- The extrapyramidal system, which originates in the corpus striatum, red nucleus, vestibular nucleus and roof of the midbrain
- The peripheral nerves, which originate in the ventral horn cells.

The pyramidal tracts are of minor importance in hoofed animals (ungulates), reaching only to the fourth cervical segment. Accordingly, lesions of the motor cortex in farm animals do not produce any deficit of gait. Neither is there any paresis, although in an acute lesion weakness may be evident for the first day or two. If the lesion is unilateral the paresis will be on the contralateral side. This is in marked contradistinction to the severe abnormalities of posture and gait that occur with lesions of the pons, medulla, and spinal cord.

The main motor nuclei in these animals are subcortical and comprise the extrapyramidal system, and most combined movements are controlled by nerve stimuli originating in the tectal nuclei, reticular nuclei, vestibular nuclei and possibly red nuclei. The pyramidal and extrapyramidal tracts comprise the upper motor neurons, which reach to the ventral horn cells of the spinal cord, which cells together with their peripheral axons form the lower motor neurons. Paralysis is a physiological end result in all cases of motor nerve injury, which if severe enough is expressed clinically. The type of paralysis is often indicative of the site of the lesion.

A **lesion of the upper motor neuron** causes:

- **Spasticity with loss of voluntary movement**
- **Increased tone of limb muscles**
- **Increased spinal reflexes.**

The spasticity of an upper motor neuron lesion usually occurs with the affected limb in extension. These are all release phenomena resulting from liberation of spinal reflex arcs from higher control.

A **lesion of the lower motor neuron** causes:

- **Paresis or paralysis with loss of voluntary movement**
- **Decreased tone of the limb muscles**
- **Absence of spinal reflexes**
- **Wasting of the affected muscle (neurogenic atrophy).**

As injuries to specific peripheral nerves are treated surgically, these are dealt with in surgical textbooks and are not repeated here.

A special form of paralysis is the **Schiff–Sherrington syndrome**, which is common in dogs but recorded rarely in large animals. It is caused by acute, severe, compressive injury of the thoracolumbar spinal cord and manifested by extensor rigidity or hypertonia of the forelimbs and hypotonic paralysis of the hindlimbs. Neurons located in the lumbar spinal cord are responsible for the tonic inhibition of extensor muscle alpha motor neurons in the cervical intumescence. The cell bodies of these neurons are located in the ventral gray column from L1–L7, with a maximum population from L2–L4. Their axons ascend to the cervical intumescence. Acute severe lesions cranial to these neurons and caudal to the cervical intumescence will suddenly deprive the cervical intumescence neurons of this source of tonic inhibition, resulting in a release of these latter neurons. This results in extensor hypertonia observed in the thoracic limbs which can function normally in the gait and postural reactions, except for the hypertonia.

The degree of paresis or paralysis needs to be defined. Paralysis is identified as an inability to make purposeful movements. Thus convulsive, uncontrolled movements as they occur in polioencephalomalacia may still fit a description of paralysis. Paresis, or weakness short of paralysis, can be classified into four categories:

- Animals that cannot rise, nor support themselves if helped up, but can make purposeful movements in attempting to rise
- Animals that cannot rise but can support themselves if helped up
- Animals that can rise but are paretic and can move the limbs well and stumble only slightly on walking
- Animals that move with difficulty and have severe incoordination and stumbling.

Probably the most difficult decision in farm animal neurology is whether a patient's inability to move is because of a nervous or muscular deficit. For example, the horse recumbent because of exertional rhabdomyolysis often resembles a horse with an injured spinal cord. Examples of paresis and paralysis include:

- **Focal inflammatory, neoplastic, traumatic lesions** in the motor pathway. These lesions usually produce **an asymmetric nervous deficit**
- **Toxic and metabolic diseases** of the nervous system in their most severe form, e.g. flaccid paralysis associated with tickbite (*Ixodes holocyclus*, *Ornithodoros* sp.), poisoning, botulism, snakebite. Comparable tetanic paralyses include tetanus, lactation tetany of mares, hypomagnesemic tetany of cows and calves. In contrast to inflammatory, neoplastic and traumatic lesions in the motor pathway, toxic and metabolic lesions usually produce **a symmetric nervous deficit**.

Neurogenic muscular atrophy

Destruction of the lower motor neurons either within the vertebral canal or peripheral to it causes neurogenic atrophy. Whether or not the atrophy is visible depends on how many neurons and therefore how many muscle fibers are affected.

ALTERED SENSATION

Lesions of the sensory system are rarely diagnosed in animals, except for those affecting sight and the vestibular apparatus, because of the impossibility of measuring subjective responses.

Thