses, such as in feeding practices, housing (stabling versus pasture), and transportation.

Weather and climate

Despite the widespread belief that colic is associated with changes in weather, particularly thunderstorms, there is no conclusive evidence of such an association.[9,10]

Medical history

Horses with a history of colic are more likely to have another episode, and horses that have had colic surgery are approximately five times more likely to have another episode of colic than are horses that have not had colic.[6,15] There is no association between dental care and incidence of colic or recent vaccination and colic.[6,9]

Parasite control

Inadequate parasite control programs have been estimated to put horses at 2–9 times greater risk of developing colic,[7] although other studies have not demonstrated a relationship between anthelmintic administration and colic.[8,15] The presence of tapeworms is associated with a 3 times greater risk of ileal impaction.[16] A recent large-scale study in the USA found an increased incidence of colic in horses on farms on which rotation of anthelmintics was practiced.[3] This apparently paradoxical finding may be because farms with a higher incidence of colic are more likely to alter rotate anthelmintics as a result of having more horses with colic.[3]

The apparently conflicting results of some of the epidemiologic studies should not deter veterinarians from recommending effective parasite control programs for horses, given the clear association at an individual level of presence of tapeworms, cyathostomes and/or large strongyles and ileocecal disease, diarrhea and ill thrift, and verminous arteritis, respectively.

Importance

Losses caused by colic in horses are due almost entirely to death of the patient. However, the cost of treatment and the emotional trauma to the owners of their horse being afflicted with a potentially fatal disease are important considerations. A 1989 survey of veterinarians in the USA rated colic the most serious medical disease in horses, ahead of viral respiratory disease[1] and recent studies estimated the cost of colic to the horse industry in the USA at $115 000 000 annually.[3]

PATHOGENESIS

The pathogenesis of equine colic is variable depending on the cause and severity of the inciting disease. A horse with a strangulating lesion involving 50% of its small intestine has a much more rapidly evolving disease, with severe abnormalities, than does a horse affected with mild spasmodic colic or impaction of the pelvic flexure of the large colon. While equine colic often involves changes in many body systems, notably the gastrointestinal, cardiovascular, metabolic and endocrine systems, there are several features and mechanisms that are common to most causes of colic and that depend only on the severity of the disease for the magnitude of their change. The features common to severe colic, and often present to a lesser degree in milder colics, are pain, gastrointestinal dysfunction, intestinal ischemia, endotoxemia, compromised cardiovascular function (shock) and metabolic abnormalities.

Pain

Pain is the **hallmark of gastrointestinal disease** in horses and is attributable to distension of the gastrointestinal tract and stimulation of stretch receptors in the bowel wall and mesentery, stretching of mesentery by displaced or entrapped bowel, and inflammation and irritation of the bowel, peritoneum or mesentery. The **intensity of the pain** is often, but not always, related to the severity of the inciting disease. Horses with mild impaction of the large colon of short duration (< 24 h) often have very mild pain, whereas a horse with a strangulating lesion of the small intestine will have very severe pain.

Gastrointestinal pain has an inhibitory effect on normal gastrointestinal function, causing a feedback loop in which the pain inhibits normal gut motility and function, allowing accumulation of ingesta and fluid, resulting in distension and further pain. Horses can respond very violently to

abdominal pain and may injure themselves when rolling or thrashing.

Gastrointestinal dysfunction

Colic is almost invariably associated with impaired gastrointestinal function, usually alterations to **motility** or **absorptive** function. Gastrointestinal motility may be increased, as is presumed to be the case in spasmodic colic, altered in its character or coordination, as in some cases of impaction colic, or absent, such as in ileus secondary to inflammation or ischemia of the bowel or to the presence of endotoxemia. Increased or uncoordinated gastrointestinal motility probably causes pain through excessive contraction of individual segments of bowel or distension of bowel because of the loss of normal propulsive activity. **Ileus** is associated with fluid distension of the small intestine and stomach and fluid and gas distension of the large colon, both of which cause severe pain and can lead to gastric or colonic rupture. The absorptive function of the intestine may be decreased by inflammation or ischemia, which results in distension of the small intestine or large colon, pain and potentially rupture of the stomach or colon.

Impairment of the **barrier function** of the gastrointestinal mucosa by inflammation or ischemia can result in leakage of endotoxin into peritoneal fluid and endotoxemia[17] (see Endotoxemia).

Ischemia of the intestinal wall

Ultimately, most forms of lethal colic involve some degree of ischemia of the intestine, with subsequent loss of barrier function, evident in its most extreme form as rupture of the viscus, endotoxemia, bacteremia, cardiovascular collapse and death. Ischemia may be the result of impaired blood flow to or from the intestine because of torsion or volvulus of the intestine, entrapment of the intestine and associated mesentery in rents or hernias, strangulation such as by a pedunculated lipoma, or thromboembolic disease. Ischemia may also result from severe gastrointestinal distension, such as occurs in the terminal stage of severe colon impaction. Mild ischemia probably impairs normal intestinal motility and function. The role of reperfusion injury in pathogenesis of ischemic disease is uncertain at this time.

Endotoxemia

Death in fatal cases of colic in which the affected viscus ruptures secondary to distension, or when ischemia and/or infarction damages a segment of bowel wall, is due to the absorption of endotoxins from the gut lumen into the systemic circulation.[17] (See Endotoxemia). Endotoxin absorption causes increased concentrations of tumor necrosis factor and interleukin 6 in peritoneal fluid and blood concentrations.[17]

Rupture of the stomach or intestine is also a characteristic termination of distension of the intestine in the horse. The resulting deposition of large quantities of highly toxic ingesta or fecal contents into the peritoneal cavity causes profound shock and death within a few hours.

Shock

The usual cause of death in severe colic is cardiovascular collapse secondary to endotoxemia and hypovolemia. In less severe colic, hypovolemia and cardiovascular dysfunction may contribute to the development of the disease, and rapid correction of hypovolemia is central to the effective treatment of colic.

Hypovolemia is due to the loss of fluid and electrolytes into the lumen of the gastrointestinal tract or loss of protein from the vascular space with subsequent reduction in the circulating blood volume. Hypovolemia impairs venous return to heart and therefore cardiac output, arterial blood pressure and oxygen delivery to tissues. Not surprisingly, measures of circulatory status are good predictors of the outcome of colic (see Prognosis, below).

Cardiorespiratory function is impaired if there is severe distension of gut, such as in large-colon torsion, because of restricted respiration by pressure on the diaphragm and reduced venous return to the heart because of pressure on the caudal vena cava.

Coagulation and fibrinolysis

Severe colic, especially that involving ischemia or necrosis of intestine, is associated with abnormalities in coagulation and fibrinolysis characterized by hypercoagulation of blood and decreases in rate of fibrinolysis.[18–21] Disseminated intravascular coagulation is common among horses with ischemia or necrosis of the gut and is a good prognostic indicator of survival.[19,20] Changes in coagulation and fibrinolysis include decreases in antithrombin activity and fibrinogen concentration and increases in prothrombin time, activated partial thromboplastin time and concentration of thrombin–antithrombin complexes in plasma.[19–21]

Overview of the pathogenesis of common colics

Simple obstructive

Simple obstructive colics are those in which there is obstruction to the aboral passage of ingesta but no ischemia or strangulation of bowel. In the terminal stages there is often ischemia caused by distension of the intestine.

Small-intestinal obstructive lesions include ileal hypertrophy, ileocecal intussusception and foreign-body obstruction of the lumen. The course of the disease is often 24–72 hours, and sometimes longer depending on the extent of the obstruction, partial obstructions having much less severe signs and disease of longer duration. The principal abnormality is reduced aboral flow of ingesta, with subsequent distension of intestine cranial to the obstruction, causing pain and, if the distension is severe, gastric rupture.

Large intestinal obstructive lesions include impaction and simple (nonstrangulating) displacements of the large colon. The course of disease is prolonged, often more than 72 hours. Signs of abdominal pain are due to distension of the bowel. There is progressive distension with fluid and gas and ultimately ischemia of the bowel and rupture.

Obstructive and strangulating

Diseases that cause both obstruction and strangulation as an initial event, such as torsion of the small intestine or volvulus of the large colon, result in severe and unrelenting pain that is little relieved with analgesics. Obstruction causes distension and strangulation causes ischemia, loss of barrier function and endotoxemia. These diseases have a short course, usually less than 24 hours and sometimes as short as 6 hours, and profound clinical signs. Endotoxemia and cardiovascular collapse are characteristic of these diseases.

Infarctive

Infarctive diseases, such as thromboembolic colic, are characterized by ischemia of the intestinal wall with subsequent alterations in motility and absorptive and barrier functions. Ileus causes distension of the intestines and stomach and altered barrier function causes endotoxemia. The course of the disease is usually less than 48 hours and is terminated by cardiovascular collapse and death.

Inflammatory

Inflammation of the intestine or peritoneum alters gastrointestinal motility and absorptive function leading to accumulation of fluid and ingesta, distension and abdominal pain.

CLINICAL FINDINGS

The bulk of the following description is generally applicable to severe acute colic. Clinical findings characteristic of each etiological type of colic are dealt with under their individual headings. The purposes of the clinical examination are **diagnostic** – to determine whether the pain is due to gastrointestinal tract disease and, if so, to determine the nature of the lesion – and **prognostic**, to provide some estimate of the likely outcome of

the disease. Veterinary clinicians are able to accurately predict the site of lesions (small versus large intestine), type of lesion (simple obstructive versus strangulating or infarctive) and outcome.[22] The ability to predict these events increases with training and experience.[22]

Accurate diagnosis of the cause of the colic has some prognostic usefulness, but assessment of the horse's physiological state by measurement of heart and respiratory rates, mucous membrane color and refill time, arterial blood pressure, hematocrit and serum total protein concentration, and other measures, allows more accurate prognostication. Furthermore, the cause of colic is determined in only approximately 20% of field cases.

Visual examination

Behavior

Pain is manifested by **pawing, stamping or kicking** at the belly or by restlessness evident as pacing in small circles and repeatedly getting up and lying down, often with exaggerated care. Other signs are looking or nipping at the flank, **rolling**, and lying on the back. Often the penis is protruded without urinating or with frequent urination of small volumes. Continuous playing with water without actually drinking (sham drinking) is common.

Pain may be continuous or, more commonly, intermittent with bouts of pain lasting as long as 10 minutes interspersed with similar periods of relaxation. In general the intensity of the pain is of about the same severity for the duration of the illness; sudden exacerbations may indicate a change in the disease status or the development of another abnormality, such as a horse with impaction of the large colon developing a displacement of the colon or horses with diarrhea developing necrotizing enteritis. Horses in the terminal phase of the disease may have a marked diminution of pain associated with relief of pressure after rupture of distended bowel and depression caused by toxemia and shock. Pain responses in colic may be so severe, and uncontrolled movements so violent, that the horse may do itself serious injury. Other causes of pain, such as pleuritis or rhabdomyositis, can be confused with colic, although a horse that goes down and rolls almost certainly has alimentary tract colic.

Posture

The posture is often abnormal, with the horse standing stretched out with the forefeet more cranial and the hindfeet more caudal than normal – the so-called 'saw-horse' stance. Some horses lie down on their backs with their legs in the air, suggesting a need to relieve tension on the mesentery.

Abdomen size

Distension of the abdomen is an uncommon but important diagnostic sign. **Symmetrical, severe distension** is usually caused by distension of the colon, sometimes including the cecum, secondary to colon torsion, or impaction of the large or small colon and subsequent fluid and gas accumulation. If only the cecum is distended the abdomen may show an **asymmetrical enlargement** in the right sublumbar fossa. Maximum distension of stomach or small intestines does not cause appreciable distension of the abdomen.

Vomiting

Projectile vomiting or regurgitation of intestinal contents through the nose is very unusual in the horse and is a serious sign suggesting severe gastric distension and impending rupture.

Defecation and feces

Defecation patterns can be misleading. It is often mistakenly assumed that there is no complete obstruction because feces are still being passed. But in the very early stages of acute intestinal obstruction there may be normal feces in the rectum, and the animal may defecate several times before the more usual sign of an empty rectum with a sticky mucosa is observed.

Physical examination

Heart and respiratory rates

The **heart rate** is a useful indicator of the severity of the disease and its progression but has little diagnostic usefulness. Horses with heart rates less than 40/min usually have mild disease whereas horses with heart rates above 120/min are usually in the terminal stages of severe disease. Horses with obstructive, non-strangulating disease often have heart rates between 40 and 60/min, whereas horses with strangulating disease or necrotic bowel will usually have heart rates over 80/min. However, heart rate is not an infallible indicator of disease severity, as horses with torsion of the colon can have heart rates of 40–50/min.

The **respiratory rate** is variable and may be as high as 80/min during periods of severe pain.

Mucous membranes and extremities

Mucous membranes of normal horses and of horses without significantly impaired cardiovascular function are pink, moist and regain their normal color within 2 seconds after firm digital pressure is removed. Dehydrated horses have dry mucous membranes, although the capillary refill time and color are normal. Horses with impaired cardiovascular function have pale, dry mucous membranes with delayed capillary refill (> 2 s). Endotoxemic horses will often have bright red mucous membranes with normal or delayed capillary refill. As the disease becomes more severe the mucous membranes develop a bluish tint and capillary refill is longer than 3 seconds. **Terminal** stages of disease are associated with cold, purple, dry mucous membranes with a capillary refill time of more than 3 seconds; necrosis of the mucosa of the gingival margins of the gums, the so-called 'toxic line', is often seen.

Cool extremities may be indicative of compromised cardiovascular function but should be interpreted with caution and only in the context of the rest of the clinical examination. **Sweating** is common in horses with severe abdominal pain and, when present in a horse with cool extremities and signs of cardiovascular collapse, is indicative of a poor prognosis.

Auscultation; percussion

Auscultation of the abdomen can provide useful diagnostic and prognostic information and should be performed thoroughly and without haste. All four quadrants (dorsal and ventral, left and right sides) of the abdomen should be examined for at least 1 minute at each site. Attention should be paid to the intensity, frequency and characteristics of the spontaneous gut sounds (borborygmi). Repeated observations are often necessary to detect intermittent or rapid changes in the character of the borborygmi.

Continuous, loud borborygmi distributed in all or most quadrants are indicative of intestinal hypermotility and consistent with spasmodic colic, impending diarrhea or the very early stages of a small-intestinal obstructive/strangulating lesion. The **absence of sounds**, or the presence of occasional high-pitched, brief sounds, sometimes with a splashing character, is consistent with ileus. These sounds should not be mistaken for the rolling, prolonged sounds of normal peristalsis.

Combined percussion and auscultation is a valuable procedure for defining the presence of extensive gas caps; a flick or abrupt tap with a finger while auscultating with a stethoscope will elicit a '**pinging**' sound similar to that made by flicking an inflated balloon. The detection of such sounds indicates the presence of tightly gas-distended bowel near the body wall. Such bowel is almost always large colon or cecum and is consistent with gas distension secondary to ileus, small or large colon impaction, gas colic or colon displacement, including torsion.

Rectal examination

A careful rectal examination is probably the most important part of the clinical examination in colic and should not be neglected. The examiner must know the anatomy of the posterior abdomen in order to make reasonably accurate decisions about the location of various organs. Recognition that an important abnormality exists is a critical factor in the decision to refer the horse for specialized evaluation and care.

Normal anatomy

The horse should be restrained so that the examination can be performed with minimal risk to both the examiner and patient. Fractious or painful horses should be tranquilized. A twitch should be applied to all but the most cooperative horses to minimize straining and the chance of kicking. Rectal examination in small or unruly horses should be approached with caution.

Only approximately 40% of the abdomen can be examined in a mature horse, the cranial and ventral structures being outside the reach of the examiner. In the normal 425 kg (1000 lb) horse there should not be any distended intestine nor should the small intestine be palpable. The **cecum** is readily palpable in the right caudal abdomen, with its ventral band running from the dorsal right quadrant ventrally and slightly to the left. The base of the cecum may be palpable as a soft, compressible structure containing fluid and gas. The caudal border of the **spleen** is readily palpable as it lies on the left side of the abdomen against the body wall. There should be no bowel between the spleen and the body wall although occasionally small colon can be detected dorsal to the spleen. Dorsal and medial to the spleen the **left kidney** should be readily palpable, as should the **nephrosplenic ligament** and **space**. There should be no bowel in the nephrosplenic space, although some horses have portions of small colon in the region of the nephrosplenic space. Portions of **large colon**, especially the pelvic flexure, can be palpated in the caudal ventral abdomen if they contain ingesta. The inguinal rings may be palpated in males. The ovaries and uterus can be palpated in mares. The bladder can be palpated if it contains urine.

Abnormal findings

Abnormalities associated with specific diseases are discussed under those headings (Table 5.5). One should be able to recognize gas and fluid distension of the cecum and colon, fluid distension of the small intestine, impaction of the large and small colon, and displacement of the large colon.

Small intestinal distension is evident as loops of tubular structures of up to 10–15 cm diameter that may extend as far caudally as the pelvic canal. The structure is often compressible, akin to squeezing a fluid-filled tubular balloon, and slightly moveable. The presence of distended small intestine is an important sign suggestive of a small-intestinal obstructive lesion or anterior enteritis.

Colonic distension, impaction and displacement. Gas and fluid distension of the **large colon** is evident as large (> 20 cm) taut structures often extending

Table 5.5 Rectal findings and associated causes of equine colic

Rectal abnormality	Disease	Clinical characteristics	Treatment
Distended small intestine	Anterior enteritis	Small intestine mildly to moderately distended. Voluminous gastric reflux. Marked pain relief on gastric decompression. Normal peritoneal fluid in most cases	Supportive. Repetitive decompression of stomach
	Strangulating intestinal lesion. Small intestinal volvulus or entrapment	Severe, tight distension of small intestinal. Gastric reflux. Severe pain not relieved by gastric decompression. Abnormal peritoneal fluid	Surgery
	Ileal impaction	Mild and progressive pain. Gastric reflux only late in disease. Impaction occasionally palpable per rectum	Medical initially, then surgery if no resolution
	Ileal hypertrophy	Mild to moderate chronic pain occurring after feeding. Hypertrophy may be palpable	Surgical resection
	Ileocecal intussusception	Moderate to severe pain. Gastric reflux later in disease. Usually young horse	Surgical correction
Large colon distension	Colon torsion	Tenia dorsal in some cases. Cecum displaced medially. Severe pain. Abdominal distension. No gastric reflux. Short disease course	Surgical correction
	Left dorsal colon displacement (renosplenic entrapment	Mild to moderate pain. Bands on rectal examination leading to renosplenic space. Ultrasonographic confirmation	Replacement by rolling horse. Surgery
	Right dorsal displacement of colon	Moderate to severe pain. Bands leading ventral to right dorsal quadrant. Colon lateral to base of cecum	Surgical correction
	Impaction of large colon	Impaction palpable per rectum	Fecal softeners and lubricants, oral and intravenous fluids. Surgery in refractory cases
	Enterolith	Obstruction usually of right dorsal or transverse colon. Not palpable rectally. Refractory pain. Radiography	Surgical removal
	Gas colic	Gas distension of large colon. Pain readily relieved with analgesics. Short course with rapid recovery. Major differential is colon torsion	Analgesics, mineral oil
	Sand colic	Mild to moderate pain. Sand auscultable in ventral abdomen. Sand in feces. Occasional watery feces	Analgesics, psyllium orally
Cecal distension	Cecal impaction	Mild to moderate pain, course of several days with sudden deterioration when cecum ruptures	Analgesics, lubricants, fecal softeners. Surgical correction
	Cecal torsion	Acute, severe pain. Rare	Surgical removal or correction
Displaced spleen	Renosplenic entrapment of large colon	See above	
	Large colon displacement.	Mild to moderate pain. Ultrasonographic diagnosis	Analgesics. Surgery
Intra-abdominal masses	Mesenteric abscess	Fever, mild chronic or intermittent abdominal pain. Increased leukocyte numbers in blood and peritoneal fluid	Long term antibiotics
	Neoplasia	Neoplastic cells in peritoneal fluid. Exploratory laparotomy	None

into the pelvic canal. Tenial bands are often not palpable because of the distension. The distended bowel may extend into the pelvic canal, preventing examination of the caudal abdomen. **Impaction** is evident as columns of firm ingesta in the large or small colon. The most common site is the pelvic flexure in the caudoventral abdomen and the inlet to the pelvic canal. The impacted material remains indented when pressed with the finger tips.

Distension of the small colon is detectable as loops of tubular structures in the caudal abdomen. The loops of intestine have a prominent antimesenteric band, a feature not present on small intestine.

Displacement of the large colon is evident rectally as tight bands extending from the ventral abdomen cranially, dorsally and to the left or cranially, dorsally and to the right in left and right displacements of the colon, respectively. Displacement of the colon, if it obstructs aboral flow of ingesta and gas, may cause distension.

Nasogastric intubation

Passage of a nasogastric tube is an essential part of the examination of a horse with colic because of the diagnostic information it provides and because relief of gastric distension may be life-saving.

The nasogastric tube **must** be passed into the stomach. This is usually evident by the release of a small amount of sweet-smelling gas as the stomach is entered. The tube should then be advanced further into the stomach and, if reflux of material does not occur spontaneously, a siphon should be established by filling the tube with approximately 500 mL of water and rapidly dropping the end of the tube below the level of the horse's stomach. This procedure should be repeated at least three or four times if reflux is not obtained. If **reflux** is obtained, its volume and character should be noted. The volume should be measured – anything more than 2 L of net reflux is likely important. If reflux is obtained, the nasogastric tube should be left in place or replaced frequently (1 h intervals) until the colic resolves. If there is no reflux but the horse remains colicky, then repeated attempts should be made to obtain reflux. **Oral medications**, such as mineral oil, should not be given to horses with nasogastric reflux.

Ancillary diagnostic techniques

Ultrasonography

Ultrasonographic examination of the abdomen of adult horses is useful in identifying a number of abnormalities, including small-intestinal distension, ileocecal intussusception, gastric distension, gastric squamous cell carcinoma, diaphragmatic hernia, peritoneal effusion and other conditions.[23] The abdomen should be examined in a systematic fashion with a 2.0–3.5 mHz transducer. Ultrasonographic examination is useful to detect small-intestinal distension (such as occurs with anterior enteritis or small intestinal accidents), reduced motility (anterior enteritis, enteritis, obstruction), thickening of intestinal wall (> 4 mm, enteritis, right dorsal colitis), volume and characteristics of peritoneal fluid (peritonitis, hemoperitoneum), abnormalities in intestinal contents (such as presence of sand or excessively fluid ingesta), presence of sacculations of the ventral colon (absence indicates distension), abnormalities in intestinal architecture (intussusceptions) and presence of abnormal structures (neoplasia, abscess). Ultrasonographic detection of small-intestinal distension is more sensitive than rectal examination.[24] Ultrasonographic examination reveals colon with a mural thickness of 9 mm or greater in horses with colon torsion. The test has a sensitivity of approximately 67% (i.e. correctly predicts the presence of colon torsion in two-thirds of horses that have the disease) and specificity of 100% (correctly rules out the diagnosis in 100% of horses that do not have the disease).[25]

Radiology

The large size of the adult horse precludes detailed radiographic examination of intra-abdominal structures. However, enteroliths and sand accumulation can be detected with reasonable certainty provided suitable radiographic equipment is available.[18] Diaphragmatic hernias can be detected on radiographic examination of the thorax.

Arterial blood pressure

Arterial blood pressure is a very good indicator of the degree of shock in colic, and the availability of a simple technique makes it a practical aid in assessing prognosis in a clinical case. If normal systolic pressure is about 100 mmHg (13.3 kPa), a pressure below 80 mmHg (10.6 kPa) indicates a critical situation (it can be as low as 50 mmHg, 6.6 kPa). In horses with very severe pain but not shock, the systolic pressure is likely to be very high, up to 250 mmHg (33.3 kPa).

Course of the disease

The course of the disease depends upon its cause and the severity of the associated lesions. Spasmodic and gas colic usually resolves within hours of onset. Horses with strangulating lesions have severe clinical signs and usually die within 24 hours of the onset of signs. Horses with nonstrangulating obstructive lesions have longer courses, often 48 hours to 1 week, and die when distension causes bowel to become devitalized and rupture.

When intestinal rupture does occur, there is a sudden onset of shock and toxemia, the acute pain that preceded it disappears and the horse becomes quiet and immobile. The terminal stages after rupture of the intestine or stomach, or due to profound endotoxemia, are very distressing. The horse may be recumbent but most continue to stand until the last few minutes, when they literally drop dead. The respiration is sobbing and there is gross muscle tremor and profuse sweating, and there is often a delirious, staggering wandering. Euthanasia should be performed before this stage is reached.

CLINICAL PATHOLOGY

Examination of various clinical pathology variables is useful in assessing the severity of the changes occurring as a consequence of the disease rather than in providing a definitive diagnosis. Therefore, some of these variables have prognostic significance (Prognostication) and should be monitored repeatedly in severe cases.

Hematology and serum biochemistry

Measurement of **hematocrit** and **plasma total protein** concentration is useful in assessing hydration status (see Chapter 2). Hematocrit increases as a consequence of splenic contraction or dehydration, making the use of this variable as a sole indicator of hydration status unreliable. However, increases in both hematocrit and total protein concentration indicate dehydration, and these variables can be used as crude estimates of response to fluid therapy. Plasma total protein concentrations may decline if there is significant loss of protein into the gut lumen or peritoneal space.

Measurement of the **blood leukocyte** count has little diagnostic significance, with the exception that the combination of leukopenia and a left shift are consistent with the endotoxemia that accompanies devitalized bowel, enteritis or peritonitis.

Horses with severe colic often have abnormalities in coagulation, with nonsurviving horses and horses with strangulating lesions having the most severe changes, characterized by low antithrombin activity and prolonged prothrombin and activated partial thromboplastin times.[18,26]

Measures of **serum electrolyte concentration** are important in providing an assessment of the horse's electrolyte status and in tailoring fluid therapy (see Chapter 2). The nature of the abnormalities depends to some extent on the

cause of the disease, but is more markedly affected by the severity of the disease. Mild hyponatremia is not uncommon but is clinically insignificant. **Hyperkalemia** is common in horses with severe acidosis and large sections of devitalized intestine. **Hypokalemia** is common in horses with more long-standing colic, for instance impaction of the large colon, that have not eaten for several days. **Hypocalcemia** and **hypomagnesemia** are common in horses with colic, especially horses with severe colic. Measurement of total concentrations (ionized plus non-ionized) can be misleading in that reductions in concentration of the physiologically important ionized component can be present in horses with normal concentrations of the total ion.[27,28] Hospitalized horses with colic or diarrhea are more likely to have hypomagnesemia than are horses with other diagnoses.[29]

Serum enzyme activities are rarely useful in aiding diagnosis or treatment of horses with colic, with the exception that **serum gamma glutamyl transferase (GGT)** activity is elevated in approximately 50% of horses with right dorsal displacement of the colon, whereas such elevations are rare in horses with left dorsal displacement.[30] The elevated GGT, and less commonly serum bilirubin concentration, in horses with right dorsal displacement is attributable to compression of the common bile duct in the hepatoduodenal ligament by the displaced colon.[30] Serum and peritoneal **alkaline phosphatase** activities are higher in horses with ischemic or inflammatory bowel disease than in horses with other forms of colic, although the differences are not sufficiently large as to be useful diagnostically.[31] Serum creatine kinase activity above the normal range (385 U/L) is associated with a fourfold increase in the likelihood that a horse with colic has small intestinal ischemia.[32]

Serum **urea nitrogen** and **creatinine** concentrations are useful indicators of hydration status and renal function. Prerenal azotemia is common in horses with colic, and may progress to acute renal failure in severe cases of colic.

High plasma concentrations of intestinal fatty acid binding protein (> 100 pg/mL) are associated with increased need for surgery in horses with colic.[32]

Horses that die of colic have higher circulating concentrations of epinephrine, cortisol and lactate than do horses that survive, indicating the greater degree of sympathetic and adrenal cortical activation in these horses.[33]

Acid–base status

Most horses with severe colic have **metabolic acidosis**, although respiratory acidosis and metabolic alkalosis also occur. Horses with less severe disease, such as simple obstructive disease or spasmodic colic, might not have abnormalities in acid–base status. Metabolic acidosis, when severe, is attributable to L-lactic acidosis.[34] An estimate of the plasma **lactate** concentration can be obtained by calculating the anion gap:

Anion gap = (sodium + potassium) – (bicarbonate + chloride).

If bicarbonate concentrations are not available, total serum carbon dioxide can be substituted. Anion gaps of less than 20 mEq/L (mmol/L) are associated with 81% survival, 20–24.9 mEq/L (mmol/L) with 47% survival, and 25 mEq/L (mmol/L) or more with 0% survival.[35]

Abdominocentesis

Analysis of peritoneal fluid is an important component of the complete examination of a horse with colic.[36] Details of the technique and interpretation of the results were discussed previously but, briefly, if there is an increase in the total protein concentration, a change in the color to red or blood-tinged, and an increase in the leukocyte count in peritoneal fluid, it is likely that there is some insult to intra-abdominal structures.[32,36] **Total protein concentration** increases when there is an insult to the gastrointestinal tract that compromises the serosal surface of the bowel, for instance strangulating lesions of the small intestine or in the terminal stages of an impaction colic in which the bowel wall is devitalized.[32,36] The presence of intracellular bacteria, plant material and degenerate neutrophils is indicative of gastrointestinal rupture provided that one is *certain* that the sample came from the peritoneal space and not from the bowel lumen (by inadvertent enterocentesis).

PROTOCOL FOR EVALUATING A COLIC PATIENT

When evaluating a horse with colic the aims are:

- Determine the nature and cause of the lesion
- Establish a prognosis
- Determine the most appropriate therapy, including consideration of euthanasia
- Determine the need for referral for specialized care, including surgery.

The suggested protocol for evaluating a horse with colic is set down below. The time intervals between repeated examinations depend on a number of factors, including severity of the disease and the accessibility of the horse. For a horse with a possible intestinal obstruction this should be every hour; for a horse with probable colonic impaction examinations every 4 hours are adequate; for a chronic colic with ileal hypertrophy an examination every day is usual. The following observations should be made.

Behavior

The following should be assessed: severity of pain, frequency and duration of attacks, whether food is taken, amount and character of feces, and frequency of urination.

Clinical and clinicopathological observations

- **Elevated pulse rate** with a fall in **pulse amplitude** are among the most reliable indicators of the state of dehydration or shock. They can be temporarily misleading in a horse that is excited because it is in strange surroundings, or separated from its dam, foal or close companion. They may also be marginally influenced by a bout of pain. A rate of more than 60/min and a steady climb in heart rate of about 20 beats/min at each hour in a series of monitoring examinations signal a deterioration in prognosis. A high rate that continues to worsen during a period of analgesia as a result of medication also indicates a bad outcome. A small-amplitude, 'thready' pulse characterizes severe shock
- **Mucous membrane color** and **capillary refill time** are assessed. Deep congestion (dark red) or cyanosis (purple) and capillary refill times much longer than 2 seconds are indicators of peripheral circulatory failure
- **Temperature** is infrequently taken unless there is some positive indication, such as suspicion of peritonitis, to do so
- **Respiratory rate,** also of minor importance except as an indicator of severity of pain, or in terminal stages of endotoxic shock or dehydration, when it becomes gasping
- **Intestinal sounds**. The disappearance of intestinal sounds indicates ileus. Hypermotility is usually a sign of less serious disease, except in the very early stages of a small intestinal accident. The development of a 'ping' on auscultation–percussion indicates accumulation of gas under some pressure
- **Rectal findings**. The development of palpable abnormalities is an ominous finding. A decision to intervene surgically is often made at this point. The inherent inadequacy of the rectal examination is that only the caudal half of the abdominal cavity can be

reached. Therefore large bowel and terminal ileal problems are more easily detected. With anterior abdomen small-intestinal lesions, distended loops do not usually come into reach until 6 hours after colic commences. They may reach back as far as the pelvis by 18 hours

- Amount and nature of **feces** is important. Failure to defecate within 12 hours of treatment is a bad sign. The empty rectum with a dry, tacky feel, or with a smear of mucus and degenerated blood some hours after the last defecation, presages a completely blocked intestine. The passage of oil but no feces suggests a partial blockage of large bowel that will permit the passage of oil but not fecal balls
- **Reflux** through a nasogastric tube. Acute gastric dilatation or small intestinal regurgitation of fluid sufficient to cause reflux of fluid via the stomach tube is a grim development. Large-bowel distension is also associated with fluid accumulations in the stomach. A negative test in a case suggestive of small intestinal obstruction should be followed by repeated tests; reflux from a lesion well down in the small intestine may take some hours to reach the stomach. In ileocecal valve impaction gastric reflux may not develop until 24 hours after the commencement of the colic
- **Abdominal paracentesis**. Repeated examinations are without serious risk and can herald the development of infarction and necrosis of gut wall, leakage and the development of peritonitis, or rupture and death due to endotoxic shock
- Visible **distension** of the abdomen
- **PCV** and **plasma protein**. A rise in PCV of 5% (i.e. from 55 to 60%) in an hour is a serious sign. A rise in PCV with a stable or declining serum protein concentration is often indicative of loss of capillary integrity and leakage of vascular proteins into extravascular spaces, such as the intestinal lumen. This is a sign of a poor prognosis
- **Skin tenting** on its own can be a very misleading indicator of the state of a horse's dehydration, but significant changes from one examination to another are likely to confirm deductions made on the basis of heart rate and mucosal color
- **Arterial blood pressure** is one of the most reliable prognostic indicators in cases of colic
- Response to **analgesics**. Diminution in the relief of pain after administration of detomidine, xylazine, butorphanol or flunixin meglumine can be interpreted as a serious decline in the status of the affected intestine.

When to refer the patient

The decision to refer a horse for specialist care and evaluation is often difficult. Most referrals occur because of the need for specialized medical or surgical treatment and therefore involve considerable expense and inconvenience to the owner. However, early referral is critical because of the improved chances of survival associated with early medical and surgical therapy of horses with severe colic.

The criteria for referral include:

- Severe persistent pain without identifiable cause for more than 24 hours. Referral should be sooner if there is evidence of compromised cardiovascular function, or any of the signs described below
- Recurrent attacks of colic over a period as long as several months
- Failure of an efficient analgesic to provide analgesia or relief for at least 20 minutes
- A rectally palpable lesion including distended small intestine, large colon, or small colon, or impaction of the large colon that does not resolve in 24 hours
- Reflux of more than 4 L of fluid through a nasogastric tube
- Abdominal distension
- Blood-tinged, high-protein peritoneal fluid with a high white cell count
- A rapid worsening of the pain and vital signs during a period of 2–4 hours.

Not all of these criteria need to be fulfilled to warrant a decision to refer and in most cases the presence of one of these findings is sufficient to justify a recommendation to the owner to refer the horse for further evaluation and specialized care.

Important in the decision to refer, or to perform a laparotomy, is the client's understanding of the **costs** involved and the **likely outcomes**. Because decisions to refer are often complicated by the emotional pressures on the owner and the need to make a decision quickly, it is important to take the time to fully inform the owner of the likely costs and outcomes before a final commitment is made to refer.

If there is doubt – refer it!

Surgery

The **decision to perform surgery** is best made by trained specialists and is usually based on a variety of clinical and clinicopathological findings with most weight given to the presence of severe unrelenting or intermittent pain, severe abdominal distension, large quantities of reflux through a nasogastric tube, intestinal distension palpable per rectum, serosanguinous peritoneal fluid, evidence of cardiovascular compromise including a high (> 60/min) and increasing heart rate, poor capillary refill, discolored mucous membranes and the absence of borborygmi.[37,38] Presence of abnormal abdominal fluid (turbid or serosanguinous) and peritoneal fluid with an elevated total protein concentration has good sensitivity (92%) and moderate specificity (74%) for the need for surgery.[36] Formal modeling of the need for surgery in horses with colic at referral institutions provides a numerical estimate of the need for surgery, but is seldom used in most referral practices.[39,40]

Prognosis

Given the enormous emotional and financial costs of having a severely ill horse with colic, there is an obvious need for accurate prognostication. Overall best predictors of survival are those clinical and clinicopathological factors that assess cardiovascular and metabolic status. The important factors include arterial blood pressure or its clinical correlates, pulse pressure and/or capillary refill time, pulse rate, mucous membrane color, indicators of hydration status (hematocrit, serum urea nitrogen concentration), blood lactate concentration and anion gap.[33,41–44]

Arterial systolic blood pressure is one of the best predictors of survival, with horses with systolic pressures of 90 mmHg (12 kPa) having a 50% chance of survival while fewer than 20% of horses with a pressure below 80 mmHg (10.6 kPa) survive.

Capillary refill time, the clinical manifestation of arterial blood pressure, is also a good predictor of the probability of survival. Capillary refill times of 3 seconds or more are associated with a survival rate of 30%. Similarly, increasing **heart rate** is associated with diminishing chances of survival – a horse with a heart rate of 80/min has a 50% chance of survival whereas one with a heart rate of 50/min has a 90% chance of surviving. Increasing blood lactate concentration and anion gap (see under Clinical pathology, above) are associated with increased chance of death. Measures of hydration status are also good indicators of prognosis. A **hematocrit** of 50% (0.50 L/L) is associated with a 50% chance of survival, while the chance of surviving drops to 15% when the hematocrit is 60% (0.60 L/L). Horses with high circulating epinephrine, cortisol or lactate concentrations are at greater risk of death.[33]

While individual variables may be good prognostic indicators, their predictive

utility improves when they are combined[40,43,44] although this introduces the need for either remembering models or keeping the model close at hand, something often not easily accomplished in the field. Furthermore, these models have been developed from cases at specific referral institutions and may not be applicable to field cases or even cases at other referral sites. However, the general principles probably apply in all circumstances even if the precise weighting appropriate for each variable does not.

NECROPSY FINDINGS

The nature of the necropsy findings depends on the underlying disease.

DIFFERENTIAL DIAGNOSIS

The following diseases may be mistaken for colic:

- Laminitis
- Pleuritis
- Enterocolitis
- Rhabdomyolysis
- Obstructive urolithiasis
- Uroperitoneum
- Foaling and dystocia
- Uterine torsion
- Peritonitis
- Cholelithiasis
- Ovulation and ovarian pain
- Esophageal obstruction
- Anterior enteritis
- Gastric ulceration
- Anthrax
- Testicular torsion
- Lactation tetany
- Tetanus
- Rabies
- Botulism
- Grass sickness
- Purpura hemorrhagica
- Clostridial myonecrosis (gas gangrene)
- Psychogenic colic

The clinical characteristics of common causes of equine colic are summarized in Table 5.6.

TREATMENT

Medical treatment

The specific treatment of each case of colic varies and depends on the nature of the lesion and the severity of the disease. However several principles are common to the treatment of most colic:

Provision of analgesia
Correction of fluid, electrolyte and acid–base abnormalities
Gastrointestinal lubrication or administration of fecal softeners
Treatment of underlying disease.

Analgesia

Analgesia is important in that it relieves the horse's discomfort, minimizes the physiological consequences of pain, including the pain-induced reduction in gastrointestinal motility, permits a thorough clinical examination and reduces the likelihood of the horse injuring itself while rolling or thrashing. Analgesics can be divided into NSAIDs, sedating analgesics and spasmolytics. The doses of these drugs are provided in Table 5.7.

The analgesic and its dose rate should be chosen such that the horse's pain is relieved but signs of progressive cardiovascular compromise indicative of the need for more aggressive therapy or surgery are not masked. **Acupuncture** does not provide effective analgesia in horses with colic and should not be used in these animals.[45]

Nonsteroidal anti-inflammatory drugs

Flunixin meglumine is a potent, long-acting analgesic with the ability to mask signs of surgical disease, with the consequence that surgery may be delayed and the chance of recovery diminished. Flunixin meglumine should only be used to control pain when the diagnosis is clear or when surgical intervention is not an option. It should not be used routinely in horses being monitored for progression of disease unless such monitoring is frequent and thorough, which may not be the situation in field colics. A horse that remains painful 30 minutes after the administration of flunixin meglumine is likely to have severe gastrointestinal disease and should be further evaluated.

Comments similar to flunixin meglumine apply to **ketoprofen** but not to **phenylbutazone**, which has relatively weak analgesic effects in colic patients (as opposed to its potent analgesic effects in musculoskeletal disease). **Dipyrone** is a weak analgesic that is useful in treatment of mild cases of colic.

Flunixin meglumine and etodolac retard recovery of equine jejunum and barrier function and flunixin inhibits electrical activity in the ventral colon.[46,47] However, these effects detected in vitro have not been demonstrated to have practical relevance to treatment of horses with colic with NSAIDs. Horses in pain should not, based on current information, be deprived of these drugs.

Alpha-2 agonists

The **alpha-2 agonists** (xylazine, detomidine, romifidine) provide potent analgesia, especially when combined with the opiate **butorphanol**. Duration is relatively short (up to 90 min for detomidine), which means that signs of progressive disease are readily detectable. The effect of alpha-2 agonists in reducing gastrointestinal motility is not clinically important in most colic cases and should not discourage use of these very useful drugs.

Opiates

Opiates, including butorphanol, meperidine (pethidine), morphine and pentazocine, are potent analgesics useful in the management of abdominal pain in the horse. These drugs are often combined with an alpha-2 agonist. Morphine and meperidine can cause excitement or urticaria in some horses. All are drugs with the potential for human abuse and the consequent limitation on their availability limits their use in horses.

Other agents

Acetylpromazine has almost no analgesic properties, although it is a potent sedative, and should not be used in the routine treatment of colic. Acetylpromazine is a potent hypotensive agent and should not be administered to any horse that is dehydrated or has compromised cardiovascular function.

Hyoscine butylbromide, a parasympatholytic drug, is widely used in certain parts of the world as the drug of choice in the initial treatment of field cases of colic. It is often combined with dipyrone and is effective in the field treatment of mild, uncomplicated colic.

Atropine causes gastrointestinal stasis in horses and should not be used in the routine treatment of colic.[48]

Lidocaine (Table 5.7) is a potent analgesic when administered systemically, but must be given by constant intravenous infusion. Overdosing results in central nervous system excitement.

Prophylaxis and treatment of endotoxemia

Treatment of endolemma has been recently reviewed.[49] Administration of plasma from horses **hyperimmunized** with *Salmonella typhimurium* or *E. coli* reduces the severity of clinical signs and shortens the duration of disease in horses with endotoxemia secondary to enterocolitis or colic.[50] **Polymyxin** (5000 IU/kg intravenously every 8–12 h) attenuates the effect of endotoxin in experimental disease and is used for the prevention and treatment of endotoxemia in hospitalized horses.[51] Its efficacy in clinical settings has not been determined. **Aspirin** (10 mg/kg orally every 48 h) is administered to diminish platelet aggregation around intravenous catheters. **Flunixin meglumine** (1 mg/kg intravenously every 8–12 h) or **phenylbutazone** (2.2 mg/kg intravenously every 12 h) is given for analgesia and to prevent endotoxin-induced increases in plasma prostaglandins. **Pentoxifylline** (8 mg/kg orally every 8 h) is administered for its putative effective in attenuating the effects of endotoxemia. The efficacy of these treatments in a clinical setting and their effect on measures of outcome of disease, such

Table 5.6 Differential diagnosis of common equine colics

	Epidemiology and history	Clinical findings	Clinical pathology	Response to treatment
Acute gastric dilatation	Feeding on grain or whey. Outflow obstruction. Lipoma at pylorus. Reflux with proximal enteritis	Acute severe pain, gut sounds negative, rectal negative. Voluminous reflux through nasogastric tube and relief of pain. Regurgitation	Depends on underlying disease. No diagnostic changes	Good to relief of gastric distension. Prognosis guarded and depends on underlying disease
Acute obstruction and infarction of small intestine	Sporadic	Acute, severe intractable pain, no gut sounds, rectal exam reveals distended loops small intestine, tight bands of mesentery at 12 h. No feces after 12 h. Nasogastric reflux	Hypovolemia. Toxemia late in disease. PCV more than 50% after 12 hours. Blood-tinged peritoneal fluid	Pain intractable. Surgical correction
Acute obstruction of large intestine	As above	As above except abdomen visibly distended. Rectal exam impeded by large loops of distended large colon	As above	As above
Ileocecal valve impaction	Feed includes finely chopped oat straw, or sorghum, Sudan grass, coastal Bermuda grass. Infestation with *A. perfoliata*	Subacute pain for 24 hours as small intestine descends. Then as for small intestinal obstruction. Impaction palpable rectally	PCV normal first 24 h. No characteristic changes	Medical therapy initially, then surgery for refractory cases
Spasmodic/tympanic colic	Sporadic. Increased incidence with poor worm control	Acute moderate pain but heart rate up to 80. Loud and gassy gut sounds. Rectal exam and feces normal, recovers spontaneously, lasts only 1–2 h	Normal	Xylazine, detomidine, butorphanol, hyoscine all effective. Mineral oil orally
Impaction of large intestine	Old horse, debilitated, poor teeth, indigestible feed. Inadequate access to water. Excessive consumption of low-energy grass	Moderate pain, depressed or absent gut sounds, rectally long columns of dry hard fecal material, distinct from individual balls	Normal	Responds well to standard analgesics, mineral oil, fecal softeners and fluid therapy
Verminous mesenteric arteritis (thromboembolic colic)	Poor worm control. Rare	Subacute pain continues for 3–4 d. No gut sounds. Rectally slightly distended loops; paralytic ileus	Slight leukocytosis and shift to left. Paracentesis yields bloody fluid	Irreversible even if surgery performed. Prevention – adequate parasite control
Enteroliths, colonic foreign bodies, phytobezoars	Endemic in some areas	Subacute or recurrent colic of moderate severity only. Masses palpable in small colon	No changes	Surgery only
Subacute obstruction of small intestine (adhesions neoplasm, idiopathic muscular hypertrophy of ileum, etc.*	History of recurrent moderate or persistent mild colic	Moderate pain. Distended loops of small intestine on rectal exam. Point of obstruction may be palpable. Gut sounds normal to loud	No changes	Excellent to surgery
Sand colic of	Access to polluted feed. Grazing on sandy country when feed sparse. Salt deficiency or boredom leading to soil-eating or licking	May be severe pain with acute impaction or chronic mild pain, often with intermittent bouts of diarrhea. May palpate impacted loops containing sand. Auscultate sand in ventral abdomen. Radiography. Ultrasonography	Normal. Mixture of feces and water allowed to stand shows heavy sand sediment	Analgesia and psyllium orally. Prevent ingestion sand
Flatulent colic	Mostly on succulent green feed. Some secondary to physical obstruction of large intestine	Severe acute pain. Visibly distended abdomen. Loud gut sounds present early. Rectal exam difficult because of size of loops	Not recorded	Trocarization through right flank or exploratory laparotomy if time and analgesia not successful
Dorsal displacement left colon (nephrosplenic ligament entrapment)	Sporadic	Intractable moderate pain continues for days. Pelvic flexure of colon missing, spleen displaced medially	No changes No changes	Rolling of anesthetized patient to replace colon very successful. Jogging with or without administration of phenylephrine
Small intestine or colon strangulation by lipoma	Only horses older than 10 years Sudden onset	Sudden onset moderate pain without toxemia. May be palpable per rectum	No changes	Surgery

The clinical picture varies with time: descriptions relate to clinical signs at 12–24 h of illness.
**Chronic intussusception, terminal ileal hypertrophy, constructive adhesions, Meckel's diverticulum, fibroma at the root of the mesentery.*

Table 5.7 Analgesics and spasmolytics for use in equine colic

Drug class	Drug	Dose	Comments
NSAIDs	Flunixin meglumine	0.25–1.0 mg/kg, IV or IM every 8–24 h	Potent analgesic for up to 12 h. May mask signs of surgical disease
	Ketoprofen	2.2 mg/kg, IV every 12 h	Potent analgesic for up to 12 h
	Phenylbutazone	2.2–4.4 mg/kg, IV or PO every 12 h	Weak analgesic for gastrointestinal pain. Minimal effect on motility
	Dipyrone	10 mg/kg, IV or IM every 4–6 h	Weak analgesic. Often combined with hyoscine in commercial preparations (Buscopan compositum)
Opiates	Butorphanol	0.025–0.1 mg/kg, IV or IM as required	Potent analgesia for 30–90 min. Safe. Often combined with an alpha-2 agonist. May cause ataxia
	Meperidine (pethidine)	0.2–2.0 mg/kg, slowly IV or IM as required	Moderate analgesia for 0.5–4 h. Can cause excitement and/or ataxia
	Pentazocine	0.5–1.0 mg/kg, IV or IM as required	Moderate analgesia. May cause ataxia
	Morphine sulfate	0.05–0.01 mg/kg slowly IV or IM as required	Potent analgesia. Can cause excitement
Alpha-2 agonists	Xylazine	0.1–1.0 mg/kg, IV or IM, as needed	Potent analgesia and sedation for up to 30 min. Decreases intestinal motility. Often combined with butorphanol
	Detomidine	10–40 µg/kg, IV or IM as needed	Potent analgesia and sedation for up to 120 min
	Romifidine	0.04–0.08 mg/kg, IV or IM	Potent analgesia and sedation
	Medetomidine	0.01–0.02 mg/kg, IV or IM.	Potent analgesia for up to 120 min. Sedation
Spasmolytics	Atropine	0.01–0.04 mg/kg IV or IM	Do not use because of induction of ileus
	Hyoscine butylbromide	0.1–0.4 mg/kg, IV or IM every 6–12 h	Reduces gastrointestinal motility. Mild analgesic. Often combined with dipyrone
Other	Acetylpromazine	0.02–0.04 mg/kg, IV or IM every 6–24 h	No analgesia but marked sedation. Potent hypotensive agent. Do not use
	Lidocaine	1.5 mg/kg IV loading dose followed by 0.05 (mg/kg)/min IV infusion	Substance P inhibitor. Analgesic, anti-inflammatory, promotility agent

IM, intramuscularly; IV, intravenously; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, orally.

as duration of illness, case fatality rate or incidence of complications, has not been determined, with the exception of hyperimmune plasma or serum.[50]

Antibiotics are often administered to horses with severe colic and evidence of toxemia because of presumed bacteremia. The antibiotics of choice should have a broad spectrum including Gram-negative and positive and anaerobic bacteria. A suitable regimen includes an aminoglycoside and a penicillin, possibly combined with metronidazole. NSAIDs are administered to prevent the increased production of prostaglandins induced by endotoxin and the associated clinical abnormalities including fever, malaise and tachycardia. However, the effect of NSAIDs in improving survival or shortening the duration of treatment has not been demonstrated.

Fluid and electrolyte therapy

Horses with evidence of dehydration, compromised cardiovascular function or electrolyte imbalances should be administered fluids intravenously, preferably a balanced, isotonic, polyionic fluid such as lactated Ringer's solution. Horses with severe colic and signs of cardiovascular collapse may require urgent resuscitation by intravenous administration of large quantities of fluids or administration of hypertonic saline followed by administration of isotonic fluids. Horses with hypoproteinemia may benefit from administration of plasma or colloidal fluids such as hetastarch. (See Chapter 2 for details on fluid therapy and the section on Shock for a discussion of the treatment of this syndrome.)

Intestinal lubricants and fecal softeners

The intestinal lubricant of choice is **mineral oil** (Table 5.8). It should be given only through a nasogastric tube as its aspiration is associated with severe and usually fatal pneumonia. Mineral oil is useful in cases of mild impaction colic and is often administered when the cause of the colic is not known, provided that there is no reflux of gastric contents through the nasogastric tube.

Dioctyl sodium sulfosuccinate (DSS) is a fecal softener with the potential to be toxic at therapeutic doses and its use is now not generally recommended.[52] **Magnesium sulfate** is an effective fecal softener useful in the treatment of impaction colic.[52] However, it can cause hypermagnesemia and toxicity characterized by depression and signs of central nervous system dysfunction.[53] **Sodium sulfate** is a safe and effective fecal softener, although it may induce mild hypernatremia and hypokalemia.[54]

Other treatments

Promotility agents (Table 5.8) may be used in cases of ileus or large colon impaction. Postoperative ileus is a common complication of surgical colic and should be treated by maintenance of hydration and electrolyte status and administration of promotility agents.[55] **Cisapride** is apparently effective in reducing the incidence of postoperative ileus and may be useful in the treatment of ileus of other cause.[56] The clinical efficacy of other putative promotility agents has not been demonstrated.

Heparin and low-molecular-weight heparins have been recommended for the treatment and prevention of coagulopathies associated with severe colic.[21] The use of heparin or low-molecular-weight heparin is associated with increased risk of hemorrhage and heparin use causes a decrease in hematocrit.[21] The efficacy of this treatment in improving survival has not been demonstrated.

Trocarization

Occasionally in severe cases of flatulent (gas) colic or in cases of colon torsion in which the abdominal distension is impairing respiration, it may be necessary to relieve the gas distension of the colon or cecum by trocarization. Trocarization is usually performed through the **right paralumbar fossa** immediately caudal to the last rib. The exact place for trocarization can be located by simultaneous flicking

Table 5.3 Promotility agents, lubricants and fecal softeners for use in horses with colic

Drug group	Drug	Dose	Comments
Lubricants	Mineral oil	10–15 mL/kg, via nasogastric tube, every 12–24 h	Safe. Lubricant only, does not soften feces. Usually passed in 12–36 h*
Fecal softeners	Dioctyl sodium sulfosuccinate (DSS)	12–25 mg/kg, via nasogastric tube, every 24 h	No more than 2 doses. Toxic at higher doses*
	Magnesium sulfate	0.5–1.0 g/kg, via nasogastric tube, in water	Osmotic cathartic. Toxic (CNS signs due to hypermagnesemia) with repeated dosing*
	Sodium sulfate	1.0 g/kg, via nasogastric tube, in water, every 12 h	Osmotic cathartic. Mild hypernatremia. Safe*
	Psyllium	1 g/kg, orally, every 24 h	Bulk laxative. Used for treatment of sand accumulation. Efficacy uncertain but widely used*
Promotility agents	Lidocaine	1.5 mg/kg slow IV, then 0.05 mg/kg infusion	Analgesic, anti-inflammatory, promotility. Used to treat ileus. Toxicity evident as CNS signs
	Metoclopramide	0.25 mg/kg IV slowly over 30 min every 12 h	Toxic. Minimally effective
	Erythromycin	0.1 (mg/kg)/h IV	Questionable efficacy. May induce colitis
	Cisapride	0.1 mg/kg, IV every 8 h	Effective in prevention and treatment of postoperative ileus. May prolong cardiac Q–T interval (importance unknown)
	Neostigmine	0.02 mg/kg, IM or SC, every 8–12 h	Increases large-colon motility, decreases small-intestine motility. May cause colon rupture around hard impaction

**None of these agents should be given if there is reflux through the nasogastric tube.*
CNS, central nervous system; IM, intramuscularly; IV, intravenously; SC, subcutaneously.

the body wall with a finger and listening with a stethoscope. The area of loudest ping will indicate the point of insertion of the trocar. A suitable trocar is a 12.5–15 cm 14–16-gauge needle. The needle is inserted through the skin and advanced into the abdomen until there is an audible expulsion of gas through the trocar. The trocar should be kept in position as long as gas is escaping. It may need to be replaced as the bowel is decompressed and moves away from the trocar. The procedure is reasonably safe but will cause inflammatory changes in the peritoneal fluid. The major danger is laceration of the colon or cecum and leakage of ingesta. It is advisable to administer systemic antibiotics to horses that have been trocarized.

Management of field colic

Initial treatment of field cases of colic that do not have signs indicative of the need for referral or surgery usually includes administration of an analgesic and an intestinal lubricant. Analgesics suitable for the initial treatment of colic in the field are an alpha-2 agonist, such as xylazine, hyoscine butylbromide, dipyrone, butorphanol or phenylbutazone. If there is no reflux through the nasogastric tube, then mineral oil should be administered. Fluids should be administered intravenously if there are signs of dehydration, cardiovascular compromise or electrolyte imbalance. The response to this therapy should be monitored as described under Protocol for evaluating a colic patient. Further doses of analgesic can be given as required and the horse should be monitored for any evidence of deterioration. If referral is contemplated, the referral institution should be contacted for advice on analgesia during transportation. Horses should be transported with a nasogastric tube in place.

Surgery

The only definitive treatment for many causes of equine colic is surgical correction or removal of the lesion. The availability of surgical facilities staffed by appropriately trained personnel has increased over the past two decades and there is often the opportunity to refer horses for examination by personnel with specialist training. Gastrointestinal surgery should not be attempted by those untrained or inexperienced in the necessary techniques or without the facilities to provide postoperative care.

The decision to perform an exploratory laparotomy on a horse with colic is based on a number of factors, including the provisional diagnosis, findings on physical and laboratory examination and degree of pain. Horses with severe pain refractory to treatment with analgesics should have an exploratory laparotomy even if no other significant abnormalities can be detected. Algorithms for the decision to perform surgery have been developed, but are not perfect and do not replace the opinion of an appropriately trained and experienced examiner.[40] Examination of peritoneal fluid contributes to the decision to perform surgery.[36] The survival rate for horses undergoing surgical correction of lesions depends on the nature and location of the underlying disease and its duration.[57] However, survival rates range from 50–75%, with approximately two thirds of horses returning to their intended use.[58–60] The survival rate of horses with small-intestinal lesions is less than that of horses with large-intestinal disease, and the survival rate for horses with strangulating disease is much less than that of horses with nonstrangulating disease.[58]

Prevention

Minimization of colic episodes depends on management factors, including ensuring adequate parasite control, feeding large quantities of forage and minimizing the amount of concentrate fed, and providing dental care. However, most cases of colic not attributable to parasites or dietary factors cannot be prevented.

COLIC IN THE PREGNANT AND POSTPARTURIENT MARE

Diagnosis and management of colic in pregnant and immediately postparturient mares is challenging because of the variety of conditions that can cause the disease, the difficulty in examination of intra-abdominal organs in late term mares and concern about the viability of the fetus. There are also substantial technical challenges in surgical correction of abnormalities of either the gastrointestinal tract or reproductive tract in the presence of a gravid uterus. Colic in late term mare can be caused by any of the causes of colic in adult horses (Table 5.4) but some disorders occur more commonly in late term mares and in addition abnormalities of the reproductive tract can cause signs of colic. Causes of colic in the late term mare include:[1–3]

- Idiopathic, chronic or recurrent, low-grade colic
- Large colon torsion
- Large colon impaction
- Incarceration of small intestine through a mesenteric rent
- Rupture of the cecum or colon
- Uterine torsion
- Uterine rupture
- Middle uterine or utero-ovarian artery rupture
- Abdominal wall hernia
- Diaphragmatic hernia
- Dystocia
- Hydrops
- Imminent foaling.

A common presentation of colic in late term mares is chronic or recurrent, low-grade abdominal pain that is not associated with any signs of compromised cardiovascular or gastrointestinal function. It is assumed that the large gravid uterus interferes with normal motility or positioning of bowel, with subsequent pain. Severe colic in late term mares is rarely associated with the uterus, with the exception of uterine torsion.

Colic in immediately post-parturient mares (< 24 h after foaling) include:[1–3]

- Cramping associated with uterine contractions and involution, often coincident with nursing or administration of oxytocin
- Rupture of the cecum or colon
- Incarceration of the small intestine through a mesenteric rent
- Rupture of the mesocolon with segmental ischemia of the small colon
- Rectal prolapse
- Uterine tear, with or without prolapse of intestine
- Uterine prolapse
- Inversion of uterine horn
- Bladder prolapse through urethra
- Hemorrhage from uterine or utero-ovarian artery
- Retained fetal membranes
- Uroperitoneum, usually secondary to rupture of the bladder.

Colic in postparturient mares that is anything more than transient and associated with passage of placenta or nursing of the foal should be considered important and the mare should be examined closely and, if the colic does not resolve, repeatedly.

Survival rates for colic associated with anatomical abnormalities in late term or postparturient mares is 50% and 30%, respectively.[3]

Clinical examination of late-term or postparturient mares with colic uses the same principles as apply to examination of nonpregnant adult horses with colic. Monitoring of vital signs, passage of a nasogastric tube, rectal examination and collection of peritoneal fluid should all be performed as indicated. However, the presence of a gravid uterus in late-term mares impairs rectal examination of the abdomen and often makes collection of peritoneal fluid impossible. Manual and visual, through a speculum, examination of the vagina and cervix should be performed.

Rectal examination should be performed and careful attention should be paid to examination of the uterus, including position and viability of the fetus, and broad ligaments. Uterine torsion can be detected by examination of the broad ligaments, which in mares with uterine torsion will be taut and spiral in the direction of the torsion. Hemorrhage into the broad ligament, which can extend into the uterus and perivaginal regions, is detectable as swelling in these structures. Additionally, affected mares will have signs of hemorrhagic shock, including tachycardia, sweating and pallor of mucous membranes. Palpation of gastrointestinal structures per rectum is limited in the late-term mare, although the cecum and small colon should be palpable. The spleen and left kidney can be palpated in almost all normal late-term mares.

The reduced uterine size in post-parturient mares permits more thorough per rectum examination of the caudal abdomen. Again, careful attention should be given to palpation of the uterus and associated structures for evidence of hemorrhage, prolapse or rupture. **Rectal prolapse** and eversion of the small colon in a postparturient mare is an ominous finding as it is usually associated with rupture of the mesocolon and ischemic necrosis of the small colon, a condition that is almost always fatal. Prolapse of small amounts of anal or perirectal tissue is not a serious concern.

The **abdominal silhouette** should be examined for evidence of abdominal distension, such as can occur with colon torsion or uterine hydrops, and abnormalities in contour caused by rupture of the prepubic tendon and herniation of abdominal contents.[4]

Vaginal and cervical examination can reveal discharge associated with impending abortion or parturition. Vaginal examination for uterine torsion is of limited value as the torsion almost always occurs cranial to the cervix so that, unlike the cow, the torsion is not apparent as

deformation of the cervix. Manual examination of the vagina, cervix and uterus of postparturient mares with colic is important to detected uterine, cervical and vaginal trauma, uterine inversion and retained fetal membranes.

Ultrasonographic examination of the abdomen in the late-term mare, both per rectum and percutaneously, allows examination of structures not palpable per rectum. The presence and any abnormalities in structure, location and motility of bowel should be noted. For example, small-intestinal distension caused by entrapment through a mesenteric rent may not be palpable per rectum but can be imaged. Peritoneal fluid should be examined for quantity and echogenicity. Intra-abdominal hemorrhage caused by uterine artery rupture is evident as large quantities of echogenic fluid that has a characteristic swirling pattern similar to turbulent blood flow imaged ultrasonographically in the cardiac ventricles of some horses. The position, number and viability of the fetus or fetuses should be ascertained. The nature of allantoic fluid should be noted.

Collection of **peritoneal fluid** from late-term mares can be difficult because of contact between the gravid uterus and the ventral abdominal wall. Ultrasonographic examination can by useful in locating pockets of fluid for collection. Collection of peritoneal fluid is more readily accomplished in the postpartum mare. Peritoneal fluid from late-term and postpartum mares, even those with assisted vaginal delivery, should have protein and cell concentrations within the reference range of normal horses.[5,6] Abnormalities in peritoneal fluid in late-term or postparturient mares should be considered to be indicative of intra-abdominal disease.[6]

The **differential diagnosis** of colic is similar to that of nonpregnant horses except as indicated above.

Treatment of colic depends on its cause. Horses with low-grade to moderate, recurrent colic respond to administration of low doses of NSAIDs, mineral oil or fecal softeners.

The **risk of abortion** in mares with colic is partially dependent on the severity of colic and especially the presence of toxemia.[1,2,7] Severely ill mares with signs of toxemia have abortion rates of almost 70%[7] while mares with less severe disease have abortion rates of 12–18%, which is not markedly different from the rate in mares without colic.[3] Approximately 40% of mares with uterine torsion abort.[1]

COLIC IN FOALS

Synopsis

Etiology See Table 5.9
Epidemiology Sporadic. Some are congenital, others heritable. Inguinal and scrotal hernias occur only in males
Clinical signs Abdominal pain evidenced by kicking at the abdomen, flank-watching, repeated tail movements as if chasing flies, repeated aborted attempts to suck, frequent lying down and standing within a short period, rolling and lying in dorsal recumbency. Abdominal distension in some diseases and straining to defecate with meconium impaction. Radiography and ultrasonography are useful in identifying affected bowel
Clinical pathology None diagnostic
Lesions Of the causative disease
Diagnostic confirmation Physical examination, radiography, ultrasonography, laparotomy, necropsy
Treatment Pain control, fluid therapy, treatment of causative disease

ETIOLOGY

Diseases that cause colic in horses less than 1 year of age include both congenital and acquired conditions and are listed in Table 5.9.

EPIDEMIOLOGY

The congenital conditions are discussed under those headings in Chapter 34, but it is notable that some, such as **ileocolonic aganglionosis** in white progeny of Overo spotted horses, are clearly heritable. Other conditions occur sporadically, although **meconium impaction** is more common in colt foals and occurs only in the newborn foal, **intussusceptions** are most common in foals of 3–5 weeks of age and particularly those with diarrhea or extraintestinal illness, and impaction of the small colon by **fecaliths** is common in miniature horse foals.[3,4] **Inguinal and scrotal hernias** occur only in male foals.[5]

Among neonatal Thoroughbred foals 50% of foals subjected to exploratory laparotomy had nonstrangulating lesions and 30% had enteritis.[6] Among foals 2 weeks to 6 months of age, 30 of foals subjected to exploratory laparotomy had gastric ulcer disease, 27% strangulating lesions, 21% nonstrangulating lesions and 17% enteritis.[6]

PATHOPHYSIOLOGY

The pathophysiology of colic in foals does not differ qualitatively from that of adult horses (see Equine colic, above). The importance of pain, gastrointestinal distension, motility and absorptive disturbances and loss of barrier function are all similar in foals and adults. Additionally, in young foals gastrointestinal disease may prevent nursing and ingestion of colostrum, causing failure of transfer of passive immunity to the foal. Failure to nurse also results in hypoglycemia and dehydration, which may exacerbate the abnormalities induced directly by the disease causing colic.

CLINICAL FINDINGS

Pain is the cardinal feature of gastrointestinal disease of foals. Foals with mild **abdominal pain** are apprehensive and walk continuously with frequent but brief (< 1 min) periods of sternal or lateral recumbency. Affected foals make frequent attempts to nurse but do not continue to suckle and may butt the mare's udder even though there is let-down of milk. The foal vigorously moves its tail as if chasing flies, looks at the abdomen and may nip at its flanks. There are often frequent attempts to urinate or defecate but without passage of significant quantities of urine or feces. Severely affected foals will roll, often violently, and may spend considerable periods of time in dorsal recumbency, often propped up against walls or fences.

Severely affected foals are **tachycardic** (> 100/min) and **tachypneic** (< 40/min) (recall that young foals have higher heart and respiratory rates and rectal temperature than do older foals and adults. **Mucous membrane color** and **capillary refill time** are similar to that of adult horses, and changes can be interpreted in the same manner as for adults.

The **external abdomen** should be examined closely for the presence of inguinal, scrotal or umbilical hernias. Abdominal distension in foals can be the result of large-colon or small-intestinal distension (or uroperitoneum), although the abdominal distension is greater with large-colon distension. Abdominal circumference should be monitored frequently by direct measurement to detect changes in the degree of abdominal distension.

Auscultation of the abdomen may reveal increased or decreased borborygmi and, if there is gas distension of the large colon or cecum, pinging sounds on simultaneous flicking and auscultation of the abdomen.

Table 5.9 Diseases causing colic in foals

Congenital anomalies	Anal atresia
	Colonic atresia
	Rectal atresia
	Ileocolonic aganglionosis
	Myenteric hypoganglionosis
	Inguinal hernia
	Diaphragmatic hernia
	Umbilical hernia
	Scrotal hernia
Gastrointestinal obstruction with or without infarction	Meconium impaction
	Ileus, secondary to extraintestinal disease including neonatal hypoxia
	Small-intestinal volvulus
	Large-intestinal volvulus
	Intussusception
	Jejuno-jejunal
	Ileocecal
	Small colon obstruction
	Fecalith
	Impaction
	Meconium
	Entrapment in hernia, mesenteric rents
	Large colon obstruction
	Impaction
	Intussusception
	Torsion
	Necrotizing enterocolitis
	Adhesions
	Colonic stricture
	Ileal impaction – foreign body
	Ascarid impaction – small intestine
	Phytobezoar
Other	Gastric ulcer
	Duodenal ulcer
	Abdominal abscess
	Umbilical abscess
	Peritonitis
	Tyzzer's disease (*Clostridium piliforme*)[1]
	Uroperitoneum
	Enteritis
	Ovarian torsion[2]

Rectal examination in foals is limited to exploration of the rectum with one or two fingers. The presence or absence of feces should be noted. Lack of fecal staining of the rectum suggests a complete obstruction such as intestinal agenesis.

Nasogastric intubation should be performed. The presence of more than 300 mL of reflux in a foal is significant and suggestive of gastric dilatation secondary to an outflow obstruction or regurgitation of small intestinal fluid into the stomach because of a small intestinal obstruction.

Meconium is usually passed within the first 10–12 hours (usually 3 hours) after birth. **Retention of meconium** is evident as signs of colic and the presence of firm meconium in the rectum. Palpation of the caudal abdomen may reveal firm material in the small colon. Enemas (see under Treatment, below) usually provide rapid relief and confirmation of the diagnosis.

Ancillary diagnostic tests

Diagnostic imaging[7]

Radiography is useful in the evaluation of foals with colic although it seldom provides a definitive diagnosis, with the possible exception of meconium impaction and contrast studies of foals with lesions of the small or large colon, or gastric outflow obstructions.[8,9] **Retrograde contrast radiography** of the lower gastrointestinal tract of foals less than 30 days old is a sensitive technique for detection of anatomic anomalies such as **atresia coli** and obstruction of the **small colon**.[9] The technique is performed by the intrarectal infusion of up to 20 mL/kg of barium sulfate (30% w/v) in sedated, laterally recumbent foals. **Meconium impaction** may be evident as a mass of radio-opaque material in the caudal abdomen with accumulation of fluid and gas oral to the obstruction. Upper gastrointestinal contrast radiography is useful to detect abnormalities of the stomach and small intestine, in particular gastric outflow obstructions.[10]

Ultrasonographic examination of the foal abdomen can demonstrate intussusceptions,[11] the presence of excessive peritoneal fluid (such as urine or blood), edematous intestine, hernias and colonic impaction. The presence of atonic, distended small intestine suggests the presence of ileus, possibly secondary to a small intestinal strangulating lesion. However, ultrasonographic differentiation of ileus secondary to enteritis from that accompanying a strangulating lesion is difficult.[12]

Endoscopy

Endoscopic examination of the stomach is indicated in any foal with recurrent or continuous mild to moderate colic, bruxism or ptyalism suggestive of gastric or duodenal ulceration. Gastroscopy reveals the presence of any ulcers and their extent and severity.[12]

CLINICAL PATHOLOGY

There are few changes detected by routine hematological or serum biochemical examination of foals with colic that provide a definitive diagnosis. However, changes in the hemogram and serum biochemical profile are useful in evaluating the physiological state of the foal and the severity of the disease. Principles used in the evaluation of these variables in adult horses apply to foals. It should be appreciated that the normal range of values for many clinical pathology variables in foals is age-dependent and markedly different from that of adult horses (see Tables 3.5, 3.6).

Profound leukopenia is more likely to be indicative of enteritis and colic secondary to ileus than of small-intestinal strangulating obstructions. Similarly, hyponatremia is uncommon with strangulating obstructions but is a common finding in foals with enteritis.

Newborn foals with colic should have the adequacy of transfer of passive immunity examined by measurement of serum immunoglobulin G concentration, or an equivalent test.

Examination of abdominal fluid is useful in the assessment of colic in foals, as it is in adults. The normal values for abdominal fluid in foals differs from that of adult horses[13] and white cell counts greater than 1500 cells/μL (1.5×10^9 cells/L) should be considered abnormal.

NECROPSY FINDINGS

The findings on necropsy examination depend on the nature of the disease.

TREATMENT

The principles of treatment of foals with colic are the same as those for adult horses: relief of pain, correction of fluid and electrolyte abnormalities, and treatment of the underlying disease. In addition, foals with **failure of transfer of passive immunity** should receive plasma.

Foals with gastrointestinal disease that cannot eat may require **parenteral**

DIFFERENTIAL DIAGNOSIS

Diagnostic features of common causes of colic in foals are listed in Table 5.10. The principal differential diagnoses for gastrointestinal disease of foals with abdominal pain are:

- Enteritis due to rotavirus infection, salmonellosis intestinal clostridiosis (*Clostridium perfringens* or *Clostridium difficile* or other causes
- Uroperitoneum
- Peritonitis
- Gastroduodenal ulcer disease

nutrition to insure adequate caloric intake.

Meconium impaction can be treated by administration of an enema of soap and warm water, commercial enema preparations or acetylcysteine. Soap and water enemas can be administered at a rate of 5 mL/kg through a soft Foley catheter inserted into the rectum. **Acetylcysteine** (8 g in 200 mL of water with 20 g sodium bicarbonate) has the advantage of actually dissolving part of the meconium, thereby enhancing passage of the meconium. Affected foals may require analgesics to control pain, intravenous fluids to correct or prevent dehydration, oral laxatives such as mineral oil (300 mL via nasogastric tube) and plasma to correct failure of transfer of passive immunity. Surgical correction of the impaction is rarely required.

Surgical treatment

The proportion of foals surviving varies with the disease and age of the foal. Younger foals (< 6 months of age) appear to have a worse prognosis after surgical correction of intestinal lesions than do older foals.[6,14] Fewer foals having surgery for colic live to race than do their normal cohorts, although affected foals that do race have similar racing careers.[6] Foals with nonstrangulating lesions and enteritis are more likely to survive than foals with gastric ulcer disease or strangulating lesions.[6] Suckling foals are at greatest risk of development of post-operative adhesions and need for repeated celiotomy.[6]

PREVENTION

Although not proven, the suspected association between diarrhea and small-intestinal surgical lesions in foals suggests that measures to reduce the incidence of enteritis in foals may reduce the incidence of colic. Adequate deworming programs that reduce or eliminate infestation with parasites should be implemented. Care should be taken when deworming foals with heavy infestations of *Parascaris equorum*, as rapid killing of the ascarids

Table 5.10 Differential diagnosis of common foal colics

Disease	History	Clinical findings	Clinical pathology	Treatment
Intestinal atresia or hypoganglionosis	White progeny of Overo horses. Otherwise sporadic. Newborn foals < 4 days old	Failure to pass feces. Abdominal distension pain	None specific	None
Small-intestinal volvulus	Any age but more common at 3–6 months. Abrupt-onset abdominal pain. Diarrhea	Severe pain. Nasogastric reflux. Abdominal distension. Ultrasonography – distended, atonic intestine. Radiography – gas and fluid distension of small bowel	Increased protein and leukocytes in abdominal fluid	Surgical. Low survival rate
Small-intestinal intussusception	Any age, but usually 3–6 weeks. Diarrhea	Severe pain, abrupt onset. Nasogastric reflux. Ultrasonography – intussusception. Radiography – gas and fluid distension of small bowel	Increased protein and leukocytes in abdominal fluid	Surgery. 40% survival rate
Ascarid impaction	More than 3 months of age. Recent history (< 3 d) of anthelmintic administration	Severe pain. Nasogastric reflux. Ultrasonography – distended, atonic bowel, ascarids	None specific	Medical therapy. Lubricants and analgesics. Surgery
Meconium impaction	Newborn. No passage of meconium. More common in males	Mild pain initially, becoming more severe. Abdominal distension. Ultrasonography – distended large colon, may see impaction. Radiography – contrast may outline impaction	None specific	Warm soapy enemas Acetylcysteine. Mineral oil orally. Surgery for refractory cases
Large-colon torsion	Sporadic	Severe pain and abdominal distension. Ultrasonography – gas distended colon. Radiography – gas distended colon	None specific	Surgery. 20% recovery rate
Large-colon impaction	Sporadic. Poor diet, eating sand-polluted feed	Mild to moderate pain initially. Progressive abdominal distension. Ultrasonography – distended colon with impacted material	None specific	Medical treatment of lubricants, fecal softeners and analgesics. Surgery
Small-colon impaction	Common in Miniature horses	Moderate to marked pain. Lack of feces. Abdominal distension. Ultrasonography – gas distended colon. Radiography – impaction of small colon	None specific	Medical as above. Surgery
Gastroduodenal ulcer	Common in foals with other disease or stress	Usually clinically inapparent. Colic, inappetence, teeth grinding, excessive salivation, diarrhea. Gastroscopy diagnostic	None diagnostic	Antacids and antiulcer compounds (Table 5.11). Rarely surgery to correct gastric outflow obstruction

may lead to impaction and obstruction of the small intestine.[14]

GASTRIC DILATATION IN THE HORSE

Etiology Gastric outflow obstruction. Idiopathic. Ingestion of excess fluid or feedstuffs
Epidemiology Sporadic. No age, breed or sex predilection
Clinical signs Colic. Reflux from nasogastric tube. Gastric rupture, acute severe peritonitis and death
Clinical pathology None diagnostic. Inflammatory cells and ingesta in peritoneal fluid of horses with gastric rupture
Diagnostic confirmation Nasogastric reflux without other identifiable cause
Lesions Gastric dilatation. Gastric rupture with hemorrhage at margins of rupture
Treatment Gastric decompression. Treat underlying disease
Control Prevent overeating. Control inciting diseases

ETIOLOGY

Chronic gastric dilatation can be caused by:

- Outflow obstruction, such as cicatricial constriction of the pylorus secondary to gastroduodenal ulceration or pressure by a tumor[1,2]
- Gastric atony in older horses or wind-sucking (aerophagic) horses.

Acute gastric dilatation is associated with:

- Reflux of intestinal contents secondary to acute intestinal obstruction, e.g. anterior enteritis, small intestinal strangulation or ileus
- Ingestion of excess fluid or feedstuffs such as whey or grain
- Acute idiopathic dilatation after racing.

EPIDEMIOLOGY

The incidence of gastric rupture, the most severe sequela to gastric dilatation, in horses with colic is approximately 5%, although in horses subjected to exploratory laparotomy the rate may be as high as 11%.[3,4] There is no detectable effect of age, breed or season on the risk of gastric rupture. Risk factors for gastric dilatation include consumption of excess grain, although horses routinely fed grain are at lower risk;[3] ingestion of palatable fluids such as whey has been implicated. **Acute idiopathic dilatation** of the stomach occurs sporadically and is a common cause of gastric rupture, representing between 16% and 60% of cases of gastric rupture.[3,4] **Chronic dilatation** secondary to pyloric obstruction due to a tumor is a sporadic occurrence in older horses,[4] whereas cicatricial obstruction secondary to gastroduodenal ulceration is more common in younger horses and those at risk of developing gastroduodenal ulcers.

Acute dilatation occurs secondarily to acute obstruction of the small intestine.

PATHOGENESIS

Acute obstruction results in gastric dilatation associated with severe pain and signs of shock, including elevated heart rate, sweating and delayed mucosal capillary refill time. Gastric rupture can occur within hours and death shortly thereafter. Chronic dilatation results from partial obstruction and delayed gastric emptying. The disease is more prolonged and clinical signs may be related to the primary disease.

The obstruction may be as aboral as the ileocecal valve. Gastric distension with fluid also occurs late in the course of impaction of the large or small colon, and in cases of large intestinal volvulus. The accumulation of fluid in these cases appears to be in response to tension on the duodenocolic fold.[5]

Gastric distension causes severe pain and there is often dehydration and hypochloremia as a result of sequestration of gastric secretions. Ingestion of material that putrefies and damages gastric mucosa may result in toxemia and development of associated signs of shock.

Engorgement of a readily fermentable carbohydrate, such as wheat, glucose or calf feeds, results in a syndrome characterized by shock, ileus and laminitis. Gastric dilatation can occur secondary to grain engorgement but the clinical signs of the gastric dilatation are often masked by the more severe signs secondary to endotoxemia.

CLINICAL FINDINGS

The clinical findings in gastric distension depend in large part on the underlying disease. However, horses with primary gastric distension have abdominal pain, often of 12–36 hours duration, that progressively worsens. The heart and respiratory rates increase progressively as the distension worsens, and the horse may sweat and exhibit signs of increasingly severe abdominal pain. Paradoxically, some horses with gastric distension, especially that which develops over several days or in horses recovering from intestinal surgery and being treated with analgesics, may not exhibit any but the most subtle signs until rupture of the stomach occurs.

Vomition in horses is very rare, is always associated with gastric distension and is usually a terminal event.

In **grain engorgement dilatation** abdominal pain is usually severe. Dehydration and shock develop rapidly, often within 6–8 hours of ingestion of the grain, and may be severe. Death from gastric rupture can occur within 18 hours.

Passage of a nasogastric tube usually results in the evacuation of large quantities of foul-smelling fluid, except in cases of grain engorgement, where the fluid is absorbed by the grain. However, significant and life-threatening gastric dilatation can be present even though there is no reflux through a nasogastric tube. If gastric dilatation is suspected then repeated, persistent efforts should be made to obtain reflux. The nasogastric tube should be left in situ until the disease has resolved.

Acute post-race dilatation occurring immediately after racing is accompanied by more serious and acute signs. There is abdominal distension, coughing and dyspnea. Tympany is also detectable on percussion of the anterior abdomen and large amounts of foul-smelling gas, and usually fluid, are passed via the stomach tube. This immediately relieves the animal's distress.

In **chronic dilatation** there is anorexia, mild pain, which is either continuous or recurrent, scanty feces and gradual loss of body weight persisting for a period of months. Vomiting and bouts of pain may occur after feeding but they are not usually severe. Dehydration may be present but is usually only of moderate degree.

The distended stomach cannot be palpated on **rectal examination**, but the presence of distended loops of small intestine should alert the clinician to the probability of gastric distension. Rupture of the stomach, or other viscus, is characterized during rectal examination by a negative pressure in the abdomen and the presence of particulate matter on the serosal surface of intestine.

Ultrasonographic examination will reveal a distended stomach containing

large quantities of fluid or ingesta and can reveal evidence of the predisposing lesion, such as presence of distended small intestine.[6] **Radiographic examination**, with or without a barium meal, may be of diagnostic value in young animals with chronic outflow obstruction. **Gastroscopy** performed after the stomach has been emptied can reveal lesions consistent with obstructed outflow, such as gastric squamous cell carcinoma or pyloric abnormalities secondary to gastric ulcer disease in foals.

CLINICAL PATHOLOGY

Horses with severe gastric dilatation often, but not always, have slightly **low serum chloride concentrations**.[4] Metabolic alkalosis, metabolic acidosis or mixed disturbances can be present.[4] Other abnormalities depend on the underlying disease.

Abdominal fluid of horses with gastric dilatation is normal whereas that of horses with gastric rupture is characterized by an elevated total protein concentration (> 2.5 g/dL, 25 g/L) and leukocyte count (> 10000 cells/μL, 10×10^9 cells/L) which is predominantly composed of degenerate neutrophils. Microscopic examination of the fluid reveals intra- and extracellular bacteria and plant material.

NECROPSY FINDINGS

After grain engorgement in horses, the stomach is distended with a doughy, malodorous mass of ingesta. In acute gastric dilatation due to other causes, the stomach is grossly distended with fluid and the wall shows patchy hemorrhages. Rupture, when it occurs, is usually along the greater curvature and results in gross contamination of the abdominal cavity with ingesta.

DIFFERENTIAL DIAGNOSIS

See Table 5.6.

TREATMENT

Relief of the gastric distension should be considered an **emergency** as gastric rupture invariably causes death. Passage of a nasogastric tube, important in diagnosing the accumulation of fluid within the stomach, also provides a means for relieving the distension. Repetition and persistence may be needed to relieve the gastric distension. Passage of the nasogastric tube through the cardia may be difficult in horses with gastric distension. Blowing into the tube to dilate the esophagus or instillation of lidocaine (20 mL of 2% solution) may facilitate passage of the tube. If there is no spontaneous reflux of material, a siphon should be formed by filling the tube with 500 mL of water and rapidly lowering the end of the tube below the level of the horse's stomach. The nasogastric tube should be left in place until there is no longer clinically significant quantities of reflux (1–2 L every 3 h for an adult 425 kg horse).

Gastric dilatation caused by overeating of grain, bread or similar material may be impossible to resolve through a nasogastric tube because of the consistency of the material. Gastric lavage using water or isotonic saline administered through a large bore nasogastric tube may aid in removal of inspissated ingesta. Surgical decompression may be attempted in refractory cases, but is technically demanding because of the position of the stomach in the adult horse.

The underlying disease should be treated to restore normal gastric emptying or stop reflux from the small intestine. Supportive therapy, including restoration of hydration and normal electrolyte and acid–base status, should be provided (see Chapter 2). Horses at risk of inhalation pneumonia should be treated with broad-spectrum antibiotics for at least 3 days.

GASTRIC IMPACTION IN HORSES

Primary gastric impaction is characterized by enlargement of the stomach, subacute pain, which may exacerbate if fluid is administered by nasogastric tube, minor fluid reflux if a tube is passed, and regurgitation of fluid and ingesta from the nostrils in some cases. At exploratory laparotomy the stomach is enlarged with dry, fibrous feed material but is not grossly nor acutely distended, and the intestines are relatively empty.[1] Gastric impaction occurs secondary to hepatic fibrosis and insufficiency associated with poisoning with *Senecio jacobea*.[2] Persimmon (*Diospyros virginiana*) causes gastric impaction, ulceration and rupture in horses.[3,4] There is usually a history of a diet of mature grass, alfalfa hay, corn, sorghum fodder or ensilage.[5] Other causes include insufficient access to water, poor teeth causing poor digestion, or the atony of old age. Long-term signs include weight loss, intermittent colic, anorexia, dullness and small amounts of hard, dry feces.[4] Treatment with an oral administration of normal saline or mineral oil is commonly applied but is not usually satisfactory because the oil does not moisten the impacted mass and is likely to bypass it. The patient may require exploratory laparotomy because of the absence of satisfactory diagnostic tests.[6] Rupture of the stomach is a potential sequel.

GASTRIC ULCERS

Gastric ulcers occur in cattle (Abomasal ulceration), swine (Esophagogastric ulceration), foals and horses. The etiology varies among the species but the condition is characterized by the development of ulcers in the nonglandular and, less frequently, glandular sections of the stomach or abomasum. Common factors in the development of gastric ulcers in all species are the presence of gastric fluid of low pH and mechanical disruption or dysfunction of the mechanism protecting gastric mucosa from damage by acid and pepsin. The clinical manifestations vary with the species affected but include hemorrhage, anemia and the presence of melena or occult blood in the feces in pigs, cattle and, rarely, foals.

GASTRIC (GASTRODUODENAL) ULCER IN FOALS

Synopsis

Etiology Unknown in most cases. NSAID intoxication
Epidemiology Foals from 1 day of age. 50% of normal foals have gastric mucosal ulceration. Clinical disease in 0.5% of foals. More severe ulceration in stressed foals or foals with other diseases
Clinical signs None in most foals. Teeth grinding, excessive salivation, colic, diarrhea, inappetence and weight loss. Sudden death with perforation. Ulcers present on gastroduodenoscopy
Clinical pathology None diagnostic
Lesions Gastric mucosal ulceration, duodenal ulceration and stenosis, esophagitis. Peracute septic peritonitis
Diagnostic confirmation Gastroscopic demonstration of ulcers in foals with appropriate clinical signs
Treatment Ranitidine 6.6 mg/kg, orally every 8–12 hours, *or* cimetidine 6.6–20 mg/kg orally or intravenously every 6 hours, *or* omeprazole 2–4 mg/kg orally or intravenously every 24 hours
Control Minimize occurrence of inciting or exacerbating diseases

ETIOLOGY

There is no established etiology, although there is an association with stress (see below). There is no evidence of an infectious etiology, for instance *Helicobacter* sp.

EPIDEMIOLOGY

Occurrence

Gastric ulcers are reported in foals in North America, Europe and Australia and probably occur worldwide. The **prevalence** of erosion and ulcers of the gastric glandular and nonglandular mucosa, detected by gastroscopic examination, averages 50% in foals less than 2 months of age that do not have signs of gastric ulcer disease.[1,2] Lesions of the squamous mucosa are present in 45% of foals, while lesions in the glandular mucosa occur in fewer than 10% of foals less than 4 months of age.

Disease attributable to gastric or duodenal ulcers occurs in approximately 0.5% of foals[3] although the prevalence is greater in foals with other diseases such as pneumonia and septicemia.[4] Duodenal ulceration was present in 4.5% of foals examined post mortem[5] but this is probably a gross overestimation of the prevalence in normal foals.

Estimates of case fatality rate are not available.

Risk factors

Age and sex

Age is an important risk factor for ulceration of the squamous epithelium, with 88% of foals less than 9 days of age affected compared to 30% of foals more than 70 days of age.[1,2] Gastric lesions occur in fewer than 10% of foals over 90 days of age.[4] There does not appear to be an effect of age on prevalence of ulceration of the gastric glandular mucosa, a much more clinically significant lesion. There is no effect of **sex** on the prevalence of ulcers.[6]

Stress/disease

Stress and disease are important risk factors for development of ulcers of the glandular mucosa.[1,2] Lesions of the gastric glandular mucosa occur in 27% of foals with another disease but in 3% of otherwise healthy foals.[4]

PATHOGENESIS

The pathogenesis of gastric ulceration in foals has not been definitively determined and much is extrapolated from the disease in humans and other animals. It is assumed that ulcers occur because of an imbalance between the erosive capability of the **low gastric pH** and the **protective mechanisms** of the gastric mucosa.[7] Low gastric pH is essential for the development of a gastric ulcer and foals as young as 2 days of age have a gastric pH of less than 4.[8] Preservation of adequate mucosal blood flow and the presence of an intact, bicarbonate-rich layer of mucus over the epithelium are essential to maintaining the resistance of the epithelium to digestion by gastric acid and pepsin. Mucosal blood flow and bicarbonate secretion into the protective mucus layer are dependent in part on normal prostaglandin E concentrations in the mucosa. Factors that inhibit prostaglandin E production, such as NSAIDs and ischemia, contribute to the development of ulcers. Trauma to the gastric epithelium may disrupt the protective layer and allow an ulcer to develop, as may the presence of compounds in duodenal fluid, such as bile salts, that intermittently reflux into the stomach of normal foals.

Normal foals develop the capacity for secretion of gastric acid and ability to achieve gastric pH less than 4 within 1–2 days of birth.[8] Ingestion of milk increases gastric pH and it is a generally held belief that frequent ingestion of milk provides a protective effect against the adverse effects of low pH on gastric mucosa.[8] However, development of gastric lesions in foals is not solely a result of prolonged exposure to low pH, although this might be a necessary factor, as ill neonatal foals that are at high risk of gastric erosion or ulceration have gastric pH that is often greater than 5–6.[9] The elevated pH, which may be alkaline in severely ill foals at greatest risk of death,[9] is not consistent with development of gastric lesions.

Most ulcers do not produce clinical signs. **Severe ulceration** is associated with delayed gastric emptying, gastric distension, gastroesophageal reflux and subsequent reflux esophagitis and pain. Ulcers may perforate the stomach wall and cause a peracute, septic peritonitis or erode into a large blood vessel with subsequent hemorrhage and occasional exsanguination. Ulcers and the attendant inflammation and pain might cause gastroparesis and delay gastric emptying and chronic lesions can result in both functional and physical obstructions to gastric emptying with subsequent gastric dilatation and reflux esophagitis.

CLINICAL FINDINGS

There are six syndromes associated with gastroduodenal ulcers in foals:

- Ulceration or epithelial desquamation of the squamous mucosa of the greater curvature and area adjacent to the margo plicatus. These lesions are very common in foals less than 60 days of age and usually do not cause clinical signs. The lesions heal without treatment
- Ulceration of the squamous epithelium of the lesser curvature and fundus. This is more common in older foals (> 60 days) and is usually associated with clinical signs including diarrhea, inappetence and colic
- Ulceration of the glandular mucosa, sometimes extending into the pylorus. This lesion occurs in foals of any age and is most common in foals with another disease. Clinical signs due to the ulcer can be severe and include teeth grinding, excessive salivation, inappetence, colic, and diarrhea. There is often reflux esophagitis
- Gastric outflow obstruction due to pyloric or duodenal stricture secondary to pyloric or duodenal ulceration. This occurs in 2–5-month-old foals and is evident as colic, inappetence, weight loss, gastric dilatation, gastroesophageal reflux, excessive salivation and teeth grinding
- Peracute peritonitis secondary to gastric perforation. This usually occurs in foals that do not have a history of signs of gastric ulceration. Clinical signs include unexpected death, shock, dehydration, sweating and an increased respiratory rate
- Hemorrhagic shock secondary to blood loss into the gastrointestinal tract from a bleeding gastric ulcer.[10] This is an unusual presentation.

The typical signs of gastric ulcers in foals include depression, teeth grinding, excessive salivation and abdominal pain that can range in intensity from very mild to acute and severe, similar to that of a foal with an acute intestinal accident. Diarrhea, with or without mild to moderate abdominal pain, is often associated with gastric ulcer disease in foals. Treatment with antiulcer drugs is sometimes associated with resolution of diarrhea and signs of gastric ulcer disease. There may be pain evinced by deep palpation of the cranial abdomen but this is not a reliable diagnostic sign.[11]

Definitive diagnosis is provided by **gastroscopic examination**. The endoscope should be 2 m in length, although a 1 m endoscope may allow partial examination of the stomach of young or small foals. Diameter of the endoscope should be less than 1 cm. Foals can usually be examined without sedation, although sedation may facilitate examination in larger or fractious foals. Ideally, older foals should have food withheld for 12 hours before the examination but this may be neither necessary nor advisable in sick foals. Young foals (those relying on milk intake for their caloric needs) should have food withheld for 1–2 hours. Adequate examination of the nonglandular stomach can usually be achieved without fasting,

especially in younger foals, but thorough examination of the glandular mucosa and pylorus requires fasting.

Nasogastric intubation may cause pain and cause affected foals to gag. Foals with gastric outflow obstruction, due either to pyloric or duodenal stricture or to gastroparesis, will have reflux of material through a nasogastric tube.

Contrast **radiographic** examination is useful in defining gastric outflow obstruction and may demonstrate filling defects in the gastric wall that are consistent with ulcers. The principal use of radiography is to establish delays in gastric emptying. Normal foals have complete emptying of barium sulfate (10–20 mL/kg BW administered through a nasoesophageal or nasogastric tube) from the stomach within 2 hours of administration. Gastric ulcers are occasionally apparent as filling defects, but contrast radiography is not sufficiently sensitive to justify its routine use for diagnosis of gastric ulceration.

CLINICAL PATHOLOGY

There are no diagnostic changes in the hemogram or serum biochemical profile. Serum pepsinogen values are of no use in diagnosing gastric ulcers in foals.[12] Testing for fecal occult blood is neither sensitive nor specific for gastric ulceration in foals. Foals with perforation of the stomach have changes consistent with septic peritonitis.

NECROPSY FINDINGS

Gastric ulcers and erosions are common findings in foals dying of unrelated disease and their presence should not be overinterpreted. The gross characteristics of the gastric lesions are described above. Foals dying of gastric ulcer disease do so from peracute diffuse peritonitis, exsanguination or starvation secondary to the gastric outflow obstruction.

DIAGNOSTIC CONFIRMATION

The combination of compatible clinical signs, endoscopic demonstration of gastric ulcers, a favorable response to antacid therapy and the elimination of other diseases permits a diagnosis of gastric ulcer disease.

DIFFERENTIAL DIAGNOSIS

The combination of teeth grinding, excessive salivation, depression, inappetence and colic in foals is virtually diagnostic of gastric ulcer disease. Other causes of colic in foals are listed in Table 5.9.

TREATMENT

The principles of treatment of gastroduodenal ulcer disease in foals are:

- Promotion of healing by reducing gastric acidity and enhancing mucosal protection
- Enhancement of gastric emptying
- Provision of nutritional and metabolic support
- Treatment of other disease.

Reduction of gastric acidity is achieved by administration of one of several drugs that reduce secretion of gastric acid and increase gastric pH (Table 5.11).[13] These drugs are either histamine type 2 (H_2) receptor antagonists or inhibitors of the proton pump in the gastric parietal cells. Administration of ranitidine (6.6 mg/kg orally every 8 h) effectively increases gastric pH in normal neonatal foals but does not affect gastric pH in hospitalized neonates.[8,9] Omeprazole (4 mg/kg orally every 24 h), a proton pump inhibitor, increases gastric pH within 2 hours of administration and for 24 hours in clinically normal neonatal foals.[14] However, similarly to ranitidine, the efficacy of omeprazole in ill neonatal foals has not been determined. Omeprazole does enhance healing of spontaneous ulcers in foals older than 28 days and does not have important or frequent adverse effects.[15,16] Sucralfate is used to provide protection of denuded gastric epithelium, although its efficacy in preventing lesions or enhancing healing of existing lesions in foals with spontaneous disease is doubted.

A common **treatment protocol** involves administration of a H_2 antagonist or omeprazole. Treatment should begin as soon as the presence of a clinically significant ulcer is suspected and should continue for at least 1 week after the resolution of clinical signs or until there is endoscopic confirmation of healing. Foals are often treated for 2–6 weeks.

Foals with gastroparesis secondary to severe gastroduodenal ulceration or gastritis may benefit from the administration of bethanechol (Table 5.11) to increase gastric motility and enhance gastric emptying. Surgical bypass of pyloric or duodenal strictures may be necessary in foals with physical obstructions to gastric emptying.[17]

Nonsteroidal anti-inflammatory drugs such as phenylbutazone or flunixin meglumine are ulcerogenic and should be used sparingly in sick foals, and should not

Table 5.11 Drugs used in the treatment of gastroduodenal ulcer disease of foals and adult horses.

Drug class	Drug	Dose, route and frequency	Comments
H_2 antagonists	Cimetidine	6.6–20 mg/kg PO every 6 h	Potent acid suppression. Short elimination half-life necessitates frequent administration. Preferably use at the higher dose rate
	Cimetidine	6.6 mg/kg IV every 6 h	Rapid and potent acid suppression. Use when oral administration is not feasible or rapid effect is required
	Ranitidine	6.6–8.8 mg/kg IV or PO every 8–12 h	Potent acid suppression and rapid resolution of clinical signs
Proton pump inhibitor	Omeprazole	4 mg/kg PO as paste every 24 h	Potent, rapid onset and long-lasting acid suppression
Pantoprazole		1.5 mg/kg ivq 12–24 h	Potent acid suppression in foals
Protectants	Sucralfate	40 mg/kg PO every 6 h	Can be given at the same time as inhibitors of acid secretion
Prostaglandin analogues	Misoprostol	5 µg/kg PO every 12 h	Causes diarrhea and mild colic. Effective as a prophylactic for NSAID-induced ulcers in humans but minimal efficacy in enhancing healing of existing ulcers
Antacids	Aluminum hydroxide	1–2 g PO every 4–6 h	Ineffective. Do not use
	Magnesium hydroxide	1–2 g PO every 4–6 h	Ineffective. Do not use
	Calcium carbonate	1–2 g PO every 4–6 h	Ineffective. Do not use
Promotility agents	Bethanechol	0.025 mg/kg SC every 6 h	Enhances gastric motility with minimal increased gastric acid secretion. Used to treat gastroparesis. Contraindicated if physical outflow obstruction exists

H_2, histamine type 2 receptor; IV, intravenously; NSAID, nonsteroidal antiinflammatory drug; PO, orally; SC, subcutaneously.

be given to foals with gastric or duodenal ulcers unless absolutely necessary.[18]

Nutritional and metabolic support should be provided as necessary to foals that are unable to eat or drink or that have abnormalities of fluid and electrolyte status.

CONTROL

Control of diseases that predispose foals to gastroduodenal ulcer may reduce the incidence or severity of ulcer disease. Prophylactic treatment of sick or stressed foals with H_2 antagonists, sucralfate or omeprazole is widely practiced. However, the efficacy of pharmacological prophylaxis in prevention of disease or death due to gastric ulceration has not been demonstrated. Indeed, suppression of gastric acidity (increasing gastric pH) in either sick or normal foals may be unwise because of the protective effect of low gastric pH on gastric colonization of bacteria.

GASTRIC ULCER IN ADULT HORSES

Synopsis

Etiology Unknown in most cases. NSAID intoxication
Epidemiology Common in Thoroughbred, Standardbred and Quarter horses in racing or training, and horses used for endurance racing. Occasionally associated with colic
Clinical signs None in most horses. Poor appetite, failure to bloom, mild colic in some horses. Ulcers or erosions present on gastroduodenoscopy
Clinical pathology None diagnostic
Necropsy lesions Gastric ulceration. Rarely a cause of death
Diagnostic confirmation Gastroscopic demonstration of ulcers
Treatment Omeprazole 1–4 mg/kg orally once daily. Ranitidine and cimetidine are used but are less efficacious and convenient
Control Minimize risk factors, including confinement and intermittent feeding. Prolonged administration of omeprazole to symptomatic horses

ETIOLOGY

The etiology of the most common occurrence of gastric ulcers in the horse is unknown but several risk factors have been identified, which are described under epidemiology. The disease is common in horses undertaking regular exercise and might be related to decreased stomach volume and subsequent exposure of the squamous mucosa of the proximal parts of the stomach to acid during exercise (see Pathogenesis, below).

Individual cases of gastric ulcers are associated with parasitic gastritis, such as in horses infested with *Gasterophilus* spp., and *Habronema megastoma* larvae. Tumors of the stomach, such as gastric squamous cell carcinoma or lymphosarcoma, may cause ulceration of the gastric mucosa. Gastric phytobezoars and persimmon seeds (*D. virginiana*) have been associated with gastric impaction, ulceration and perforation of the glandular portion of the stomach of a horse.[1] There is no evidence that infection by *Helicobacter* sp. or similar organisms is associated with gastric ulcer disease in horses.

EPIDEMIOLOGY

Occurrence

The occurrence of gastric ulceration is detected by either postmortem examination or gastroscopic examination. The frequency with which gastric ulcers are detected depends the method of examination, the group of horses examined and the reasons for examining them. Studies reporting on incidence of gastric ulceration in horses with clinical abnormalities or at necropsy examination revealed a high frequency of gastric lesions in horses with colic and in race horses.[2–5] More recent studies have examined large numbers of horses without clinical signs of gastric ulcer disease but from populations at risk and have demonstrated a high prevalence in horses undertaking strenuous exercise on a regular basis.[6–10]

Gastric ulcer disease in horses is a recently recognized disease, with most reports originating after 1990 and coinciding with the widespread availability of endoscopes of sufficient length to permit examination of the stomach of adult horses. However, a longitudinal study of horses submitted for postmortem examination in Sweden demonstrated that horses have been affected with gastric ulcers since 1924.[3]

The condition is common in race horses and other breeds of horse used for athletic events and this population represents the most important occurrence of the disease.[6–10]

Thoroughbred and Standardbred horses in training or racing have a high prevalence of gastric lesions. Gastroscopic studies of convenience samples of clinically normal Thoroughbred race horses in training reveal a prevalence of lesions of the gastric mucosa of 82–93%.[8,9] Gastric lesions are detected in 63–87% of Standardbred horses in training and actively racing.[6,7] Postmortem examination of Thoroughbred race horses in Hong Kong, where many horses that retire from racing are examined post mortem, reveals a prevalence of gastric lesions of 66%, with the prevalence increasing to 80% when only horses that had raced recently were considered.[5] Among race horses selected for gastroscopic examination because of clinical abnormalities, including inappetence, failure to race to expectation, poor hair coat or poor body condition, lesions of the gastric mucosa were detected in 86–90%.[2,11]

There were lesions of the gastric mucosa in approximately 20 of 30 **endurance horses** examined immediately after racing 50–80 km.[10] Eight horses had lesions of the gastric glandular mucosa. Gastric lesions were present in 58% of **show horses** that had competed in the 30 days prior to gastroscopic examination.[12]

Risk factors

Risk factors for gastric lesions in horses include being in training for an athletic event, exercise and the amount of time exercising, and colic. Suspected risk factors include the disposition of the horse (nervous horses are at greater risk), diet, feeding practices, housing (pasture vs stall), stress (although the definition of stress is often not clear) and administration of NSAIDs such as phenylbutazone.[13] While each of these risk factors can be considered separately, it is likely that many are related and act in concert to increase the risk of development of lesions of the gastric mucosa. For instance, being in training often coincides with confined housing, intermittent feeding, daily bouts of strenuous exercise and administration of

NSAIDs. The combination of these factors, even without NSAID administration, reliably induces ulcers in Thoroughbred race horses.[14] Young horses (2 years old) that had arrived at the track within the month before first gastroscopic examination had a marked increase in severity of lesions at the time of a second gastroscopic examination 1 month later.[10]

Animal risk factors

Among adult horses, age and sex are only weak risk factors, if at all, for presence of gastric lesions.[6–8] Gastric lesions tend to be more severe in older horses.[6,7,9] Among Standardbred race horses, trotters are twice as likely as pacers to have gastric lesions.[7] Horses with a nervous disposition are considered to be at greater risk of developing gastric lesions but objective evidence is not available to support this observation.[8] NSAIDs are ulcerogenic and often administered to horses in training. However, among Thoroughbred race horses there is no clear association between administration of these drugs and risk of having gastric lesions.[8]

Colic is associated with presence of gastric lesions, although a cause and effect relationship is often not clear in individual cases. In a series of 111 horses with clinical evidence of abdominal discomfort of varying duration and severity, 91 had endoscopic evidence of gastric ulceration.[4] Other abnormalities of the gastrointestinal tract or abdominal viscera were not found in 57 of the 91 horses with gastric ulcers. Thus gastric ulceration was the primary cause of colic, based on lack of concurrent abnormalities, clinical response to treatment with H_2 antagonists, and confirmation of improvement or resolution of gastric ulceration by endoscopy.[4] However, 34 of the 91 horses with gastric ulceration had concurrent abnormalities of the gastrointestinal tract, demonstrating that gastric lesions can develop in horses with colic. Thus, colic can cause gastric lesions and gastric ulcers can cause colic.

Management and environmental risk factors

Race horses in **training** have a higher prevalence of ulcers than do race horses that are spelling (not in active training)[5,7,9] and horses that are racing regularly have a higher prevalence than resting horses or horses in training but not racing.[7] Standardbred race horses in training are 2.2 times more likely to have gastric lesions, and those racing regularly are 9.3 times more likely to have gastric lesions, than are horses not training or racing.[7] Although, as discussed above, many factors can contribute to the likelihood of a horse having gastric lesions, exercise is strongly associated with development of gastric lesions in horses. This is probably through the increase in intragastric pressure and decrease in pH in the proximal (nonglandular) stomach that occurs during exercise.[14]

Feed withholding causes gastric ulcers in horses, probably because of the lack of buffering of acid produced during periods when the stomach is empty.[15] It is likely that the intermittent access to feed that occurs in many stables results in periods of time during each day when horses do not have feed within the stomach. The loss of buffering is due to lack of feed material in the stomach and to decreased production of saliva, which normally buffers gastric acid. Horses grazing at pasture eat frequently and have food in the stomach almost all the time. **Diet** is suggested to be a risk factor for development of gastric ulcers, but definitive studies are lacking. Horses in training for racing are usually fed diets high in concentrated rations and this is suspected to predispose these horses to gastric ulcers. Feeding of alfalfa hay and grain was associated with fewer gastric lesions in six research horses than was feeding brome grass hay.[16]

Confinement to stalls is associated with an increased prevalence of gastric lesions, whereas gastric lesions are uncommon to rare in horses at pasture. Horses with gastric lesions during confinement have healing of these lesions when they are pastured. Again, there is considerable confounding among the various risk factors, as housing at pasture is associated with constant access to feed, and therefore no periods of feed withholding, changes in diet from that rich in concentrates to that predominated by grasses, and, often, cessation of forced exercise.

PATHOGENESIS

The equine stomach is comparatively small relative to the size of the gastrointestinal tract. The stomach mucosa is divided into two parts. The proventricular part is glistening white in color, is composed of thick **stratified squamous epithelium** and contains no glands. It covers approximately one-third of the mucosal area and ends abruptly at the margo plicatus, a slightly raised irregular serrated border with the glandular mucosa. Most gastric lesions in horses occur in squamous mucosa.

The **glandular mucosa** has a velvet-like structure and is usually covered by a thick layer of viscous mucus. The mucosa contains three main gland types: mucus-secreting cardiac glands; fundic glands, which contain mucus-secreting cells, hydrochloric-acid-producing parietal cells and pepsinogen-secreting chief cells; and pyloric glands, which consist largely of mucus-secreting cells. The stratified squamous epithelial mucosa has minimal resistance to gastric acid. The glandular epithelium has elaborate mechanisms, including the mucus–bicarbonate barrier, prostaglandins, mucosal blood flow and cellular restitution, to protect itself from peptic injury. Hydrochloric acid and pepsinogens, which are converted to the proteolytic enzyme pepsin in an acidic environment, are secreted in the glandular mucosa by parietal cells and chief cells, respectively. The horse is a continuous, variable hydrochloric acid secretor, and the pH of equine gastric contents in the pylorus and antrum is often less than 2.0. Gastric pH is lowest, and acidity highest, when horses have been deprived of feed or have voluntarily stopped eating, often for as little as 2 hours. Thus there are periods during the day when gastric acidity is high. Periods of prolonged high gastric acidity ($pH < 2.0$) can be induced in horses by intermittent deprivation of feed, which often results in severe ulceration in the gastric squamous epithelial mucosa. Concurrent administration of the H_2 antagonist ranitidine during feed deprivation substantially reduces the area of lesion in the gastric squamous epithelial mucosa.[17]

The pathogenesis of gastric ulcer is uncertain. Exposure of squamous mucosa to acid is probably involved in the development of ulcers in most horses. During exercise intragastric pressure increases from approximately 14 mmHg at rest to as high as 50 mmHg, stomach volume decreases and the acidity of fluid within the proximal part of the stomach declines from 5–7 to 2–4.[14] The combination of reduced blood flow and exposure to low pH increases the likelihood of mucosal damage, loss of protective mechanisms and development of gastric mucosal lesions.

Other factors, including physical injury to gastric mucosa, reflux of bile acids from the duodenum[18] and presence of volatile fatty acids in the stomach all may contribute to the development of gastric lesions,[19] but the definitive roles, if any, of each of these factors have not been determined.

CLINICAL FINDINGS

The vast majority of horses with lesions of the gastric mucosa, including ulceration, do not have clinical signs. Among race horses, signs of poor performance, feed refusal, fussy eating (not consuming all of the meal at a constant rate) and poor body condition have been associated with presence of gastric ulcers. Of these signs only poor hair coat and poor body condition have been proved to be

associated with gastric ulcers.[7,8] The high prevalence of both some of the clinical signs, for instance failure to perform to expectation, and gastric ulcers means that there is a high likelihood that horses with a given clinical sign will have an ulcer by chance. However, clinical experience indicates that horses with more extensive or severe lesions will have more severe clinical signs, including colic.

Colic is associated with presence of lesions of the gastric mucosa, including ulceration. Ulceration can result from lesions elsewhere in the gastrointestinal tract, probably because of feed withholding or feed refusal by horses with colic. Alternatively, gastric ulceration can cause colic. The four criteria to determine whether gastric ulceration is the primary cause of colic in horses are:

- Endoscopic confirmation of gastric ulceration
- Absence of another alimentary tract abnormality
- Clinical response to treatment that effectively suppresses or neutralizes gastric acidity
- Confirmation of improvement or complete healing of gastric lesions.[4]

Most gastric ulcers in horses are not associated with hemorrhage and so signs of anemia or melena are unusual in horses. Horses with severe gastric ulceration and reflux esophagitis often have bruxism and retching. Rupture of gastric ulcers, perforation and subsequent peritonitis, and exsanguination from a bleeding ulcer are rare in adult horses.

Involvement of the spleen in the horse with a perforating gastric ulcer, a rare event, results in fever, anorexia, toxemia, pain on deep palpation over the left flank and leukocytosis with a left shift.

Gastroscopic examination is the only means of demonstrating gastric lesions and assessing their extent and severity. Gastroscopic examination of the adult horse requires an endoscope of at least 2.5 m in length, although 3 m is preferable. Presence of feed material within the stomach prevents complete examination of the gastric mucosa, and in particular of the pylorus and antrum. The horse should be prepared by having feed withheld for at least 12 hours and water withheld for 4 hours before examination. If the horse is stabled on edible material such as straw or shavings, it should be muzzled to prevent it eating this material. The horse may need to be sedated before examination (xylazine hydrochloride 0.1–0.3 mg/kg intravenously) and a twitch applied. The gastric mucosa is examined in a systematic fashion. As the end of the endoscope passes through the cardia. the greater curvature and margo plicatus are examined. The endoscope is then advanced and rotated so that the lesser curvature and cardia are examined. The stomach should be inflated with air during the procedure. Excess fluid in the pylorus and antrum can be aspirated to allow better visualization of these regions. Careful attention should be paid to the margo plicatus as this is the most common site for lesions. The gastric glandular mucosa should be examined carefully for lesions as they are easily missed in this region.[20] Material adherent to the mucosa should be washed away by flushing water through the endoscope. The endoscope can be passed into the duodenum to permit complete examination of the antrum. Endoscopic examination usually underestimates the number of gastric ulcers, compared to necropsy examination, and does not accurately predict the severity or depth of ulcers.[20]

Grading systems for description of gastric lesions in horses are:[20]

Gastric ulcer number score

Score	Number of lesions
0	No lesions
1	1–2 localized lesions
2	3–5 localized lesions
3	6–10 lesions
4	> 10 lesions

Gastric ulcer severity score

Score	Description
0	No lesions
1	Appears superficial
2	Deeper structures involved (deeper than #1)
3	Multiple lesions and variable severity
4	Same as #2 and in addition presence of hyperemia or darkened lesion crater
5	Same as #4 but hemorrhage or blood clot adherent to ulcer

A simplified scoring system recommended for use in practice is:[21]

Score	Description
0	Intact mucosal epithelium
1	Intact mucosal epithelium with reddening or hyperkeratosis
2	Small single or small multifocal lesions
3	Large single or large multifocal lesions or extensive superficial lesions
4	Extensive often coalescing lesions with areas of apparent deep ulceration

Most lesions in race horses are in the gastric squamous mucosa with less than 20% of lesions being in the glandular mucosa. The situation is different in hospitalized adult horses, in which lesions in the squamous and glandular mucosa occur with about the same frequency (58%).[22] Most lesions in the glandular mucosa of hospitalized horses occur in the antrum or pylorus, as opposed to the glandular mucosa of the body of the stomach.[22]

Idiopathic gastroesophageal reflux disease occurs sporadically and rarely in adult horses.[23] Affected horses have bruxism and ptyalism that can be severe. Endoscopic examination reveals ulceration and erosion of the esophagus that is more severe in the distal esophagus. Often there is no evidence of impaired gastric outflow, as is common in foals with this disease.

CLINICAL PATHOLOGY

There are no specific laboratory tests for gastric ulceration. Horses with gastric ulcers have higher concentrations of creatinine and activity of alkaline phosphatase in serum than do unaffected horses, but these differences are not sufficient to be clinically useful.[8] Horses with gastric ulcer disease are typically not anemic. A test using concentrations of sucrose greater than 0.7 mg/dL in urine after intragastric administration of 10% sucrose (1 g/kg orally after feeding) solution has a sensitivity and specificity of 83% and 90%, respectively, for detection of gastric ulceration.[24] Sucrose is absorbed intact across the damaged gastric mucosa and excreted in urine, whereas that entering the small intestine is degraded to fructose and glucose.

NECROPSY FINDINGS

Ulcers may be singular or multiple and are most commonly located in the squamous epithelial mucosa adjacent to the margo plicatus along the lesser curvature of the stomach. They may be linear or irregular in shape; with the exception of those in the glandular mucosa, they are rarely circular in appearance. Ulcers in the squamous mucosa often have slightly raised brown-stained keratinized borders and contain small amounts of necrotic material at their base; frank blood is uncommon. Ulcers in the glandular zone are less common and are usually circular or oval depressions surrounded by an intense zone of inflammation.

When perforation has occurred, there is an area of local peritonitis, the stomach wall is adherent to the tip of the spleen and an extensive suppurative splenitis may be present. In some cases, especially when the stomach is full at the time of

perforation, a long tear develops in the wall and large quantities of ingesta spill into the peritoneal cavity. Tumor masses may be present and accompanied by several glandular ulcers.

DIFFERENTIAL DIAGNOSIS

Gastric ulceration of adult horses must be differentiated from the common causes of recurrent colic.

TREATMENT

The goals of treatment of horses with gastric ulcer disease are: healing of the ulcer, suppression of pain and prevention of ulcer recurrence. The principle underlying treatment of gastric ulcers in horses is suppression of gastric acidity (increase intragastric pH). This can be achieved by inhibiting acid production or increasing buffering of acid. Mucosal protectants are administered with the aim of preventing exposure of damaged mucosa to acid. Management changes may reduce the risk of horses developing disease.

Acid suppression

The agents available to suppress acid production are compounds including omeprazole and lansoprazole that block the proton pump on the luminal surface of gastric parietal cells, and H_2 receptor antagonists including cimetidine, ranitidine and famotidine.

Omeprazole

Omeprazole is currently the favored treatment for gastric ulcer disease in horses. The pharmacokinetics, pharmacodynamics, safety, and efficacy of the drug have been extensively investigated in horses under a variety of conditions and management systems. Omeprazole (4 mg/kg body weight orally every 24 h) as a commercial suspension (Gastrogard®) is very effective in promoting healing of ulcers in horses that continue to train or race, a situation in which ulcers will not heal spontaneously.[21,25,26] Omeprazole is safe and no adverse effects from its administration have been reported. Original studies were conducted using omeprazole at a high dose (4 mg/kg), whereas more recent evidence suggests that it may be effective at lower doses (1 mg/kg orally every 24 h), especially when administered as acid-resistant enteric-coated granules.[27] A frequently used treatment regimen is omeprazole 4 mg/kg once daily for 14 days followed by maintenance therapy of 1–2 mg/kg once daily for as long as the horse is at risk of developing gastric ulcers. Omeprazole paste administered at 1 mg/kg orally once daily is effective in both preventing development of ulcers in horses entering race training and preventing recurrence of ulcers in horses in which ulcers have healed during treatment with a higher dose of omeprazole.[28,29]

The composition of the excipients and form of omeprazole is important in determining efficacy. Forms of omeprazole other than that in the commercial preparation are associated with reduced or nil efficacy.[30,31] Omeprazole is more effective than cimetidine (20 mg/kg orally every 8 h) for treatment of gastric ulcers in race horses.[32,33]

Cimetidine

Cimetidine is the prototypical H_2 receptor antagonist. It acts by blocking action of histamine on the basilar membrane of the gastric parietal cells. It is used for treatment of gastric ulcer disease in horses, for which is must be administered frequently and in high doses (20–25 mg/kg orally every 6–8 h). The drug has variable absorption after oral administration to horses.[34] It is usually cheaper than omeprazole, but is less effective.[32,33] Cimetidine can be administered intravenously (7 mg/kg every 6 h) if rapid action is needed or the animal cannot take medication orally (e.g. a horse with colic).

Ranitidine and famotidine

Ranitidine (6.6 mg/kg orally every 8 h) effectively suppresses gastric acidity and prevents development of ulcers in horses deprived of feed.[35] Commercial preparations for use in horses are marketed in some countries. It is effective in preventing ulcers induced in experimental horses, but its efficacy in field situations is not reported.

Famotidine is an H_2 receptor antagonist marketed for use in humans. It is effective in suppressing gastric acidity in horses (3 mg/kg orally every 12 h or 0.3 mg/kg intravenously every 12 hours) but is expensive.

Gastric antacids

Gastric antacids given orally neutralize stomach acid to form water and a neutral salt. They are not absorbed and decrease pepsin activity, binding to bile salts in the stomach, and stimulate local prostaglandin. One oral dose of 30 g of aluminum hydroxide and 15 g magnesium hydroxide can result in a significant increase in gastric pH for up to 4 hours.[36] The short duration of action, minimal and transient effect on gastric pH and need for administration of large volumes orally render these products less than optimal. Moreover, there is evidence that antacids are not effective in treatment of gastric ulcers in race horses.[32]

Protectants

Sucralfate is an antiulcer drug with cytoprotective effect on the gastric mucosa. Sucralfate dissociates in gastric acid to sucrose octasulfate and aluminum hydroxide. The aluminum hydroxide acts as an antacid and the sucrose octasulfate polymerizes to a viscous, sticky substance that creates a protective effect by binding to ulcerated mucosa. This prevents back diffusion of hydrogen ions, inactivates pepsin and absorbs bile acid. Sucralfate is administered to horses (22 mg/kg orally every 8 h) but is not effective in promoting healing in induced disease nor associated with a lower risk of gastric ulcers in race horses administered the compound.[32]

Pectin–lecithin complexes are not effective in treatment of gastric ulcer disease in horses.[37]

Management changes

Horses with gastric ulcers experience spontaneous healing when removed from training and kept at pasture. These management changes are not appropriate in most instances, and emphasis should be place on feeding diets that have a low ulcerogenic potential (such as alfalfa hay) and using feeding practices that minimize or eliminate periods when the horse does not have access to feed. Hay should be constantly available to horses, if at all possible.

Overview of treatment

The usual approach to treatment is to promote healing of the ulcer by administration of effective agents (omeprazole or possibly ranitidine) at high dose until the ulcer has healed, as demonstrated by gastroscopy. The horse is then administered omeprazole at a lower dose (1–2 mg/kg orally every 24 h) for the duration of time that it is at risk of developing gastric ulcers. Changes in management, including importantly feeding practices and diet, should be instituted at the start of treatment. While not statistically associated with risk of gastric ulceration, use of phenylbutazone or other NSAID should be minimized in horses at high risk of disease.

CONTROL

Prevention of gastric ulcer disease in athletic horses centers upon minimizing the effect of factors that promote ulcer development. This may involve the chronic administration of omeprazole (1 mg/kg orally once daily),[29] but should include attention to dietary and feeding practices (discussed above) that minimize the time that horses have no feed in their stomach. Ideally, horses at risk would be kept at pasture, but this is not feasible under many management or husbandry systems. All horses in athletic training and confined to stalls should be considered at high risk of development of gastric ulcers and should be managed

accordingly. Horses at pasture, such as brood mares, are at minimal risk of development of gastric ulcer disease and no specific control measures are indicated.

INTESTINAL OBSTRUCTION IN HORSES

Intestinal obstruction is an important cause of colic in horses, and can involve the small intestine, cecum, large (ascending) colon, or small (descending) colon. Because the clinical characteristics of obstruction of the various bowel segments are quite different, intestinal obstruction is discussed based on the site affected (small intestine, cecum, large or small colon).

SMALL-INTESTINAL OBSTRUCTION IN HORSES

Synopsis

Etiology Volvulus; intussusception; incarceration and strangulation in epiploic foramen, Meckel's diverticulum, mesenteric rents, or umbilical, inguinal or diaphragmatic hernia, or by pedunculated lipoma; obstruction due to foreign bodies, intramural tumors including hematomas, neoplasms and abscesses; ileal hypertrophy; ileal impaction

Epidemiology Mostly sporadic diseases, although the age affected can vary with the disease

Clinical signs Strangulating lesions cause acute, severe disease with intense pain, tachycardia, dehydration and hemoconcentration, and usually distended loops of small intestine palpable rectally. Death occurs in untreated horses within 48 hours. Obstructive, nonstrangulating lesions cause less severe pain and clinical abnormalities and have a longer course until death

Clinical pathology None diagnostic. Hemoconcentration and azotemia are indicative of dehydration. Leukopenia and left shift are consistent with endotoxemia and peritonitis. Peritoneal fluid may be serosanguinous with infarcted intestine

Lesions Consistent with the disease

Diagnostic confirmation Surgical exploration or necropsy

Treatment Surgical correction of lesion. Analgesia. Correction of fluid, electrolyte and acid–base abnormalities

ETIOLOGY

A working classification is outlined below.

Obstruction with infarction

- Volvulus or torsion of the mesentery
- Incarceration in or strangulation by:
  - Mesenteric rents[1]
  - Epiploic foramen[2]
  - Meckel's diverticulum[3]
  - Pedunculated lipoma[4]
  - Adhesions
  - Inguinal hernia[5]
  - Umbilical hernia[6]
  - Diaphragmatic hernia[7]
  - Rents in mesentery or intra-abdominal ligaments (e.g. gastrosplenic) or spleen[8]
  - Spermatic cord in geldings[9]
  - Developmental defects in mesentery[10]

Obstruction without infarction

- Intussusception:
  - Jejunojejunal, ileoileal, and other small intestinal[11,12]
  - Acute and chronic ileocecal[13,14]
- Foreign body:
  - Wood chip or fencing material impaction of duodenum or jejunum[15]
  - Phytobezoars
  - Linear foreign bodies such as string or baling twine
  - Impaction of the duodenum or jejunum by molasses-containing feedblocks[16]
- Impaction of *Parascaris equorum*[17]
- Impaction of the terminal ileum[18]
- Muscular hypertrophy of the terminal ileum[19]
- Intramural masses such as neoplasms (intestinal adenocarcinoma, focal lymphosarcoma, leiomyoma),[20] hematomas,[21] abscesses and fungal infections (intestinal pythiosis), focal eosinophilic enteritis[22] and *Lawsonia intracellularis* proliferative enteropathy
- Compression of intestine by intra-abdominal masses including abscesses and neoplastic tumors.

Functional obstruction

- Anterior enteritis
- Postoperative ileus
- Myenteric ganglioneuritis[23]
- Intestinal ischemia of any cause (thromboembolic colic, mesenteric accidents, post-exertional ileus.[24]

The classification used above should be used only as a guide, as the actual clinical presentation may vary. For instance, intussusceptions usually result in infarction of the intussuscepted segment but, because this segment is effectively isolated from the body, the clinical signs are often not characteristic of a horse with an infarctive lesion. Similarly, horses with small intestine entrapped in the epiploic foramen often have less severe clinical signs than anticipated for the severity of the lesion.

EPIDEMIOLOGY

The epidemiology of colic is covered in a previous section. There are no recognized risk factors for small-intestinal volvulus and for many small-intestinal accidents. Epidemiological information is available for some small-intestinal obstructive diseases and is presented below. Obstructive diseases of the small intestine compromise approximately 20% of colic cases referred for further evaluation and treatment.[25] For small-intestinal diseases requiring surgical correction, the case fatality rate is 100% if surgery is not performed. Short-term survival of horses undergoing surgical correction of small intestinal obstruction is 34–74%.[26,27] Mortality rate is greatest in the perioperative period.[27] Survival rates vary depending on the nature and severity of the lesion, with long-term survival rates being lower for horses that require

resection of intestine, especially for resections of more than 2 m or more than one surgery.[28,29]

Intestinal herniation through the epiploic foramen

This occurs in approximately 5% of horses with small intestinal disease requiring surgery.[2] Geldings are four times more likely than mares to be affected. Thoroughbreds were over-represented in two studies, suggesting a breed predisposition, and there was no effect of age on incidence.[2,30] There appears to be an increased in incidence of the disease between October and March in Britain.[30] The **case fatality rate** for horses subjected to surgery was between 30% and 40%,[2,24,30] although older reports of the disease had a much higher case fatality rate. Horses with colic that crib (a behavioral abnormality in which horses grasp a fixed object such as a fence rail or post with the incisors, flex the neck and draw air into the esophagus) are 8–34 times more likely to have herniation of the small intestine through the epiploic foramen than are horses that do not crib.[30,31] The reason for this association is not known but may be related to factors that predispose horses to both cribbing and intestinal herniation through the epiploic foramen, such as diet, exercise or housing. Alternatively, cribbing might cause changes in intra-abdominal pressure that favor herniation.[31] There is no age predisposition to development of this disorder.[26]

Pedunculated lipomas

The prevalence of colic caused by pedunculated lipoma is 1–2.6% of horses with colic and 1–17% of all horses that have a celiotomy because of small intestinal disease.[4,26] The prevalence varies depending on the population of horses studied. The proportion of horses with colic due to pedunculated lipomas increases with age, with the median age of affected horses being 19 years.[26] Pedunculated lipomas cause small intestinal obstruction in older horses (> 8 years) with geldings (2 ×) and ponies (4 ×) being at increased risk.[4] Pedunculated lipomas occasionally (5 of 75 cases) cause strangulating obstructive lesions of the small colon.[4] The case fatality rate for horses subjected to surgery is over 60%.

Inguinal hernias

Inguinal hernias occur only in males. **Congenital inguinal hernias** are usually self-limiting, do not require medical or surgical therapy and resolve by the time foals are 3–6 months of age. Congenital inguinal hernias rarely cause a strangulating lesion of the small intestine (see Colic in foals). **Acquired inguinal hernias** occur almost exclusively in stallions, the disease being rare in geldings.[5] There is no apparent breed or age predilection. The case fatality rate for horses subjected to surgery is 25%.

Intussusception

Small-intestinal intussusception occurs more commonly in young horses and foals but also occurs in adult horses.[11,12] Approximately 50% of intussusceptions in adult horses are associated with a luminal or mural mass, whereas this is not the case in younger horses and foals.[11,12] The case fatality rate of horses subjected to surgery is 25–60%.

Both acute and chronic **ileocecal intussusceptions** occur more commonly in young (6–30 months) horses, although they are rare in foals.[13,14] There is no breed or sex predilection. The disease is acute in approximately 70% of cases and chronic in the remainder.[13] Ileocecal intussusceptions constitute approximately 75% of all intussusceptions involving the small intestine, and 60% of all intussusceptions.[13] The **case fatality rate** for horses with acute ileocecal intussusception when surgery is available is approximately 70%, whereas that for chronic intussusception is less than 10%.[13,14] There is strong evidence of an association between tapeworm (*Anoplocephala perfoliata*) infestation and ileocecal disease causing colic in horses.[32,33]

Foreign body

Foreign body obstructions occur most frequently in foals and yearlings, possibly because of their tendency to explore and eat unusual items. Impaction by *Parascaris equorum* occurs in foals between 3 and 18 months of age and is often associated with the administration of anthelmintics to previously untreated foals.[17] Small-intestinal obstruction by feedblocks containing molasses is associated with ingestion of large quantities of the material.[26]

Impaction

Ileal impaction occurs more commonly in mares and only in animals over 1 year of age.[18] The disease represented 7% of surgical colic cases in one series.[34] The case fatality rate of animals treated at a referral institution was 64%.[20] The disease is attributed to the feeding of finely ground, high-fiber feed such as Bermuda hay.[35] Horses with colic that have been fed coastal Bermuda hay are approximately three times more likely to have ileal impaction than are horses with colic that have not been fed this feedstuff.[35] Similarly, lack of administration of a compound effective against tapeworms is associated with a three-times greater risk of ileal impaction among horses with colic,[35] and tapeworm infestation is associated with an increased incidence of spasmodic colic and ileocecal impaction in Thoroughbred race horses.[36]

Mesenteric rents

Incarceration of small intestine through mesenteric rents is a cause of colic in approximately 2% of colic patients undergoing exploratory celiotomy.[1] The long-term survival rate is approximately 40%. There are no identified age, breed or sex predilections.

PATHOGENESIS

The effects of intestinal obstruction and the particular influence of the related endotoxemia in horses have been detailed earlier. The type of lesion is important, depending on whether the blood supply to a large section of intestine is occluded or whether effective circulation is maintained. Obstructions that do not cause widespread intestinal ischemia, such those caused by focal external pressure, such as occurs with some forms of disease caused by pedunculated lipomas, or caused by internal foreign bodies such as phytobezoars, are less acutely lethal and do not cause as severe signs as do volvulus and forms of intussusception that result in ischemia of large sections of intestine. In the latter case, endotoxins from the gut lumen pass through the devitalized tissues of the gut wall into the circulation, resulting in signs of toxemia and cardiovascular collapse.

CLINICAL FINDINGS

Acute disease – infarctive lesions

In acute, complete obstructions of the small intestine, with intestinal ischemia due to volvulus, intussusception or strangulation, there is usually an almost immediate onset of severe abdominal pain. The pain may be minimally or only transiently responsive to administration of analgesics. During this early stage intestinal sounds may still be present and feces still passed. The pulse rate increases to 60–80/min, the respiratory rate may be as high as 80/min, and sweating begins in many horses. It may be 8–12 hours before distended loops of intestine are palpable on rectal examination and it is about the same time that clinical and laboratory evidence of hypovolemia is first apparent. Depending on the site of the obstruction there may be reflux of fluid on passage of a nasogastric tube. More proximal lesions result in distension of the stomach earlier in the course of the disease. Small-intestinal distension is readily detected by percutaneous or rectal ultrasonographic examination. The sensitivity and specificity of ultrasonographic examination for detecting small-intestinal distension (98% and 84%, respectively) is greater

than that of rectal examination (50% and 98%, respectively).[37]

In the period 12–24 hours after obstruction commences, the pulse rate rises to 80–100/min, loops of distended intestine can be palpated per rectum, gut sounds and defecation cease, and the rectum is empty and sticky to the touch. Abdominal paracentesis yields blood-stained fluid. From 24 hours onwards, signs of hypovolemia and toxic shock become marked but the pain may not worsen. The horse will often appear depressed and poorly responsive to external stimuli. Sweating may persist. The heart rate increases to 100–120/min, intestinal loops are easily palpable, and reflux filling of the stomach occurs, with much fluid being evacuated via the stomach tube; the horse may vomit. Death due to endotoxemia or rupture of the intestine usually occurs within 48 hours. The terminal stage is one of severe endotoxic shock, with or without intestinal rupture and peracute diffuse peritonitis.

Subacute cases – noninfarctive lesions

If there is no vascular involvement in the small-intestinal obstruction, the pain is less severe than for horses with infarctive lesions, it is usually responsive to analgesics and the heart rate is only mildly elevated (50–60 bpm). The pain may be low-level continuous or intermittent with moderate attacks of pain alternating with periods of uneasiness without signs of overt pain. Pain is usually responsive to administration of analgesics. The duration of colic in these cases may be several days to several weeks. Palpable intestinal distension and clinical and laboratory evidence of hypovolemia may be evident. Surgical intervention becomes an option because of the failure of the patient to improve.

Intussusception of the small intestine

This may cause a syndrome of acute, subacute or chronic colic, depending on the degree of involvement of the blood supply. Horses with **acute ileocecal intussusception** have an abrupt onset of moderate to severe abdominal pain, tachycardia, reflux through a nasogastric tube, complete absence of borborygmi, and tightly distended small intestine evident on rectal palpation. The course of the disease is usually less than 24 hours. Horses with **chronic ileocecal intussusception** have a history of chronic, intermittent colic occurring after feeding, weight loss and reduced fecal volume.[13,14] The abdominal pain is mild and intermittent and the horses are not dehydrated or tachycardic. Rectal examination may reveal the presence of mildly distended small intestine, especially after a meal, and in approximately 25% of cases the intussusception can be palpated per rectum. Mild abdominal pain may be present for weeks without an abdominal crisis occurring. Ultrasonographic examination may reveal the intussusception in the right flank.

Volvulus of the small intestine

This presents a typical syndrome of acute intestinal obstruction and infarction. The onset of signs is abrupt and there is severe pain, tachycardia, sweating and a rapid deterioration in the horse's clinical condition.

Strangulated inguinal hernia

This entity is often missed in the early stages because the distension of the scrotum is easily missed unless a specific examination of that area is performed. Severe pain in an entire male, even when distended loops of small intestine are not palpable, should prompt a thorough examination of the scrotum and, per rectum, the internal inguinal rings.

Strangulated diaphragmatic hernia

When acquired after birth, this lesion may have no distinguishing characteristics and may be identified only on thoracic radiography or exploratory laparotomy. There is often a history of trauma, such as dystocia or, in adults, a fall or being hit by a car. The clinical course is characteristic of any acute, strangulating intestinal lesion. Small intestine or large colon may herniate into the thoracic cavity and be evident on radiographic or ultrasonographic examination of the thorax.[7]

Epiploic foramen entrapment

Entrapment of small intestine in the epiploic foramen is associated with an array of clinical signs, some of which are subtle. Strangulation of small intestine through the epiploic foramen typically causes signs of acute abdominal pain with reflux of material through a nasogastric tube.[2,38] However, approximately 40% of affected horses do not have signs of abdominal pain when examined at a referral center and 52% do not have nasogastric reflux.[2] Horses with less severe clinical signs presumably have shorter lengths of incarcerated small intestine or incomplete obstructions to passage of luminal material or blood flow. Herniation of the parietal (antimesenteric) margin of the small intestine is sometimes associated with incomplete obstruction of the small intestine and signs of mild disease.[39] Because of the anterior location of the lesion, distended small intestine cannot usually be palpated per rectum and is not identifiable without ultrasonographic examination or surgical intervention. A fatal complication of epiploic foraminal herniation is rupture of the portal vein, leading to sudden death from internal hemorrhage. Tension by the incarcerated section of gut on the portal vein causes tearing of its wall and subsequent hemorrhage.[34] Hemoperitoneum in a horse with colic should prompt consideration of entrapment of small intestine in the epiploic foramen as a cause of the disease. The outcome of this combination of diseases is almost always fatal.

Functional obstruction

Functional obstructions due to anterior enteritis, intestinal ischemia or postoperative ileus can be difficult to discriminate from obstructive lesions of the small intestine that require surgical correction. Postoperative ileus is characterized by continued pain and reflux through a nasogastric tube after surgical correction of an intestinal lesion. The ileus is probably a result of the diffuse peritonitis and inflammation of the intestine that results from surgical exploration of the abdomen. If sufficient doubt exists over the cause of a horse's signs of intestinal obstruction, then laparotomy or repeat laparotomy should be performed.

Foreign body

Foreign body impaction of the duodenum by agglomerations of chewed wood or cracked corn kernels cause signs of acute obstruction but without the endotoxemia caused by infarction.[15]

Ileocecal valve impaction

Impaction of the ileocecal valve is manifest as an initial period of 8–12 hours of subacute abdominal pain with mild increases in heart rate. Intestinal sounds are increased in frequency and intensity. Rectal examination may reveal the enlarged, impacted ileum in the upper right flank at the base of the cecum in approximately 10% of cases.[35] It is easily confused with an impaction of the small colon. Reflux on nasogastric intubation occurs in approximately 50% of cases. After 24–36 hours the pain increases in severity. There is severe depression, patchy sweating and coldness of the extremities and the animal stands with its head hung down, sits on its haunches and rolls and struggles violently. The abdominal pain becomes severe and continuous, the pulse rate rises to between 80–120/min and the pulse is weak. The abdominal sounds are absent and there is reflux of sanguineous fluid through a nasogastric tube. On rectal examination the small intestine is tightly distended with gas and fluid. Death usually occurs within 36–48 hours after the onset of illness without surgical or effective medical intervention.

Idiopathic muscular hypertrophy (terminal ileal hypertrophy)

This causes a long-term chronic or mild intermittent colic, with reduced appetite and weight loss, which persists over a period of weeks, sometimes months, in horses more than 5 years and up to 18 years old.[19] Colic pain is associated with feeding. On rectal examination the greatly thickened ileum can be palpated at the base of the cecum, and there may also be distended loops of thick-walled ileum.

Difficulty can be experienced in differentiating ileal hypertrophy from chronic intussusception, especially of the terminal ileum into the cecum. Fluid ingesta can pass the much constricted lumen of an intussusception so that mural hypertrophy occurs orally. A similar clinical picture results from stenosis of the small intestine by adhesions, usually resulting from verminous migration. In all three diseases there is increased motility of the small intestine and there is no interference with the blood supply.

Caudal abdominal obstructions

Obstructive lesions of small intestine in the caudal abdomen, and therefore more likely to be palpable, include strangulation through tears in the mesentery, through a defect in the gastrosplenic ligament, entrapment behind the ventral ligament of the bladder or through a tear in the broad ligament of the uterus.

Radiography is not useful in diagnosing the cause of small-intestinal obstruction in adult horses, but **ultrasonographic** examination of the abdomen is rewarding and has greater sensitivity for detection of distended loops of small intestine than does rectal examination.[2,37] If available, ultrasonographic examination is indicated in the initial or second examination of all horses with colic. Ultrasonographic examination can detect, in addition to distended small intestine, reductions in or absence of motility associated with ileus, thickening of the intestinal wall, intussusceptions, increased volume of peritoneal fluid and abnormalities in the echogenicity of peritoneal fluid.[40]

CLINICAL PATHOLOGY

While laboratory examinations of animals with intestinal obstruction may not be used in the diagnosis of the obstruction, they are useful in assessing its severity. In general, the laboratory findings in acute intestinal obstruction include the following:

- Hemoconcentration (the PCV usually exceeds 50%)
- Increase in serum creatinine concentration (depending on severity of the decrease in circulating blood volume)
- Decreases in plasma bicarbonate and pH, with increases in lactate concentration and anion gap
- Leukopenia and neutropenia. This is due to devitalization of infarcted intestine and the development of endotoxemia and, in some cases, peritonitis
- An increase in the total number of leukocytes, erythrocytes and the protein concentration in the peritoneal fluid obtained by paracentesis. In acute intestinal obstruction with infarction, the peritoneal fluid will be bloodstained. As necrosis and gangrene develop there is an increase in the total number of leukocytes with an increase in the number of immature neutrophils. As devitalization proceeds, but prior to perforation of the gut wall, intra- and extracellular bacteria may be seen in the fluid. Peritoneal fluid from horses with intestinal infarctive lesions has a higher alkaline phosphatase activity than fluid from horses with nonstrangulating obstructions.[41]

NECROPSY FINDINGS

The physical lesions are characteristic of the disease.

DIFFERENTIAL DIAGNOSIS

Other diseases that may mimic pain caused by gastrointestinal disease are listed under Differential diagnosis in equine colic. Gastrointestinal causes of colic that must be differentiated from small intestinal obstructive disease include:

- Enteritis and acute diarrhea
- Equine monocytic ehrlichiosis
- Anterior enteritis
- Gastric ulcer in foals and adults
- Disorders of the large or small colon
- Intestinal tympany (gas colic)
- Thromboembolic colc.

See also Table 5.6.

TREATMENT

The principles of treatment of horses with small intestinal obstructive lesions are similar to those of any colic and are set out in detail under Equine colic, above.

Every attempt should be made to relieve the horse's pain using appropriate doses of effective analgesics (see Table 5.7). Care should be taken when using flunixin meglumine that signs of a lesion requiring surgical correction are not masked until the severity of the disease makes successful treatment unlikely.

Almost all obstructive lesions of the small intestine require surgical correction. In addition to surgery, attention should be paid to maintaining the horse's fluid, acid–base and electrolyte status, as discussed under Equine colic and in Chapter 2. Treatment of postoperative ileus should be aggressive and include correction of acid–base, fluid and electrolyte abnormalities, continued gastric decompression through a nasogastric tube and administration of promotility drugs such as cisapride, lidocaine, erythromycin and metoclopramide (Table 5.8).

Ileal impactions can be treated medically by the administration of intravenous fluids, gastric decompression and administration of mineral oil.[42] Horses treated medically should be closely monitored as prompt surgical intervention may be necessary if the horse's condition deteriorates.

ANTERIOR ENTERITIS (DUODENITIS – PROXIMAL JEJUNITIS, PROXIMAL ENTERITIS)

Synopsis

Etiology Unknown
Epidemiology Sporadic disease. Case fatality rate of 6–75%
Clinical signs Colic, voluminous reflux on nasogastric intubation, mild fever, resolution of pain on gastric decompression
Clinical pathology None diagnostic
Lesions Duodenitis, proximal jejunitis. Gastric and small intestinal distension
Diagnostic confirmation None. Resolution of disease
Treatment Gastric decompression. Correction of fluid and electrolyte abnormalities

ETIOLOGY

The etiology of anterior enteritis is unknown. *C. difficile* might be involved[1] Experimental intoxication with culture media of *Fusarium moniliforme* produces histological, but not clinical, signs consistent with the disease.[2]

EPIDEMIOLOGY

The disease is reported from the USA and Europe.[2,3] There is no apparent effect of age, with the exception that the disease is not reported in horses less than 1 year of age and is uncommon in horses less than 2 years of age.[4] There is no breed or sex predilection for the disease. There are anecdotal reports of farms with a high incidence of the disease, especially among brood mares. Similarly, some consider feeding of large amounts of concentrated feeds to horses to be a risk factor for the disease. Anterior enteritis occurs more commonly in the warmer months.[4] There are no reports of the incidence, morbidity/mortality of anterior enteritis. The **case fatality rate** varies from 6% to 75%.[4,5]

PATHOGENESIS

The primary lesion is inflammation and edema of the duodenum and jejunum with sloughing of villus epithelium and villus atrophy.[5] These lesions are probably associated with ileus and failure of small intestinal absorptive function. Fluid accumulation in the atonic small intestine causes distension and pain and reflux of alkaline small-intestinal contents into the stomach. Sequestration of fluid, electrolytes and bicarbonate in the stomach and small intestine causes a reduction in blood volume, shock and metabolic acidosis. Gastric and small intestinal distension and hypovolemia cause tachycardia. Disruption of the small intestinal mucosal barrier allows absorption of toxins, including endotoxins, that further compromise cardiovascular and metabolic function. Death in untreated cases results from acute, diffuse peritonitis secondary to gastric rupture, or shock and metabolic disturbances secondary to hypovolemia and endotoxemia.

CLINICAL FINDINGS

The onset of clinical signs is usually abrupt and characterized by mild to severe colic. Affected horses are **depressed**, **dehydrated** and have prolonged capillary refill time and heart rates between 50 and 80/min. The respiratory rate is variable. The horse may sweat profusely and there are muscle fasciculations in severely affected cases. **Borborygmi are absent** although there may be tinkling sounds of gas bubbling in fluid-filled atonic intestine. **Rectal examination** usually reveals the presence of multiple loops of moderately to severely distended small intestine. **Reflux of fluid** through a nasogastric tube is a consistent finding, and usually results in marked relief of pain and resolution of tachycardia. The fluid is often sanguineous, malodorous, alkaline and of large (10–12 L) volume.[4]

Gastric decompression and administration of intravenous fluids results in marked improvement of clinical signs, although affected horses may continue to have nasogastric reflux for 24 hours to 10 days. Most cases resolve within 5 days. If untreated, horses develop severe gastric distension with subsequent rupture and death from peracute, diffuse peritonitis, or die as a result of hypovolemia and toxemia. A common sequela is the development of laminitis. Approximately 10% of horses with anterior enteritis have cardiac arrhythmias, including ventricular depolarizations and atrio-ventricular conduction disturbances.[6] Arrhythmia resolves with resolution of the anterior enteritis.

CLINICAL PATHOLOGY

There is hemoconcentration with hematocrits as high as 0.70 L/L (70%) and total serum protein as high as 96 g/L (9.6 g/dL) in severely affected horses. The leukogram is variable and not diagnostic – leukocytosis and left shift are common.[5] Serum potassium concentration may be mildly low and blood bicarbonate concentration and pH are low in most cases. Horses with anterior enteritis have serum bilirubin concentrations and serum gamma-glutamyl transpeptidase, aspartate aminotransferase and alkaline phosphatase activities higher than horses with small intestinal infarctive lesions.[7] However, the differences are not sufficiently large for these variables to be useful in the differentiation of horses with anterior enteritis from horses with small-intestinal infarctive lesions.

Peritoneal fluid has a normal nucleated cell count in 65% of cases; in the remaining cases it is increased.[4] Peritoneal fluid protein concentration is often normal in cases sampled early in the disease but may be increased in more severe or prolonged disease and is a useful prognostic indicator.[8]

NECROPSY FINDINGS

Gross lesions are restricted to the stomach, duodenum and jejunum in most cases. The affected stomach and small intestine are distended and the serosal surface has numerous petechial and ecchymotic hemorrhages.[5] The mucosa is deep red and contains petechial hemorrhages and occasional foci of necrosis and ulceration. Histological changes include neutrophilic inflammation, edema, hyperemia, epithelial sloughing and villus atrophy. There is necrosis of mucosa, fibrin-rich edema and heavy neutrophil infiltration of the submucosa, and extensive hemorrhage in the tunica muscularis and serosa.[5] A proportion of horses with anterior enteritis have biochemical and histological evidence of liver disease, including hepatocellular vacuolization and neutrophilic inflammation.[7] Some horses with anterior enteritis have myocarditis.[6]

DIFFERENTIAL DIAGNOSIS

The most important differential diagnosis is a small intestinal obstructive lesion.

DIAGNOSTIC CONFIRMATION

Horses with small-intestinal obstructive lesions require urgent surgical correction, while horses with anterior enteritis respond well to medical therapy. The differentiation of anterior enteritis and a small-intestinal obstructive lesion on clinical grounds is difficult and there is no one variable that allows the distinction to be made reliably. Horses with anterior enteritis have a lower heart rate, higher rectal temperature (fever), lower volume of gastric reflux and less turgid small intestine on rectal examination than do horses with obstructive lesions,[4] although others report that horses with anterior enteritis have a higher volume of reflux at first examination and during the first

24 hours of disease.[7] However, these differences are not sufficiently great to be conclusive. Horses with anterior enteritis more often have normal peritoneal fluid than do horses with small-intestinal obstructive lesions. The response to gastric decompression and intravenous fluid therapy is useful in discriminating between diseases as horses with anterior enteritis have marked resolution of abdominal pain and tachycardia within minutes of gastric decompression, whereas horses with small-intestinal obstruction have minimal or no resolution of these signs. In general, horses with a heart rate below 60/min after gastric decompression, mildly to moderately distended loops of small intestine, resolution of abdominal pain after gastric decompression and normal peritoneal fluid probably have anterior enteritis. However, horses should be examined frequently for changes in clinical condition. Worsening pain and cardiovascular status in the face of adequate fluid therapy warrant reconsideration of a diagnosis of anterior enteritis.

TREATMENT

The principles of treatment of anterior enteritis are gastric decompression, correction of fluid, acid–base and electrolyte abnormalities and provision of maintenance fluid and electrolytes, relief of pain, and prophylaxis of laminitis.

Gastric decompression is an urgent need in affected horses and can be accomplished by nasogastric intubation. The nasogastric tube should be left in place, or replaced frequently, for as long as there is reflux of clinically significant quantities of fluid (more than 2–4 L/4 h in a 425 kg horse). Discontinuation of gastric siphonage should be approached cautiously and the should be patient monitored for any increase in heart rate or development of abdominal pain that may indicate recurrence of gastric distension. After the nasogastric tube is removed, the horse should be reintroduced cautiously to oral fluids and food. Small amounts (1–2 L) of water should be offered frequently (every 1–2 h) during the first 12–24 hours. Horses should not be given immediate access to ad libitum water as some horses in the early convalescent period from anterior enteritis will consume a large quantity of water and develop gastric dilatation and colic. Feed should be reintroduced gradually over 24–48 hours.

Complications of prolonged or repeated gastric siphonage through a nasogastric tube are pharyngitis, esophagitis, esophageal stricture and esophageal perforation with subsequent cellulitis.

Fluid, electrolyte and acid–base abnormalities should be corrected by the administration of intravenous fluid. Isotonic, polyionic fluids such as lactated Ringer's solution are suitable. Affected horses may loss considerable chloride and potassium in reflux fluid necessitating supplementation of fluids with potassium (up to 20 mEq/L).

Analgesia can be provided by administration of any of a number of drugs, including flunixin meglumine or ketoprofen (Table 5.7). If the diagnosis of anterior enteritis is uncertain, potent analgesics such as flunixin meglumine should not be used until there is no possibility that a lesion requiring surgical correction exists.

Promotility agents such as lidocaine and cisapride (Table 5.8) and antacids such as cimetidine (Table 5.11) are sometimes administered, although their efficacy has not been determined.[9]

Antibiotics, such as penicillin and an aminoglycoside, are often administered to affected horses because of the presumed bacteremia associated with the disease.

Surgical treatment of the disease is described[3,5] but most cases resolve without surgical intervention.[4]

DISEASES OF THE CECUM

ETIOLOGY

- Cecal impaction
- Cecal rupture
- Cecocecal and cecocolic intussusceptions
- Cecal torsion
- Cecal tympany
- Cecal infarction.

There is strong support for a role of *Anoplocephala perfoliata* infestation in cecal disease of horses.[1–3] Infestation with *A. perfoliata* results in edema, hyperemia and hemorrhagic foci in the ileocecal valve mucosa with light parasitism through regional necrotizing enteritis, with extension of lesions to the muscularis mucosa and eosinophilic inflammation around arterioles and submucosal neural plexus with heavy parasitism.[3]

Synopsis

Etiology Cecal impaction, perforation, cecocecal and cecocolic intussusceptions, cecal torsion and cecal tympany
Epidemiology Sporadic diseases. Cecal impaction and cecal perforation are reported in horses hospitalized for unrelated conditions. Cecal rupture occurs in mares during parturition
Clinical signs Cecal impaction is evident as mild, intermittent colic that may not be noticed by a casual observer. Cecal perforation or rupture is evident as acute shock, sweating and tachycardia secondary to diffuse peritonitis. Cecocolic intussusception causes acute severe colic while cecocecal intussusception causes mild, intermittent colic
Clinical pathology None diagnostic
Lesions Gross lesions consistent with the disease
Diagnostic confirmation Physical examination, exploratory laparotomy, or necropsy examination
Treatment Cecal impaction treated medically with overhydration, fecal softeners and analgesics. No treatment for cecal rupture or perforation. Surgical correction of some cecal impactions and all cecocecal and cecocolic intussusceptions

Larval cyathostomiasis is also associated with cecocolic and cecocecal intussusception in young horses.[4] Other causes include intramural and extramural masses, including cecal abscesses, and alterations in cecal and colonic motility.

Disturbed cecal motility or dehydration of cecal contents secondary to dietary changes are thought to be the cause of most cases of cecal impaction and rupture.[5] Horses with recurrent cecal impaction have lower neurone densities in muscle layers of the base of the cecum and cecal body than do normal horses, supporting the hypothesis that disturbed motility secondary to neuronal abnormalities is a cause of the disease.[6] Administration of drugs that interfere with cecal motility or secretory function has the potential to increase the risk of cecal disease.

EPIDEMIOLOGY

Cecal disease accounts for approximately 4–10% of colic in horses examined for abdominal pain at referral centers.[7,8]

Cecal impaction

Cecal impaction is the cause of colic in approximately 5% of horses treated for colic in referral institutions. This estimate probably reflects a selection bias, with horses with less severe disease not being referred for further examination. Cecal impaction is therefore probably much less common as a cause of colic in field cases. Cecal impaction is the most common cause of cecal disease.[7] There is no sex predisposition to the disease but Arabians,

Morgans and Appaloosa breeds might be at greater risk of developing cecal impactions.[9] Older horses are disproportionately affected, with horses over 15 years at increased risk compared to horses less than 7 years of age.[9,10] The disease occurs sporadically but is reported in horses hospitalized for unrelated disease, and it is speculated that anesthesia, surgery and/or administration of NSAIDs are risk factors for the disease.[10] Fasting, poor dentition, poor-quality feed and restricted water intake might also be risk factors for the disease. The **case fatality rate** is approximately 50%.[10]

Cecal rupture

Cecal rupture at parturition occurs in 0.1% of mares.[11] Cecal rupture represents approximately 27% of cecal disease in horses, that associated with concurrent but apparently unrelated disease being the most common (13%).[7] Cecal rupture or perforation is otherwise a sporadic disease that is often, but not always, a sequela to cecal impaction.[12] The case fatality rate is 100%.[12] Cecal rupture, often without recognized pre-existing disease, is recognized as a complication of anesthesia and phenylbutazone administration.[9,12,13] As with other cecal diseases, infestation with *A. perfoliata* has been implicated as a cause of cecal rupture, although not all horses with cecal rupture have tapeworms.[9]

Cecocecal or cecocolic intussusceptions

Cecocolic and cecocecal intussusceptions are the cause of 1% of colic cases treated surgically and approximately 3–7% of cecal disease.[7,14] The case fatality rate is approximately 50–70%.[14,15] There are no recognized epidemiological patterns to the occurrence of **cecal or cecocolic intussusceptions**, with the exception that younger horses (< 3 years) and Standardbreds are disproportionately affected.[14,15] Infestation with tapeworm (*A. perfoliata*) is suspected to increase the risk of cecal intussusceptions, although this suspicion is not universal.[15,16]

Cecal torsion

Cecal torsion occurs rarely and is associated with hypoplasia of the cecocolic fold in some but not all cases.[7,17]

Primary **cecal tympany** is rare. Cecal infarction is caused by thromboembolic disease secondary to *Strongylus vulgaris* arteritis or necrotizing enterocolitis.[18]

PATHOGENESIS

Cecal impaction is probably a result of impaired or altered cecal motility, with resultant reduced cecal emptying into the right ventral colon.[5] Accumulation of feed material causes cecal distension and excessive tension in the wall of the cecum with ischemia, necrosis and rupture. Infestation by tapeworms, including *A. perfoliata*, cause disruption of the cecal mucosa and submucosa, necrosis and inflammation, changes that could contribute to cecal dysfunction.[3] Death results from peracute diffuse peritonitis.

Cecal rupture at parturition is probably the result of high intra-abdominal pressures associated with expulsion of the fetus. The pathogenesis of cecal rupture without cecal impaction is unknown.

CLINICAL FINDINGS

Cecal distension and impaction

Cecal distension occurs as two clinical syndromes. Cases in which the cecum is **impacted** and distended with inspissated feed material usually have signs of mild to moderate abdominal pain that is often intermittent over a 1–4-day period. The signs of pain may be sufficiently mild as to be missed by a casual observer. Affected horses are usually mildly depressed and have a diminished appetite. The heart rate is 40–60/min, borborygmi are reduced and there may be mild dehydration. Nasogastric intubation yields reflux fluid only late in the course of the disease. Rectal examination reveals a doughy mass in the right caudal abdomen. The ventral, and occasionally the medial, tenia of the cecum are palpable, as is firm feed material in the base and body of the cecum. The mass extends cranially, ventrally and across the midline of the abdomen. If not treated, the cecum ruptures, causing an acute onset of tachycardia, sweating, delayed capillary refill and shock, with death occurring in hours. It is not unusual for the initial signs of the disease to be missed and the problem to be recognized only after the cecum ruptures.

Horses with chronic, **recurrent cecal impaction** have a mild disease characterized by recurrent subtle to moderate signs of colic, reduced food intake, weight loss and loose feces.[19]

Cecal distension also occurs as a syndrome in which **fluid** accumulates in the cecum. This disease has a much more acute course and is characterized by severe abdominal pain, tachycardia and signs consistent with toxemia. Rectal examination demonstrates a cecum tightly distended with fluid ingesta. Without surgical intervention the outcome is cecal rupture and death.

Perforation

Cecal perforation may occur secondary to cecal distension or as a primary entity. There are usually only very mild premonitory signs and the disease becomes apparent when the cecum ruptures and acute diffuse peritonitis develops. Detection of serosa with a gritty feel and free gas in the abdomen on rectal examination is diagnostic of a ruptured viscus and diffuse peritonitis.

Intussusception

Cecocecal intussusception may present as an acute severe colic or as a mild intermittent colic, depending on the degree of involvement of the apex of the cecum. Small intussusceptions that cause little obstruction and no infarction of the invaginated section cause only mild pain.

Cecocolic intussusception causes acute and severe pain and has a short course. Rectal examination may reveal a mass in the right dorsal quadrant, lack of a cecum and pain on palpation of the right dorsal quadrant. Ultrasonographic examination of the right flank reveals the presence of the cecum in the colon, apparent in cross-section as a 'target-like' pattern or taurus.[20]

CLINICAL PATHOLOGY

Cecal impaction with feed material is usually associated with mild hemoconcentration. Cecal perforation results in severe leukopenia and left shift, hemoconcentration (hematocrit > 50%, 0.50 L/L) and azotemia.

Peritoneal fluid from horses with cecal impaction is usually normal. However, if the cecum becomes ischemic, then the fluid is sanguineous with an elevated white blood cell count (> 8000 cells/μL, 8×10^9 cells/L) and protein concentration (> 2.5 g/dL, 25 g/L).[10] Cecal perforation is evident as a high proportion of degenerate neutrophils, intra- and extracellular bacteria and plant material.

NECROPSY FINDINGS

The distended cecum and diffuse peritonitis are readily apparent. Cases of cecal perforation without distension will have diffuse peritonitis but the cause is only apparent on close examination of the intestinal tract. There is usually no underlying disease apparent on histologic examination.

DIFFERENTIAL DIAGNOSIS

Causes of colic are set out in Table 5.6.

TREATMENT

Treatment of cecal impaction involves control of pain (Table 5.7), restoration of normal fluid, acid–base and electrolyte status (see Ch. 2), and administration of fecal softeners such as sodium sulfate (Table 5.8). Mineral oil, although frequently used, may not be sufficient alone to facilitate passage of the impaction because it does not cause fecal softening.

Intravenous administration of fluid at 2–3 times maintenance needs is often

used in an attempt to hasten fecal softening by increasing secretion of water into the impaction. **Oral administration** of large quantities of water (4 L every 2 h for 24 h) may soften the impaction.

Horses with cecal impaction should be **closely monitored** for signs of deterioration, and especially of cecal ischemia, by frequent physical examinations and repeated abdominocentesis. Lack of resolution within 24 hours or signs of deterioration should prompt surgical exploration with typhlotomy and evacuation of the cecum and possible partial cecal bypass.[12,21]

Horses with **cecal perforation** always die and should be euthanized without delay.

Cecocecal and cecocolic intussusceptions must be corrected surgically.

DISPLACEMENT AND VOLVULUS OF THE LARGE (ASCENDING) COLON

Syndromes: nephrosplenic entrapment, renosplenic entrapment, left dorsal displacement of the large colon, right dorsal displacement of the large colon.

ETIOLOGY

- Left dorsal displacement of the large colon (renosplenic or nephrosplenic entrapment and entrapment of the large colon lateral to the spleen)
- Right dorsal displacement of the large colon
- Volvulus (both strangulating and nonstrangulating).

The etiology of these conditions is unknown but presumably involves some disturbance to normal colonic motility. Other causes of obstruction of the large colon include congenital abnormalities of the right ventral colon,[1] cystic duplication of the ascending colon,[2] defects in the mesocolon[3] and incarceration in epiploic foramen or gastrosplenic ligament.[4,5] Intussusception of the large colon causes infarction and severe colic.[5]

The term volvulus refers to rotation of the segment of bowel about the long axis of its mesentery, while torsion refers to rotation about the long axis of the bowel. Because of the anatomical arrangement of the mesocolon, either term may be correctly used to describe displacements of the large intestine.[5]

Synopsis

Etiology Unknown, probably involves disturbance of colonic motility
Epidemiology Volvulus is more common in mares during late gestation or after parturition. Left dorsal displacement (renosplenic entrapment) may be more common in large male horses
Clinical signs Left displacement of the large colon causes signs of mild to moderate colic. Rectal examination reveals large colon in the renosplenic space and ultrasonographic examination confirms the diagnosis. Right dorsal colon displacement causes mild to moderate colic. Rectal examination reveals colon lateral to the base of the cecum. Volvulus of the large colon causes mild to extremely severe abdominal pain, tachycardia, shock and abdominal distension. Rectal examination reveals the distended, displaced colon
Clinical pathology None diagnostic
Lesions Displaced large colon
Diagnostic confirmation Physical examination, laparotomy, necropsy examination
Treatment Volvulus and right dorsal displacement should be treated by surgical correction. Left dorsal displacement can be corrected by rolling the anesthetized horse or jogging the horse after administration of phenylephrine

EPIDEMIOLOGY

Left dorsal displacement of the large colon (Fig. 5.1) is the cause of 2–10% of colic cases referred for specialist treatment.[6] There is no breed, age or sex predisposition, although some authors suggest that males and large horses are more likely to be affected. The case fatality rate is approximately 5% for horses treated correctly.[7–10]

Right dorsal displacement of the large colon (Fig. 5.2) occurs sporadically and without recognized risk factors. The case fatality rate is reported to be as high as 43%.[10]

Risk factors for noninfarctive displacement of the large colon include cribbing or wind sucking (odds ratio (OR) = 90), number of hours stabled per day (OR for 24 h stabling = 35), lack of regular exercise (OR = 3.3), change in exercise program (OR = 9), lack of anthelmintic administration (OR = 13) and history of transport in the previous 24 hours (OR = 17).[11]

Volvulus of the large colon is the cause of colic in 11–17% of colic cases in which abdominal surgery is performed.[12] The disease occurs commonly in mares, especially those late in gestation or having recently foaled.[13,14] The disease has a recurrence rate of up to 15% in brood mares.[15] The disease occurs in horses from 2 days of age and there does not appear to be an effect of breed on occurrence of the disease.[16] The **case fatality rate** varies depending on the extent of the volvulus, with lesser degrees of volvulus (< 270°) having a 30% fatality rate and volvulus of 360° or more having a 65% fatality rate.[13]

Ingestion of large quantities of grain, such as might be fed to horses in heavy work, is associated with changes in plasma electrolyte concentrations, presence of dehydrated, foamy and homogeneous right dorsal colon contents, and fetid, less formed feces.[17] These effects of a high-grain diet may be associated with colonic disease in horses.[17]

PATHOGENESIS

Proximate factors leading to volvulus or displacement are unknown, although risk factors have been identified (see above). A plausible scenario is that altered colonic motility and subsequent distension with gas or ingesta predisposes the colon to displacement, either spontaneously or as a result of the horse rolling or lying down in response to abdominal pain.

Left dorsal and right dorsal displacements of the colon rarely compromise colon blood flow and represent nonstrangulating obstructive lesions. Pathogenesis in equine colic section). The displacement of the large colon (Figs 5.1 & 5.2) impedes aboral movement of ingesta and gas and may result in colonic distension. Should the distension become sufficiently severe, colon blood flow will be impaired and cause ischemia and necrosis of the colon. The obstruction to blood flow is predominantly in venous drainage, resulting in hemorrhagic strangulating

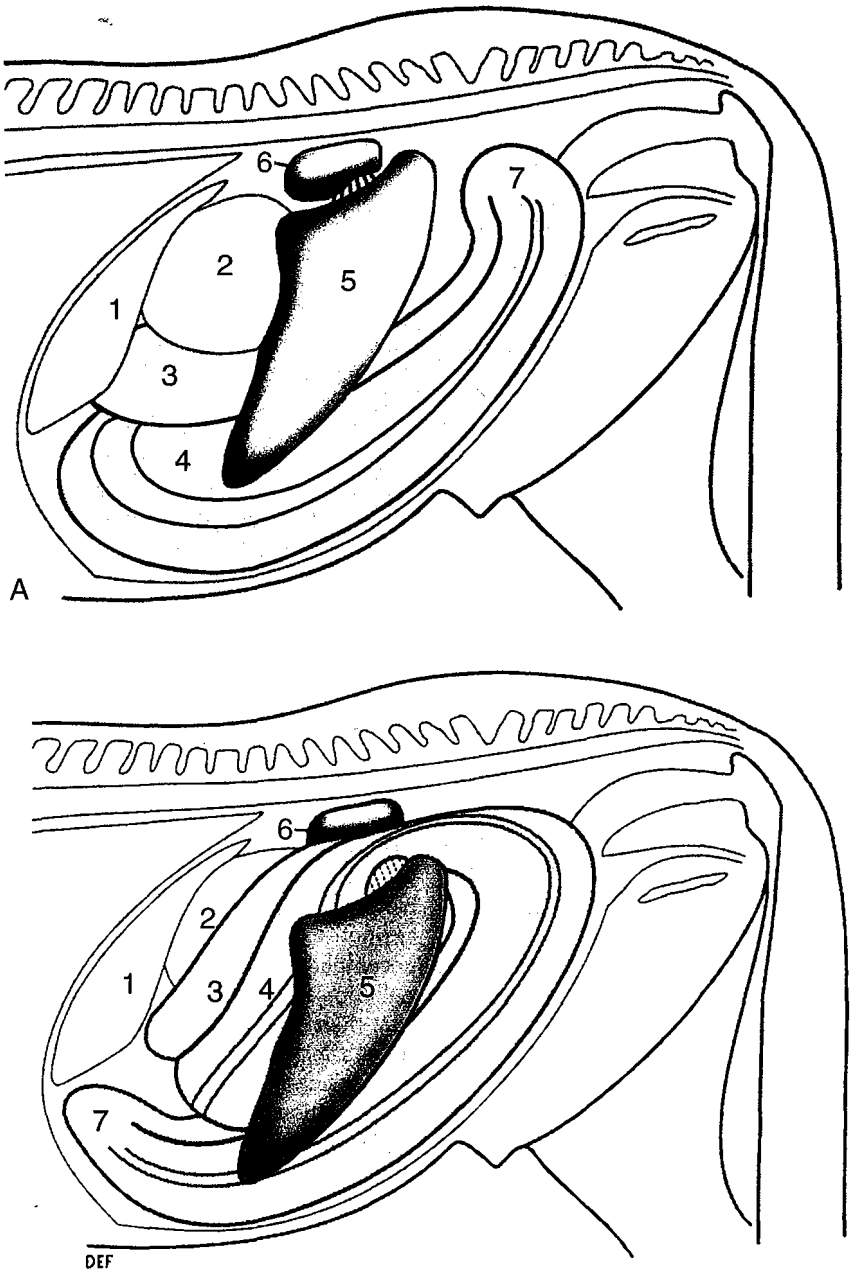

Fig. 5.1 **A** Left lateral view of abdomen of a normal horse. **B** Left dorsal displacement of the left colon, left lateral view. The left ventral and dorsal colon is displaced lateral and dorsal to the spleen and occupies the renosplenic space. 1 = liver, 2 = stomach, 3 = left dorsal colon, 4 = left ventral colon, 5 = spleen, 6 = left kidney and renosplenic ligament, 7 = pelvic flexure. (With permission from Johnston JK, Freeman DE. Vet Clin North Am Equine Pract 1997; 13:317.)

obstruction with progressive development of intramural edema, extravasation of red blood cells, microvascular thrombosis, mesothelial cell loss from the serosal surface, and mucosal necrosis with loss of colonic epithelium.[18]

Volvulus of the large colon of less than 270° does not compromise blood supply but does impede aboral movement of ingesta and gas.[13] Volvulus of 360° or more causes ischemia through occlusion of both arterial and venous circulation of the involved large colon with rapid loss of colonic mucosal integrity and colon viability. Irreversible mucosal damage occurs after 3–4 hours of ischemia. Loss of mucosal integrity impairs normal barrier function and permits toxins and substances normally confined to the colonic lumen to enter the systemic circulation. Additionally, loss of barrier function allows leakage of vascular proteins and in severe cases red blood cells into the colonic lumen. Subsequent signs are typical of strangulating obstruction (see Equine colic) with development of toxemia, cardiovascular collapse and death within 12–18 hours.

The most common displacement is medial and dorsal movement of the ventral colon to complete a 360° volvulus of the large intestine (Fig. 5.3).[16] Lateral and dorsal displacement of the ventral colon is much less common. The volvulus is usually at the level of the cecocolic fold, although volvulus involving the cecum or at the diaphragmatic and sternal flexures does occur.

CLINICAL FINDINGS

Left dorsal displacement (renosplenic entrapment)

The disease usually has an acute onset and a duration of up to 4 days, although it can be a cause of chronic, recurrent colic.[6,9] Abdominal pain in the initial stages is mild to moderate and becomes progressively more severe as distension of the large colon develops. The heart rate is usually between 50 and 70/min, but may be as low as 30/min. Rectal temperature is within normal limits. Mucous membrane color and refill time are usually normal provided that there is no ischemia of the colon. **Abdominal distension** is appreciable in some affected horses.[6] There is more than 2 L of reflux from a **nasogastric tube** in approximately 28% of cases, although rarely is there profuse reflux.[9] **Rectal examination** reveals the presence of bowel in the renosplenic space in approximately 70% of cases with the typical finding of taenia of the ventral colon being traced into that space. Distension of the large colon may impair detection of bowel in the nephrosplenic space. The spleen is usually displaced caudally, medially and ventrally from its normal position against the left body wall (Fig. 5.1).

Ultrasonographic demonstration of colon in the renosplenic space confirms the diagnosis with an accuracy of 88%.[19] Gas in the displaced colon obscures the left kidney and dorsal border of the spleen normally visible on ultrasonographic examination of the left paralumbar region.[19]

Approximately 8% of horses with nephrosplenic entrapment have an additional lesion.[9] Entrapment in which the sternal and diaphragmatic flexures are displaced cranial to the stomach and liver occurs in less than 3% of cases.[9]

Right dorsal displacement

Severity of colic varies from mild to severe in horses with right dorsal displacement of the colon. Tachycardia (50–80/min) and mild abdominal distension are characteristic provided that the entrapped bowel is not ischemic. There is usually no reflux from a nasogastric tube, although as the disease progresses gastric distension may occur. **Rectal examination** reveals the presence of large colon lateral to the base

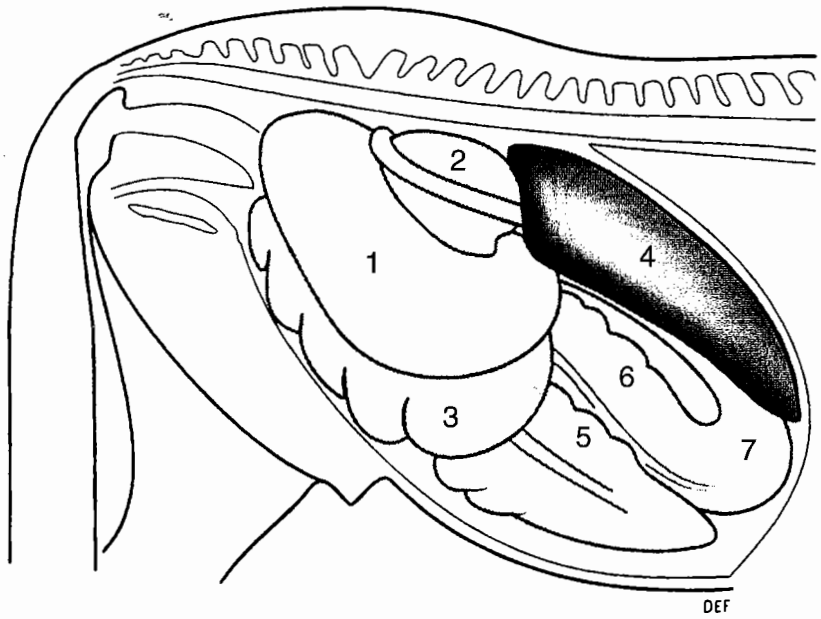

Fig. 5.2 Right dorsal displacement of the colon, right lateral view. The colon has passed lateral to the cecum, the pelvic flexure is displaced cranially and the sternal and diaphragmatic flexures are displaced caudally. 1 = right dorsal colon, 2 = base of cecum, 3 = right ventral colon, 4 = liver, 5 = cecum, 6 = left ventral colon, 7 = pelvic flexure. (With permission from Johnston JK, Freeman DE. Vet Clin North Am Equine Pract 1997; 13:317.)

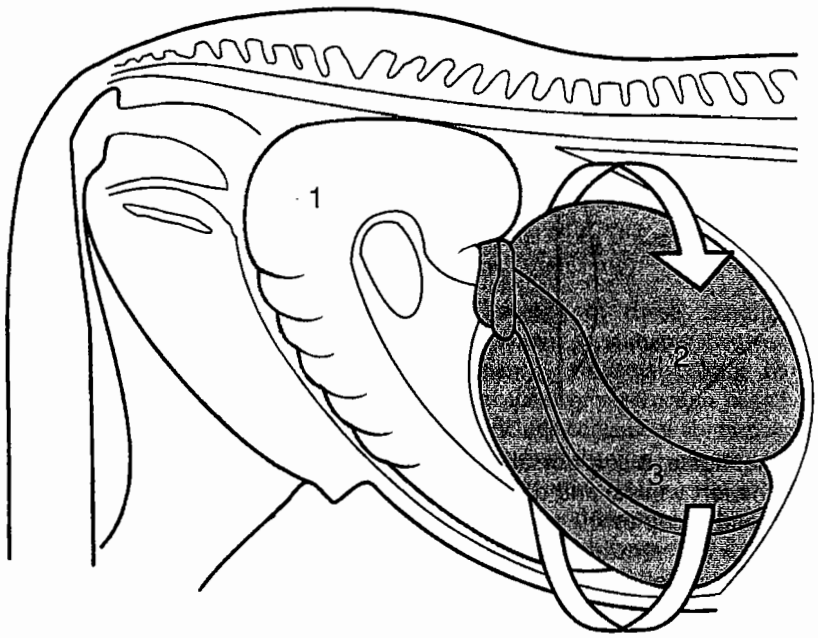

Fig. 5.3 A 360° clockwise volvulus of the colon viewed from the right side. The volvulus has occurred in the direction of the arrow. 1 = cecum, 2 = right dorsal colon, 3 = right ventral colon. (With permission from Johnston JK, Freeman DE. Vet Clin North Am Equine Pract 1997; 13:317.)

of the cecum, although colonic distension may make detection of the displaced bowel difficult. Right dorsal displacement is a not uncommon sequel to impaction of the pelvic flexure.

Volvulus

The onset of pain is abrupt and the duration of the disease ranges from hours, in horses with strangulating lesions, to days in horses with torsion of less than 270°. The pain ranges from mild to severe and intractable, with the horse violently throwing itself to the ground. Pain in horses with volvulus of 360° or greater is often unresponsive to any analgesics. Heartrate is variable and may be less than 40/min in horses with severe disease, although usually it is more than 60/min and increases with severity of the disease. Rectal temperature is within the normal range. The mucous membranes are dark red to blue and capillary refill time is more than 3 seconds in severely affected horses. Abdominal distension is marked, usually severe, and may impair respiration in horses with 360° or greater volvulus. **Auscultation** of the abdomen reveals a lack of borborygmi and the presence of high-pitched, tympanitic 'pings' on simultaneous percussion and auscultation. The pings are due to the presence of gas in tightly distended large colon or cecum. There is usually no reflux through a nasogastric tube. **Rectal examination** may be limited by the distended, gas-filled colon occupying the caudal abdomen. In untreated cases death occurs within 12–24 hours from cardiovascular collapse. **Ultrasonographic** examination reveals colon with a mural thickness of 9 mm or greater in horses with colon torsion. The test has a sensitivity of approximately 67% (i.e. correctly predicts presence of colon torsion in two-thirds of horses that have the disease) and specificity of 100% (correctly rules out the diagnosis in 100% of horses that do not have the disease).[20]

CLINICAL PATHOLOGY

Changes in the hemogram, serum biochemical profile and peritoneal fluid are non-existent to mild in horses with uncomplicated left dorsal displacement, right dorsal displacement and volvulus of less than 270°. Horses with ischemic colon as a result of strangulation usually have a leukopenia with left shift, hemoconcentration and increased anion gap.[16]

Serum gamma glutamyl transferase (GGT) activity is elevated in approximately 50% of horses with right dorsal displacement of the colon, whereas such elevations are rare in horses with left dorsal displacement.[21] The elevated GGT, and less commonly serum bilirubin concentration, in horses with right dorsal displacement is attributable to compression of the common bile duct in the hepatoduodenal ligament by the displaced colon.[21]

Horses with large-colon volvulus have a high prevalence of abnormalities in hemostatic variables, including thrombin–antithrombin concentration, D-dimer concentration, antithrombin activity, prothrombin time and platelet count. Nonsurviving horses have lower platelet counts, increased prothrombin time and reduced antithrombin activity.[22]

Peritoneal fluid often has an increased total protein concentration (> 25 g/L, 2.5 g/dL) and white blood cell count (> 8000 cells/μL, 8×10^9 cells/L) in horses with compromised bowel. Examination of peritoneal fluid is often not necessary to achieve a diagnosis in horses with colon torsion, although it does have prognostic value in that horses with blood-tinged

peritoneal fluid have a poor prognosis. The risk of inadvertent enterocentesis is increased in horses with severe distension of the colon and abdominocentesis should be attempted with caution in such cases. Use of a bovine teat cannula or similar blunt instrument is preferred to the use of a needle.

NECROPSY FINDINGS

The colon is displaced as described above for each of the diseases. Death usually results from ischemic necrosis of the colon and the associated peritonitis, endotoxemia and shock. Histological lesions in horses dying of colon volvulus are more severe than of those that survive and are characterized by hemorrhage into the lamina propria, edema and loss of the mucosal cells and crypt architecture.[13]

DIFFERENTIAL DIAGNOSIS

See Table 5.6. Less common conditions of the large colon include:

- Entrapment of the pelvic flexure in the epiploic foramen[23]
- Colocolic intussusceptions[24]
- Colonic adenocarcinoma[25,26]

TREATMENT

Treatment should consist of pain control, correction of fluid, acid–base and electrolyte abnormalities, support of cardiovascular function and correction of the underlying disease (Equine colic). Decompression by trocarization of gas-distended colon or cecum may be beneficial. Correction of colon volvulus or right dorsal displacement of the colon requires surgical exploration of the abdomen and manual correction of the displacement.

Left displacement

Correction of left dorsal displacement can be achieved by either nonsurgical or surgical means. **Nonsurgical correction** is achieved by rolling the anesthetized horse in a particular sequence that causes the displaced colon to return to its normal position in the abdomen. Nonsurgical correction is successful in approximately 80% of cases,[7,27] although complications are reported,[28] and is recommended as the initial definitive treatment for horses with uncomplicated left dorsal displacement.[27] The sequence of events following diagnosis of the condition is depicted in Figure 5.4.[29] **Phenylephrine** (0.02–0.04 mg/kg, intravenously as a 10 min infusion) causes splenic contraction and is thought to increase the chances of the colon returning to its normal position. The horse is anesthetized within 10 minutes of phenylephrine administration and placed in right lateral recumbency. The horse is then slowly rolled into dorsal recumbency and the abdomen is vigorously massaged in an attempt to cause the colon to move ventrally and medially. If a hoist is available the horse can be lifted into dorsal recumbency. The sequence ends with the horse being rolled into left lateral recumbency and a rectal or ultrasound examination being performed to determine the position of the colon.

An alternative means of nonsurgical correction involves administration of phenylephrine (0.01 mg/kg, intravenously, slowly) and then jogging the horse.[30,31] This technique was successful in correcting the displacement in 11 of 12 horses.[31] It may be advantageous to relieve large-colon distension by percutaneous trocarization before jogging.[9]

Cases that are refractory to nonsurgical treatment require laparotomy (ventral midline or left flank) and manual correction of the displacement. Recurrence of the displacement occurs in 3–7% of cases.[7] Horses with recurrent disease may benefit from surgical ablation of the nephrosplenic space.[32]

Right dorsal displacement and colon volvulus

These diseases require surgical correction of the anatomical abnormality.

IMPACTION OF THE LARGE INTESTINE OF THE HORSE

Synopsis

Etiology Idiopathic, often associated with restricted exercise, poor-quality diet or restricted access to water
Epidemiology Sporadic, more common in mares. Accounts for approximately 10–15% of colics at referral institutions. Case fatality rate of 20%
Clinical signs Mild to moderate colic often of several days duration. Rectal examination reveals impacted, distended large colon
Clinical pathology No diagnostic changes
Lesions Impaction of large colon, usually pelvic flexure or right dorsal colon
Diagnostic confirmation Physical examination
Treatment Pain control. Administration of fecal softeners (sodium sulfate). Overhydration by oral or intravenous administration of isotonic fluids at 3–5 times maintenance needs

ETIOLOGY

The cause of most impactions of the large colon is unknown. Known or speculated causes include:

- Poor dentition, such as occurs in older horses
- Poor feeding regimens, such as infrequent feeding of stalled horses
- Horses not fed, in preparation for surgery or racing, and then given unrestricted access to feed or allowed to eat bedding materials
- Horses fed diets too high in fiber, e.g. mature sorghum or maize plants, or even mature Bermuda grass (*Cynodon* spp.) meadow hay, especially if their water intake is limited;[1] ingestion of large volumes of indigestible seeds, e.g. *Crataegus crusgalli* (cockspur hawthorn), may cause outbreaks of impaction of the right dorsal colon[2]
- Horses that come into loose boxes and are offered hard feed after being on soft grass on pasture are also likely to develop impaction colic
- American miniature horses develop impaction of the colon[3]
- General debility
- Enteroliths and fiber balls may also cause obstruction of the large intestine and usually result in recurrent attacks of colic
- Amitraz, a formamidine acaricide for cattle, causes impaction colic in horses[4]
- Retention of the meconium in foals (see Colic in foals)
- Administration of NSAIDs, which alter colonic motility and might predispose to impaction,[5] although epidemiological support of this etiology is not available
- Restricted water intake, such as during winter when watering points freeze or water is unpalatable.

EPIDEMIOLOGY

The disease occurs in horses of any age and is more common in females.[6] There does not appear to be a breed predisposition. The disease represented 13% of colics treated at a referral facility.[6,7] An important risk factor is a change in management, especially one that involves a reduction in exercise and change in diet.[6] Risk factors for nonstrangulating disease of the large colon, including pelvic flexure impaction, include cribbing or wind sucking, stabling with the risk increasing with the number of hours stabled per day, change in regular exercise program, travel within the previous 24 hours and lack of anthelmintic administration.[8] The **case fatality rate** is approximately 1–20%.[6,7]

PATHOGENESIS

Development of impaction of the large colon is frequently attributed to abnormal colonic motility.[9] Other factors, including mild dehydration as a result of limited water intake or ingestion of poorly digestible material, cause impaction in many instances. Ingestion of large quantities of grain, such as might be fed to horses in heavy work, is associated with changes in plasma electrolyte concentrations, presence of dehydrated, foamy and homogenous right dorsal colon contents, and fetid, less formed feces.[10] These effects of a high grain diet may be associated with colonic disease in horses.[10] The end result is accumulation of a large mass of inspissated feed material in the large colon. Material usually accumulates first at the pelvic flexure or right dorsal colon, presumably because of the reduction in lumen diameter at those points. **Accumulation of inspissated material** causes distension of the colon and prevents aboral passage of ingesta. **Distension** causes pain and changes in colonic motility that exacerbate or perpetuate the impaction. If the distension is sufficiently severe or prolonged the colon may become ischemic and necrotic with subsequent rupture, peracute diffuse peritonitis and death.

CLINICAL FINDINGS

Moderate abdominal pain is the typical sign in affected horses and pulse rate and respiration are relatively normal. This often continues for 3–4 days and sometimes for as long as 2 weeks. The horse is not violent, the principal manifestation of pain being stretching out and lying down and the bouts of pain are of moderate severity occurring at intervals of up to a half-hour. There is anorexia and the feces are passed in small amounts and are hard and covered with thick, sticky mucus. Intestinal sounds are absent or much decreased in intensity. The pulse rate is usually less than 50/min.

On **rectal examination** impaction of the pelvic flexure of the large colon is the commonest site and the distended, solid loop of the intestine often extends to the pelvic brim or even to the right of the midline. Lying on the floor of the abdomen, it is easily palpated, the fecal mass can be indented with the fingers and the curvature and groove between the dorsal and ventral loops of the left colon can be easily discerned. Impaction of the right dorsal colon cannot usually be palpated per rectum and the only abnormality may be distension of the colon with soft ingesta that has accumulated behind the obstruction.

CLINICAL PATHOLOGY

Hemogram, blood chemistry and peritoneal fluid are normal until the colon becomes ischemic at which time there is a leukopenia with left shift, and an increase in the white blood cell count and protein concentration in peritoneal fluid.

NECROPSY FINDINGS

The large intestine is packed full of firm, dry fecal material and rupture may have occurred.

DIFFERENTIAL DIAGNOSIS

See Table 5.6.

- Impaction of the pelvic flexure is readily diagnosed on rectal examination
- A clinical similar syndrome is produced by strictures of the large colon[11]

TREATMENT

The principles of treatment are pain control, correction of fluid and electrolyte abnormalities and softening of ingesta to facilitate its passage. Pain control is discussed in Table 5.7. Fluid therapy is discussed in Chapter 2.

Softening of ingesta is achieved by rehydrating the inspissated material and providing lubrication to hasten its passage. **Fecal softeners** (Table 5.8) such as magnesium sulfate or sodium sulfate can be given to increase the fecal water content and soften the impacted, inspissated ingesta. Magnesium sulfate is associated with a small risk of hypermagnesemia and neurologic signs[12] whereas sodium sulfate causes a mild hypernatremia and hypokalemia.[13] Oral administration of a balanced, polyionic electrolyte solution is associated with the greatest increase in colonic water content and no change in serum electrolyte concentrations.[13] Enteral administration of 10 L/h (to a 500 kg horse) of a balanced, isotonic, polyionic electrolyte solution is more effective than intravenous administration of the same quantity of fluid in combination with oral administration of MgO_4 in hydrating colonic contents in normal horses.[14] Mineral oil (Table 5.8) is a lubricant and may not penetrate the impacted ingesta sufficiently to soften the material although it is frequently given to horses with colon impaction.

Overhydration by oral administration of polyionic, isotonic fluids at 3–5 times maintenance needs (approximately 10 L/h) is the **treatment of choice** for colon impaction.[6,13] Water can be given by nasogastric tube at a rate of 4–10 L for a 450 kg horse every 1–2 hours until the impaction softens. However, some horses develop decreased small intestinal motility or ileus with the disease, have delayed gastric emptying and have reflux of fluid through the nasogastric tube. Such horses should not be administered any medication or water through the nasogastric tube until reflux has resolved. Alternatively, isotonic fluids can be given intravenously at 10 mL/kg/h until the impaction is passed.

Promotility agents such as neostigmine are usually contraindicated because of the risk of rupture of the distended colon when vigorous contractions are induced pharmacologically.

Horses may need to be treated for 1–6 days until the impaction resolves and should **not be fed** during this time. When feed is again provided it should be easily digestible and initially be of limited volume. Horses recovered from impaction of the large intestine have a higher than expected rate of recurrence of colic (30%).[6]

Surgical treatment may be needed for refractory cases (about 15%) but is associated with a poor prognosis because of the risk of iatrogenic rupture of the colon during attempts to exteriorize it from the abdomen during surgery.[6] Impaction of the right dorsal colon is more likely to require surgical treatment.[15]

ENTEROLITHS AND FECALITHS

ETIOLOGY

Enteroliths are rock-like concretions, which are either spherical or tetrahedral, that form in the large colon of horses, usually around a foreign body.[1] Most enteroliths in the large colon of horses are of two major types: magnesium phosphates/struvite and magnesium vivianite.[1,2] There is wide variability in macrotexture and ionic concentrations between and within enteroliths of ammonium magnesium phosphate (struvite).[1] Affected horses often have more than one enterolith and the enteroliths can weigh up to 12 kg.

Fecaliths are aggregations of indigestible material, such as fencing, plastic or rope, that often have an irregular shape.

EPIDEMIOLOGY

Enteroliths occur sporadically in horses in most regions of the world but there is a greater than expected incidence in certain areas, such as California.[3] Equids with enterolithiasis represented 15.1% of patients admitted for treatment colic, and 27.5% of patients undergoing celiotomy for treatment of colic in a study from California but less than 2% of horses with colic examined at a referral center in Texas.[4,5] Arabians and Arabian crosses, Morgans, American Saddlebreds and donkeys are over-represented, and Thoroughbreds, Standardbreds, warmbloods and stallions are under-represented in some studies, suggesting a predilection of these breeds for the disease.[3–5] Enteroliths rarely occur in horses less than 4 years of age and are more common in older horses (> 11 years).[4,6] The disease is reported in American Miniature Horses.[7] Feeding alfalfa hay and stabling for more than 12 hours a day are associated with increased risk of enterolithiasis.[5,8] The mean pH of colonic contents from horses with enterolithiasis is significantly higher than for control horses and horses with enterolithiasis have a significantly lower percentage of dry matter in colonic fecal samples and higher mean mineral concentrations than controls.[8] About 15% of cases examined at referral institutions that see large numbers of cases develop a ruptured viscus caused by the enterolith and die. The long-term survival rate of horses treated surgically is approximately 90%.[4]

Fecaliths occur sporadically and appear to be more common in younger horses, perhaps because of their propensity to dietary exploration and ingestion of foreign materials.

PATHOGENESIS

The mechanism underlying enterolith formation is not known. Enteroliths are formed in the large colon and, rarely, the cecum. They are clinically inapparent, even if quite large, until they cause obstruction of aboral passage of ingesta, usually by occluding the right dorsal or transverse colon. Occasional enteroliths pass into the small colon. Obstruction of the colon causes mild to moderate, often intermittent, colic, presumably when the enterolith or fecalith obstructs the colon, with the pain resolving when the enterolith moves and the obstruction

clears. Complete obstruction results in obstruction of aboral movement of ingesta, accumulation of gas and ingesta proximal to the obstruction and distension of the large colon. There is no loss of integrity of the colon early in the disease but with time and distension there is ischemia and necrosis of the colon, with subsequent perforation, development of acute peritonitis, and death.

CLINICAL FINDINGS

The most common historic manifestation of enterolithiasis in horses is recurrent, intermittent colic (about one-third of cases), often with passage of enteroliths in feces (about 10% of cases).[4,9] Horses with acute obstruction have signs typical of obstructive, nonstrangulating disease of the large colon, including mild to moderate colic with failure to pass feces. The heart rate is 50–70/min, borborygmi are decreased but not absent, and there is mild abdominal distension. **Rectal examination** may reveal mildly distended large colon but the offending enterolith is never palpable, except on the rare occasion that the enterolith or fecalith is lodged in the small colon. Over a period of 6–12 hours the severity of pain increases and there is readily apparent distension of the large colon. There is usually no reflux through a nasogastric tube. The terminal phase, which may take 72 hours to occur and is due to rupture of a viscus, is marked by moderate to severe pain, abdominal distension, tachycardia (> 80/min), decreased capillary refill time and discolored mucous membranes, sweating, muscle fasciculations and death. Rupture of a viscus and acute peritonitis occurs in approximately 15% of cases.[4]

Radiography of the abdomen is useful in identifying enteroliths in horses with colic.[10,11] The accuracy of the diagnosis is approximately 80% for enteroliths in the large colon and 40% for those in the small colon.[11] The most common reason for not detecting an enterolith is poor imaging of the abdomen because of inadequate penetration by the X-ray beam,[11] emphasizing the need for appropriate radiographic equipment.

CLINICAL PATHOLOGY

There are no diagnostic changes in the hemogram, serum biochemical profile or examination of peritoneal fluid. Horses with enteroliths have higher serum bilirubin concentrations on examination at referral centers, but this change is not sufficiently large to be useful as a diagnostic aid.[5] Similarly, horses with enteroliths have higher protein and white cell counts in peritoneal fluid than do horses with other forms of colic but again these differences are too small to be of diagnostic significance.[5] Changes in hematological and biochemical variables during the terminal phases of the disease are characteristic of acute, diffuse peritonitis and include leukopenia with left shift, hemoconcentration and azotemia.

NECROPSY FINDINGS

Enteroliths are frequent incidental findings at necropsy examination of mature horses and their presence should not be overinterpreted. Obstructive disease caused by an enterolith is characterized by colon distension, presence of an enterolith in the right dorsal, transverse or small colon and, in cases dying of the disease, acute diffuse peritonitis resulting from colon rupture or perforation at the site of the enterolith. Tetrahedral enteroliths with sharp points are believed to be more dangerous than are spherical enteroliths.[6]

DIFFERENTIAL DIAGNOSIS

See Table 5.6.

The main differential diagnosis is colon impaction, which may be difficult to differentiate from enterolith obstruction in the absence of radiographic examination of the abdomen.

TREATMENT

The definitive treatment is surgical removal of the enterolith. Supportive care including analgesia and fluid therapy should be provided as described under Equine colic.

CONTROL

Prevention of ingestion of foreign bodies, such as small pieces of metal, may decrease the incidence of the disease.[3] Strategies that decrease fecal pH and mineral content of feces might also decrease the incidence of the disease.[8]

SAND COLIC

Sand colic is a disease of horses grazing sandy fields with short pasture, fed on sandy ground or provided with feed contaminated with sand. It is often associated with underfeeding. Horses of all ages are affected, including foals, which acquire the sand while eating dirt. The **case fatality rate** for horses treated by surgical removal of sand is 20–40%.[1,2] The disease is attributable to sand accumulation in the right dorsal or transverse colon, or pelvic flexure, causing obstruction. Sand in the ventral colon does not cause obstruction but is associated with colon volvulus and displacement.

Clinical signs are of mild to moderate, chronic colic with **diarrhea** and anorexia. The colic is often very mild unless there is colon torsion or volvulus, in which case the signs are typical of that disease. The diarrhea is watery but not profuse or malodorous. **Auscultation** over the cranial ventral abdomen just caudal to the xiphoid reveals sounds similar to those made when a paper bag is partially filled with sand and rotated.[3] This sound is diagnostic of sand accumulation in the ventral colon. **Rectal palpation** may reveal sand impaction in the ventral colon, but more frequently colon distension with gas is present.[1,2] Rectal palpation will not detect sand accumulation in the transverse colon. **Radiography** will demonstrate sand in the ventral and dorsal colons and can be used to monitor the efficacy of treatment.[4–6] **Ultrasonography** has good sensitivity (88%) and specificity (88%) compared to radiography for detection of sand in the ventral colon.[7] Ultrasonography is not as effective at detecting sand in the right dorsal or transverse colon.[7] Abdominal fluid is normal except when there is ischemia or necrosis of the colon or when peritonitis is present.[4] Sand will settle out when feces is mixed with water in a clear plastic rectal sleeve and hung for 30 minutes.

Treatment consists of pain relief, correction of fluid and electrolyte abnormalities, prevention of continued ingestion of sand and removal of the sand. In horses with acute obstruction of the right dorsal or transverse colon by sand, surgical removal is indicated. **Medical treatment** to effect sand removal is indicated in less acute cases. A widely used medical treatment is administration of **psyllium mucilloid** (0.5–1 g/kg orally every 12 h for 4–8 weeks) administered via a nasogastric tube or as a dressing on feed. However, in an experimental model of the disease this treatment was no more effective than no specific treatment in removal of sand from the cecum and colons.[8] Mineral oil (1 mL/kg) or $MgSO_4$ (1 g/kg) orally may hasten sand removal.[6] Pasturing of horses with sand accumulation housed in stables aids removal of the sand.[6] Control of the disease is by preventing ingestion of sand by feeding horses hay and grain from clean feeding

bins, providing adequate roughage in the diet, pasturing horses in fields with adequate grass cover, and perhaps, in areas where sand ingestion is unavoidable, daily administration of psyllium mucilloid.

RIGHT DORSAL COLITIS

This is a chronic disease caused by ulcerative colitis of the right dorsal colon. The disease is associated with prolonged administration of NSAIDs, such as phenylbutazone, in most, but not all, cases.[1] The case fatality rate is greater than 50%, although descriptions of large numbers of affected horses are not available.

The **pathogenesis** involves inhibition of mucosal prostaglandin synthesis and consequent decreases in water, chloride and bicarbonate secretion by mucosa of the right dorsal colon and apoptosis (programmed cell death) of mucosal cells.[2] Loss of secretion of bicarbonate might be associated with failure of alkalinization of right dorsal colon contents and subsequent development of mucosal lesions. The right dorsal colon is the only section of the colon with net water secretion, and this unique activity may predispose this section of colon to disease. Exposure of mucosal cells to phenylbutazone can occur both from the lumen and from blood. Luminal exposure may be related to release of phenylbutazone from ingesta in the right dorsal colon.[3] Ulceration of the colonic mucosa allows leakage of plasma constituents into the colonic lumen, resulting in hypoalbuminemia and loss of electrolytes, and entry of colonic substances such as endotoxin into the systemic circulation, with consequent signs of endotoxemia and systemic inflammatory response (leukopenia, hyperfibrinogenemia, fever). Chronic and extensive mucosal ulceration causes growth of granulation tissue and fibrosis of the right dorsal colon with subsequent loss of secretory function, stricture and partial obstruction.[4]

Clinical signs include depression, anorexia, mild fever (38.6–39.5°C, 101.5–103°F), mild intermittent colic, ventral edema, weight loss and occasionally mild diarrhea. There is almost always a history of administration of a NSAID. The disease can persist for weeks and often prompts inappropriate administration of nonsteroidal anti-inflammatory drugs. Rectal examination is unremarkable. **Ultrasonography** is useful in the diagnosis of right dorsal colitis by detecting the presence of a hypoechogenic submucosal layer and permitting measurement of the wall thickness of the right dorsal colon.[5] The hypoechogenic layer in the wall of the right dorsal colon corresponds with edema and cellular infiltrates observed histologically. The right dorsal colon in adult horses has a maximal thickness of 6 mm while that in horses with right dorsal colitis is greater than 8 mm and can be as great as 16 mm.[5] Additionally, the ratio of right dorsal colon to right ventral colon wall thickness is up to 1.6 in normal horses and greater than 2.0 in affected horses.[5] **Scintigraphic** detection of right dorsal colitis is achieved by administration of technicium-^{99}m hexamethylpropyleneamine-oxime-labeled white blood cells.[6] Images obtained 20 hours after administration of labeled white cells demonstrate uptake of cells into the right dorsal colon (right cranioventral abdomen).

There is often mild **peritonitis** (neutrophilia in peritoneal fluid). Leukopenia with left shift and hypoproteinemia are characteristic. **Serum biochemical abnormalities** include hypoalbuminemia, hyponatremia (< 135 mEq/L), hypochloremia (< 90 mEq/L) and azotemia (serum creatinine > 2 mg/dL, 170 µmol/L).[1,7]

Necropsy examination reveals ulcerative colitis of the right dorsal colon. In chronic cases there may be stricture of the right colon with subsequent impaction of ingesta and colon rupture.[1]

Treatment is often unrewarding although successful treatment by feeding of a low residue diet, such as a complete pelleted ration fed 4–6 times daily, is reported.[8] Psyllium (120 g once daily) for 3–6 weeks might enhance healing of the colon. Administration of misoprostol (Table 5.11) has been suggested but has no demonstrated efficacy. Surgical excision of the lesion is difficult because of its location in the abdomen but bypass of the right dorsal colon may be beneficial. **Control** involves minimizing the amount of NSAIDs administered to horses.

SMALL COLON OBSTRUCTION

ETIOLOGY

- Small colon impaction[1,2]
- Obstruction by enterolith or fecalith[1]
- Meconium retention (see Foal colic)
- Atresia coli (see Foal colic)
- Strangulation by pedunculated lipoma,[3] volvulus, intussusception,[4] herniation through mesenteric rents including the mesocolon or gastrosplenic ligament[5,6] or enlarged ovary[7]
- Neoplasia (intramural)
- Hematoma
- Rectal prolapse
- Rupture of mesocolon[8]
- Colonic lipomatosis[9]
- Perirectal abscess.

EPIDEMIOLOGY

Small colon disease is present in approximately 2.5–5% of horses treated for colic at referral institutions and small colon impaction represents approximately 2% of horses with colic.[1,2,10] Aged female horses are most commonly affected although the conditions can occur in horses of any age.[3] Arabians, ponies and Miniature horses are reported to be at increased risk of small colon disease although others have not detected this apparent predilection.[3,10] Rupture of the mesocolon occurs during parturition.[4] The **case fatality rate** depends on the condition and is 30–40% for impaction of the small colon.[2,10] Small colon impaction can occur as limited outbreaks in a number of horses on a single farm over a period of days to weeks, without obvious predisposing causes or inciting events.

PATHOGENESIS

Obstruction of the small colon causes accumulation of ingesta and gas in the small colon aboral to the obstruction and in the large colon, with subsequent distension, pain and reduced motility. Distension of the small colon may impair blood flow with subsequent ischemia, necrosis and rupture or perforation of the small colon. Incarceration of the small colon results in ischemia of the entrapped segment and restriction of flow of ingesta. Subsequent signs are characteristic of toxemia and intestinal obstruction. The high proportion of affected horses from which *Salmonella* spp. are isolated suggests a role for colitis in the pathogenesis of small colon impaction.[2,10]

CLINICAL FINDINGS

Nonstrangulating lesions

Nonstrangulating lesions manifest as mild to moderate colic that may persist without a change in severity for up to 36 hours. The heart rate depends on the severity of the colic but averages 60/min with a range of 30–110/min.[2] There is mild dehydration. **Abdominal distension** is usually mild initially but increases as the disease progresses. Borborygmi are reduced and tympanitic sounds may develop as the large colon and cecum become distended. **Rectal examination** reveals the presence of distended large colon but no evidence of colon displacement.

Small colon impaction is palpable as a tubular column of material in the small colon although it may be missed if the impaction is in the cranial section of the small colon. Approximately 30% of cases have diarrhea and 13% strain to defecate.[10] Complete examination per rectum may be difficult because of large colon distension and accumulation of feces in the distal small colon. There is reflux through the nasogastric tube in approximately 30% of cases.[2]

Strangulating lesions

Strangulating lesions that interfere with small colon blood supply usually present as acute colic of moderate to severe intensity. There is tachycardia and evidence of toxemia. Abdominal distension is usually marked and there is an absence of borborygmi. Rectal examination reveals distension of the large colon and occasionally soft, compressible distension of the small colon.

Avulsion of the mesocolon occurs during parturition and is often evident as a **rectal prolapse** in the mare. Avulsion results in ischemia of the distal colon. Initially the mare does not display signs of pain but, as the section of the colon from which the mesocolon has avulsed becomes necrotic, signs of toxemia develop.

CLINICAL PATHOLOGY

There are no characteristic changes in the hemogram or serum biochemical profile. Peritoneal fluid is normal until the viability of the small colon is compromised, at which time the protein concentration and white blood cell count increase. *Salmonella* spp. are isolated from approximately 20% of cases of small colon impaction, suggesting a role for colitis in the pathogenesis of the disease.[10]

NECROPSY FINDINGS

Small colon impaction is evident as a tubular column of firm ingesta in the small colon with large colon distension. Small colon accidents, such as rupture of the mesocolon at parturition and intussusception, are readily apparent.[4,8]

DIFFERENTIAL DIAGNOSIS

See Table 5.6.

TREATMENT

Small-colon impaction

The principles of treatment of small-colon impaction are relief of pain and of the impaction. Horses with signs of mild to moderate colic easily controlled with analgesics should be treated medically. Horses with intractable pain or progressively worsening pain, abdominal distension or abnormal peritoneal fluid should be treated surgically. Horses treated surgically have a worse prognosis than do horses treated medically, probably because the former group has more severe disease.[2,10]

Medical treatment of small-colon impaction involves administration of analgesics (see Table 5.7), correction of fluid, electrolyte and acid–base abnormalities, and administration of fecal softeners (Table 5.8). Treatments to hasten softening and passage of the impaction include overhydration, administration of sodium or magnesium sulfate and a lubricant such as mineral oil, and occasionally administration of an enema to the standing horse. Overhydration should be achieved by either intravenous or oral administration of polyionic fluids at 3–5 times maintenance (10 mL/kg/h). Administration of enemas to standing horses is controversial and should be done with care so as not to rupture the small colon. Trocarization of the large colon or cecum may be necessary in horses with severe abdominal distension.

Small-colon accidents including strangulation and intussusception require surgical correction. Surgical correction of rupture of the mesocolon is not available because of limited surgical access to the site of the lesion.

SPASMODIC COLIC

ETIOLOGY

Spasmodic colic occurs sporadically and causative factors are not usually identified. Suggested causes include excitement, such as occurs during thunderstorms, preparations for showing or racing, and drinks of cold water when hot and sweating after work, although epidemiologic evidence of these associations is lacking. Presence of a heavy burden of tapeworms is associated with a high incidence of spasmodic (undiagnosed) colic.[1] Mucosal penetration and submucosal migration of *Strongylus vulgaris* larvae are known to cause changes in ileal myoelectrical activity that could lead to the development of colic in horses.[2] Psychogenic colic occurs rarely in horses.[3]

EPIDEMIOLOGY

The condition is sporadic. It affects horses of all ages but is not recognized in young foals. No apparent breed or sex predisposition is noted.

PATHOGENESIS

The hypermotility of spasmodic colic in horses is thought to arise by an increase in parasympathetic tone under the influence of the causative factors mentioned above.

CLINICAL FINDINGS

Spasmodic colic of horses is characterized by **brief attacks of abdominal pain**. The pain is intermittent, the horse rolling, pawing and kicking for a few minutes, then shaking itself and standing normally for a few minutes until the next bout of pain occurs. Intestinal sounds are often audible some distance from the horse and loud, rumbling borborygmi are heard on auscultation. The pulse is elevated moderately to about 60/min and there may be some patchy sweating, but rectal findings are negative and there is no diarrhea. Rectal examination is usually unremarkable. The signs usually disappear spontaneously within a few hours.

CLINICAL PATHOLOGY AND NECROPSY fiNDINGS

Laboratory examinations are not used in diagnosis and the disease is not fatal.

DIFFERENTIAL DIAGNOSIS

See Table 5.6.

TREATMENT

Acute hypermotility as manifested by spasmodic colic is usually transient and the use of specific spasmolytics is not necessary. Detomidine, xylazine or butorphanol are effective analgesics. Administration of hyoscine is effective. Affected horses are often administered mineral oil (1 mL/kg) by nasogastric intubation.

INTESTINAL TYMPANY IN HORSES

ETIOLOGY

The cause of most cases of idiopathic intestinal tympany is unknown, although the ingestion of highly fermentable green feed is considered to be a risk factor. Feeding of rations rich in grains is associated with changes in colonic contents that might predispose to tympany.[1] Intestinal tympany occurs secondary to obstructive diseases that prevent aboral passage of ingesta and gas.

PATHOGENESIS

The excessive production of gas or its retention in a segment of bowel causes distension and acute abdominal pain. Intestinal distension reduces intestinal motility and may contribute to the course of the disease. Severe tympany may interfere with normal respiration and cardiovascular function (see Pathogenesis of equine colic).

CLINICAL FINDINGS

Abdominal distension is evident and pain is acute and severe. Peristaltic sounds are reduced but fluid may be heard moving in gas-filled intestinal loops, producing a tinkling, metallic sound. Pinging sounds consistent with tightly distended viscus may be heard on simultaneous flicking and auscultation of the abdomen. On rectal examination, gas-filled loops of intestine fill the abdominal cavity and make proper examination of its contents impossible. In primary tympany much flatus is passed. It is important to differentiate primary tympany from that occurring secondary to obstructive diseases such as enterolithiasis and displacement of the colon.

CLINICAL PATHOLOGY

Laboratory examinations are of no value in diagnosis.

NECROPSY FINDINGS

In cases of secondary tympany, the causative obstruction is evident. In primary cases, the intestines are filled with gas and the feces are usually pasty and loose.

DIFFERENTIAL DIAGNOSIS

See Table 5.6.

TREATMENT

The principles of treatment are the relief of pain and distension, maintenance of hydration and reduction of gas production. In secondary tympany the primary disease should be identified and treated.

Pain should be relieved by administration of xylazine, detomidine or butorphanol, or similar agents (Table 5.7). Distension of the bowel should be relieved by trocarization but trocarization should only be performed if there is no or minimal response to analgesic medication and no return of normal peristaltic activity. Normal hydration should be restored by intravenous administration of polyionic fluids. Intestinal gas production should be minimized by the administration of mineral oil or a similar laxative (Table 5.8).

VERMINOUS MESENTERIC ARTERITIS (VERMINOUS ANEURYSM, THROMBOEMBOLIC COLIC)

ETIOLOGY

Unknown, although it is presumed to result from thromboemboli originating at sites of verminous arteritis in the cranial mesenteric artery.

EPIDEMIOLOGY

The disease is assumed to be more prevalent among horses on poor parasite control programs; however, except in extreme cases that die and have a necropsy examination or exploratory laparotomy, the diagnosis is not confirmed. Therefore accurate measures of its incidence are not available. Cases may occur in foals as young as 3–6 months.[1] The incidence of the disease has decreased remarkably with the advent of effective broad-spectrum anthelmintics and almost complete prevention of *Strongylus* spp. infection in horses in developed countries.

PATHOGENESIS

Migration of the larvae of *Strongylus vulgaris* into the wall of the **cranial mesenteric artery** and its branches occurs commonly in horses and may cause thromboemboli that restrict blood supply to the intestines, with subsequent ischemia and dysfunction.[2] The recurrent colic of verminous arteritis is possibly due to impairment of the vascular and nerve supply to the intestine. The disease is basically an infarction of bowel wall without displacement of the bowel. The small intestine, colon and cecum can be affected. The disease has been associated with larval cyathostomiasis.[3]

CLINICAL FINDINGS

Signs vary depending on the severity of the disease. It is assumed that **mild, intermittent colics** that respond to analgesics in the short term and anthelmintics in the long term are due to verminous arteritis. Affected horses are often depressed and spend long periods recumbent. Weight loss and inappetence are features of the disease in some horses. The disease can have a course of weeks to months.

Acute, severe cases of the disease are due to infarction of parts or all of the small intestine, cecum or colon. Affected horses have an acute onset of severe abdominal pain, tachycardia (> 100/min) and sweating. Auscultation reveals decreased borborygmi. There is mild distension of small intestine or large colon, depending on the segment of bowel affected, on rectal examination. There are rarely signs of intestinal obstruction. Palpation of the cranial mesenteric artery may reveal thickening and pain but is not a useful diagnostic sign for the acute disease. **Death** is due to peritonitis secondary to devitalization of the intestine, usually within 24 hours of the onset of signs.

CLINICAL PATHOLOGY

There are no diagnostic changes in the hemogram or serum biochemical profile. Peritoneal fluid in mild cases may have mild elevations in protein concentration and white blood cell count. In severe cases, peritoneal fluid protein concentration is increased (> 25 g/L, 2.5 g/dL) as is white blood cell count (9000–100 000 cells/μL, 9–100 × 10^9 cells/L).[4]

NECROPSY FINDINGS

Infarction of the colon and cecum is most common and evident as either gangrene of large sections of the organ or multifocal mottled lesions that are red and edematous. Histological examination rarely reveals the presence of thrombi. There may be venninous arteritis of the cranial mesenteric artery, evident as thickening of the intima and narrowing of the lumen.

DIFFERENTIAL DIAGNOSIS

See Table 5.6.

TREATMENT

Mild, recurrent cases are treated with analgesics such as flunixin meglumine (Table 5.7), laxatives such as mineral oil (Table 5.8), and anthelmintics (ivermectin 200 µg/kg orally once; or fenbendazole 50 mg/kg orally every 24 h for 3 d).

Severe cases are treated with analgesics (Table 5.7), intravenous fluids (Ch. 2) and supportive care. Usually the severity of the colic prompts surgical exploration of the abdomen with resection of small lesions. Most severe cases do not survive.

GASTRITIS (INFLAMMATION OF THE MONOGASTRIC STOMACH, ABOMASITIS)

Inflammation of the stomach is manifested clinically by vomiting and is commonly associated with enteritis in gastroenteritis.

ETIOLOGY

Gastritis may be acute or chronic but both forms of the disease may be caused by the same etiological agents acting with varying degrees of severity and for varying periods. The inflammation may be associated with physical, chemical, bacterial, viral or metazoan agents.

Cattle and sheep

Diseases of the rumen and abomasum are presented in Chapter 6. For comparative purposes the causes of abomasitis are listed here. For sheep there is no information other than about parasites. They are listed with cattle for convenience sake.

Physical agents

Physical agents such as frosted feeds affect only the rumen. In calves, gross overeating and the ingestion of foreign materials may cause abomasitis. In adults, there is a very low incidence of foreign bodies in the abomasum,[1] half the cases being associated with traumatic reticulitis.

Chemical agents

All the irritant and caustic poisons, including arsenic, mercury, copper, phosphorus and lead, cause abomasitis. Fungal toxins cause abomasal irritation, especially those of *Fusarium* spp. and *Stachybotris alternans*. Acute lactic acidosis due to engorgement on carbohydrate-rich food causes rumenitis with some run-off into the abomasum and the development of some abomasitis/enteritis.

Infectious agents

Only the viruses of rinderpest, bovine virus diarrhea and bovine malignant catarrh cause abomasal erosions. Bacterial causes are very rare – sporadic cases of extension from oral necrobacillosis, hemorrhagic enterotoxemia due to *C. perfringens* types A, B, C, rarely as an adjunct to colibacillosis and its enteric lesion in calves. Fungi, e.g. *Mucor* spp. and *Aspergillus* spp. complicate abomasal ulcer due to other causes.

Metazoan agents

Nematodes – *Trichostrongylus axei*, *Ostertagia* spp., *Haemonchus* spp. larval paramphistomes migrating to the rumen.

Pigs

Physical agents

Foreign bodies, bedding, frosted feeds, moldy and fermented feeds are all possible causes.

Chemical agents

As listed under cattle, these are also possible causes of gastritis in pigs.

Infectious agents

Venous hyperemia and infarction of the gastric mucosa occur in erysipelas, salmonellosis, swine dysentery and acute colibacillosis in weaned pigs. Similar lesions occur in swine fever, African swine fever and swine influenza. Fungal gastritis also occurs secondarily.

Metazoan agents

The red stomach worm, *Hyostrongylus rubidus*, and the thick stomach worms *Ascarops strongylina* and *Physocephalus sexalatus* are of low pathogenicity but cannot be disregarded as causes of gastritis in pigs.

Horses

Physical and chemical agents as listed under cattle may cause gastritis rarely. Infectious causes of gastritis are rare in the horse but emphysematous gastritis associated with *C. perfringens* has been recorded.

Metazoan agents causing gastritis in horses include massive infestation with botfly larvae (*Gasterophilus* spp.); *Habronema muscae* and *Habronema microstoma* infestation; *Habronema megastoma* causes granulomatous and ulcerative lesions and may lead to perforation and peritonitis.

PATHOGENESIS

Gastritis does not often occur in animals without involvement of other parts of the alimentary tract. Even in parasitic infestations where the nematodes are relatively selective in their habitat, infestation with one nematode is usually accompanied by infestation with others, so that gastroenteritis is produced. It is dealt with as a specific entity here because it may occur as such, and enteritis is common without gastric involvement. The net effects of gastroenteritis can be determined by a summation of the effects of gastritis and enteritis.

The reactions of the stomach to inflammation include increased motility and increased secretion. There is an increase in the secretion of mucus, which protects the mucosa to some extent but also delays digestion and may allow putrefactive breakdown of the ingesta. This abnormal digestion may cause further inflammation and favors spread of the inflammation to the intestines. In acute gastritis, the major effect is on motility; in chronic gastritis, on secretion. In acute gastritis there is an increase in motility, causing abdominal pain and more rapid emptying of the stomach, either by vomiting or via the pylorus in animals unable to vomit. In chronic gastritis, the emptying of the stomach is prolonged because of the delay in digestion caused by excessive secretion of mucus. This may result in chronic gastric dilatation. The motility is not necessarily diminished and there may be subacute abdominal pain or a depraved appetite due to increased stomach contractions equivalent to hunger pains.

CLINICAL FINDINGS

Acute gastritis

When the inflammation is severe, pigs and, rarely, horses and ruminants vomit (or ruminants regurgitate excessive quantities of rumen contents). In monogastric animals, such as pigs, the vomitus contains much mucus, sometimes blood, and is small in amount, and vomiting is repeated, with forceful retching movements. The appetite is always reduced, often absent, but thirst is usually excessive and pigs affected with gastroenteritis may stand continually lapping water or even licking cool objects. The breath has an offensive odor and there may be abdominal pain. Diarrhea is not marked unless there is an accompanying enteritis but the feces are usually pasty and soft. Additional signs are usually evident when gastritis is part of a primary disease syndrome. Dehydration and alkalosis with tetany and rapid breathing may develop if vomiting is excessive.

Chronic gastritis

Chronic gastritis is much less severe. The appetite is depressed or depraved and vomiting occurs only sporadically, usually after feeding. The vomitus contains much viscid mucus. Abdominal pain is minor and dehydration is unlikely to occur, but the animal becomes emaciated through lack of food intake and incomplete digestion.

Anorexia, tympanites, gastritis, pyloric stenosis and gastric ulcers are the clinical

manifestations of abomasal foreign body in cattle.

CLINICAL PATHOLOGY

Specimens taken for laboratory examination are usually for the purpose of identifying the causative agent in specific diseases. Estimations of gastric acidity are not usually undertaken but samples of vomitus should be collected if a chemical poison is suspected.

NECROPSY FINDINGS

The signs of inflammation vary in severity from a diffuse catarrhal gastritis to severe hemorrhagic and ulcerative erosion of the mucosa. In the mucosal diseases there are discrete erosive lesions. In parasitic gastritis there is usually marked thickening and edema of the wall if the process has been in existence for some time. Chemical inflammation is usually most marked on the tips of the rugae and in the pyloric region. In severe cases the stomach contents may be hemorrhagic; in chronic cases the wall is thickened and the contents contain much mucus and have a rancid odor suggestive of a prolonged sojourn and putrefaction of the food.

It is important to differentiate between gastritis and the erythematous flush of normal gastric mucosa in animals that have died suddenly. Venous infarction in the stomach wall occurs in a number of bacterial and viral septicemias of pigs and causes extensive submucosal hemorrhages, which may easily be mistaken for hemorrhagic gastritis.

DIFFERENTIAL DIAGNOSIS

- Gastritis and gastric dilatation have many similarities but in the latter the vomitus is more profuse and vomiting is of a more projectile nature, although this difference is not so marked in the horse, in which any form of vomiting is severe
- Gastritis in the horse is not usually accompanied by vomiting but it may occur in gastric dilatation
- In esophageal obstruction, the vomitus is neutral in reaction and does not have the rancid odor of stomach contents
- Intestinal obstruction may be accompanied by vomiting and, although the vomitus is alkaline and may contain bile or even fecal material, this may also be the case in gastritis when intestinal contents are regurgitated into the stomach
- Vomiting of central origin is extremely rare in farm animals
- Determination of the cause of gastritis may be difficult but the presence of signs of the specific diseases and history of access to poisons or physical agents listed under etiology above may provide the necessary clues
- Analysis of vomitus or food materials may have diagnostic value if chemical poisoning is suspected

TREATMENT

Treatment of the primary disease is the first principle and requires a specific diagnosis. Ancillary treatment includes the withholding of feed, the use of gastric sedatives, the administration of electrolyte solutions to replace fluids and electrolytes lost by vomiting, and stimulation of normal stomach motility in the convalescent period.

In horses and pigs, gastric lavage may be attempted to remove irritant chemicals. Gastric sedatives usually contain insoluble magnesium hydroxide or carbonate, kaolin, pectin or charcoal. Frequent dosing at intervals of 2–3 hours is advisable. If purgatives are used to empty the alimentary tract, they should be bland preparations such as mineral oil to avoid further irritation to the mucosa.

If vomiting is severe, large quantities of electrolyte solution should be administered parenterally. Details of the available solutions are given under the heading of disturbances of body water. If the liquids can be given orally without vomiting occurring, this route of administration is satisfactory.

During convalescence, the animal should be offered only soft, palatable, highly nutritious foods. Bran mashes for cattle and horses and gruels for calves and pigs are most suitable and are relished by the animal.

ACUTE GASTRIC DILATATION IN PIGS

In the pig, **simple gastric distension** is usually readily relieved by vomiting.

ACUTE GASTRIC TORSION IN SOWS

This is a much more serious problem.[1] Torsion is thought to occur because the sow eats a large, sloppy meal very quickly. The occurrence is specifically related to intense excitement and activity occurring at feeding time. Death occurs 6–24 hours after the pig's last meal. At necropsy the stomach is enormous (50–60 cm diameter), with engorgement of vessels and hemorrhagic effusion into the stomach, which contains much gas and usually a lot of food. Rotation varies in degree from 90–360° and is usually to the right. The spleen is markedly displaced, the liver is bloodless and the diaphragm encroaches deeply into the chest.[2]

INTESTINAL REFLUX

Acute dilatation also occurs in pigs secondarily to acute obstruction of the small intestine. The obstruction may be as far down as the ileocecal valve. The oral segment of intestine dilates and fills with fluid, and refluxes into the stomach, filling it. In the pig vomiting follows. The outcome depends on whether sufficient gastric motility returns to evacuate the stomach.

DIAGNOSIS

The vomiting in gastric dilatation is more profuse and projectile than that of gastritis or enteritis but may be simulated by that of obstruction of the upper part of the small intestine.

INTESTINAL OBSTRUCTION IN PIGS

ETIOLOGY

Some causes of intestinal obstruction are:

- Torsion of the coiled colon about its mesentery occurs in adult pigs
- Obstruction of the terminal small colon in young piglets causes very hard fecal balls, or barley chaff used as bedding may be implicated in obstruction
- Heavy feeding on lactose[1] causes a dilatation and atony of the intestine in the same way as grain feeding does in ruminants.

CLINICAL FINDINGS

In pigs, distension of the abdomen, absence of feces and complete anorexia are evident. The distension may be extreme in young pigs when the terminal colon is obstructed. Death usually occurs in 3–6 days.

IMPACTION OF THE LARGE INTESTINE OF PIGS

ETIOLOGY

- In pigs impaction of the colon and rectum occurs sporadically, usually in adult sows that get little exercise and are fed wholly on grain. The disease also occurs in pigs that are overcrowded in sandy or gravelly outdoor yards
- A special occurrence in young weaned pigs causes obstruction of the coiled colon
- A presumed inherited megacolon of fattening pigs is reported as a cause of abdominal distension, constipation and wasting. There is no anal stricture.[1]

CLINICAL FINDINGS

In impaction of the large intestine the effects appear to be due largely to autointoxication, although the commonly occurring posterior paresis seems more likely to be due to pressure from inspissated fecal material.

Retention of the meconium has no specific signs. There is anorexia and dullness and the pig is recumbent much of the time. Feces passed are scanty, very hard and covered with mucus. Weakness to the point of inability to rise occurs in some cases. Hard balls of feces in the rectum are usually detected when a thermometer is inserted.

In paralysis of the rectum there is inability to defecate and usually some straining. The anus and rectum are ballooned and manual removal of the feces does not result in contraction of the rectum. Spontaneous recovery usually occurs 3–4 days after parturition.

INTESTINAL TYMPANY IN PIGS

ETIOLOGY

- Primary tympany occurs with ingestion of excess whey. Recorded in adult dry sows. Distension of proximal colon causes rupture with death from endotoxic shock[1]
- Secondary large bowel tympany – usually secondary to acute intestinal obstruction.

REFERENCE

1. McCausland IP, Southgate W. Aust Vet J 1980; 56:190.

ENTERITIS (INCLUDING MALABSORPTION, ENTEROPATHY AND DIARRHEA)

The term enteritis is used to describe inflammation of the intestinal mucosa resulting in diarrhea and sometimes dysentery, abdominal pain occasionally, and varying degrees of dehydration and acid–base imbalance, depending on the cause of the lesion, its severity and location. In many cases, gastritis also occurs together with enteritis.

There are several diseases of the intestines of farm animals in which diarrhea and dehydration are major clinical findings, but classical inflammation of the mucosa may not be present. The best example of this is the diarrhea associated with enterotoxigenic *E. coli*, which elaborate an enterotoxin that causes a large net increase of secretion of fluids into the lumen of the gut, with very minor, if any, structural changes in the intestinal mucosa. This suggests that a word other than enteritis may be necessary to describe alterations in the intestinal secretory and absorptive mechanisms that result in diarrhea but in which pathological lesions are not present. However, with the above qualifications, we have chosen, for convenience, to continue to use the term enteritis to describe those diseases in which diarrhea is a major clinical finding due to malabsorption in the intestinal tract.

ETIOLOGY AND EPIDEMIOLOGY

There are many causes of enteritis or malabsorption in farm animals and the disease varies considerably in its severity depending upon the causative agent. Enteropathogens include bacteria, viruses, fungi, protozoa and helminths. Many chemicals and toxins can also cause enteritis (Tables 5.12–5.15). In addition to the primary etiological agents of enteritis, there are many epidemiological characteristics of the animal and the environment that are important in facilitating or suppressing the ability of the causative agent to cause enteritis. Thus newborn calves and piglets that are deficient in colostral immunoglobulins are much more susceptible to diarrhea, and with a high mortality rate from diarrhea, than animals with adequate levels. Enteric salmonellosis is commonly precipitated by the stressors of transportation or deprivation of feed and water. The stress

Table 5.12 Epidemiological and clinical features of diseases of cattle in which diarrhea is a significant clinical finding

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings and diagnostic criteria
Bacteria		
Enterotoxigenic *E. coli*	Newborn calves < 3–5 days of age, colostral immune status determines survival. Outbreaks common	Acute profuse watery diarrhea, dehydration and acidosis. Culture feces for enteropathogenic type
Salmonella spp.	All ages. Outbreaks occur. Stress-induced	Acute diarrhea, dysentery, fever and high mortality possible. Culture feces
Clostridium perfringens types B and C	Young well nourished calves < 10 days of age	Severe hemorrhagic enterotoxemia, rapid death. Fecal smear
Mycobacterium avium subsp. *paratuberculosis*	Mature cattle, sporadic, single animal	Chronic diarrhea with loss of weight, long course. No response to therapy. Special tests
Proteus spp. and *Pseudomonas* spp.	Calves treated for diarrhea with prolonged course of antibiotics	Chronic to subacute diarrhea, poor response to treatment, progressive loss of weight. Culture feces
Fungi		
Candida spp.	Young calves following prolonged use of oral antibacterials	Chronic diarrhea, no response to treatment. Fecal smears
Viruses		
Rotavirus and coronavirus	Newborn calves, 5–21 days old, explosive outbreaks	Acute profuse watery diarrhea. Demonstrate virus in feces
Winter dysentery (*Coronavirus*)	Mature housed cows, explosive outbreaks	Acute epizootic of transient diarrhea and dysentery lasting 24 hours. Definitive diagnosis not possible currently
Bovine virus diarrhea (mucosal disease)	Young cattle 8 months to 2 years. Usually sporadic but epidemics occur	Erosive gastroenteritis and stomatitis. Usually fatal. Virus isolation
Rinderpest	Highly contagious, occurs in plague form	Erosive stomatitis and gastroenteritis. High morbidity and mortality
Bovine malignant catarrh	Usually mature cattle, sporadic but small outbreaks occur	Erosive stomatitis and gastroenteritis, enlarged lymph nodes, ocular lesions, hematuria and terminal encephalitis. Transmission with whole blood
Helminths		
Ostertagiasis	Young cattle on pasture	Acute or chronic diarrhea, dehydration and hypoproteinemia. Fecal examination. Plasma pepsinogen
Protozoa		
Eimeria spp.	Calves over 3 weeks old and cattle up to 12 months of age. Outbreaks common	Dysentery, tenesmus, nervous signs. Fecal examination diagnostic
Cryptosporidium spp.	Calves 5–35 days of age	Diarrhea. Fecal smear and special stain

Table 5.12 (*Cont'd*) Epidemiological and clinical features of diseases of cattle in which diarrhea is a significant clinical finding

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings and diagnostic criteria
Chemical agents		
Arsenic, fluorine, copper, sodium chloride, mercury, molybdenum, nitrates, poisonous plants, mycotoxicoses	All ages, history of access to substance. Outbreaks occur	All severities of diarrhea, dysentery, abdominal pain, in some cases nervous signs, dehydration, toxemia. Fecal and tissue analyses
Physical agents		
Sand, soil, silage, feed containing lactic acid (sour brewers' grains)	Usually mature cattle, history of access. Outbreaks occur	Acute, subacute diarrhea and toxemia. See sand in feces. Rumen pH
Nutritional deficiency		
Copper deficiency, conditioned by excess molybdenum	Usually mature cattle on pasture with high levels of molybdenum	Subacute and chronic diarrhea, osteodystrophy, no systemic effects, hair color changes. Liver and blood analyses
Dietary		
Overfeeding	Young calves overfed on milk	Mild diarrhea, feces voluminous and pale yellow. Clinical diagnosis
Simple indigestion	Change of ration of mature cows (hay to silage) or grain to feedlot cattle	Subacute diarrhea. Normal in 24 hours. Clinical diagnosis usually sufficient
Inferior milk replacers	Heat-denatured skim milk used in manufacturing of milk replacers for calves	Subacute to chronic diarrhea, progressive emaciation, no response to conventional treatment except cow's whole milk. Clotting tests on milk replacer
Miscellaneous or uncertain etiology		
Intestinal disaccharidase deficiency	May occur in young calves. Sporadic	Subacute diarrhea unresponsive to usual therapy except withdrawal of milk. Lactose digestion tests
Congestive heart failure	Sporadic. Mature cattle.	Profuse watery diarrhea associated with visceral edema.
Toxemia (peracute coliform mastitis)	Sporadic	Acute diarrhea due to endotoxemia from peracute mastitis. Culture milk

Table 5.13 The epidemiological and clinical features of horses with diarrhea

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings; *diagnostic criteria*
Bacteria		
Salmonella spp.	Young foals; mature horses, following stress	Acute profuse diarrhea, severe dehydration, foul-smelling feces; *leukopenia and neutropenia, culture feces, hyponatremia*
Rhodococcus equi	Foals 2–5 months of age, some with history of respiratory disease	Diarrhea associated with *R. equi* pneumonia; *culture respiratory tract*
Clostridium perfringens or C. difficile	Mature horses administered antibiotics. Young foals	Profuse, watery diarrhea, hypovolemia, hyponatremia. *Fecal culture and demonstration of toxin in feces*
Aeromonas spp.	Adult horses, tends to be more common in summer. Often isolated from horses with diarrhea. Definitive etiological role not proved	Febrile, acute diarrhea. *Culture feces*
Viruses and rickettsia		
Neorickettsia risticii (formerly *Ehrlichia risticii*)	Endemic to certain regions in North and South America and Europe. Ingestion of organism spread by insects (mayflies)	Profuse watery diarrhea, fever, laminitis. *IFA, PCR*
Parasites		
Cyathostomes and large strongyles	Individual horses. Poor deworming history. Seasonal occurrence of larval cyathostomiasis	Acute to chronic diarrhea. *Patent infections evident by fecal examination for parasite eggs*
Physical		
Sand accumulation	Individual horses or farm problem. Ingestion of sand or gravel	Watery diarrhea, not malodorous, not profuse. *Abdominal radiography or ultrasonography, examination of feces*
Overdosing of cathartics (DSS, $MgSO_4$, $NaSO_4$, castor oil)	Treated animals	Moderate to profuse diarrhea. *Historical confirmation of administration of compounds*
Miscellaneous or unknown		
Colitis X	Single animal. Adult horses. High death rate	Acute, pyrexic diarrhea, hypovolemia, leukopenia. *Post mortem examination*
Granulomatous or eosinophilic colitis	Single animal. Adults	Chronic diarrhea. *Necropsy or colonic biopsy*
Right dorsal colitis/ phenylbutazone toxicity	Administration of NSAIDs in large doses or prolonged administration	Mild diarrhea. Low grade fever. Mild colic. Hypoproteinemia, hyponatremia. *Necropsy, surgery*
Antibiotic-induced diarrhea	History of antimicrobial administration. High case fatality rate	Acute onset diarrhea with or without fever. Leukopenia, hypovolemia. *History*

DSS, dioctyl sodium sulfosuccinate; IFA, indirect fluorescence antibody test; NSAIDs, nonsteroidal anti-inflammatory drugs; PCR, polymerase chain reaction.

Table 5.14. Epidemiological and clinical features of diseases of the pig in which diarrhea is a significant clinical finding

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings and diagnostic criteria
Viruses		
Classical and African swine fever	Hemorrhagic diarrhea at any age	Many other signs(pyrexia) variety of lab tests (isolation, ELISA, PCR etc.)
Transmissible gastroenteritis (TGE)	Explosive outbreaks in newborn piglets. High morbidity and mortality	Acute diarrhea, vomition, dehydration and death. No response to treatment (lab tests include virus isolation, ELISA, EM, FATs)
Rotavirus and coronavirus (Epidemic diarrhea)	Outbreaks in newborn piglets and weaned piglets. May occur in well-managed herds	Acute diarrhea and dehydration. May continue to suck the sow. Death in 2–4 days. Virus isolation and pathology of gut, EM, FATs (PED), PAGE for rotavirus
Bacteria		
Enterotoxigenic *E. coli*	Common disease of newborn, 3-week-old and weaned piglets. Outbreaks. Colostral immune status important	Acute diarrhea, dehydration. Responds to early treatment. Fecal culture and serotype. Virulence factor determination
Salmonella spp.	All ages. Most common in feeder pigs	Acute septicemia or chronic diarrhea. Responds to early treatment. Culture and serotyping
Clostridium perfringens type C	Newborn piglets. High mortality	Acute and peracute hemorrhagic enterotoxemia. Toxin demonstration and culture
Clostridium perfringens type A	Slightly older pigs, first week of life, lower mortality	As above
Clostridium difficile	Diarrhea in preweaned pigs	Smears of colon wall, culture, FAT, PCR
Brachyspira hyodysenteriae (swine dysentery)	Usually feeder pigs. Outbreaks common	Dysentery, acute to subacute, fever. Responds to treatment. Culture, FATs, PCR on mucosal smears
Lawsonia intracellularis (PIA, PHE)	Growing and mature pigs. Outbreaks common	Acute dysentery and death. MZN on mucosal smears, PCR, silver-stained sections
Brachyspira pilosicoli	Usually weaned pigs	PCR
Protozoa		
Isospora spp.	Newborn piglets 5–14 days of age. High morbidity, low mortality	Acute diarrhea. Poor response to therapy with amprolium. Fecal examination for oocysts
Other species (*Eimeria*)	In older pigs	Histology of gut sections
Parasites		
Ascaris suum and	Young pigs	
A. lumbricoides	All ages, usually older pigs	Mild diarrhea for few days. Worm egg count
Trichuris suis		Diarrhea, dysentery and loss of weight. Fecal examination and gross pathology
Nutritional deficiency		
Iron deficiency	Young piglets 6–8 weeks. Not common in well managed swine herds	Mild diarrhea and anemia

ELISA, enzyme-linked immunoassay; EM, electron micrograph; FATs, fluorescence antibody transfer; MZN, Modified ziehl-neilson; PAGE, Poly acrylamide get electrophoresis; PCR, polymerase chain reaction; PED, Porcine epidemic diarrhea.

of weaning in pigs is a risk factor for postweaning diarrhea. The prolonged use of antimicrobials orally in all species may alter the intestinal microflora and allow the development of a superinfection by organisms that would not normally cause disease.

The salient epidemiological characteristics and clinical findings of the diseases in which diarrhea, due to enteritis or malabsorption, is a principal clinical finding in each species are summarized by species in Tables 5.12–5.15. There are many other diseases in which diarrhea may be present but in which it is only of minor importance.

PATHOGENESIS

Normal intestinal absorption

Under normal conditions, a large quantity of fluid enters the small intestine from the saliva, stomach, pancreas, liver and intestinal mucosa. This fluid and its electrolytes and other nutrients must be absorbed, mainly by the small intestines, although large quantities move into the large intestine for digestion and absorption, especially in the horse. The brush border membrane of the villous epithelial cells is of paramount importance for the absorption of water, electrolytes and nutrients.

Details of the physiology and pathophysiology of epithelial secretion in the gastrointestinal tract are becoming clear, leading to new models of the mechanisms underlying diarrhea.[1] The enteric nervous system is a critical component of the mechanism regulating fluid secretion in the normal intestine and a key element in the pathophysiology of diarrhea. Neural reflex pathways increase epithelial fluid secretion in response to several enteric pathogens of veterinary importance such as *Salmonella* spp., *Cryptosporidium parvum*, rotavirus and *C. difficile*. The enteric nervous system also has an important role in epithelial secretion triggered by products of activated leukocytes during inflammation.

Mechanisms of diarrhea

Any dysfunction of the intestines will result in failure of adequate absorption and diarrhea. Depending on the causative agent, intestinal malabsorption may be the result of at least four different mechanisms:

Osmotic diarrhea
Exudative diarrhea
Secretory diarrhea
Abnormal intestinal motility.

Osmotic diarrhea

There may be an osmotic effect when substances within the lumen of the intestine increase the osmotic pressure over a greater than normal length of intestine, resulting in an osmotic movement of an excessive amount of fluid into the lumen of the intestine. The fluid is not reabsorbed and accumulates in the lumen. Examples include **saline purgatives**, **overfeeding**, **indigestible feeds** and **disaccharidase deficiencies**. A deficiency of a disaccharidase leads to incomplete digestion and the accumulation of large quantities of undigested material, which acts as a hypertonic solution.

Malabsorption is associated with several epitheliotropic viruses that affect the villous absorptive cells, causing a disaccharidase deficiency. Examples include the TGE (transmissible gastroenteritis)

Table 5.15 Epidemiological and clinical features of the diseases of sheep and goats in which diarrhea is a significant clinical finding

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings and diagnostic criteria
Bacteria		
Enterotoxigenic *Escherichia coli* (colibacillosis)	Newborn lambs in crowded lambing sheds. Cold chilling weather. Outbreaks. Inadequate colostrum. Mismothering problems. Poor udder development	Acute diarrhea (yellow feces), septicemia and rapid death. Culture feces for enterotoxigenic *E. coli*
Clostridium perfringens type B (lamb dysentery)	Newborn lambs up to 10 days of age. Overcrowded lambing sheds	Sudden death, diarrhea, dysentery, toxemia. Fecal smear
Clostridium perfringens type D (enterotoxemia)	Adult lactating does	Peracute, acute and chronic forms occur. Enterocolitis. Watery diarrhea with feces containing blood and mucus, weakness, abdominal colic
Salmonella spp.	Newborn lambs. Adult sheep in pregnancy	Acute diarrhea and dysentery in lambs. Acute toxemia, diarrhea in ewes followed by abortion. Fecal culture and pathology
Mycobacterium paratuberculosis	Mature sheep and goats; several animals may be affected	Loss of weight, chronic diarrhea, long course, no response to therapy. Serological tests
Viruses		
Rotavirus and coronavirus	Newborn lambs. Many lambs affected	Acute profuse watery diarrhea. No toxemia. Usually recover spontaneously if no secondary complications. Virus isolation
Parasites		
Nematodirus spp.	Lambs 4–10 weeks of age on pasture. Sudden onset. Outbreaks. Ideal environmental conditions for parasite are necessary	Anorexia, diarrhea, thirsty, 10–20% of lambs may die if not treated. Fecal examination
Ostertagia spp.	Lambs 10 weeks of age and older lambs and young ewes on grass. Types I and II	Many lambs develop diarrhea, weight loss. Abomasitis
Trichostrongylus spp.	Older lambs 4–9 months of age	Dull, anorexic, loss of weight and chronic diarrhea. Fecal examination
Protozoa		
Eimeria spp.	Overstocking on pasture and overcrowding indoors, poor sanitation and hygiene. Commonly occurs following weaning and introduction into feedlot	Acute and subacute diarrhea and dysentery. Loss of weight. Mortality may be high. Fecal examination
Cryptosporidium	Lambs 7–10 days of age	Dullness, anorexia, afebrile, diarrhea, may die in 2–3 days, survivors may be unthrifty. Examination of feces and intestinal mucosa. No specific treatment

virus in newborn piglets, and rotavirus and coronavirus infections in newborn calves and other species. The usual pathogenetic sequence of events is selective destruction of villous absorptive cells, villous atrophy, loss of digestive and absorptive capacities (malabsorption), diarrhea, crypt hyperplasia and recovery. Recovery depends on the severity of the lesion, the relative injury done to the villous cells and crypt epithelium, and the age of the animal. Newborn piglets affected with TGE commonly die of dehydration and starvation before there is sufficient time for regeneration of the villous cells from the crypt epithelium. In contrast, older pigs have greater capacity for regeneration of the villous cells and the diarrhea may be only transient.

Exudative diarrhea

Acute or chronic inflammation or necrosis of the intestinal mucosa results in a net increase in fluid production, inflammatory products, including loss of serum proteins, and a reduction in absorption of fluids and electrolytes. Examples include many of the diseases associated with bacteria, viruses, fungi, protozoa, chemical agents and tumors that are summarized in Tables 5.12–5.15. The classic example is enteric salmonellosis, in which there is severe inflammation with the production of fibrinous, hemorrhagic enteritis. Other notable examples include swine dysentery, bovine virus diarrhea and inorganic arsenic poisoning.

Secretory diarrhea

A **secretory–absorptive imbalance** results in a large net increase in fluid secretion with little if any structural change in the mucosal cells. The enterotoxin elaborated by enterotoxigenic *E. coli* results in intestinal hypersecretion. The villi, along with their digestive and absorptive capabilities, remain intact. The crypts also remain intact; however, their secretion is increased beyond the absorptive capacity of the intestines, resulting in diarrhea. The increased secretion is due to an increase in cyclic adenosine monophosphate, which in turn may be stimulated by prostaglandins. The integrity of the mucosal structure is maintained and the secreted fluid is isotonic, electrolyte-rich, alkaline and free of exudates. This is useful diagnostically in enterotoxic colibacillosis.

An important therapeutic principle can be applied in secretory diarrhea disease. Whenever possible, because of the cost of parenteral fluid therapy, fluids and electrolytes should be given orally. The mucosa remains relatively intact and retains normal absorptive capacity. Fluid replacement solutions containing water, glucose and amino acids can be given orally and are absorbed efficiently. Glucose and amino acids enhance the absorption of sodium and water, thus replacing or diminishing fluid and electrolyte losses.

There is also evidence that active electrolyte secretion occurs in enterocolitis due to salmonellosis in several species of animal. In diseases such as swine dysentery, the permeability of the colon may remain normal or even decrease, but the absorption of water and electrolytes is decreased. This suggests that the primary cause of fluid and electrolyte loss in some diseases of the colon may be failure of the affected epithelium to absorb fluids and electrolytes.

Abnormal intestinal motility

Hyperexcitability, convulsions and the stress of unexpected sudden confinement may result in diarrhea, which may be due to increased peristalsis, resulting in '**intestinal hurry**' and reduced intestinal absorption due to rapid passage of intestinal fluids in an otherwise normal intestine. This can occur in animals that are being assembled for transportation and during transportation.

Location of lesion

The location of the lesion in the intestinal tract may also influence the severity of the enteritis or malabsorption. Lesions involving the small intestine are considered to be more acute and severe than those in the large intestine because approximately 75–80% of the intestinal fluids are absorbed by the small intestine and much lesser quantities by the large intestine. Thus, in general, when lesions of the large intestine predominate, the fluid and electrolyte losses are not as acute nor as severe as when the lesions of the small intestine predominate. However, the horse is an exception. The total amount of fluid entering the large intestine from the small intestine, plus the amount entering from the mucosa of the large intestine, is equal to the animal's total extracellular fluid volume, and 95% of this is reabsorbed by the large intestine. This illustrates the major importance of the large intestine of the horse in absorbing a large quantity of fluid originating from saliva, the stomach, liver, pancreas, small intestine and large intestine. Any significant dysfunction of the absorptive mechanism of the large intestine of the horse results in large losses of fluids and electrolytes. This may explain the rapid dehydration and circulatory collapse that occurs in horses with colitis-X. Moderate to severe ulcerative colitis of the right dorsal colon in horses treated with phenylbutazone results in marked dehydration, endotoxic shock and death.[2]

Dehydration, electrolyte and acid–base imbalance

The net effect of an increase in the total amount of fluid in the intestinal lumen and a reduction in intestinal absorption is a loss of fluids and electrolytes at the expense of body fluids and electrolytes and the normal intestinal juices. The fluid that is lost consists primarily of water, the electrolytes sodium, chloride, potassium and bicarbonate, and varying quantities of protein. Protein is lost (protein-losing enteropathy) in both acute and chronic inflammation, leading to hypoproteinemia in some cases. The loss of bicarbonate results in **metabolic acidosis**, which is of major importance in acute diarrhea. The loss of sodium, chloride and potassium results in **serum electrolyte imbalances**. In the horse with enteric salmonellosis, there is severe dehydration and marked hyponatremia. In the calf with neonatal diarrhea there are varying **degrees of dehydration** and a moderate loss of all electrolytes. With acute severe diarrhea, there is severe acidosis and reduced circulating blood volume, resulting in reduced perfusion of the liver and kidney and of peripheral tissues. This results in uremia, anaerobic oxidation and lactic acidosis, which accentuates the metabolic acidosis. Hyperventilation occurs in some animals in an attempt to compensate for the acidosis.

In acute diarrhea, large quantities of intestinal fluid are lost in the feces and large quantities are present in the intestinal lumen (**intraluminal dehydration**), which accounts for the remarkable clinical dehydration in some affected animals. The fluid moves out of the intravascular compartment first, then out of the extravascular compartment (interstitial spaces), followed lastly by fluid from the intracellular space. Thus in acute diarrhea of sudden onset the actual degree of dehydration present initially may be much more severe than is recognizable clinically; as the diarrhea continues, the degree of clinical dehydration becomes much more evident.

Chronic enteritis

In chronic enteritis, as a sequel to acute enteritis or developing insidiously, the intestinal wall becomes thickened and mucus secretion is stimulated, the absorption of intestinal fluids is also decreased but not of the same magnitude as in acute enteritis. In chronic enteritis there is a negative nutrient balance because of decreased digestion of nutrients and decreased absorption, resulting in body wasting. The animal may continue to drink and maintain almost normal hydration. In some cases of chronic enteritis, depending on the cause, there is continuous loss of protein, leading to clinical hypoproteinemia. Intestinal helminthiasis of all species, Johne's disease of ruminants, and chronic diarrheas of the horse are examples. Lymphocytic plasmacytic enteritis causing chronic weight loss occurs in the horse.[3]

Regional ileitis is a functional obstruction of the lower ileum associated with granulation tissue proliferation in the lamina propria and submucosa, with or without ulceration of the mucosa, and a massive muscular hypertrophy of the wall of affected areas of the intestine. It has been recognized with increased frequency in recent years in pigs, horses and lambs. The lesion undoubtedly interferes with normal digestion and absorption but diarrhea is not a common clinical finding.

Replacement of villous epithelial cells

The villous absorptive epithelial cells of the small intestine are involved in almost every type of enteritis or malabsorptive syndrome. These cells that line the villi and face the lumen of the intestine contain important digestive enzymes such as the disaccharidases. They are also involved in absorption of fluids, electrolytes, monosaccharides such as glucose, and amino acids, and in the transport of fat micelles. Their replacement time is up to several days in the newborn calf and piglet, and only a few days when these animals are older (at 3 weeks). This may explain the relatively greater susceptibility of the newborn to the viral enteritides, such as TGE in piglets and rotavirus infection in all newborn farm animal species. Almost any noxious influence can increase the rate of extrusion of these cells, which are then replaced by cells that are immature and not fully functional. The villi become shortened (villous atrophy) and chronic malabsorption similar to the 'sprue gut' of humans may be the result. The destruction of villous epithelial cells explains the long recovery period of several days in some animals with acute enteritis and the chronic diarrhea in others with chronic villous atrophy.

The literature on the mechanisms of intestinal mucosal repair has been reviewed.[4]

Role of neutrophils in intestinal mucosal injury

Neutrophils are critical elements of the cascade of events that culminates in mucosal injury in many inflammatory diseases of the gastrointestinal tract, including ischemia and reperfusion injury.[5] Neutrophils mediate their detrimental actions by several mechanisms, especially physical disruption of the epithelium. These findings have resulted in consideration of strategies to attenuate neutrophil-mediated mucosal injury by preventing neutrophil transendothelial migration into the intestinal mucosa and subsequent activation during inflammation. Newer pharmacological drugs that inhibit beta-2-integrin activation, and therefore beta 2-integrin function, may be useful clinically to inhibit neutrophil-mediated injury during inflammation.[5]

Intestinal motility in enteritis

The motility of the intestinal tract in animals with enteritis has not been sufficiently examined and little information is available. It was thought for many years that intestinal hypermotility, and increased frequency and amplitude of peristalsis, was present in most enteritides as a response to the enteritis and that the hypermotility accounted for the reduced absorption. However, when the pathogenesis of the infectious enteritides is considered, for example the unique secretory effect of enterotoxin, it seems more likely that, if hypermotility is present, it is a response to the distension of the intestinal lumen with fluid rather than a response to irritation. With a fluid-filled intestinal lumen, very little intestinal

peristalsis would be necessary to move large quantities of fluid down the intestinal tract. This may explain the fluid-rushing sounds that are audible on auscultation of the abdomen in animals with enteritis. It is possible that the intestines may be in a state of relative hypomotility rather than hypermotility, which makes the use of antimotility drugs for the treatment of enteritis questionable.

Concurrent gastritis

Gastritis commonly accompanies enteritis but does not cause vomition except perhaps in the pig. Gastritis (or abomasitis) may also be the primary lesion, resulting in a profuse diarrhea without lesions of the intestines. Examples are ostertagiasis and abomasal ulceration in cattle. Presumably the excessive amount of fluid secreted into the affected abomasum cannot be reabsorbed by the intestines.

Effects of enteritis on pharmacodynamics of drugs

Enteritis may alter the pharmacodynamics of orally administered drugs. In acute diarrheal states there is delayed or impaired absorption, resulting in subtherapeutic plasma concentration. In chronic malabsorption states, decreased, increased or delayed absorption may occur, depending on the drug. Also, gastric antacids, anticholinergic drugs and opiates, administered orally for the treatment of diarrhea, may impair absorption of other drugs by altering solubility or delaying gastric emptying time.

CLINICAL FINDINGS

The major clinical finding in enteritis or malabsorption is **diarrhea**. **Dehydration**, **abdominal pain**, **septicemia** and **toxemia** with **fever** occur commonly and their degree of severity depends on the causative agent, the age and species of the animal and the stage of the disease.

In **acute enteritis**, the feces are soft or fluid in consistency and may have an unpleasant odor. They may contain blood (**dysentery**), fibrinous casts and mucus or obvious foreign material such as sand. The color of the feces will vary considerably: they are usually pale yellow because of the dilution of the brown bile pigments but almost any color other than the normal is possible and, with the exception of frank blood (**hematochezia**) or **melena** (**black tarry feces**), the color of the feces is usually not representative of a particular disease. When the feces are watery, they may escape notice on clinical examination. Some indication of the nature of the enteritis may be obtained from the distribution of the feces on the animal's perineum. Thus, in calves, the smudge pattern may suggest coccidiosis when both the staining that accompanies it and the feces are smeared horizontally across the ischial tuberosities and the adjoining tail, or helminth infestation when there is little smearing on the pinbones but the tail and insides of the hocks are liberally coated with feces. Straining may occur, especially in calves, and be followed by rectal prolapse, particularly when the lesions are present in the colon and rectum. Intussusception may occur when the enteritis involves the small intestine.

There are a number of diseases in which **dysentery** with or without toxemia occurs and death may occur rapidly. These include lamb dysentery, hemorrhagic enterotoxemia of calves, acute swine dysentery and hemorrhagic bowel syndrome of pigs.

Acute intraluminal hemorrhage due to ulceration of unknown etiology in the small intestine has been recorded in adult cows.[6] Duodenal ulceration may also occur in cattle in association with left-side displacement of the abomasum.[7]

Systemic effects

The **systemic effects in enteritis** vary considerably. Septicemia, toxemia and fever are common in the infectious enteritides. An increased body temperature may return to normal following the onset of diarrhea or if circulatory collapse and shock are imminent. **Dehydration** will vary from being just barely detectable at 4–6% of body weight up to 10–12% of body weight, when it is clinically very evident. The degree of dehydration can be best assessed by tenting the skin of the upper eyelid or neck and determining the time taken for the skin fold to return to normal. The degree of recession of the eyeball is also a useful aid. In the early stages of acute enteritis, the degree of clinical dehydration may be underestimated because of the time required for fluid to shift from the interstitial and intracellular spaces to the intravascular space to replace fluids already lost. Dehydration is usually evident by 10–12 hours following the onset of acute enteritis and clinically obvious by 18–24 hours. Peripheral circulatory collapse (**shock**) occurs commonly in acute and peracute cases. There may be tachycardia or bradycardia and arrhythmia depending on the degree of acidosis and electrolyte imbalance. In acute enteritis, there may be severe abdominal pain, which is most severe in the horse and is often sufficient in this species to cause rolling and kicking at the abdomen. Abdominal pain in enteritis is unusual in the other species although it does occur in heavy inorganic metal poisonings, such as arsenic and lead, and in acute salmonellosis in cattle. Some severe cases of enteric colibacillosis in calves are characterized by abdominal pain evidenced by intermittent bouts of stretching and kicking at the abdomen. The passage of intestinal gas also occurs commonly in horses with acute and chronic diarrhea.

Intestinal sounds in enteritis

Auscultation of the abdomen usually reveals sounds of **increased peristalsis** and **fluid-rushing sounds** in the early stages of acute enteritis. Later there may be **paralytic ileus** and an absence of peristaltic sounds with only fluid and gas tinkling sounds. The abdomen may be distended in the early stages because of distension of intestines and gaunt in the later stages when the fluid has been passed out in the feces. Pain may be evidenced on palpation of the abdomen in young animals.

Chronic enteritis

In **chronic enteritis,** the feces are usually soft and homogeneous in consistency, contain considerable mucus and usually do not have a grossly abnormal odor. Progressive weight loss and emaciation or 'runting' are common and there are usually no systemic abnormalities. Animals with chronic enteritis will often drink and absorb sufficient water to maintain clinical hydration but there may be laboratory evidence of dehydration and electrolyte loss. In parasitic enteritis and abomasitis there may be hypoproteinemia and subcutaneous edema. In terminal ileitis, there is usually chronic progressive weight loss and occasionally some mild diarrhea. The lesion is usually recognized only at necropsy. Intestinal adenomatosis of pigs, rectal strictures in pigs, granulomatous enteritis of horses and lymphosarcoma of the intestine of horses are examples of enteric disease causing chronic anorexia and progressive weight loss, usually without clinical evidence of diarrhea. These are commonly referred to as malabsorption syndromes.

CLINICAL PATHOLOGY

The laboratory testing of animals to obtain an etiological diagnosis of enteritis can be a complex and expensive procedure, which requires careful consideration of the history, the clinical findings and the number of animals affected. In outbreaks of enteric syndromes, it may be important to submit samples from both affected and normal animals. The details of the sampling techniques and the tissues required for the diagnosis of diseases of the digestive tract caused by feeding mismanagement, infections, toxins and other agents have been outlined and this is recommended as a reference.[8]

Fecal examination

Examination of the feces to determine the presence of causative **bacteria**, **helminths**, **protozoa**, **viruses** and **chemical agents** is described under specific diseases throughout this book. It is important that fecal specimens be taken as the differentiation of the etiological groups depends on laboratory examinations. In outbreaks of diarrhea, fecal samples should also be taken from a representative number of normal animals in the same group as the affected animals. Comparison of the fecal examination results between affected and normal animals will improve the accuracy of interpretation.

Fecal samples can be examined for the presence of leukocytes and epithelial cells, which occur in exudative enteritis.

Intestinal tissue samples

In outbreaks of diarrhea, especially in neonates, it may be useful to do necropsies on selected early untreated cases of acute diarrhea. The lesions associated with the enteropathogens are well known and a provisional etiological diagnosis may be possible by gross and histopathological examination of the intestinal mucosa.

Hematology and serum biochemistry

With increasing sophistication in diagnostic laboratories and in large-animal practice, it is becoming common to do considerable laboratory evaluation to determine the actual changes that are present, for purposes of a more rational approach to therapy. For each specific enteritis there are changes in the hemogram and serum biochemistry that aid in the diagnosis and differential diagnosis. In bacterial enteritis, such as acute enteric salmonellosis in the horse, there may be marked changes in the total and differential leukocyte count, which is a useful diagnostic aid. In most cases of acute enteritis there is hemoconcentration, metabolic acidosis, an increase in total serum solids concentration, a decrease in plasma bicarbonate, hyponatremia, hypochloremia and hypokalemia. However, abnormalities in body fluid compartments caused by diarrhea depend on the pathogenetic mechanisms involved and the duration of the diarrhea. In horses with diarrhea of less than 6 days' duration, the most common abnormality may be a combined anion gap, metabolic acidosis and metabolic alkalosis characterized by hyponatremia, hypochloremia and hyperkalemia. The **acid–base imbalances** may vary considerably from case to case and it is suggested that optimal fluid therapy should be based on laboratory evaluation of the animal's blood gas and electrolytes. **Hyperkalemia** may occur in severe acidosis. An increase in serum creatinine may be due to inadequate renal perfusion associated with the dehydration and circulatory failure.

Digestion/absorption tests

Digestion and absorption tests are available for the investigation of chronic malabsorptive conditions, particularly in the horse. Intestinal biopsy may be necessary for a definitive diagnosis of chronic intestinal lesions that cannot be determined by the usual diagnostic tests. Examples include intestinal lymphosarcoma, granulomatous enteritis and perhaps Johne's disease. Serum electrophoresis and the administration of radioactively labeled albumin may be necessary to determine the presence of a protein-losing enteropathy.

NECROPSY FINDINGS

The pathology of enteritis or malabsorption varies considerably depending on the cause. There may be an absence of grossly visible changes of the mucosa but the intestinal lumen will be fluid-filled or relatively empty, depending on the stage of examination in enterotoxigenic colibacillosis. When there is gross evidence of inflammation of the mucosa there will be varying degrees of edema, hyperemia, hemorrhage, foul-smelling intestinal contents, fibrinous inflammation, ulceration and necrosis of the mucosa. With acute necrosis there is evidence of frank blood, fibrinous casts and epithelial shreds. The mesenteric lymph nodes show varying degrees of enlargement, edema and congestion, and secondary involvement of spleen and liver is not unusual. In chronic enteritis, the epithelium may appear relatively normal but the wall is usually thickened and may be edematous. In some specific diseases there are lesions typical of the particular disease.

DIFFERENTIAL DIAGNOSIS

Approach

- The approach to the diagnosis of diarrhea requires a consideration of the epidemiological history and the nature and severity of the clinical findings. With the exception of the acute enteritides in newborn farm animals, most of the other common enteritides have reasonably distinct epidemiological and clinical features
- In some cases, a necropsy on an untreated case of diarrhea in the early stages of the disease can be very useful
- If possible, a hemogram should be obtained to assist in determining the presence or absence of infection

Appearance of feces

- The gross appearance of the feces may provide some clues about the cause of the diarrhea. In general, the diarrheas caused by lesions of the small intestine are profuse and the feces are liquid and sometimes as clear as water. The diarrheas associated with lesions of the large intestine are characterized by small volumes of soft feces, often containing excess quantities of mucus
- The presence of toxemia and fever-marked changes in the total and differential leukocyte count suggest bacterial enteritis, possibly with septicemia. This is of particular importance in horses and cattle with salmonellosis
- The presence of frank blood and/or fibrinous casts in the feces usually indicates a severe inflammatory lesion of the intestines. In sand-induced diarrhea in horses the feces may contain sand

Weight loss

- A chronic diarrhea with a history of chronic weight loss in a mature cow suggests Johne's disease
- Chronic weight loss and chronic diarrhea, or even the absence of diarrhea, in the horse may indicate the presence of granulomatous enteritis, chronic eosinophilic gastroenteritis, alimentary lymphosarcoma, tuberculosis and histoplasmosis

Dietary diarrhea and toxicities

- In dietary diarrhea the feces are usually voluminous, soft and odoriferous, the animal is usually bright and alert and there are minimal systemic effects. An examination of the diet will usually reveal if the composition of the diet or irregular feeding practices are responsible for the diarrhea. Analysis of samples of new feed may be necessary to determine the presence of toxic chemical agents
- Arsenic poisoning is characterized by dysentery, toxemia, normal temperature and nervous signs
- Copper deficiency conditioned by an excess of molybdenum causes a moderately profuse diarrhea with soft feces, moderate weight loss and there is usually normal hydration and possibly depigmentation of hair

Parasitism

- Intestinal helminthiasis such as ostertagiasis causes a profuse diarrhea and marked loss of weight; the temperature is normal and there is no toxemia

Miscellaneous causes

- In cattle, the oral cavity must be examined for evidence of lesions characteristic of viral diseases
- Many diseases of the stomach, including ulceration, parasitism, gastritis and tumors, may result in diarrhea and must be considered in the differential diagnosis of chronic diarrhea
- The soft scant feces associated with some cases of incomplete obstruction of the digestive tract of cattle affected with the complications of traumatic reticuloperitonitis must not be confused with diarrhea

TREATMENT

The principles of treatment of enteritis are:

- Removal of the causative agent
- Alteration of the diet
- Fluids and electrolytes
- Intestinal protectants and adsorbents
- Antidiarrheal drugs.

Removal of causative agent

Specific treatment is usually directed at intestinal helminthiasis with anthelmintics, antiprotozoan agents against diseases such as coccidiosis and antimicrobial agents against the bacterial enteritides. There are no specific treatments available for the viral enteritides in farm animals.

While considerable investigations have been done on the enteritides on farm animals, the emphasis has been on the immunology, pathology, microbiology and body fluid dynamics, each with different emphasis in different species. For example, there is considerable information on the microbiology and immunology of the common enteritides in calves and piglets in addition to the extensive knowledge of the body fluid dynamics in calves. In the horse there is some information on body fluid dynamics but the microbiology of the diarrheas is not well understood. In none of the species is there sufficient information on the effects of antibiotics on the intestinal microflora.

Antimicrobials

The use of antimicrobials, either orally or parenterally, or by both routes simultaneously, for the treatment of bacterial enteritides is a controversial subject in both human and veterinary medicine. Those who support their use in acute bacterial enteritis claim that they are necessary to help reduce the overgrowth of pathogenic bacteria responsible for the enteritis and to prevent or treat bacteremia or septicemia that may occur secondary to an enteritis. Those who suggest that they are contraindicated or unnecessary in bacterial enteritis suggest that the drugs may eliminate a significant proportion of the intestinal flora in addition to the pathogenic flora. This may reduce the effect of competitive antagonism in the intestine, which in turn may permit the development of a superinfection (the appearance of bacteriological and clinical evidence of a new infection during the chemotherapy of a primary one). Also, the use of antimicrobials in infectious enteric disease allows the development of **multiple drug resistance**, which is a major public health concern. The use of antimicrobials may also increase the length of time over which affected animals excrete the organisms which, for example, may occur in enteric salmonellosis.

Many different antimicrobial preparations for both oral and parenteral administration are available. The choice will depend on previous experience, the disease suspected and the results of culture and drug sensitivity tests. Parenteral preparations are indicated in animals with acute diarrhea, toxemia and fever. Many antimicrobials, when given parenterally, are excreted by the liver into the lumen of the intestine and oral preparations may not be necessary. In cases of subacute diarrhea with minimal systemic effects, the use of an oral preparation may be sufficient. However, oral preparations should not be used for more than 3 days to avoid a superinfection. The preparations and doses of the antimicrobials commonly used in bacterial enteritides are described under each disease.

Mass medication of feed and water supplies

Mass medication of the drinking water supply with antimicrobials for the treatment of outbreaks of specific infectious enteritides in animals is used commonly and with success. One of the best examples is the use of antimicrobials in the drinking water of pigs affected with swine dysentery. However, not all affected animals will drink a sufficient quantity of the medicated water and daily intake must be monitored carefully. Severely affected animals in an outbreak need individual treatment.

Alteration of the diet

If the cause of the diarrhea is dietary in origin the feed should be removed until the animal has fully recovered; feed should then be replaced by another source or reintroduced gradually. The question of whether or not a normally digestible diet should be removed temporarily or the total daily intake reduced in animals with acute enteritis is a difficult one. The rationale is that in acute enteritis the digestibility of nutrients is reduced considerably and undigested feed provides a substrate for fermentation and putrefaction to occur, the products of which may accentuate the malabsorptive state. However, temporary withdrawal of feed presents practical problems, especially in the young. For example, the temporary removal from the sow of newborn piglets affected with acute enteritis presents practical problems and is of doubtful value; similarly with beef calves nursing cows on pasture. With foals it is relatively easy to muzzle them for 24 hours. With weaned piglets affected with weanling diarrhea and feeder pigs with swine dysentery, it is common practice to reduce the normal daily intake by half for a few days until recovery is apparent. Mature horses affected with diarrhea should not have access to any feed for at least 24 hours. During the period of temporary starvation, the oral intake of fluids containing glucose and electrolytes is desirable and necessary to assist in maintaining hydration. In newborn calves with diarrhea, if oral fluid intake is maintained, the total loss of water from feces and through the kidney is not significantly greater than in normal calves because in diarrheic calves the kidney will effectively compensate for fecal losses. When recovery is apparent, the animal's usual diet may be reintroduced gradually over a period of a few days.

Fluids and electrolytes

The initial goals of fluid and electrolyte therapy for the effects of enteritis are: the restoration of the body fluids to normal volume, effective osmolality, composition and acid–base balance. The quality and quantity of fluids required to achieve these goals depend on the characteristics of the dehydration and acid–base electrolyte imbalance. Under ideal conditions when a laboratory is available, the determination of packed cell volume, total serum proteins, plasma bicarbonate, blood pH, serum electrolytes and a hemogram would provide the clinician with a laboratory evaluation initially and throughout the course of therapy, to assess the effectiveness of the treatment. However, such laboratory service is expensive and usually not readily available. The clinician must therefore assess the degree of clinical dehydration and, based on the history and clinical findings, estimate the degree of acidosis and electrolyte deficits that are likely to be present. A practical approach to fluid therapy in the horse has been described. Fluids should be given orally whenever possible to save time and expense and to avoid the complications that can arise from long-term parenteral fluid therapy. Also, fluids should be given as early as possible to minimize the degree of dehydration. With good kidney function there is a wider safe latitude in the solution used.

The three major abnormalities of **dehydration**, **acidosis** and **electrolyte deficit** are usually corrected simultaneously with fluid therapy. When severe acidosis is suspected, this should be corrected immediately with a hypertonic (5%) solution of bicarbonate given intravenously at the rate of 5–7 mL/kg BW at a speed of about 100 mL/min. This is followed by the administration of electrolyte solutions in quantities necessary to correct the dehydration. With severe dehydration, equivalent to 10% of BW, large amounts of fluids are necessary.

Animal	Dehydration (%)	Fluid deficit (L)
500 kg horse	10	50
75 kg foal	10	7.5
45 kg calf	10	4.5

The initial hydration therapy should be given over the first 4–6 hours by continuous intravenous infusion, followed by maintenance therapy for the next 20–24 hours, or for the duration of the diarrhea if severe, at a rate of 100–150 mL/kg BW/24 h. Horses with acute enteritis have severe hyponatremia and following fluid therapy may become severely hypokalemic, as evidenced by weakness and muscular tremors. The hypertonic solution of sodium bicarbonate will assist in correcting the hyponatremia but potassium chloride may need to be added to the large quantity of fluids given for dehydration; 1 g of potassium chloride added to each liter of fluid will provide an additional 14 mosmol/L (14 mmol/L) of potassium. In preruminant calves with diarrhea, the fluids and electrolytes required for maintenance may be given orally in divided doses every few hours. In the early stage of acute diarrhea and for animals that are not severely dehydrated, the oral route can also be used successfully to correct dehydration and prevent it from becoming worse. The formulae of oral glucose–electrolyte solutions are given in the section under colibacillosis. Piglets and lambs affected with dehydration are most effectively treated using balanced electrolyte solutions given subcutaneously at the dose rates of 20 mL/kg BW every 4 hours and orally at 20 mL/kg BW every 2 hours. Details of the treatment of fluid and electrolyte disturbances are given under that heading in Chapter 2.

Intestinal protectants and adsorbents

Kaolin and pectin mixtures are used widely to coat the intestinal mucosa, inhibit secretions and increase the bulk of the feces in animals with enteritis. In children with diarrhea, kaolin and pectin will result in formed rather than watery feces, but the water content of the feces is unchanged. It is not possible at this time to make a recommendation on their use in animals.

Antidiarrheal drugs

Antimotility drugs

Anticholinergic drugs and opiates are available to decrease intestinal motility. The anticholinergic drugs block the action of acetylcholine on smooth muscle and glands. This results in decreased gastric secretion and emptying and a reduction on both segmental and propulsive movements of the intestines. Dosages of anticholinergics necessary to produce effectiveness may also cause side effects such as xerostomia, photophobia, tachycardia, urinary retention and neuromuscular paralysis. The opiates function by producing an increase in segmentation while reducing propulsive movements in the intestine. The net effect is an increase in resistance to passage of intestinal contents and more complete absorption of both water and nutrients occurs with a subsequent decrease in the frequency of defecation. There are no published reports of clinical trials using antimotility drugs for the treatment of diarrhea in farm animals and at the present time, therefore, they cannot be recommended with any assurance of effectiveness.

Antisecretory drugs

Antisecretory drugs are also available for the treatment of diarrhea due to the hypersecretory activity of enterotoxin produced by bacteria such as enterotoxigenic *E. coli*. Loperamide hydrochloride given orally to calves with experimentally induced diarrhea can delay the onset of diarrhea by its inhibition of fluid secretion. Antisecretory drugs include chlorpromazine, opiates, atropine and prostaglandin inhibitors. These have not yet been adequately evaluated and the provision of balanced fluids and electrolytes, containing sodium chloride, sodium bicarbonate, potassium chloride and glucose, given both parenterally and orally, are considered to be adequate and effective for treating the effects of the hypersecretion.

Because prostaglandins have an important reparative role in the intestine, NSAIDs may retard recovery of ischemic-injured intestine and are contraindicated.[9]

CONTROL

The control and prevention of enteritis in farm animals is a major topic and activity of large-animal practice. The control of each specific enteritis is presented under each specific disease in Part II of this book. The principles of control include the following:

- Reduce infection pressure by controlling population density
- Ensure adequate nonspecific resistance by adequate colostrum intake of neonatal farm animals and maintaining adequate nutritional status
- Vaccinate for those diseases for which there is an effective vaccine
- Minimize managemental and environmental stressors
- Monitor morbidity and mortality and ensure that a diagnosis is obtained so that control measures for newly introduced diseases into a herd can be instituted.

ACUTE DIARRHEA OF ADULT (NONSUCKLING) HORSES

Etiology *Salmonella* spp., *Strongylus* spp., cyathostomes, *Neorickettsia* (*Ehrlichia*) *risticii*, *Clostridium* spp., antibiotic administration, idiopathic
Epidemiology Usually a sporadic disease of young horses, often temporally associated with mild respiratory disease or a stressful event such as transport. Helminthiasis has a seasonal distribution and can occur as a herd problem. *N. risticii* has a defined geographical distribution
Clinical signs Acute onset of profuse watery diarrhea. Depression, fever, dehydration and anorexia are common
Clinical pathology Leukopenia, hemoconcentration, hyponatremia, hypokalemia or hyperkalemia, metabolic acidosis. IFA or PCR for *N. risticii*, fecal culture of *Salmonella* spp. may be positive. Fecal culture for *Clostridium* spp. and ELISA to demonstrate toxin in feces
Lesions Colitis with or without enteritis
Diagnostic confirmation Cause is frequently not confirmed
Treatment Intense supportive care including maintenance of hydration and correction of acid–base and electrolyte abnormalities. Oxytetracycline for equine monocytic ehrlichiosis. Metronidazole for *C. difficile*-associated diarrhea
Control None

ETIOLOGY

Causes are as follows:

- **Salmonellosis:** Various *Salmonella* spp.

- **Helminthiasis:** *Strongylus* sp., cyathostomes
- **Equine monocytic ehrlichiosis** (Potomac horse fever Equine neorickettsiasis): *Neorickettsia risticii*
- **Antibiotic administration:** macrolides (lincomycin, tylosin, erythromycin), tetracyclines, ciprofloxacin, trimethoprim–sulfonamide combination, penicillin, aminoglycosides, ceftiofur, and others
- **Intestinal clostridiosis:** *C. perfringens* (types A and C),[1] toxigenic strains of *C. difficile*[2] and possibly *Clostridium cadaveris*
- **Aeromonas spp.**: Isolated from horses with diarrhea, definitive role as a causative agent has not been demonstrated[3]
- **Colitis-X:** Idiopathic.

E. coli does not appear to be an important cause of diarrhea in adult horses.[4]

In most cases (65%) of acute diarrhea in horses the cause is not determined, or if the cause is determined it is frequently at necropsy examination or after the horse has recovered.[5]

EPIDEMIOLOGY

Occurrence

The syndrome of acute diarrhea occurs **worldwide** in adult horses of all breeds and both sexes. The pattern of occurrence of the syndrome is dependent on the causative factors, with **equine monocytic ehrlichiosis** (equine neorickettsiasis), associated with *N. risticii*, having a geographical distribution and **acute cyathostomiasis** having a seasonal distribution. Salmonellosis can occur sporadically or as outbreaks in stables, barns and veterinary hospitals. *C. difficile* enterocolitis is associated with hospitalization and/or antibiotic administration to adult horses.[2] The disease also occurs in foals.

Colitis-X is usually a sporadic disease, but multiple cases can occur in a barn or racing stable over a period of weeks and cause considerable economic hardship. With the exception of salmonellosis, equine monocytic ehrlichiosis, strongylosis and colitis-X, the syndrome is characterized by a **sporadic** distribution. Estimates of incidence, morbidity and mortality are not available for all diseases.

The **case fatality rate** for the spontaneous disease can be 25–50% even in intensively treated horses.[5–8] The case fatality rate is higher for horses with *C. difficile*-induced diarrhea than for horses with acute diarrhea of other causes[2] and for horses with antibiotic-induced diarrhea.[8] The prognosis is worse in horses with tachycardia, severe dehydration (PCV > 45% (0.45 L/L)), azotemia, metabolic acidosis, low serum albumin concentration or higher immature neutrophil (band cell) count in peripheral blood.[6–8]

Risk factors

The risk factors for salmonellosis, equine monocytic ehrlichiosis and strongylosis are addressed under those topics.

Stress

Stressful episodes, such as shipping or racing, hospitalization, surgery, administration of antibiotics or mild respiratory disease, frequently precede the onset of diarrhea.[6]

Celiotomy

Celiotomy for colic is associated with an incidence of severe diarrhea of up to 27% in surviving horses.[9] The risk of diarrhea is greatest in horses with large-colon disease or with enterotomy, but is not influenced by the type of antibiotic administered after surgery.[9]

Antibiotic administration

Antibiotic administration is associated with acute diarrhea in horses. The macrolide antibiotic **lincomycin** causes acute, often fatal, disease of horses even when administered at relatively low doses, such as that resulting from horses ingesting medicated pig feed.[10] **Tetracyclines** have been associated with the development of acute diarrhea but, when given intravenously at therapeutic doses (6.6 mg/kg every 12–24 h) are probably no more likely to cause diarrhea than other broad-spectrum antibiotics. Tetracycline contamination of feed causes outbreaks of diarrhea on horse farms.[11] **Ciprofloxacin** might be a cause of diarrhea in horses.[12] The combination of **trimethoprim and sulfadiazine** given orally causes diarrhea in 7% of hospitalized horses, whereas pivampicillin, a prodrug of ampicillin, causes diarrhea in 3%.[13] However, horses treated with trimethoprim–sulfadiazine combinations are not at greater risk of developing diarrhea than horses treated with penicillin.[14] Almost all adult horses with diarrhea from which *C. difficile* or its toxin can be isolated were administered antibiotics before onset of diarrhea.[15]

PATHOGENESIS

Diarrhea is the result of abnormalities in colonic water and electrolyte metabolism. Approximately 90 L of isotonic fluid enters the colon of an adult (450 kg) horse every 24 hours, and any disruption to the normal absorption of this fluid results in increased fecal water and electrolyte excretion. Colitis results from physical, chemical or infectious causes that induce inflammation in the colon. The proximate causes vary with the etiology of the disease. For example, colitis due to infection by toxigenic strains of *C. perfringens* type C is attributable to binding of beta-2 toxin to colonic mucosa,[16] whereas colitis due to salmonellosis is associated with invasion of the organism and loss of colonic mucosa. Colitis is associated with increased production of inflammatory cytokines, including tumor necrosis factor, in the colon,[17] and with impaired mucosal absorptive function. Additionally, bacterial toxins and inflammation result in an increase in mucosal permeability with loss of plasma proteins into the colonic lumen and systemic absorption of toxins, including endotoxin. Loss of plasma proteins causes a reduction in plasma colloidal oncotic pressure with subsequent extravasation of water and electrolytes and development of edema and decreased effective intravascular volume (hypovolemia). The effect of the decrease in oncotic pressure becomes most apparent in horses that are treated aggressively with fluids. These horses, which often receive excessive amounts of sodium, rapidly develop edema of the ventral body wall and colon, among other tissues. Loss of other plasma proteins, including antithrombin III, and absorption from the gut of activators of coagulation, fibrinolysis or inflammation, may contribute to the disseminated intravascular coagulation often observed in horses with enterocolitis.

The large volume of diarrhea in horses causes a reduction in body water and electrolyte content. Hypovolemia, hyponatremia, hypochloremia and hypoproteinemia develop. Derangements in acid–base and electrolyte status impair gastrointestinal motility. Hypovolemia impairs perfusion of peripheral tissues, which, combined with absorption of endotoxin through the damaged colonic mucosa, results in toxemia, lactic acidosis and death.

CLINICAL SIGNS

The onset of clinical signs is usually abrupt, although in some horses diarrhea may be presaged for up to several days by inappetence, mild depression and a mild fever. The disease varies in severity from short-lived with mild to moderate diarrhea and minimal systemic signs of disease to a fulminant disease with death in hours. The description here is of the more severe forms of the disease. Once diarrhea occurs there is **rapid progression**, with some horses dying within 12 hours of initial clinical signs, although most survive at least 24 hours. In a peracute form of the disease horses die, often within 6 hours, before developing diarrhea.

Typically horses are often severely depressed and stand with their heads down. They may play in water, but rarely eat or drink. Horses are usually mildly

pyrexic (101.5–103°F, 38.6–39.5°C) but markedly tachycardic (80–100 bpm), tachypneic (30–40 bpm) and dehydrated (8–12%). There is slow capillary refill of mucous membranes, which are usually bright red initially and then become bluish-purple as toxemia and dehydration become severe. The development of a purple line at the gingival margins is a sign of a poor prognosis. Most horses are oliguric.

The diarrhea is profuse and watery. **Abdominal pain** is usually present but mild; the onset of severe abdominal pain is often associated with necrosis of the large colon or cecum and impending death. **Rectal examination** reveals large amounts of fluid feces with minimal distension of the large colon.

Complications of acute, severe enterocolitis include laminitis, thrombophlebitis of the jugular veins, **thrombosis** of vessels including arteries in the limbs.[18] renal failure, pulmonary aspergillosis[19–21] and necrotizing enterocolitis.[22] Laminitis develops within 1–3 days of onset of diarrhea in approximately 10% of cases and can occur in any horse with enterocolitis, but is most common in horses with Potomac horse fever (equine monocytic ehrlichiosis). Thrombophlebitis, which may or may not be septic, usually affects veins, usually jugular, that have or have had catheters placed or are the site of frequent intravenous injections. Thrombosis of the vein can occur several days to a week after removal of the catheter, although most occur while the catheter is in place. Renal failure occurs as a result of the combined insults of hypovolemia, endotoxemia and administration of nephrotoxic drugs, including aminoglycosides and NSAIDs. Pulmonary aspergillosis is usually clinically inapparent.[20] Clinically affected horses have rapidly progressive toxemia, respiratory distress, hypoxemia and blood-tinged, frothy nasal exudates. Fatal necrotizing enterocolitis of horses is characterized by a brief course, most horses dying within 48 hours of onset of diarrhea, profound dehydration, electrolyte derangements, severe metabolic acidosis and, terminally, severe abdominal pain.[22]

Most horses that survive have resolution of diarrhea in about 7 days, although a small but clinically important proportion develop chronic diarrhea.

CLINICAL PATHOLOGY

Hematological examination reveals an increased hematocrit (45–60%), variable changes in plasma protein concentration and neutropenia with a marked left shift. As the disease progresses and horses are treated by intravenous administration of fluids, plasma protein concentrations and plasma oncotic pressure decline. Plasma or serum albumin concentration may be as low as 1.2 g/dL (12 g/L). Changes in **coagulation and fibrinolysis** are evident as increases in one or more of one-stage prothrombin time, activated partial thromboplastin time and concentration of fibrin degradation products, variable changes in plasma fibrinogen concentration and a reduction in blood platelet concentration.[23] Approximately one-third of horses hospitalized for treatment of severe diarrhea have subclinical evidence of disseminated intravascular coagulation,[23] which carries a reduced likelihood of recovery.

Serum biochemical analysis usually reveals hyponatremia, hypochloremia, variable changes in serum potassium concentration, hypocalcemia (both concentrations of ionized and total calcium[24]), azotemia (increased serum urea nitrogen and creatinine concentrations), hyperphosphatemia and increased activities of enzymes indicative of muscle (creatine kinase) or intestinal damage (aspartate aminotransferase and alkaline phosphatase).

Blood gas analysis often reveals a severe metabolic acidosis, and the more negative the base excess the worse the prognosis.[7] Interpretation of acid–base status in horses with severe enterocolitis is difficult because of the opposing effects of hypoproteinemia and combination of lactic acidosis and electrolyte loss on blood pH. Hypoproteinemia causes a metabolic alkalosis whereas increases in plasma lactate concentration and hyponatremia cause metabolic acidosis. The presence of hypoproteinemia therefore tends to diminish the effect of lactic acidosis on blood pH, which underestimates the severity of the acidosis. Acid–base status in horses with severe abnormalities in plasma protein concentration should be ascertained by examination of base excess, strong ion gap or strong ion difference.[25]

Plasma endothelin concentrations are higher in horses with enterocolitis than in normal horses,[26] although the clinical significance of this finding is unclear.

Abdominal fluid is usually normal initially but becomes bloody and has an increased white blood cell count and protein concentration if intestinal necrosis occurs.

DIAGNOSTIC CONFIRMATION

This depends on the results of fecal culture for *Salmonella* sp., fecal examination for helminth eggs or larvae, and indirect fluorescent antibody (IFA) or polymerase chain reaction (PCR) tests for *N. risticii*. Demonstration of large numbers of salmonellae in feces on multiple fecal samples, or in lymph nodes of horses dying of the disease, is persuasive evidence that the horse had **salmonellosis**. However, demonstration of low numbers of salmonellae in a single fecal culture is not definitive evidence that *Salmonella* sp. infection was the cause of the horse's diarrhea. **Fecal examinations** for helminth eggs may be negative in cases of **acute cyathostomiasis**, although large numbers of fourth stage larvae may be present in the feces. Diagnosis of *N. risticii* infection is based on a positive IFA test. Isolation of *Clostridium* sp. *and* demonstration of **clostridial enterotoxin** in feces of horses with acute diarrhea supports a diagnosis of intestinal clostridiosis, although demonstration of toxin alone is usually considered sufficient evidence for diagnosis.[27] **Latex agglutination tests** are available for the detection of *C. perfringens* type A and *C. difficile* toxins.[1,28]

NECROPSY

There are extensive lesions at necropsy examination, the most dramatic being in the large intestine, especially the cecum and ventral colon. These include hyperemia, extensive petechiation, and edema of the gut wall in the early stages, and later an intense, greenish black, hemorrhagic necrosis. The contents are fluid, often foamy and foul-smelling, and may be bloodstained.

Histological examination demonstrates mucosal necrosis with a fibrinohemorrhagic exudate and extensive inflammation of the mucosa and submucosa.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:

- Salmonellosis
- Equine monocytic ehrlichiosis (equine neorickettsiasis) (Potomac horse fever)
- Cyathostomiasis
- Antibiotic-induced diarrhea
- *Clostridium* sp. infection (*C. difficile*)
- Colitis-X
- Intoxication with inorganic arseni, cantharidin or purgatives such as castor oil
- The incipient disease in horses before onset of diarrhea can resemble colon torsion or ischemia of the large colon secondary to verminous arteritis

TREATMENT

Horses with mild disease, those that do not manifest systemic signs of disease, usually recover with symptomatic treatment. However, horses with severe disease require more specific treatment and supportive care, which is often intensive and expensive.

The **principles of treatment** for horses with acute diarrhea are:

- **Restoration and maintenance of normal hydration**
- **Correction of electrolyte and acid–base abnormalities**
- **Provision of analgesia**
- **Prophylaxis and treatment of the effects of endotoxemia**
- **Prevention of absorption of toxins**
- **Correction and prevention of disseminated intravascular coagulation.**

Restoration of hydration

Restoration of hydration should be considered an **emergency procedure** in severely affected horses. Fluids should be administered intravenously until hydration is restored, after which hydration can be maintained by either oral (via nasogastric tube) or intravenous administration of fluids. Suitable fluids for restoration of hydration are sodium-rich, isotonic, preferably polyionic, electrolyte solutions such as **lactated Ringer's** or Ringer's solution. **Isotonic sodium chloride** is also suitable. Isotonic dextrose solutions are not suitable because they do not contain any electrolytes. After correction of dehydration, attention should be paid to sodium balance because administration of excessive quantities of sodium, especially to horses with plasma oncotic pressure that is lower than normal, may cause expansion of the extracellular fluid volume and edema.

Fluid therapy is discussed elsewhere. **Maintenance of hydration** in severely affected horses can be challenging and is best accomplished by intravenous administration of fluids. **Oral administration** of fluids to horses with diarrhea, although not providing ideal rehydration or maintenance of hydration, may be effective and less costly than intravenous administration.[29–31]

Horses that become hypoproteinemic may require **transfusions of plasma**. Clinical signs indicating the need for transfusion include a persistently elevated heart rate and poor peripheral perfusion in spite of administration of large quantities of fluids. Ventral edema and edema of the head and legs may develop in hypoproteinemic horses. Sufficient plasma should be administered to restore the plasma protein concentration to at least 40 g/L.

Electrolyte and acid–base status

Hyponatremia and hypochloremia will usually be corrected by administration of isotonic, sodium-rich electrolyte solutions such as lactated Ringer's solution. If this does not occur, then sodium chloride or sodium bicarbonate can be added to the intravenous fluids, or given orally. **Hypocalcemia** can be corrected by the addition of calcium gluconate (20 mL of 23% calcium gluconate per liter of fluids) to the fluids, provided that the fluids do not contain sodium bicarbonate. The mixture of sodium bicarbonate and calcium gluconate causes calcium to precipitate out of solution. Affected horses have **total body potassium depletion**,[32] even though serum potassium concentrations may be normal or elevated, and maintenance fluids should contain potassium at up to 25 mEq/L. Fluids with high potassium concentration should be administered slowly. Alternatively, potassium chloride can be given orally (50–100 g per 450 kg every 12 h).

The **metabolic acidosis** in horses with acute diarrhea often resolves either partially or completely when hydration is restored. However, severe acidosis can be treated with intravenous **sodium bicarbonate**. Oral administration of sodium bicarbonate (100 g per 450 kg every 8–12 h) is often adequate in restoring and maintaining normal acid–base status. The serum sodium concentration should be monitored if large quantities of sodium bicarbonate are administered.

Antimicrobial therapy

Administration of tetracycline to horses with acute diarrhea associated with *N. risticii* is clearly indicated and is often curative. However, the administration of antimicrobial drugs to horses with acute diarrhea other than that associated with *N. risticii* is controversial. There is no evidence that administration of antimicrobials improves the prognosis of horses with acute diarrhea.[7,33] The concern with antimicrobial administration is that antimicrobials may exacerbate the diarrhea in some cases. Conversely, withholding antimicrobials from severely ill horses with damaged colonic mucosa, and therefore presumably increased risk of bacteremia, is problematic. Regardless, many clinicians chose to treat horses with acute diarrhea with broad-spectrum antibiotics such as the combination of potassium penicillin (20 000 IU/kg, intravenously every 6 h) and gentamicin (7 mg/kg intravenously or intramuscularly every 24 h) or trimethoprim and sulfadiazine (30 mg/kg intravenously or orally every 12 h). Metronidazole (15–20 mg/kg orally every 6–12 h) or vancomycin have been recommended for horses with intestinal clostridiosis, although the wisdom of veterinary use of vancomycin, a drug used for the treatment of methicillin-resistant staphylococci in humans, could be questioned.[34] In areas in which **equine monocytic ehrlichiosis** (equine neorickettsiasis) is endemic, all suspected cases should be treated with tetracycline (6.6 mg/kg intravenously every 12 h for 3 d), or another effective antibiotic, pending confirmation of the disease. Isolates of toxigenic *C. difficile* from horses with diarrhea are almost always susceptible to metronidazole (15–29 mg/kg orally every 6–12 h).[15]

Prophylaxis and treatment of endotoxemia

Treatment of endolemma has been recently reviewed.[35] Administration of plasma from horses **hyperimmunized** with *Salmonella typhimurium* or *E. coli* reduces the severity of clinical signs and shortens the duration of disease in horses with endotoxemia secondary to enterocolitis or colic.[36] **Polymyxin** (5000 IU/kg intravenously every 12 h) attenuates the effect of endotoxin in experimental disease and is used for the prevention and treatment of endotoxemia in hospitalized horses.[37] Its efficacy in clinical settings has not been determined. **Aspirin** (10 mg/kg orally every 48 h) is administered to diminish platelet aggregation around intravenous catheters. **Flunixin meglumine** (1 mg/kg intravenously every 8–12 h) or **phenylbutazone** (2.2 mg/kg intravenously every 12 h) is given for analgesia and to prevent endotoxin-induced increases in plasma prostaglandins. **Pentoxifylline** (8 mg/kg orally every 8 h) is administered for its putative effective in attenuating the effects of endotoxemia. The efficacy of these treatments in a clinical setting and their effect on measures of outcome of disease, such as duration of illness, case fatality rate and incidence of complications, has not been determined, with the exception of hyperimmune plasma or serum.[36]

Binding of toxins

Smectite or activated charcoal are sometimes administered to horses with acute enterocolitis in an attempt to adsorb toxins, such as those produced by *Clostridium* spp., and prevent systemic absorption. There is in-vitro evidence that smectite may bind clostridial toxins and endotoxin,[38] but evidence of efficacy in vivo is lacking.

Disseminated intravascular coagulation

Prevention and treatment of disseminated intravascular coagulation includes monitoring for changes in variables indicative of coagulation and fibrinolysis including D-dimer concentration, antithrombin III activity, one-stage prothrombin and activated partial thromboplastin times, platelet count and fibrinogen concentration. Plasma can be administered to increase blood antithrombin III activity,

often in conjunction with heparin or low-molecular-weight heparin (dalteparin or enoxaparin). Doses of 50 U of dalteparin or 40 U of enoxaparin per kilogram subcutaneously every 24 hours seem to be adequate for prophylactic anticoagulatory treatment of horses. For treatment of coagulation disorders or for ill horses that are considered to be at high risk of developing thrombotic disease, dosages may need to be increased to 100 U of dalteparin or 80 U of enoxaparin per kilogram subcutaneously every 24 hours.[39]

CONTROL

Specific control measures for *Salmonella* spp. infection, equine monocytic ehrlichiosis and cyathostomiasis are discussed under those headings. The incidence of antibiotic-induced colitis can be reduced by minimizing the frequency with which antibiotics are administered to horses.

CHRONIC UNDIFFERENTIATED DIARRHEA OF HORSES

Synopsis

Etiology Common sign of many enteric and non-enteric diseases
Epidemiology Sporadic disease of adult horses, except for cyathostomiasis and salmonellosis, which are discussed under those headings
Clinical signs Passage of unformed or liquid feces, either in increased or normal quantities. Weight loss, increased appetite. Otherwise normal physical examination. Rectal examination is usually normal
Lesions Colitis in most cases
Diagnostic confirmation Examination of feces for cyathostome larvae, rectal biopsy demonstrating lymphoma or granulomatous enteritis, *Salmonella* spp. in rectal mucosal biopsy or feces. Sand in feces or evident on abdominal radiography
Treatment Supportive: anthelmintics, corticosteroids, antidiarrheal preparations
Control As for cyathostomiasis and salmonellosis

ETIOLOGY

Chronic diarrhea is the **final common sign** of a number of causes of colonic dysfunction in horses. Diseases that cause chronic (more than 2 weeks duration) diarrhea in horses include: cyathostomiasis, chronic idiopathic colitis, salmonellosis, alimentary lymphosarcoma, granulomatous colitis, eosinophilic colitis, ingestion of sand, chronic liver disease, peritonitis, lymphangiectasia and as a sequela to acute diarrhea. Immune deficiency, including variable adult onset B-cell deficiency, may predispose to the disease.[1] *Brachyspira* sp. have been implicated as a cause of chronic diarrhea in horses in Australia and Japan.[2,3]

There are many causes and their relative importance varies between locations. Even with concerted effort, a definitive antemortem diagnosis is achieved in fewer than 30% of cases.[4]

EPIDEMIOLOGY

The occurrence is sporadic, with only single cases occurring in a group. Other horses in contact are not affected. The case fatality rate is 35–65%.[5] There appears to be no age-related, sex-related or breed-related variation in incidence. Older horses do not appear to be at increased risk of having chronic diarrhea.[6] The epidemiology of cyathostomiasis and salmonellosis are discussed under those headings.

PATHOGENESIS

Diarrhea is attributable to colonic dysfunction, which may result in excessive loss of electrolytes in feces and diminished absorption of nutrients from the large colon. Disease of exclusively the small intestine does not cause diarrhea in horses. Protein-losing enteropathy may be present. Colonic dysfunction may be associated with inflammatory or infiltrative lesions of the colon but in many cases an anatomical lesion is not detected. However, the colonic contents of affected horses have a greater fermentative capacity than those of normal horses, suggesting that in some horses the disease is essentially one of abnormal colonic digestion and absorption.[7]

CLINICAL FINDINGS

The characteristic finding is chronic diarrhea. The feces vary in consistency from thick porridge (oatmeal), through undigested fibers in liquid, to liquid without fiber. The consistency of the feces in an individual horse may vary widely from one day to the next. The duration of the diarrhea is variable but may be lifelong. Death or euthanasia usually results from progressive weight loss. The onset of diarrhea is usually abrupt and may be associated with signs of toxemia and dehydration, as described under Acute diarrhea, above. However, often there is no toxemia or other systemic sign apart from weight loss, and affected horses are bright and alert and have a normal or increased appetite.

Rectal examination usually fails to reveal any abnormalities, although horses with granulomatous enteritis or alimentary lymphosarcoma may have enlarged mesenteric lymph nodes.

Abdominal radiography may reveal the presence of excessive amounts of sand in the large colon.

CLINICAL PATHOLOGY

- Hematological examination may reveal a mild **neutrophilia** and **anemia**, but these changes are of little use in determining the etiology of the diarrhea
- Serum biochemical examination typically demonstrates a mild **hypoalbuminemia**, **hypoglobulinemia**, **hyponatremia** and **hypokalemia**, but again these changes are not specific for any particular disease
- Hypoalbuminemia is consistent with the presence of protein-losing enteropathies such as chronic colitis, alimentary lymphosarcoma, cyathostomiasis and granulomatous colitis

- **Hyperbilirubinemia** and elevated serum concentrations of **serum bile acids** are suggestive of liver disease
- Increases in **serum alkaline phosphatase** activity, while common, are of no diagnostic utility
- Horses with cyathostomiasis may have increased concentrations of beta-globulins, although the sensitivity of this test is low.[5]

Peritoneal fluid has a neutrophilic leukocytosis and increased (>25 g/L) protein concentration in horses with peritonitis but is normal in most horses with chronic diarrhea, including those with alimentary lymphosarcoma or granulomatous colitis.

Fecal examination of horses with cyathostomiasis may reveal strongyle-type ova or fourth-stage cyathostome larvae. The presence of **sand** in feces, demonstrated by allowing feces to settle in a transparent rectal glove or similar container, suggests sand accumulation in the colon as a cause of the diarrhea. The presence of **protozoa** in feces has no diagnostic significance.[8] ***Giardia* spp.** are commonly found in feces of normal horses of all ages and, despite earlier reports of their presence in feces of horses with diarrhea, they are not associated with disease.[9] **Coccidiosis** is very uncommon in horses, and *Eimeria leuckarti* is probably not pathogenic.[10]

Demonstration of *Salmonella* spp. in feces or rectal mucosal biopsy, either by culture or PCR, is suggestive but not diagnostic of salmonellosis, given the high proportion of normal horses that shed *Salmonella* spp. in feces. Isolation of *Rhodococcus equi* from feces of young horses with diarrhea is suggestive of enteric disease associated with that organism.

An abnormal **D-xylose**, **glucose** or **starch absorption test** indicates small-intestinal disease and is suggestive of granulomatous enteritis, although most horses with this disease do not have diarrhea.

Exploratory laparotomy, either ventral midline under general anesthesia or through the left flank under local anesthesia, and **intestinal biopsy** may demonstrate alimentary lymphosarcoma, granulomatous enteritis, eosinophilic enteritis, chronic colitis and other abdominal disease. **Rectal biopsy** is less expensive and invasive but has a relatively poor sensitivity, although good specificity for granulomatous enteritis, eosinophilic enteritis and alimentary lymphosarcoma.[11]

NECROPSY FINDINGS

Necropsy findings are consistent with the underlying disease, although in many cases gross lesions are not evident. The histological changes in some cases are restricted to a mild inflammatory response and may be difficult to correlate with the severity of clinical disease. In some of these cases the diarrhea probably reflects an imbalance in the microflora of the large bowel, and demonstration of a specific etiological agent is an unrealistic goal. Conversely, isolation of *Salmonella* spp. from the gastrointestinal tract or mesenteric lymph nodes should be interpreted with caution in the absence of histological evidence of salmonellosis.

Because of the wide variety of potential causes of chronic diarrhea of horses it is not possible to list all the samples required to 'confirm' a diagnosis. In most instances, formalin-fixed samples from the liver, mesenteric lymph nodes and numerous levels of the gastrointestinal tract comprise the minimum diagnostic material required. Regardless of what other testing is performed, it is prudent to hold back frozen segments of both large and small bowel (with content) in case other tests are deemed necessary.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:

- Chronic idiopathic colitis
- Salmonellosis
- Cyathostomiasis
- Granulomatous colitis
- Sand ingestion[12]
- Lymphosarcoma
- Peritonitis
- Intestinal lymphangiectasia
- Hyperlipemia
- Liver disease
- Basophilic enteritis
- Eosinophilic gastroenteritis.

TREATMENT

The **principles of treatment** are to deal with the underlying disease, correct fluid and electrolyte disturbances, give symptomatic treatment of diarrhea and provide supportive care. Except in cases of cyathostomiasis or sand accumulation, treatment of horses with chronic diarrhea is frequently unrewarding.

Specific treatments

Cyathostomiasis should be treated with larvicidal doses of anthelmintics such as fenbendazole (50 mg/kg once, or 7.5 mg/kg daily for 3 d), moxidectin (400 μg/kg) or ivermectin (200 μg/kg). Treatment may be unrewarding if there is severe damage to the large colon.

Diarrhea secondary to **sand accumulation** in the gastrointestinal tract should be treated by preventing the horse from ingesting sand and, although the efficacy is debatable, with psyllium mucilloid (1–2 g/kg orally once daily for 4–5 weeks.

Chronic idiopathic colitis may be treated with corticosteroids (dexamethasone 0.2–0.4 mg/kg once daily) or prednisolone (0.5–1.0 mg/kg once daily) for 3–4 weeks and the dose reduced as clinical signs permit.

Chronic salmonellosis has been treated with enrofloxacin (2.5–5 mg/kg orally every 12 h for 3–4 weeks), sometimes in combination with metronidazole (15–20 mg/kg orally every 6–12 h), but one should be aware of the risk of articular cartilage damage in horses treated with enrofloxacin.

Many diseases commonly associated with chronic diarrhea are not treatable.

Symptomatic and supportive treatments

Symptomatic treatments include **metronidazole** (7.5–20 mg/kg orally every 6–12 h) or **iodochlorhydroxyquin** (10–20 mg/kg orally once daily). While some horses have resolution of diarrhea while being treated with these compounds, there is no clear demonstration of their efficacy. **Antibiotic** administration, other than as described above, does not usually alter the course of the disease. **Antidiarrheal** preparations such as codeine phosphate, **loperamide** and **bismuth subsalicylate** often provide temporary improvement in fecal consistency. Some horses with chronic diarrhea respond to **transfaunation**, whereby 5–10 L of colonic fluid collected immediately after death from a horse without enteric disease is administered via nasogastric intubation.

Supportive treatment includes provision of supplemental electrolytes, principally sodium, potassium and bicarbonate, as a feed additive. Suitable supplements include some commercial products designed for fluid replacement in diarrhetic calves, or a mixture of potassium chloride (300 g), sodium chloride (400 g) and sodium bicarbonate (300 g). This mixture is isotonic when dissolved at the rate of 90 g/12 L, or can be given orally at the rate of 30–90 g per 400 kg horse every 24 hours. Unsupplemented water should be supplied without restriction and serum electrolyte concentrations should be monitored. **Severely affected** horses may require intravenous administration of polyionic isotonic electrolyte solutions or plasma.

Nutritional support should include provision of a diet of high-quality roughage and grain. Some trials may be needed to determine the diet that is best for individual horses, but care should be taken that the diet contains adequate energy and is nutritionally balanced. Horses should be fed to attain, and then maintain, an ideal body weight.

Spontaneous recovery does occur, particularly in young horses, and this, and the often lengthy duration (6–12 months) of the illness, make it difficult to decide accurately the value of the treatment.

CONTROL

Control of cyathostomiasis and salmonellosis is discussed under those headings. Diarrhea due to sand accumulation in the colon should be prevented by not feeding horses on the ground and by avoiding grazing of short pastures on sandy soil.

ACUTE DIARRHEA OF SUCKLING FOALS

ETIOLOGY

The causes of diarrhea in suckling foals are listed in Table 5.16. In a large proportion of foals the cause of diarrhea is not determined, in part because the

Table 5.16 Epidemiological and clinical features of suckling foals with diarrhea

Etiological agent or disease	Important epidemiological factors	Major clinical findings; *diagnostic criteria*
Idiopathic		
Foal heat diarrhea	Foals < 2 weeks of age.	No systemic signs of disease. Diarrhea is mild and pasty. No specific diagnostic criteria
Bacterial causes		
Septicemia (coliforms, *Actinobacillus* sp., *Salmonella* sp., *Klebsiella* sp. and others)	Newborn foal to < 2 weeks of age. Failure of transfer of passive immunity	Signs of systemic sepsis in addition to diarrhea. Fever, depression, recumbency, failure to nurse, swollen joints, pneumonia, omphalitis or omphalophlebitis. *Blood culture*
Salmonella sp.	Outbreaks in newborn foals, even those with adequate passive immunity. Mare likely carrier. Hygiene at parturition may prevent disease	Acute onset diarrhea, depression, fever, toxemia. *Culture of blood and feces*
Escherichia coli	Not well documented disease in foals (cf. calves and piglets)	Nonfetid diarrhea. *Culture of feces yields heavy growth of mucoid* E. coli (*circumstantial evidence only*)
Enterococcus (*Streptococcus*) *durans*	Young foals. Disease is rarely reported	Diarrhea. *Demonstration of S. durans in feces*
Rhodococcus equi	Foals 2–5 months of age, some with history of respiratory disease	Diarrhea associated with R. equi pneumonia; *culture respiratory tract*
Clostridium difficile	< 2 weeks of age.	Colic, fever, ileus, hematochezia, toxemia, depression. *Fecal culture and demonstration of toxin in feces*
Clostridium perfringens type c	Neonatal foals. Sporadic disease to annual outbreaks on breeding farms. Most foals excrete *C. perfringens* type A, which rarely causes diseases in foals	Colic, fever, ileus, hematochezia, toxemia, depression. *Culture of C. perfringens type C in feces, demonstration of toxin in feces*
Lawsonia intracellularis	Older suckling foals and weanlings. Sporadic or outbreaks on farms	Weight loss, mild to moderate diarrhea, ventral edema, depression, hypoproteinemia. *Serology and PCR on feces*
Yersinia pseudotuberculosis	Suckling foals. Outbreaks on breeding farms	Watery diarrhea and suppurative pneumonia. *Culture of feces and lesions*
Aeromonas hydrophila	Reports of disease are uncommon. Uncertain importance	Diarrhea. *Culture of feces*
Viral causes		
Rotavirus	< 3 months of age. Occurs as outbreaks or endemic disease on farm. Highly contagious	Profuse watery diarrhea with variable hypovolemia and depression. *Detection of virus in feces by electron microscopy, IFA, ELISA*
Adenovirus	Immunodeficient foals (Arabians with severe combined immunodeficiency)	Diarrhea, depression. May be associated with other diseases including pneumonia. *Detection of virus in feces by electron microscopy*
Coronavirus	Young foals (age range not well defined). Apparently rare cause of diarrhea in foals	Diarrhea. *Detection of virus in feces by electron microscopy*
Parasites		
Cryptosporidium sp.	Foals of any age. May be spread from other species, including calves and cria	Inapparent infection to fulminant disease with diarrhea, hypovolemia, and collapse. Chronic diarrhea. *Detection of oocysts in feces, IFA*
Strongyloides westerii	Individual foals. Uncertain importance as a cause of diarrhea	Acute to chronic diarrhea. *Patent infections evident by fecal examination for parasite eggs*
Other		
Nutritional	Sporadic. Orphan foals fed inappropriate or poor-quality milk replacers. Nursing foals fed inappropriate supplements	Mild to moderate chronic diarrhea. Failure to thrive. *Feed diet intended for foals (not plant-protein- or bovine-milk-based)*
Lactose intolerance	Nursing foals	Moderate to profuse diarrhea. *Historical confirmation of administration of compounds*
Overdosing of cathartics (DSS, $MgSO_4$, $NaSO_4$, castor oil)	Sporadic. Secondary to viral diarrhea. Occurs only in milk-fed foals	Moderate to severe watery, acidic diarrhea. *Oral lactose tolerance test or trial administration of lactase with milk feedings*
Enema	History of administration. Diarrhea short-lived	Bright alert and responsive foal with mild to moderate diarrhea. No specific diagnostic tests
Antibiotic-induced	Administration of antibiotics	Mild to moderate diarrhea. May be associated with *Candida* sp. or *C. difficile*. *Culture of feces, examination for C. difficile toxin*

disease is usually sporadic, mild and transient. The more common causes of diarrhea in foals on breeding farms in Britain include *Clostridium perfringens*, rotavirus, *Salmonella*, *Cryptosporidium* sp., and *Strongyloides westerii*,[1–3] although the relative importance of various pathogens varies from year to year, from farm to farm and from region to region.

C. perfringens causes diarrhea in young foals. There are five major types of *C. perfringens* and, while the organism is clearly associated with disease, a definitive role for each of these types in causing disease has not been established, partly because toxin production for strains isolated from foals with diarrhea has not been routinely documented. However, there is clear evidence that *C. perfringens* type C causes diarrhea in foals.[4] *C. perfringens* types A, B, D and E might be associated with disease in foals, but definitive proof is lacking. *E. coli*, an important cause of disease in neonates of other livestock species, does not appear to be an important cause of diarrhea in foals, although some strains are pathogenic.[5,6] Similarly, although there are reports of coronavirus causing severe disease in foals, this does not appear to be a common cause of diarrhea in foals.[7,8] *Candida* spp. can cause diarrhea in critically ill foals and those administered antibiotics.[9] *Yersinia* spp. have been associated with diarrhea in foals but do not appear to be a common cause of disease.[10] *Bacteroides fragilis* is an uncommon cause of diarrheal disease in foals. The role of *Campylobacter* spp. in foal diarrhea, if there is any, is unclear.

EPIDEMIOLOGY

Diarrhea is common in suckling foals worldwide although studies of its incidence, risk factors and outcome are exiguous. Diarrhea affects 21% of foals annually in Texas, being second only to respiratory disease (22%) as a cause of disease.[11] The frequency of disease varies with age: 25% of foals 0–7 days of age have diarrhea, compared to 40% and 8% of foals aged 8–31 days and 32–180 days, respectively.[11] While a common disease syndrome, diarrhea is not associated with a high death rate (2.6%).[11] Results of the Texas study may not be applicable to foals in other regions.

Among the common causes of diarrhea the highest death rates are associated with diarrhea associated with *C. perfringens*, *Salmonella* sp. and *Cryptosporidium* sp.[2]

Risk factors for development of the diarrhea vary depending on its etiology, but in general the disease is less common in foals born at pasture and at low stocking density.[11]

Rotavirus diarrhea is often endemic on farms and the disease occurs as outbreaks on successive years. Affected foals range in age from less than 7 days to more than 3 months.

Diarrhea due to ***Rhodococcus equi*** occurs in foals with *R. equi* pneumonia and the disease is endemic on some farms. Not all foals with *R. equi* pneumonia develop diarrhea. The disease occurs in foals 2–5 months of age.

Salmonellosis also occurs as outbreaks of disease among foals less than 8 days of age on breeding farms and is associated with a carrier status in mares.[12]

Diarrhea associated with ***C. perfringens*** type C occurs in foals less than 10 days of age with most foals being less than 6 days old[4] and can occur as a farm problem with multiple foals affected on each of several successive years.[13] Farm risk factors include presence of other livestock, stock-horse-type foals, foals born on dirt, and stall or dry lot confinement for the first few days of life.[14] *C. perfringens* type A is excreted in feces of most normal foals, whereas *C. perfringens* type C is rarely isolated from feces of normal foals.[15] ***Clostridium difficile*** causes diarrhea in foals not administered antibiotics,[16] in contrast to the situation in adult horses, and usually affects foals less than 14 days of age, although foals up to 120 days of age may be affected.[17] Failure of transfer of passive immunity is not a risk factor for *C. perfringens* or *C. difficile* enteritis in foals.

Lawsonia intracellularis causes mild to moderate diarrhea in older suckling or weaned foals. The disease occurs as outbreaks on breeding farms. There are no recognized foal or farm risk factors.

PATHOGENESIS

The pathogenesis of diarrhea varies somewhat depending on the inciting cause (see appropriate sections of this text for discussion of pathogenesis), although if sufficiently severe all cause excessive loss of fluid and electrolytes in feces and subsequent hypovolemia, electrolyte abnormalities, metabolic acidosis and weakness. Although not demonstrated in foals, diarrhea in calves causes metabolic acidosis through loss of sodium and other cations in feces, which results in a decrease in the strong ion difference in blood, causing acidosis. Bicarbonate loss, per se, is not a cause of the metabolic acidosis, at least in calves. Infectious agents generally cause enteritis, although rotavirus infection is associated with loss of villus cells and subsequent loss of enzyme activity derived from the mature epithelial cell. The loss of enzyme activity, including that of disaccharidases, causes malabsorption of nutrients in milk and other feed. Failure to absorb nutrients in the small intestine causes them to be delivered to the cecum and large intestine where they are fermented. Subsequent reductions in colonic pH and increases in osmotic activity of the colon contents results in excretion of large quantities of fluid and electrolytes. *C. difficile* and *C. perfringens* produce enterotoxins that cause damage to intestinal cells and accumulation of hemorrhagic fluid in the intestine.[16] *L. intracellularis* causes an infiltrative and proliferative enteropathy with subsequent protein loss and, possibly, malabsorption.

CLINICAL SIGNS

Clinical signs vary from mild, pasty diarrhea that adheres to the perineum and causes no detectable systemic signs of disease to profuse water diarrhea with rapid development of loss of suckling, depressed mentation, tachycardia, increased skin tent, ileus and recumbency.

Signs of systemic disease include failure to nurse, increased frequency or prolonged duration of recumbency, foals at pasture may fail to follow the mare, fatigue, less frequent urination, production of concentrated urine (urine from normal foals is normally dilute) and weakness. Affected foals often have depressed mentation, tachycardia, fever (depending on the cause of the diarrhea), decreased capillary refill time, dry mucous membranes, increased skin tent and eyes that are retracted into the orbit (consistent with dehydration). Depending on the cause of the diarrhea, foals may have colic, which can range from mild with intermittent flank watching or biting and restlessness, through profound agitation, rolling and dorsal recumbency. Severely affected foals may have seizures as a result of profound hyponatremia.[18]

Chronic diarrhea and that due to nutritional imbalance or lactose intolerance causes rapid weight loss, failure to thrive, poor hair coat and lethargy. Chronic fecal contamination of the perineum and escutcheon causes excoriation and loss of hair.

Diarrhea associated with foal heat is usually mild and transient and not associated with systemic signs of disease. However, diarrhea due to infectious agents is often severe and accompanied by systemic signs of disease.

Diseases associated with *Clostridium* sp. are often severe with rapid onset of signs of toxemia, colic, hypovolemia and death. Diarrhea is usually present and is often bloody, although it may be watery and profuse. Severely affected foals may have signs of colic, toxemia and ileus and not develop diarrhea before dying. Salmonellosis can present as septicemia, with subsequent development of diarrhea, although in older foals diarrhea is a common presenting sign.

CLINICAL PATHOLOGY

Diarrhea in foals with systemic signs of disease cause hyponatremia, hyperkalemia, hypochloremia, metabolic acidosis, hypoproteinemia and azotemia. The magnitude of abnormalities varies with the cause of disease and its severity. Hyponatremia may be profound (< 100 mEq/L). Hypoproteinemia may be a result of loss of protein from the inflamed intestine or a reflection of failure of transfer of passive immunity. All young foals with diarrhea should have serum or plasma immunoglobin concentrations measured or some other test for transfer of passive immunity performed.

Viral causes of diarrhea can be diagnosed by examination of feces by electron microscopy. However, more rapid and sufficiently sensitive and specific tests exist for diagnosis of rotaviral disease (ELISA, IFA). Culture of feces will demonstrate Salmonella spp in most cases if they are the cause of disease. Fecal culture yielding *C. perfringens* or *C. difficile* is insufficient for diagnosis of clostridial enterocolitis as these organisms can be recovered from normal foals. Confirmation of the diagnosis is achieved by demonstration of clostridial toxins in feces, which can be problematic given that the toxins are very labile.

DIAGNOSTIC CONFIRMATION

For diagnostic criteria for specific diseases, see the appropriate sections in this text.

LESIONS

Lesions associated with diarrhea in foals depend on the inciting cause. Characteristically in severe cases there is enteritis and colitis with ulceration of intestinal mucosa. Foals with rotavirus diarrhea, most of which survive, have flattening of small-intestinal epithelium.

TREATMENT

The principles of treatment are:

- Correction and maintenance of hydration, acid–base and electrolyte status
- Ensuring adequate transfer of passive immunity
- Ensuring adequate nutrition
- Preventing complications of disease, including bacteremia.

Correction of hypovolemia and electrolyte abnormalities should follow the general guidelines presented elsewhere in this text. Mildly affected foals, such as those with no systemic signs of disease, might not require administration of fluids orally or parenterally. More severely affected foals might require oral supplementation with balanced, isotonic electrolyte rehydration solutions, such as those marketed for use in calves. The amount and frequency will depend upon the size of the foal, severity of disease and response to treatment. Foals that have clear signs of hypovolemia should be administered fluids intravenously. These fluids should ideally be selected based on the foal's serum electrolyte concentrations, but in most instances a balanced, polyionic, isotonic fluid such as lactated Ringer's solution is appropriate. Correction of hyponatremia in some but not all foals requires administration of hypertonic (7%) sodium chloride intravenously. However, rapid correction of hyponatremia, especially if it is long-standing (more than 24 h) might be associated with an increased risk of cerebral demyelination. Correction of hyponatremia will resolve seizure activity.

Correction of acid–base usually occurs with correction of fluid and electrolyte abnormalities. Provision of fluids that are sodium-rich and have a high strong ion gap, for instance lactated Ringer's solution, will usually correct the metabolic acidosis common in foals with diarrhea. However in some foals the rate of fecal loss of cations including sodium, and perhaps bicarbonate, prevents resolution of metabolic acidosis without administration of sodium bicarbonate. Sodium bicarbonate can be administered intravenously or orally. Oral administration has the advantages that it is convenient and does not require administration of large amounts of fluid or of hypertonic solutions. The dose of sodium bicarbonate can be calculated from the foal's body weight and base deficit. As a guideline, a 40 kg foal that is not hypovolemic but has continued profuse watery diarrhea and metabolic acidosis should receive 30 g sodium bicarbonate orally every 6 hours. Serum sodium and bicarbonate concentrations should be measured at least daily and doses of sodium bicarbonate should be adjusted on the basis of these values. Overdosing, or continued dosing when diarrhea has resolved, results in hypernatremia and metabolic alkalosis.

Foals with diarrhea should have serum immunoglobulin concentrations measured. Hypogammaglobulinemic foals should be administered plasma intravenously (20–40 mL/kg BW).

Ensuring that foals affected by diarrhea continue to ingest sufficient calories is critical to the foal's survival. Foals require up to 150 (kcal/kg)/d for growth but can maintain weight on as little as 50 (kcal/kg)/d, especially if the nutrients are provided intravenously. Foals with mild to moderate diarrhea should be permitted to nurse at will. If there is concern that the foal is not nursing sufficiently, a feeding tube can be placed and the foal's diet supplemented with mare's milk, milk substitute lactose-free milk. Lactase is sometimes added to the milk on the assumption that enteritis causes lactase deficiency (for details of lactose tolerance testing in foals).

Foals with severe diarrhea benefit from parenteral administration of nutrition and gastrointestinal rest. Feed withholding results in a marked reduction in fecal volume and the extent of electrolyte and acid–base abnormalities. However, it is critical for foal recovery that complete feed withholding be accompanied by partial parenteral nutrition.

Antibiotics are usually administered to foals with severe diarrhea on the presumption that such foals are more likely to have bacteremia. Although there is no evidence that parenteral administration of antibiotics reduces morbidity or case fatality rate, the precaution has merit, as it does in calves.[19] Oral administration of antimicrobials to foals with diarrhea is common but is not recommended because of the risk of exacerbating the disease, and unknown efficacy. Foals with suspected clostridial enterocolitis should be administered metronidazole (15–20 mg/kg, intravenously or orally, every 6–12 h).

Drugs that affect gastrointestinal motility, such as loperamide, parasympatholytics and narcotics, have no demonstrated efficacy in reducing morbidity or case fatality rate and their use is not recommended.

CONTROL

Control of foal diarrhea is problematic because it is very common, many cases are mild and transient, a definitive diagnosis is frequently not available in a timely fashion, and it can be associated with a wide variety of infectious and noninfectious agents. Basic principles include ensuring adequate transfer of passive immunity, reducing exposure to pathogens and minimizing the effect of other risk factors.

Of the important causes of disease, in terms of morbidity and case fatality rate, control of diarrhea associated with rotavirus and clostridial species is most important. Control of rotaviral diarrhea is discussed elsewhere. Control of clostridial diarrhea on farms with an endemic problems includes vaccinating of mares, administration of metronidazole to at-risk foals and supplementation of passive immunity with antitoxins to clostridial toxins. Vaccination of mares with toxoids (*C. perfringens* type c and d toxoid) prepared for use in other species has been practiced, but there are no reports of safety or efficacy. Administration of antitoxin raised against *C. perfringens* C, D and E

may provide protection against the alpha, beta and epsilon toxins that have the potential to affect foals. The antiserum, which is intended for use in ruminants, is administered orally (50–100 mL per foal) soon after birth. The efficacy of this practice has not been determined. Foals at risk may also be administered metronidazole (10 mg/kg every 12 h) for the first 4–5 days of life. Again, the efficacy of this practice has not been determined.

Administration of a probiotic containing *Lactobacillus pentosus* WE7 did not confer any protection against development of diarrhea in foals, and was associated with an increased risk of clinical disease, including diarrhea.[20]

INTESTINAL HYPERMOTILITY

A functional increase in intestinal motility seems to be the basis of a number of diseases of animals. Clinically there is some abdominal pain and, on auscultation, an increase in alimentary tract sounds and, in some cases, diarrhea. Affected animals do not usually die and necropsy lesions cannot be defined but it is probable that the classification as it is used here includes many of the diseases often referred to as catarrhal enteritis or indigestion.

The major occurrence of intestinal hypermotility is spasmodic colic of the horse. Other circumstances in which hypermotility and diarrhea occur without evidence of enteritis include allergic and anaphylactic states and a change of feed to lush pasture.

DIETARY DIARRHEA

Dietary diarrhea occurs in all species and all ages but is most common in neonatal animals that ingest too much milk or a diet that is indigestible.

ETIOLOGY

Milk replacers

The use of inferior-quality milk replacers in young calves under 3 weeks of age is one of the commonest causes of dietary diarrhea. The quality of the milk replacer may be affected by the use of skim-milk powder that was heat-denatured during processing, resulting in a decrease in the concentration of noncasein proteins. This results in ineffective clotting in the abomasum and reduced digestibility. The use of excessive quantities of nonmilk carbohydrates and proteins in milk replacers for calves is also associated with a high incidence of diarrhea, loss of weight, emaciation and starvation. The use of large quantities of soybean protein and fish protein concentration in milk replacers for calves will result in chronic diarrhea and poor growth rates.

Most attempts to raise calves on diets based on large amounts of certain soybean products, such as heated soybean flour, have been unsuccessful because the animals developed diarrhea, loss of appetite and weight or inferior growth rate. Preruminant calves develop gastrointestinal hypersensitive responses to certain soybean products because major proteases of the digestive tract do not denature soluble antigenic constituents of the soybean protein.[1]

Diarrhea of nutritional origin has become one of the most important problems where large numbers of calves are raised under intensive conditions. Because of the relatively high cost of good-quality skim-milk powder, large quantities of both nonmilk proteins and carbohydrates are used in formulating milk replacers. While some calves in these large units can satisfactorily digest the nutrients in these milk replacers, many cannot and this leads to a high incidence of diarrhea and secondary colibacillosis and enteric salmonellosis.

Milk replacers made from bovine milk and milk byproducts used to feed orphan piglets, lambs and foals may cause nutritional diarrhea for the same reasons as given above. In milk-replacer-fed calves, increasing the total daily fluid intake as a percentage of body weight causes a greater incidence of loose feces, dehydration and dullness than lower levels of fluid intake and higher dry matter concentration. This suggests that a greater amount of fluid intake increases the passage rate of dry matter and decreases absorption. The concentration of solids in the liquid diet should range between 10% and 13% and should be offered at 8% of body weight in calves fed milk replacer once daily and allowed free access to calf starter.

Overfeeding of milk

The feeding of excessive amounts of cows' whole milk to hand-fed calves will result in large amounts of abnormal feces but usually not a profuse watery diarrhea with dehydration and loss of weight. This suggests that simple overfeeding of milk may not be a cause of acute neonatal diarrhea of calves. However, it may predispose to secondary colibacillosis. There is some limited evidence that dietary diarrhea may occur in nursing beef calves ingesting milk that does not clot properly. Only the milk from cows with diarrheic calves showed evidence of impaired clotting in an in-vitro test.

The ingestion of excessive quantities of sows' milk by piglets at 3 weeks of age is thought to be a contributory cause of 3-week diarrhea of piglets. This may be due to the sow reaching peak production at 3 weeks.

Beef calves sucking high-producing cows grazing on lush pasture are often affected with a mild diarrhea at about 3 weeks of age. The cause is thought to be simple overconsumption of milk. Similarly, vigorous lambs sucking high-producing ewes may develop diarrhea.

Foals commonly have diarrhea at about 9 days of age, which coincides with the foal heat of the mare. It has been thought for many years that the cause was a sudden change in the composition of the mare's milk but this has not been supported by analyses of mares' milk at that time. The fecal composition in foal heat diarrhea suggests that the diarrhea is a secretory-type hypersecretion of the small intestine mucosa, which may not be controlled by an immature colon.[2]

There is considerable interest in the optimal conditions for feeding liquid diets to young calves. The temperature of the liquid when fed, feeding once or twice daily and the amount of dry matter intake can affect the performance of calves. However, there is a range of safety in which the performance of the calves will not be significantly affected if management is good.

Change of diet

Dietary diarrhea also occurs in all species following a sudden change in diet, but particularly in animals at weaning time. This is particularly important in the pig weaned at 3 weeks of age and not adjusted to the postweaning ration. Diarrhea occurs commonly when animals are moved from a dry pasture to a lush pasture and when first introduced to

liberal quantities of concentrates containing a large percentage of the common cereal grains.

PATHOGENESIS

Digestion of milk

In calves, the ingestion of excessive quantities of cows' whole milk after several hours of no intake causes gross distension of the abomasum and possibly of the rumen. Under these conditions, the milk-clotting capacity of the abomasum may be limited, resulting in incomplete clotting. The flow of nutrients from the abomasum is more uniform in calves fed twice daily than once daily, which suggests that twice-daily feeding allows for more effective clotting and digestion.

Under normal conditions, the milk clot forms in the abomasum within minutes after feeding, and the whey moves to the duodenum 5–10 minutes later. The dilution of cows' whole milk will result in increased clotting time when treated with rennin (chymosin). Overfeeding could result in whole milk or excessive quantities of whey entering the duodenum, which cannot digest whole milk or satisfactorily digest and hydrolyze the substrates in whey. The presence of excessive quantities of such substrate, especially lactose, in the intestinal lumen would serve as a hydragogue and result in a large increase in intestinal fluid, failure of complete absorption and abnormal feces. The speed of drinking is probably also important. Prolongation of drinking time results in dilution of the milk with saliva and the production of a more easily digested milk clot. Failure of the esophageal reflex in pail-fed calves may also be important. The milk enters the rumen, where it undergoes putrefaction.

Milk replacers and diarrhea

The pathogenesis of diarrhea in calves fed inferior-quality milk replacers is well known. In calves fed low-heat-treated skim-milk powder milk replacer, curd formation in the abomasum, compared with no curd formation, slows down the passage of total abomasal content (retained matter from the last feeding, residual matter from the penultimate feeding, saliva, and gastric secretions), dry matter, crude protein and fat from the abomasum to the intestine.[3] Heat-denatured skim-milk powder is incompletely clotted in the abomasum, leading to reduced digestibility.

Nonmilk carbohydrates and nonmilk proteins are not well digested by preruminant calves under 3 weeks of age because their amylase, maltase and sucrase activities are insignificant, and their pepsin-HCl activity is not well developed until at least 3 weeks of age. Following the ingestion of these nutrients, there is reduced digestibility, malabsorption and diarrhea. This results in a negative nutrient balance, loss of body weight and gradual starvation, all of which are reversible by the feeding of cows' whole milk. The digestion of fat is particularly affected, resulting in varying degrees of steatorrhea. Preruminant calves fed milk replacer containing corn oil will have diarrhea and not do well because of inadequate dispersion of the oil.[4]

The mechanism for the diarrhea, which may occur in all species following a sudden change in diet, is not well understood. However, several days may be necessary for the necessary qualitative and quantitative changes to occur in the digestive enzyme capacity. Not much is known about the development of intestinal enzymes in the fetus and newborn, but this is likely to be of importance in individual animals. In calves, lactase activity is fully developed at birth and in the period between birth and weaning there are significant changes in enzyme activity, some of them influenced by the presence or absence of dietary substances.

In dietary diarrhea, the presence of undigested substrate in the intestine may result in marked changes of the bacterial flora, which may result in excess fermentation of carbohydrates and putrefaction of protein, the products of which accentuate the malabsorption. If enteropathogenic *E. coli* or *Salmonella* spp. are present they may colonize, proliferate in large numbers and cause enteric colibacillosis and salmonellosis.

CLINICAL FINDINGS

Nursing beef calves

Dietary diarrhea of beef calves 3 weeks of age on pasture is characterized by the passage of light yellow feces that are foul-smelling and soft. The perineum and tail are usually smudged with feces. The calves are bright and alert and usually recover spontaneously without treatment in a few days.

Hand-fed dairy calves

When overfed on cow's whole milk these animals are usually dull, anorexic and their feces are voluminous, foul-smelling and contain considerable mucus. The abdomen may be distended because of distension of the abomasum and intestines. Secondary enteric colibacillosis and salmonellosis may occur, resulting in severe dehydration. Most uncomplicated cases will respond to oral fluid therapy and withdrawal from or deprivation of milk.

Milk replacer diarrhea

In calves fed inferior-quality milk replacers, there will be a chronic diarrhea with gradual weight loss. The calves are bright and alert, they usually drink normally, appear distended after drinking and spend considerable time in recumbency. Not uncommonly, many treatments will have been tried unsuccessfully. The diarrhea and weight loss continues and in 2–4 weeks emaciation is evident and death from starvation may occur. Affected calves will often have a depraved appetite and eat bedding and other indigestible materials, which further accentuates the condition. When large numbers of calves are involved, the incidence of enteric colibacillosis and salmonellosis may become high and the case mortality very high. This is a common situation in veal-calf-rearing units.

Alopecia occurs occasionally in calves fed a milk replacer, but the cause is unknown.

CLINICAL PATHOLOGY

Laboratory evaluation of the animals with dietary diarrhea is usually not necessary other than for elimination of other possible causes of the diarrhea. When milk replacers are being used the determination of the rennet-clotting time of the milk replacer compared with whole milk is a useful aid in assessing the quality of the skim-milk powder for calves.

NECROPSY FINDINGS

Emaciation, an absence of body fat, dehydration and serous atrophy are present in calves which have died from diarrhea and starvation while being fed inferior quality milk replacers.

DIFFERENTIAL DIAGNOSIS

- Dietary diarrhea occurs following a change in diet, the consumption of too much feed at once, or poor quality feed. There are usually no systemic signs and recovery occurs spontaneously when the dietary abnormality is corrected or the animal adapts to a new diet
- Dietary diarrhea must be differentiated from all other common causes of diarrhea in a particular age group within each species
- Examination of the recent dietary history and examination of the diet and its components will usually provide the evidence for a dietary diarrhea

TREATMENT

Alter diet of hand-fed calves

In hand-fed calves affected with dietary diarrhea, milk feeding should be stopped and oral electrolyte solutions given for 24 hours. Milk is then gradually reintroduced. If milk replacers are being used their nutrient composition and quality should be examined for evidence of indigestible nutrients. Occasional cases of dietary diarrhea in calves will require intensive fluid therapy and antibacterials

orally and parenterally. The feeding practices should be examined and the necessary adjustments made.

The care and management of hand-fed calves to minimize the incidence of dietary diarrhea is an art. Much has been said about the use of slow-flowing nipple bottles and pails to reduce dietary diarrhea but they are not a replacement for good management. Calves that are raised for herd replacements should be fed on whole milk if possible for up to 3 weeks. When large numbers of calves are reared for veal or for feedlots the milk replacer used should be formulated using the highest quality milk and milk by-products that are economically possible. The more inferior the milk replacer the more impeccable must become the management, which is difficult given today's labor situation.

Monitor beef calves with dietary diarrhea

Beef calves affected with dietary diarrhea while sucking the cow and running on pasture do not usually require treatment unless complications develop. They must be observed daily for evidence of dullness, anorexia, inactivity and profuse watery diarrhea, at which point they need some medical care.

Muzzle foals

Foals with dietary diarrhea should be muzzled for 12 hours, which may require hand-stripping of the mare to relieve tension in the udder and to prevent engorgement when the foal begins to suck again. Antidiarrheal compounds containing electrolytes, kaolin and pectin with or without antibiotics are used commonly but are probably not any more effective than oral electrolyte solutions for 24 hours.

INTESTINAL OR DUODENAL ULCERATION

Intestinal ulceration occurs in animals only as a result of enteritis and clinically with manifestations of enteritis. As far as is known there is no counterpart of the psychosomatic disease that occurs in humans. Ulceration does occur in many specific erosive diseases listed elsewhere, and in salmonellosis and swine fever, but the lesions are present in the terminal part of the ileum, and more commonly in the cecum and colon.

Duodenal ulcers in cattle and horses have a similar epidemiological distribution to gastric ulcers and also resemble them clinically. Occasionally they perforate, causing subacute peritonitis. A perforated duodenal ulcer in a foal is recorded as causing acute, fatal peritonitis manifested by pain, dyspnea and vomiting. Moderate to severe ulceration of the mucosa of the cecum and colon is described in phenylbutazone toxicity in ponies. The dose rate of phenylbutazone was 12 mg/kg BW per day for 8 days. There is significant hypoproteinemia due to protein loss from the gut. A similar hypoproteinemia has been produced in Thoroughbred horses, but there was no clinical illness.

DIVERTICULITIS AND ILEITIS OF PIGS (PROLIFERATIVE ILEITIS)

In this disease there is thickening of the wall of the ileum, particularly in the terminal portion, so that the intestine becomes thick and rigid. There is a close clinical similarity to Crohn's disease in humans and the etiology of both conditions is obscure. Familial predisposition is probable in humans and has been suggested in pigs.

The signs are those of acute peritonitis due to ulceration and, sometimes, perforation of the affected ileum. Illness occurs suddenly with loss of appetite, excessive thirst, dullness and disinclination to rise. The temperature is subnormal, the respiration is distressed and there is a bluish discoloration of the skin. Death occurs in 24–36 hours. Acute cases occur in young pigs up to 3 months of age, and chronic cases, due to ulceration and chronic peritonitis, in the 7–8-month age group.

At necropsy there may be diffuse peritonitis due to leakage of alimentary tract contents through perforating ileal ulcers. Gross thickening of the ileal wall with nodular proliferation of the ileal mucosa and enlargement of the mesenteric lymph nodes are common accompaniments. Although the macroscopic findings are similar to those of Crohn's disease in man, the histopathological findings differ markedly. There is an obvious and significant protein loss through the intestinal lesion and a marked hypoproteinemia.

RECTAL PROLAPSE

Prolapse of the rectum occurs commonly in pigs, is an occasional occurrence in cattle and is rarely seen in the other species. In a prospective study of rectal prolapse in a commercial swine herd, 1% of the pigs prolapsed between 12 and 28 weeks of age, with a peak incidence occurring at 14–16 weeks of age.[1] Prolapse rates were highest during the winter and autumn months. Other risk factors included:

- Male – relative risk 2.3
- Birth weight less than 1000 g – relative risk 3.4
- A particular Yorkshire boar – relative risk 2.8
- Dams of litter number 1 – relative risk 14.9; number 2 – relative risk 8.2; number 3 – relative risk 9.8.

There was no evidence to support the hypothesis that diarrhea and coughing are factors associated with a risk of prolapse. Feeding rations with lysine concentrations in excess of the requirements is considered a risk factor for rectal prolapse in swine.[2]

The common causes include enteritis with profuse diarrhea, violent straining such as occurs in coccidiosis in young cattle, in rabies sometimes, in spinal cord abscess and also when the pelvic organs are engorged. The use of estrogens as a growth stimulant and access to estrogenic fungal toxins predispose to rectal prolapse for this reason. It has been suggested that mycotoxins in swine rations are a cause of rectal prolapse but there is insufficient evidence to make such a claim.

Treatment is surgical.[3]

RECTAL STRICTURE

There are two notable occurrences: as part of an inherited rectovaginal constriction in Jersey cattle and a syndrome of acquired rectal stricture that occurs in feeder pigs at about 2–3 months of age. Although the latter is generally classed as a sequel to enteric salmonellosis associated with *Salmonella typhimurium*, it has been suggested that there is an inherited component in the etiology. The presumed pathogenesis is that a prolonged enterocolitis with ulcerative proctitis results in an annular cicatrization of the rectal wall 2–5 cm anterior to the anorectal junction. This results in colonic dilatation and compression atrophy of the abdominal and thoracic viscera. Clinically there is progressive abdominal distension, inappetence, emaciation, dehydration and watery to pasty feces. The stricture of the rectum can be palpated on digital examination of the rectum. Most affected pigs die or are destroyed but a surgical technique for relief of the condition is described. Some pigs with incomplete strictures are unaffected clinically. The disease can be reproduced experimentally with *S. typhimurium* or the surgical manipulation of the rectal arterial blood supply, resulting in ischemic ulcerative proctitis.

At necropsy there is a low-grade peritonitis and dilatation of the colon, and sometimes the terminal ileum also. A stricture is present 2–5 cm from the anus, and may be so severe that it exists as a scirrhous cord with or without a narrow luminal remnant in the center. Histologically there is necrotic debris and granulation tissue at the site of the stricture.

Congenital defects of the alimentary tract

HARELIP AND CLEFT PALATE

Harelip may be unilateral or bilateral and may involve only the lip or extend to the nostril. It may be associated with cleft palate and cause dysphagia and nasal regurgitation of milk and food, and a risk of inhalation pneumonia. It may be inherited or result from poisoning of lambs with *Veratrum californicum*. Cleft palate is difficult to correct surgically, especially in foals, in which it is a common congenital defect. Cleft palate (palatoschisis) is a common inherited defect in calves and is described under that heading.

ATRESIA OF THE SALIVARY DUCTS

Congenital atresia of salivary ducts usually results in distension of the gland followed by atrophy. Rarely the gland may continue secreting, resulting in a gross distension of the duct.

AGNATHIA, MICROGNATHIA AND BRACHYGNATHIA

These are variations of a developmental deficiency of the mandible, relatively common in sheep. The mandible and its associated structures are partially or completely absent. Single cases of a similar defect, combined with cleft palate, are recorded in calves.[1]

Brachygnathia is an abnormal shortening of the mandible, resulting in malocclusion of the maxillary and mandibular dental arcades and creating the appearance of a maxillary overbite.[2] It is considered to be a congenital abnormality but may be acquired within the first few months of life. The incisive malocclusion is of little consequence to the nursing foal but can affect the ability to prehend and masticate as the animal matures. It is not known to spontaneously regress and surgical intervention is necessary to correct the malocclusion.

The cause may be genetic or environmental. Some reports indicate a genetic influence but the mode of inheritance is controversial. One report suggests that brachygnathia in Angus calves was transmitted by a single autosomal recessive gene but such mode of inheritance has not been supported in other studies.[2] In a series of 20 horses with brachygnathia the amount of disparity between the mandible and premaxilla varied between 0.75 and 3.0 cm. Surgical correction of the abnormality resulted in improved incisive occlusion. Complete correction of the malocclusion was more likely to occur if foals were treated before 6 months of age.

PERSISTENCE OF THE RIGHT AORTIC ARCH

Persistence of the right aortic arch as a fibrous band may occlude the esophagus and cause signs of obstruction, particularly chronic bloat in young calves.

CHOANAL ATRESIA

Failure of the bucconasal membrane to rupture during fetal life prevents the animal breathing through the nostrils. The membrane separates the alimentary tract and the nasal cavities in the pharynx. It is incompatible with life in foals and lambs, the two species in which it is identified.[3] The defect is usually bilateral; a unilateral lesion is tolerable. Surgical correction is likely to be only partially effective.

CONGENITAL ATRESIA OF THE INTESTINE AND ANUS

Congenital intestinal atresia is characterized by the complete closure of some segment of the intestinal tract. Intestinal atresia has been reported in calves, lambs, foals and piglets and the affected newborn usually dies of autointoxication within a few days of birth. The incidence of intestinal atresia in 31 Irish dairy herds monitored over 1 year was 0.3% of all calves born.[4]

ATRESIA OF THE ANUS

This is recorded as a congenital defect in pigs, sheep and calves.[5] Its occurrence is usually sporadic and no genetic or management factors can be indicated as causes. In other circumstances the occurrence can be suggestive of conditioning by inheritance, or be at such a rate as to suggest some environmental cause. Atresia of the ileum and colon is probably conditioned by inheritance in Swedish Highland cattle. Congenital atresia of the intestine can be differentiated from retention of meconium in foals, and rarely calves, by the passage of some fecal color in the latter. Affected animals die at about 7–19 days of age unless the defect is corrected surgically. The intestine is grossly distended by then and the abdomen is obviously swollen as a result. There is marked absence of feces. When the rectal lumen is quite close to the perineum, surgical intervention is easy and the results, in terms of salvaging the animals for meat production, are good. These animals can usually be identified by the way in which the rectal distension bulges in the perineum where the anus should be; pressure on the abdomen provokes a tensing or further distension of this bulge. Other signs include tenesmus with anal pumping and inability to pass a proctoscope or other instrument.

INTESTINAL ATRESIAS

Intestinal atresias have been classified into type I – membrane atresia caused by a diaphragm or membrane; type II – cord atresia caused by blind ends joined by a small cord of fibrous or muscular tissue or both, with or without mesentery; and type III – blind-end atresia, caused by absence of a segment of the intestine, with disconnected blind ends and a gap in the mesentery, and often a short small intestine.[6]

ATRESIA OF THE TERMINAL COLON

This occurs in foals,[7] especially those of the Overoo breed; the ileum and colon are affected in calves[8] and the small intestine in lambs. Atresia coli has been reported in Holstein, Ayrshire, Shorthorn, Simmental, Hereford, Angus and Maine Anjou breeds and in crossbred cattle. In one dairy herd over a 10-year period, the overall incidence of atresia coli in calves was 0.76%.[9] All the affected calves were related to one another, some were inbred and the frequency was higher in males than females. Some affected calves were aborted or born dead at term. More calves were born with atresia coli from dams in which pregnancy was diagnosed prior to 41 days of gestation than from dams diagnosed as pregnant at a later date.

It is suggested that atresia coli in calves has an inherited basis and that affected calves are homozygous recessives for the defective allele for atresia coli. This is supported by planned matings between putative carrier sires and putative carrier dams.[10] The estimated minimum gene frequency of atresia coli in cattle is 0.026 and it is thought that the defective allele for atresia coli is at high frequency in Holstein cattle in the USA. It is also plausible that early pregnancy diagnosis by palpating the amniotic sac before 40 days of gestation may be a contributing factor, but it is not essential for all cases.[11] Intestinal atresia can be produced experimentally by terminating the mesenteric blood supply to some parts of the intestine during development.

In atresia coli, the abdomen may be grossly distended before birth when the

defect is in the small intestine and the distension may interfere with normal parturition. In defects of the large intestine, distension usually occurs after birth. In these the anus is normal and the part of the intestine caudal to the obstructed section may be normal or absent. The principal clinical findings are depression, anorexia and abdominal distension. Frequently the owner has not seen the calf pass meconium or feces. Thick mucus may be passed through the anus if it is patent or through the vagina in heifers with concomitant rectovaginal fistula. In many cases the animal has not sucked since the first day and 5–6-day-old animals are very weak and recumbent. The intestine may rupture and acute diffuse peritonitis develop. Intestinal segmental atresia has been produced experimentally by occluding the blood supply to the intestine in fetal lambs. In one large series of congenital defects in calves the most common site of atresia was the mid-portion of the spiral loop of colon.[12] The passage of a rectal tube or the infusion of barium and radiography may assist in the detection of atresia of the intestine. There are usually large quantities of thick tenacious mucus in the rectum with no evidence of meconium or feces. In the latter case only exploratory laparotomy can reveal the extent and nature of the defect.[13] The differential diagnosis of atresia coli in calves includes acute intestinal obstructions such as volvulus and intussusception, diffuse peritonitis and septicemia. **The presence of feces in the rectum rules out the presence of atresia coli.**

Surgical repair appears to be a satisfactory outcome in 30–50% of cases.[14] In a series of intestinal atresia in calves admitted to a veterinary teaching hospital over a period of 10 years, the survival rate was influenced by the atretic segments affected.[15] In a series of 58 cases of intestinal atresia in calves, seven of 18 cases corrected surgically made a satisfactory recovery; the remaining 40 calves were euthanized for different reasons.[16]

The incidence of **atresia coli in foals** has been reported at 0.44% of foals under 2 weeks of age admitted to veterinary teaching hospitals over a period of 27 years.[17] Clinical findings included progressive abdominal distension, colic, lack of feces and lack of response to enemas. A neutropenia may reflect the presence of toxemia. The large transverse and/or small colon is commonly involved. Agenesis of the mesocolon in a 1-month-old foal with colic has been described.[18] The prognosis for most cases is grave and surgical correction is usually unsuccessful.

The common causes of colic in newborn foals include ileus with or without gas distension, intussusception, diaphragmatic hernia, gastroduodenal ulcers, necrotizing enterocolitis, small and large intestinal strangulation, large intestine displacement, intraluminal obstruction other than meconium, ruptured bladder and congenital abnormalities of the gastrointestinal tract.

MULTIPLE ORGAN DEFECTS

In many animals the congenital defects of the intestine are accompanied by defects in other organs,[8,12] especially the lower urinary tract, so that reparative surgery is not possible. For example multiple gut and urogenital defects are recorded in one calf[19] and gut defects plus defects of the pancreas and gallbladder in another.[20]

Congenital constriction of the anus and vagina is an inherited defect of Jersey cattle and is recorded under that heading. The defect may be combined with rectovaginal fistula manifested by the passage of feces via the vulva or penile urethra.[21]

Neoplasms of the alimentary tract

MOUTH

Oral neoplasms in ruminants, other than viral papillomas, may be associated with heavy bracken intake. The tumors are usually squamous cell carcinomas arising from the gums and cause interference with mastication. They occur most commonly in aged animals and probably arise from alveolar epithelium after periodontitis has caused chronic hyperplasia. Sporadic occurrences of other tumors, e.g. adenocarcinoma, cause obvious local swelling and dysphagia.

PHARYNX AND ESOPHAGUS

Papillomas sometimes involve the pharynx, esophagus, esophageal groove and reticulum and cause chronic ruminal tympany in cattle. A high incidence of malignant neoplasia affecting the pharynx, esophagus and rumen has been recorded in one area in South Africa. The tumors were multicentric in origin and showed evidence of malignancy on histological examination. The clinical disease was chronic and confined to adult animals with persistent, moderate tympany of the rumen and progressive emaciation as typical signs. A similar occurrence has been recorded in cattle in western Scotland and related to the long-term consumption of bracken. The tumors were squamous cell carcinoma in the pharynx and dorsal esophagus. The principal clinical abnormality was difficulty in eating and swallowing. Many of the carcinomas arise in pre-existing papillomas, which are associated with a virus infection. The carcinomas occur only in cattle more than 6 years of age.

STOMACH AND RUMEN

Squamous cell carcinomas occasionally develop in the mouth and stomach of horses and the rumen of cattle. In the stomach of the horse, they occur in the cardiac portion and may cause obscure indigestion syndromes, lack of appetite, weight loss, anemia, obstruction of the lower esophagus,[1] dysphagia, colic and occasionally chronic diarrhea. Or a tumor may ulcerate to terminate with perforation of the stomach wall and the development of peritonitis. Metastases may spread to abdominal and thoracic cavities with fluid accumulating there. Subcutaneous edema is a common accompanying sign. There may also be pleural effusion due to metastases in the pleura.[2] Metastases in the female genital tract have also been noted. Most affected animals are euthanized because of anorexia and chronic weight loss. Large masses of metastatic tumor tissue may be palpable on rectal examination. In such cases an examination of paracentesis fluid sample cells should be valuable.

Lymphosarcoma in horses is often manifested by chronic diarrhea due to massive infiltration of the intestinal wall. There is severe weight loss, even in the absence of diarrhea in some cases, usually a large appetite and often severe ascites, and anasarca and sometimes colic. The same signs are recorded in a case of mesothelioma in a horse. The oral glucose absorption test is abnormal with a poor

absorption response. Rectal examination may reveal large masses of hard nodular tissue and hematological examination may be of assistance in diagnosis. Paracentesis and examination of cells in the fluid for the presence of mitotic figures is an essential part of an examination in suspected cases of neoplasia in the abdominal cavity. Nasal fibergastroscopy is an obvious technique for visualizing this tumor but suffers the limitation that standard instruments are not long enough.[3] The course of this disease in horses is very variable, with the period of illness lasting from 3 weeks to 3 months.

Ruminal tumors may obstruct the cardia and cause chronic tympany. In lymphomatosis of cattle, there is frequently gross involvement in the abomasal wall causing persistent diarrhea. Ulceration, hemorrhage and pyloric obstruction may also occur.

INTESTINES

A higher than normal rate of occurrence of carcinoma of the small intestine has been recorded in sheep in Iceland, Norway[4] and New Zealand and in cows only in New Zealand.[5] A series of intestinal carcinomas is also recorded in Europe, and another series in Australia.[6] The tumors in the Australian series were located at abattoirs and were causing intestinal stenosis. Metastasis to regional lymph nodes occurred readily. In New Zealand there appeared to be a much higher prevalence in British-breed ewes (0.9–0.15%) compared to Merino and Corriedale ewes (0.2–0.4%), and significantly higher tumor rates were observed in sheep that had been pastured on foodstuffs sprayed recently with phenoxy or picolinic acid herbicides.[7] The use of the herbicides 2,4-D, 2,4,5-T, MCPA, piclorum and clopyralid has been associated with an increased incidence of these tumors. A higher prevalence in sheep kept at higher stocking rates was also suggested.

Occasional tumors of the intestine are recorded in abattoir findings but they can cause clinical signs such as chronic bloat and intermittent diarrhea[8] in cattle, persistent colic due to partial intestinal obstruction in horses[9] and anorexia and a distended abdomen in sheep.[10] A series of cases of lymphoma in horses were characterized by malabsorption without diarrhea but with anemia in some.[11]

Occasional tumors recorded as causing colic in horses include an intramural ganglioneuroma occluding the jejunum,[12] an intraluminal leiomyoma causing an intussusception of the small colon,[13] a granulosa cell tumor of an ovary causing external pressure and occlusion of a small colon.[14] A juvenile granulosa cell tumor in a weanling filly caused a fatal volvulus and severe continuous colic.[15] Anorexia, weight loss, abdominal distension, constant chewing and swallowing movements are the prominent signs in gastric leiomyoma[16] and squamous cell carcinoma.[17] Metastases in the peritoneal cavity are palpable in some cases. Leiomyosarcomas have caused chronic intermittent colic due to constriction of the duodenum and partial intestinal obstruction.[18] A colonic adenocarcinoma has caused weight loss, intermittent colic, poor appetite and scant feces and a mass palpable in the abdomen.[19]

Tumors of the anus are rare: a mucoepidermoid carcinoma is recorded in a goat[20] but most tumors of the perineal area are anogenital papillomata.

Diseases of the peritoneum

PERITONITIS

Inflammation of the peritoneum is accompanied by abdominal pain, fever, toxemia and a reduction in the amount of feces. Symptoms vary in degree with the severity and extent of the peritonitis.

ETIOLOGY

Peritonitis may occur as a primary disease or secondarily as part of an etiologically specific disease. As a primary disease it results most commonly from injury of the serosal surfaces of the alimentary tract within the abdomen, allowing gastrointestinal contents to enter the peritoneal cavity. Less commonly there is perforation of the abdominal wall from the exterior from traumatic injury, perforation of the reproductive tract, or the introduction of pathogens or irritating substances as result of injections into the peritoneal cavity or exploratory laparotomy. Some of the more common individual causes are as follows.

Cattle

- Traumatic reticuloperitonitis
- Secondary to ruminal trocarization
- Perforation or leakage of abomasal ulcer
- Concurrent abomasal displacement and perforating ulcer[1]
- Necrosis and rupture of abomasal wall after abomasal volvulus
- Rumenitis of cattle subsequent to acute carbohydrate indigestion
- Complication of caesarean section
- Rupture of vagina in young heifers during violent coitus with a young, active bull
- Deposition of semen into the peritoneal cavity by any means
- Injection of sterile hypertonic solutions, e.g. calcium preparations for milk fever. The chemical peritonitis that results may lead to formation of constrictive adhesions between loops of the coiled colon
- Transection of small intestine that becomes pinched between the uterus and the pelvic cavity at parturition
- Intraperitoneal injection of nonsterile solutions
- Spontaneous uterine rupture during parturition, or during manual correction of dystocia
- Sadistic rupture of vagina
- Spontaneous rupture of rectum at calving[2]
- As part of specific diseases such as tuberculosis.

Horses

Peritonitis in horses is usually secondary to infectious, chemical, or parasitic peritoneal injuries, and can be a major complication after abdominal surgery.[3]

- Rupture of dorsal sac of cecum or colon[4] at foaling, usually related to a large meal given just beforehand
- Cecal rupture in foals subjected to anesthesia and gastric endoscopy[5]
- Administration of NSAIDs causing cecal stasis and dilatation and eventually perforation[6]
- Rectal rupture or tear during rectal examination, predisposed to by inflammation of mucosa and overenthusiasm by the operator; this subject is presented separately under the heading of **rectal tear**
- Extension from a retroperitoneal infection, e.g. *Streptococcus equi* after an attack of strangles, *Rhodococcus equi* in foals under 1 year of age, both probably assisted by migration of *Strongylus vulgaris* larvae

- Gastric erosion or rupture related to ulceration associated with larvae of *Gasterophilus* or *Habronema* spp.
- Colonic perforation associated with aberrant migration of *Gasterophilus intestinalis*[7]
- Leakage from a cecal perforation apparently associated with a heavy infestation of *Anoplocephala perfoliata* tapeworms
- Spontaneous gastric rupture
- *Actinobacillus equuli* infection by unknown means.[8,9] Septicemia and peritonitis due to *A. equuli* infection in an adult horse has been described.[10]

Pigs

- Ileal perforation in regional ileitis
- Glasser's disease associated with *Haemophilus suis*.

Sheep

- Spread from intestinal wall abscess following infestation with *Esophagostomum* sp. larvae
- Serositis-arthritis associated with *Mycoplasma* sp.

Goats

- Serositis-arthritis associated with *Mycoplasma* sp.

All species

- Traumatic perforation from the exterior of the abdominal wall by horn gore, stake wound
- Faulty asepsis at laparotomy, peritoneal injection, trocarization for tympany of rumen or cecum
- Leakage through wall of infarcted gut segment

  Spread from subperitoneal sites in spleen, liver, umbilical vessels.

PATHOGENESIS

At least six factors account for the clinical findings and the various consequences of peritonitis. They are toxemia or septicemia, shock and hemorrhage, abdominal pain, paralytic ileus, accumulation of fluid exudate and the development of adhesions.

Toxemia and septicemia

Toxins produced by bacteria and by the breakdown of tissue are absorbed readily through the peritoneum. The resulting toxemia is the most important factor in the production of clinical illness and its severity is usually governed by the size of the area of peritoneum involved. In **acute diffuse peritonitis**, the toxemia is profound; in local inflammation, it is negligible. The type of infection present is obviously important because of variations between bacteria in their virulence and toxin production.

With rupture of the alimentary tract wall and the spillage of a large quantity of gut contents into the peritoneal cavity, some acute peritonitis does develop, but death is usually too sudden, within 2–3 hours in horses, for more than an early lesion to develop. These animals die of endotoxic shock due to absorption of toxins from the gut contents. In acute diffuse peritonitis due solely to bacterial contamination from the gut, the reaction depends on the bacteria that gain entry and the capacity of the omentum to deal with the peritonitis, and the amount of body movement that the animal has to perform. Cows that suffer penetration of the reticular wall at calving have lowered immunological competence, a greater than normal negative pressure in the peritoneal cavity, are invaded by *F. necrophorum*, *Corynebacterium* spp. and *E. coli*, and are required to walk to the milking parlor, to the feed supply and so on. They are likely to develop a massive diffuse purulent peritonitis and a profound toxemia and die within 24 hours. By contrast, horses that develop acute peritonitis due to streptococci or *A. equuli* show little toxemia and manifest only abdominal pain due to the inflammatory reaction of the peritoneum.

Shock and hemorrhage

The shock caused by sudden deposition of gut contents, or infected uterine contents, into the peritoneal cavity, plus the hemorrhage resulting from the rupture, may be significant contributors to the common fatal outcome when an infected viscus ruptures. Following rupture of the uterus in cows, the shock and hemorrhage may be minor and peritonitis may not develop if the uterine contents are not contaminated. Failure of the uterus to heal or be repaired may be followed by peritonitis several days later.

Abdominal pain

Abdominal pain is a variable sign in peritonitis. In acute, diffuse peritonitis, the toxemia may be sufficiently severe to depress the response of the animal to pain stimuli, but in less severe cases the animal usually adopts an arched-back posture and shows evidence of pain on palpation of the abdominal wall. Inflammation of the serous surfaces of the peritoneum causes pain, which may be severe enough to result in rigidity of the abdominal wall and the assumption of an abnormal humped-up posture.

Paralytic ileus

Paralytic ileus occurs as a result of reflex inhibition of alimentary tract tone and movement in acute peritonitis. It is also an important sequel to intestinal obstruction and to traumatic abdominal surgery, in which much handling of viscera is unavoidable. Rarely, it arises because of ganglionitis and a loss of neural control of peristalsis, similar to the idiopathic intestinal pseudo-obstruction of humans.[11] The net effect is **functional obstruction of the intestine**, which, if persistent, will increase the likelihood of death. The end result is a complete absence of defecation, often with no feces present in the rectum.

Accumulation of fluid exudate

Accumulation of large quantities of inflammatory exudate in the peritoneal cavity may cause visible abdominal distension and, if severe enough, interfere with respiration by obstruction of diaphragmatic movement. It is a comparatively rare occurrence but needs to be considered in the differential diagnosis of abdominal distension.

Adhesions

Trauma to the peritoneum results in a serosanguineous exudate, which contains two closely bound proteins: fibrinogen and plasminogen. **Fibrinogen** is converted by thrombin to fibrin, forming an early fibrinous adhesion. **Plasminogen** may be converted by plasminogen activators to plasmin, a specific fibrinolytic enzyme favoring lysis of the early adhesion. Peritoneal mesothelial cells are a source of plasminogen activators and each species of domestic animal has its own baseline peritoneal plasminogen activity. Cattle have a high capacity to respond to trauma with fibrin deposition.[6] Intra-abdominal fibrin deposition and adhesion formation is the most important factor in localizing peritonitis after peritoneal trauma from penetrating foreign bodies or abomasal ulcers. However, these adhesions can cause mechanical or functional intestinal obstruction.

In **chronic peritonitis**, the formation of adhesions is more important than either of the two preceding pathogenetic mechanisms. Adhesions are an essential part of the healing process and are important to localize the inflammation to a particular segment of the peritoneum. If this healing process is developing satisfactorily and the signs of peritonitis are diminishing, it is a common experience to find that vigorous exercise causes breakdown of the adhesions, spread of the peritonitis and return of the clinical signs. Thus, a cow treated conservatively for traumatic reticuloperitonitis by immobilization may show an excellent recovery by the third day but, if allowed to go out to pasture at this time, may suffer an acute relapse. The secondary adverse effects of adhesions may cause partial or complete **obstruction of the intestine** or stomach, or by fixation to the body wall interfere with normal gut motility. Adhesions are important in the pathogenesis of vagus indigestion in cattle.

CLINICAL FINDINGS

Peritonitis is common in cattle, less common in horses and rarely, if ever, identified clinically in sheep, pigs or goats. There are general signs applicable to all species and most forms of the disease in a general way. In addition, there are special findings peculiar to individual species and to various forms of the disease.

Acute and subacute peritonitis

Inappetence and anorexia

Inappetence occurs in less severe and chronic cases, and complete anorexia in acute diffuse peritonitis.

Toxemia and fever

Toxemia, usually with a fever, is often present but the severity varies depending on the area of peritoneum involved, the identity of the pathogens and the amount of tissue injury. For example, in cattle with acute local peritonitis the temperature will be elevated (39.5°C; 103°F) for the first 24–36 hours, but then return to normal even though the animal may still be partly or completely anorexic. A high fever (up to 41.5°C; 106°F) suggests an acute diffuse peritonitis, but in the terminal stages the temperature usually falls to subnormal. It is most noteworthy that a normal temperature does not preclude the presence of peritonitis. In horses with peritonitis, the temperature will usually exceed 38.5°C but the fever may be intermittent.[12] There is usually a moderate increase in heart and respiratory rates, the latter contributed to by the relative fixation of the abdominal wall because of pain. In some cases there is spontaneous grunting at the end of each expiratory movement.

Feces

The amount and composition of feces is usually abnormal. The transit time of ingesta through the alimentary tract is increased and the dry matter content of the feces increases. The amount of feces is reduced, although in the early stages there may be transient period of increased frequency of passage of small volumes of soft feces, which may give the false impression of increased fecal output. In some horses with peritonitis, periods of diarrhea may occur but the feces are usually reduced in amount.[12] Feces may be completely absent for periods of up to 3 days, even in animals that recover, and the rectum may be so dry and tacky, because of the presence of small amounts of tenacious mucus, that it is difficult to do a rectal examination. This may suggest a complete intestinal obstruction.

In pastured cattle with peritonitis the feces are characteristically scant, dark and like small fecal balls accompanied by thick, jelly-like mucus. The feces may alternatively have a thick, sludge-like consistency, be tenacious and difficult to remove from a rubber glove, and have a foul smell.

Alimentary tract stasis

As well as absence of feces, there are other indicators of intestinal stasis. In cows with acute peritonitis ruminal contractions are reduced or absent; in chronic peritonitis the contractions may be present but are weaker than normal. In the horse, intestinal stasis is evidenced by an absence or reduction of typical intestinal peristaltic sounds on auscultation, although the tinkling sounds of paralytic ileus may be audible. It is very important to differentiate the two.

Abdominal pain evidenced by posture and movement

In cattle with acute peritonitis there is a disinclination to move, disinclination to lie down, lying down with great care and grunting with pain. The posture includes a characteristically arched back, the gait is shuffling and cautious, with the back held rigid and arched. Grunting at each step and when feces or urine are passed is common, and when urine is eventually passed it is usually in a very large volume. Sudden movements are avoided and there is an absence of kicking or bellowing or licking the coat.

In horses these overt signs of peritonitis that characterize the condition in cattle are uncommon, which makes the diagnosis difficult. In the horse peritonitis is often manifested as an episode of abdominal pain including flank watching, kicking at the belly and going down and rolling, which suggests colic caused by intestinal obstruction.[8,11]

In a series of 51 cases of peritonitis associated with *A. equuli* in horses, most had tachycardia, increased respiratory rates, fever and reduced intestinal borborygmi.[9] Affected horses were depressed, lethargic and inapparent. Mild to moderate abdominal pain was manifested as reluctance to move, pawing on the ground, lying down or splinting of the abdominal musculature. The onset of clinical signs was acute (< 24 h) in 30 horses, 1–4 days in 8 horses, or longer and associated with weight loss in 3 horses. In 10 horses, there was no record of the duration of clinical signs.

Abdominal pain as evidenced by deep palpation

In cattle, deep firm palpation of the abdominal wall elicits an easily recognized pain response. It may be possible to elicit pain over the entire abdominal wall if the peritonitis is widespread. If it is localized the response may be detectable over only a very small area. Increased tenseness of the abdominal wall is not usually detectable in the cow, although it is responsible for the characteristic arched-back posture and apparent gauntness of the abdomen, because the wall is already tightly stretched anyway.

Several methods are used to elicit a grunt in cattle with abdominal pain. In average-sized cows with acute local peritonitis (most commonly traumatic reticuloperitonitis), while listening over the trachea with a stethoscope, a controlled upward push with the closed fist of the ventral body wall caudal to the xiphoid sternum is most successful. In large bulls, especially if the peritonitis is subsiding, it may be difficult to elicit a grunt with this method. In these cases, the best technique is to use a heavy pole held horizontally under the area immediately caudal to the xiphoid sternum to provide a sharp lift given by assistants holding the pole on either side. **Pinching of the withers** while auscultating over the trachea is also used and with some clinical experience is highly reliable.

In horses with acute or subacute peritonitis, it is usually easy to elicit a pain response manifested by the animal lifting its leg and turning its head with anger when its lower flank is firmly lifted, but not punched. The abdominal wall also feels tense if it is lifted firmly with the heel of the hand. In all cases of peritonitis in all species a pain response is always much more evident in the early stages of the disease and severe chronic peritonitis can be present without pain being detected on palpation.

Rectal examination

The general absence of feces is characteristic. In cattle, it may be possible to palpate slightly distended, saggy, thick-walled loops of intestine in some cases. Also, it may be possible to feel fibrinous adhesions separating as the intestines are manipulated. Adhesions are not often palpable and their absence should not be interpreted as precluding the presence of peritonitis. Only adhesions in the caudal part of the abdomen may be palpable. Tough, fibrous adhesions may be present in long-standing cases. In horses, there are no specific rectal findings, other than a reduced fecal output, to indicate the presence of peritonitis. Distension of segments of both the small and large intestines may provide indirect evidence of paralytic ileus. However, there is a lack of clarity as to what can be felt in chronic cases because of the presence of fibrin deposits and thickening of the peritoneum. There may also be more than usual pain when an inflamed area is palpated or a mesenteric band or adhesion is manipulated.

In rupture of the rectum associated with a difficult dystocia, the rupture is usually easily palpable rectally in the ventral aspect of the rectum deep in the abdomen.[2] Distended loops of intestine may become entrapped in the rectal tear.

Peracute diffuse peritonitis

In those cases in which profound toxemia occurs, especially in cows immediately after calving or when rupture of the alimentary tract occurs, the syndrome is quite different. There is severe weakness, depression and circulatory failure. The animal is recumbent and often unable to rise, depressed almost to the point of coma, has a subnormal temperature of 37–37.5°C (99–100°F), a high heart rate (110–120/min) and a weak pulse. No abdominal pain is evidenced spontaneously or on palpation of the abdominal wall. In mares that rupture the dorsal sac of the cecum during foaling, the owner observes that the mare has been straining and getting results when suddenly she stops making violent muscular contractions, and progress towards expelling the foal ceases.[13] Moderate abdominal pain followed by shock are characteristic developments. Death follows 4–15 hours after the rupture.

The outcome in cases of acute, diffuse peritonitis varies with the severity. Peracute cases accompanied by severe toxemia usually die within 24–48 hours. The more common, less severe cases may be fatal in 4–7 days, but adequate treatment may result in recovery in about the same length of time.

In a series of 31 cases of generalized peritonitis in cattle most cases occurred peripartum.[14] The most consistent clinical findings were depression, anorexia, decreased fecal output and varying degrees of dehydration. The duration of illness ranged from 1–90 days with a median of 4 days. In 19 animals, the duration of clinical disease was less than 1 week and in 12 cases the duration of illness was more than 1 week. All animals died or were euthanized.

Chronic peritonitis

Cattle

The development of adhesions, which interfere with normal alimentary tract movements, and gradual spread of infection as adhesions break down combine to produce a chronic syndrome of indigestion and toxemia that is punctuated by short, recurrent attacks of more severe illness. The adhesions may be detectable on rectal examination but they are usually situated in the anterior abdomen and are impalpable. If partial intestinal obstruction occurs, the bouts of pain are usually accompanied by a marked increase in alimentary tract sounds and palpable distension of intestinal loops with gas and fluid. The course in chronic peritonitis may be several weeks and the prognosis is not favorable because of the presence of physical lesions caused by scar tissue and adhesions. In some cases there is marked abdominal distension with many liters of turbid-infected fluid present. This may be restricted in its location to the omental bursa.[15] Detection of fluid in the peritoneal cavity of a cow is not easy because of the fluid nature of the ruminal contents. Results obtained by testing for a fluid wave should be interpreted cautiously. Collection of fluid by paracentesis abdominis is the critical test.

Horses

Horses with chronic peritonitis usually have a history of ill-thrift for a period of several weeks. Weight loss is severe and there are usually intermittent episodes of abdominal pain suggesting intestinal colic. Gut sounds are greatly diminished or absent, and subcutaneous edema of the ventral abdominal wall occurs in some cases. There may also be a contiguous pleurisy. Identification of the cause of the colic depends on the examination of a sample of peritoneal fluid.

Diagnostic medical imaging

In cattle with traumatic reticuloperitonitis, inflammatory fibrinous changes, and abscesses can be imaged[16] (see also Ch. 6).

In cattle, standing reticular radiography is a useful aid for the diagnosis and management of traumatic reticuloperitonitis.[5] It can accurately detect the presence of a foreign body and in most instances if that foreign body is perforating the reticular wall.

CLINICAL PATHOLOGY

Hematology

The total and differential leukocyte count is a useful aid in the diagnosis of peritonitis and in assessing its severity. In acute diffuse peritonitis with toxemia there is usually a leukopenia, neutropenia and a marked increase in immature neutrophils (a degenerative left shift). There is 'toxic' granulation of neutrophils. In less severe forms of acute peritonitis of a few days' duration there may be a leukocytosis due to a neutrophilia with the appearance of immature neutrophils. In acute local peritonitis, commonly seen in acute traumatic reticuloperitonitis in cattle, there is commonly a normal total leukocyte count, or a slight increase, with regenerative left shift. In chronic peritonitis, depending on the extent of the lesion (diffuse or local), the total and differential leukocyte count may be normal, or there may be a leukocytosis with a marked neutrophilia and occasionally an increase in the total numbers of lymphocytes and monocytes. The plasma fibrinogen levels in cattle, in general, tend to increase as the severity of acute peritonitis increases and may be a useful adjunct to the cell counts for assessing severity.[5]

In horses with peritonitis associated with *A. equuli*, there was hemoconcentration, hypoproteinemia and a neutrophilia count with a left shift.

Abdominocentesis and peritoneal fluid

Examination of peritoneal fluid obtained by paracentesis is a valuable aid in the diagnosis of peritonitis and in assessing its severity. It may also provide an indication of the kind of antibacterial treatment required. The values in healthy horses, and horses with various intestinal or peritoneal diseases are provided in Table 5.2. The maximum peritoneal fluid nucleated cell counts in healthy foals is much lower than reported maximum values for adult horses[17] and similarly for calves. Particular attention should be paid to:

- The ease of collection of the sample as a guide to the amount of fluid present
- Whether it is bloodstained, indicating damage to a wall of the viscus
- The presence of feed or fecal material, indicating intestinal ischemic necrosis or rupture
- Whether it clots and has a high protein content, indicating inflammation rather than simple transudation
- The number and kinds of leukocytes present, as an indication of the presence of inflammation, and also its duration
- Microbiological examination.

When these results are available they should be interpreted in conjunction with the history, clinical signs and other results, including hematology, serum chemistry and possibly radiology. In particular, it must be noted that failure to obtain a sample does not preclude a possible diagnosis of peritonitis.

Interpretation of peritoneal fluid is also influenced by simple manipulation of the abdominal viscera and the response is greater than that following opening and closing of the abdomen without manipulation of the viscera. Surgical manipulation results in a significant and rapid postoperative peritoneal inflammatory reaction.[11]

In peritonitis in horses associated with *A. equuli*, the peritoneal fluid was turbid and had an abnormal color in 98% of cases. The protein content was elevated above normal in 50 samples (range 25–84 g/L, mean 44 g/L, normal < 20 g/L).

Total nucleated cell count was elevated in all samples (range 46–810 $\times 10^9$ cells/L, mean 230 $\times 10^9$ cells/L, normal < 10 $\times 10^9$ cells/L). A nucleated cell count above 100 $\times 10^9$ cells/L, was present in 88% of animals.[9] Pleomorphic Gram-negative rods were seen on cytology in 53% of samples, and a positive culture of *A equuli* was obtained in 72% of samples.

Experimentally, resection and anastomosis of the small colon in healthy horses causes a different inflammatory response than does manipulation. Absolute values in the peritoneal fluid for cell count, total protein and differential count are inadequate to differentiate between a normal surgical reaction and a postoperative infection. Cytological examination of peritoneal fluid is necessary to demonstrate degenerative cell changes and the presence of bacteria and ingesta. The peripheral leukon and fibrinogen concentration should always be compared with the peritoneal fluid for evidence of postsurgical infection. The nucleated cell and red blood counts of peritoneal fluid are commonly elevated for several days in horses following open castration.[15] These elevated counts may be mistaken for peritonitis.

Septic peritonitis in the horse

Diagnosis of septic peritonitis is routinely made on the basis of physical examination and hematologic findings, and peritoneal fluid analysis.[18] After abdominal surgery, differentiation between septic peritonitis and other postoperative complications can be difficult using physical and hematological findings alone. As a result of the exploratory process itself, diagnosis of septic peritonitis is often complicated in horses after surgery because the total nucleated cell count and protein concentration in the peritoneal fluid are often high. Consequently, identification of bacteria on cytological evaluation or isolation of bacteria from peritoneal fluid is a more definitive indicator of septic peritonitis, but sometimes there are false-negative results. Although bacterial cultures are considered the standard criterion for the diagnosis of sepsis, positive results may not always be obtained and results may be delayed by a minimum of 24 hours for aerobic organisms and up to 10–14 days for anaerobic organisms. Thus ancillary tests such as pH, glucose concentrations and lactate dehydrogenase (LDH) activity in equine pleural and synovial fluid have been used to detect sepsis with the potential advantages of speed, ease of measurement and lower cost relative to bacterial cultures.[18]

Horses with septic peritonitis have significantly lower peritoneal fluid pH and glucose concentrations than horses with nonseptic peritonitis and healthy horses.[18] Compared with other tests, serum-to-peritoneal fluid glucose concentration differences of more than 50 mg/dL had the highest diagnostic use for detection of septic peritonitis. Peritoneal fluid pH below 7.3, glucose concentration below 30 mg/dL and fibrinogen concentration above 200 mg/dL were also highly indicative of septic peritonitis.

NECROPSY FINDINGS

In acute diffuse peritonitis, the entire peritoneum is involved but the most severe lesions are usually in the ventral abdomen. Gross hemorrhage into the subserosa, exudation and fibrin deposits in the peritoneal cavity and fresh adhesions that are easily broken down are present. In less acute cases, the exudate is purulent and may be less fluid, often forming a thick, cheesy covering over most of the viscera. In cattle, *F. necrophorum* and *Actinomyces (Corynebacterium) pyogenes* are often present in large numbers and produce a typical, nauseating odor. Acute local peritonitis and chronic peritonitis are not usually fatal and the lesions are discovered only if the animal dies of intercurrent disease such as traumatic pericarditis or intestinal obstruction.

DIAGNOSIS

The diagnosis of peritonitis can be difficult because the predominant clinical findings are often common to other diseases. The clinical features that are the most reliable as indicators of peritonitis are:

- Abnormal feces – in amount and composition
- Alimentary tract stasis based on auscultation and evaluation of the passage of feces
- Abdominal pain evinced as a groan with each respiration or on light or deep percussion of the abdomen
- Abnormality of intestines on rectal palpation
- Fibrinous or fibrous adhesions on rectal palpation
- Abnormal peritoneal fluid with an increased leukocyte count collected by paracentesis
- A normal or low blood leukocyte count with a degenerative left shift
- The peritonitis may be chemical, so that, although microbiological examination usually yields positive results, these are not essential to a diagnosis of peritonitis.

PROGNOSIS

Case fatality rate in horses

Peritonitis in the horse is a potentially life-threatening disease that must be treated promptly and aggressively.[20]

DIFFERENTIAL DIAGNOSIS

The diseases which could be considered in the differential diagnosis of peritonitis are as follows.

Cattle

- **Acute local peritonitis** – Traumatic reticuloperitonitis, acute intestinal obstruction, splenic or hepatic abscess, simple indigestion, abomasal displacement (right and left), postpartum metritis, ketosis
- **Acute diffuse peritonitis** – Parturient paresis, coliform mastitis (peracute form), acute carbohydrate indigestion, perforation of or rupture at abomasal ulcer, acute intestinal obstruction, uterine rupture, postpartum metritis
- **Chronic peritonitis** – Vagus indigestion, lipomatosis or extensive fat necrosis of the mesentery and omentum, persistent minor leakage from an intestinal lesion, large accumulations of fluid as in ascites, rupture of bladder, chronic pneumonia and chronic toxemias due to a great variety of causes
- **Ascites** associated most commonly with primary or secondary cardiac disease, cor pulmonale with chronic pneumonia, endocarditis, thrombosis of the caudal vena cava, and diffuse abdominal epithelioid mesothelioma[19]

Horses

- **Acute and subacute peritonitis** – Acute intestinal obstruction and thromboembolic colic
- **Chronic peritonitis** – Repeated overeating causing colic, internal abdominal abscess (retroperitoneal or mesenteric abscess) may be classified as chronic peritonitis but is dealt with separately under the heading of retroperitoneal abscess. Horses with both intra-abdominal neoplasms and abscesses will have clinical findings including anorexia, weight loss, fever, colic and depression.[13] Both groups may also have peritoneal fluid that can be classified as an exudate

Pigs, sheep and goats

Peritonitis is not usually diagnosed antemortem in these species.

Therapy must be aimed at reducing systemic shock and hypovolemia, correction of the primary cause, antibiotic therapy, and abdominal drainage and lavage. The reported case fatality rates for peritonitis in horses range from 30–67%. In a series of 67 cases of peritonitis in horses, of those which developed peritonitis after abdominal surgery the case fatality was 56%.[3] Peritonitis not associated with intestinal rupture or abdominal surgery had a lower case fatality rate of 43%. Horses that died had higher heart rates, red blood cell count, serum creatinine concentration, PCV and anion gap; lower venous blood pH; and a greater number of bacterial species

cultured from the peritoneal fluid compared with survivors. Those that died were more likely to have clinical evidence of abdominal pain, shock and bacteria in the peritoneal fluid.

TREATMENT

The specific cause must be treated in each case and the treatments used are described under the specific diseases listed above. An exploratory laparotomy may be indicated to determine the cause of the peritonitis and to effect repair. The literature on the treatment of peritonitis in horses has been reviewed.[20]

Antimicrobials

Broad-spectrum antimicrobials given intravenously or intramuscularly are indicated for the infection and toxemia. However, there are no published reports of clinical trials to evaluate the effectiveness of various antimicrobials for the treatment of peritonitis in cattle or horses. Thus the recommendations are empirical. In general, **peritonitis in cattle** is commonly treated with any of the broad-spectrum antimicrobials, with the choice dependent on ease of administration and drug withdrawal times necessary in lactating dairy cattle. Treatment for traumatic reticuloperitonitis has commonly been restricted to the use of antimicrobials; supportive therapy has not been indicated with the exception of diffuse peritonitis.

Peritonitis in horses associated with abdominal surgery or rupture of the gastrointestinal tract is likely be accompanied by a mixed flora of bacteria, and broad-spectrum antimicrobials are necessary. They must be given at doses high enough to achieve high blood and tissue levels and maintained daily until recovery has occurred. In a series of cases of peritonitis in horses, the most commonly used antimicrobials were gentamicin at 2.2–3.3 mg/kg BW intravenously every 8–12 hours; penicillin at 22 000 IU/kg BW intravenously or intramuscularly every 6–12 hours. Metronidazole given orally at 15–25 mg/kg BW has also been used in horses with peritonitis.[3]

Horses with peritonitis associated with *A. equuli* respond quickly to treatment with penicillin at 20 mg/kg BW intramuscularly twice daily for 5 days to 2 weeks.[9] Most isolates of the organism are sensitive to penicillin but some are resistant and gentamicin sulfate at 6.6 mg/kg BW intravenously once daily for 5 days to 2 weeks in combination with the penicillin has also been used successfully.[9] In a series of 51 cases in horses, the recovery rate following treatment with penicillin and gentamicin and supportive therapy was 100%.[9] Most horses responded favorably within 48 hours following commencement of treatment.

Administration of antimicrobials into the peritoneal cavity has been attempted on the basis that higher levels of the drug may be achieved at the site of the inflammation. However, there is no scientific evidence that it is superior to daily parenteral administration and there is some danger of causing adhesions and subsequent intestinal obstruction.

Fluid and electrolytes

Intensive intravenous fluid and electrolyte therapy is a vital part of treatment of peritonitis when accompanied by severe toxemia and shock, especially during the first 24–72 hours following abdominal surgery in the horse. It is continued until recovery is apparent and the animal is drinking water voluntarily; water can then be supplemented with electrolytes. (See Ch. 2 for details of fluid and electrolyte therapy for the treatment of dehydration and toxemia.)

Nonsteroidal anti-inflammatory drugs

Flunixin meglumine is recommended at 0.25–1.1 mg/kg BW intravenously every 8–12 hours when the peritonitis is accompanied by shock. However, no information is available on efficacy.

Lavage

Peritoneal lavage with large volumes of fluid containing antimicrobials is rational and has been attempted when large quantities of exudate are present. However, it is not easy to maintain the patency of drains, especially in cattle. Also, peritoneum is highly susceptible to inflammation and chemical peritonitis is common following the introduction of certain materials into the peritoneal cavity. Peritoneal lavage of ponies with saline and antimicrobials induces a mild, transient inflammatory response with minimal change visible at necropsy.[21] Solutions containing povidone-iodine induced chemical peritonitis, which was severe when 10% povidone-iodine solution was used. A 3% solution also causes peritonitis and the use of these solutions is not recommended. Extreme caution is required when foreign materials are introduced into the cavity in order to avoid exacerbating the existing inflammation. The peritoneum is also a very vascular organ and toxic material is rapidly absorbed from it.

An **active intra-abdominal drain** has been used successfully to treat abdominal contamination in horses.[22] Closed-suction abdominal drains were placed, mostly under general anesthesia. Abdominal lavage was done every 4–12 hours and about 83% of the peritoneal lavage solution was retrieved.

Prevention of adhesions

No attempt is made to prevent the development of adhesions.

RECTAL TEARS

Iatrogenic tears of the equine rectum are a serious problem in equine practice. They are a leading cause of malpractice suits for the veterinarian, comprising approximately 7% of insurance claims against veterinarians in equine practice in the USA,[1] and can be a large economic loss for the owner. Occurrence of rectal tears is often an emotionally charged event because they are unexpected and they usually occur in otherwise healthy horses being subjected to routine rectal examination. Prompt diagnosis and vigorous treatment, along with frank disclosure of the event to the horse's owner or handler, is essential in increasing the likelihood of a good outcome both for the horse and for the veterinarian–client relationship.

ETIOLOGY

The etiology of rectal tears is usually readily apparent, with the vast majority of rectal tears in horses being iatrogenic. Iatrogenic rupture occurs during rectal examination by veterinarians or laypersons for reproductive management (brood mares), or examination of other

intra-abdominal structures, for example during evaluation of a horse with colic.[2] Spontaneous or non-iatrogenic rupture can occur associated with infarctive lesions of the distal small colon or rectum, injuries during parturition or coitus, and malicious trauma caused by insertion of foreign objects by attendants.[3] It is important that rectal tears should not be assumed to be iatrogenic until a thorough evaluation of the animal and the history has been performed.

EPIDEMIOLOGY

Risk factors for rectal tears in horses have not been well quantified but include:

- Age – young animals appear to be at increased risk, perhaps because they are smaller and less accepting of rectal palpation
- Sex – stallions and geldings have a smaller pelvic inlet than do mares and appear to have a rectum of smaller diameter than mares, thus increasing the risk of tension on the wall of the rectum, with subsequent tearing
- Breed – Arabian horses appear to be at increased risk of iatrogenic rectal tears
- Size – smaller animals can be at increased risk
- Inadequate restraint – horses must be adequately restrained for rectal examination (see Prevention, below)
- Inadequate preparation of the rectum – the rectum and distal small colon should be emptied of feces before an examination of the reproductive organs or gastrointestinal tract is performed
- The experience of the examiner is not a factor in the risk of rectal tears in horses[4]
- The use of ultrasonographic probes per rectum does not appear to increase the risk of rectal tears.[4]

The **case fatality rate** varies depending on the type of tear (see Clinical signs, below). Horses with grade I or II tears almost all survive, whereas the survival rate for horses with grade III tears treated appropriately is 60–70%.[5] Almost all horses with Grade IV rectal tears die.

PATHOGENESIS

Rectal tears occur in horses because the rectum of the horse is so sensitive and fragile and powerful contractions occur during rectal palpation. In contrast, the bovine rectum is relatively durable and, while often traumatized, is rarely ruptured. Tears occur because of excessive tension on the rectal wall. This usually occurs in horses by peristalsis and contraction of the rectum over the examiner's hand, with splitting of the rectum often occurring over the back (knuckles) of the hand.

Complete rupture of the peritoneal portion of the rectum results in fecal contamination of the abdomen and rapid onset of septic peritonitis and death. Tears in the nonperitoneal portion of the rectum (that is, caudal to the peritoneal reflection) cause perirectal cellulites and abscessation.

CLINICAL SIGNS

The prominent clinical sign of the occurrence of a rectal tear is the presence of blood on the rectal sleeve of the examiner. Slight blood staining of mucus or lubricant is usually not associated with rectal tears (although this should be verified by repeat examination) whereas the presence of frank hemorrhage on the sleeve is usually indicative of a rectal tear. The rectum in an adult, 450 kg horse, is approximately 30 cm long and is partially within the abdomen, where it is covered by peritoneum, and partially in the pelvic canal, where it is not surrounded by peritoneum but is supported by thick connective tissue and muscle. The peritoneal portion of the rectum is supported dorsally by the mesorectum (mesocolon). Most iatrogenic rectal tears in horses occur within 25–30 cm of the anus, but can occur up to 60 cm from the anus, in the peritoneal portion of the rectum. The tears are almost always in the dorsal or dorsolateral wall and are longitudinal (parallel to the long axis of the rectum). It is speculated that the dorsal wall of the rectum is weaker than other segments because it is not covered by serosa, and blood vessels perforate the muscularis layers, thereby weakening it.[5]

Rectal tears in the horse have been classified according to the layers of the rectal wall disrupted. The classification is also a useful guide to the clinical signs to be expected and the treatment that is indicated (see under 'Treatment' for management of each grade of tear):

- Grade I – Disruption of the mucosa only, or the mucosa and submucosa. There are usually no clinical signs other than some blood on the examiner's sleeve. Most of these injuries occur to the mucosa of the ventral aspect of the rectum[5]
- Grade II – Disruption of the muscular layer of the rectal wall with the mucosal and serosal surfaces intact. This is a rarely recognized form of tear. There are minimal clinical signs
- Grade IIIa – Tear includes mucosa, submucosa and muscularis but the serosal surface is intact. This degree of tear usually causes septic peritonitis. If the tear is caudal to the peritoneal reflection the pelvic fascia becomes infected, but the infection may remain contained within it for 7–10 days, forming a local cellulitis or abscess. During this period, the horse is likely to be affected by mild chronic peritonitis, with mild abdominal pain, fever and mild toxemia. At the end of this time, the infection can erode through the peritoneum and cause an acute, severe, diffuse peritonitis, or rupture through the perianal tissue causing a fistula
- Grade IIIb – Tear is on the dorsal wall and includes the mucosa, submucosa and muscularis. Because there is no serosa at this position, the tear extends into the mesocolon. There is usually septic peritonitis
- Grade IV – Complete rupture with leakage of fecal material into the peritoneal space. Clinical signs of septic peritonitis are severe and death is inevitable.

Horses with a rectal tear will not display any immediate signs of discomfort. However, if there is grade III or grade IV tear, the horse will have signs of septic peritonitis, including elevated heart and respiratory rates, sweating, colic, increased capillary refill time and discolored mucus membranes, within 1–2 hours.

CLINICAL PATHOLOGY

Hematological and serum biochemical changes in horses with grade III and grade IV tears are consistent with acute septic peritonitis. These changes include leukopenia and neutropenia, increased band cell count, elevated hematocrit and total protein concentration initially, after which serum total protein concentration can decline as protein leaks into the abdomen. Peritoneal fluid has a high white blood cell count and protein concentration. Cytological examination reveals the presence of degenerate neutrophils, intra- and extracellular bacteria and plant material.

PROGNOSIS

The prognosis depends of the size, grade and location of the tear and the time between occurrence and treatment. All horses with grade I or II lesions survive, approximately 60–70% of horses with grade III lesions survive, and almost all horses with grade IV lesions die.[5]

TREATMENT

If the person doing the rectal examination feels the mucosa tear, if there is blood on the rectal sleeve, or if a horse that has had a rectal examination up to 2 hours previously starts to sweat and manifest abdominal pain, a rectal tear should be suspected. A thorough examination should be conducted immediately but great care is necessary to avoid damaging the rectum further. The principles of care are to: verify the presence of a tear,

determine its severity, prevent leakage of fecal material into the peritoneum or tissues surrounding the tear, treat for septic peritonitis, prevent extension of the tear and provide pain relief.

Immediate care[6]

If a rectal tear is suspected the horse should be appropriately restrained and examined immediately. There should be no delay in conducting this examination. The client should be informed of the concern about a rectal tear. First aid measures taken at the time of a grade III or IV tear can have a marked influence on the outcome.[2,5] Horses with grade III or IV rectal tears should receive first aid treatment and then be referred for further evaluation and treatment.
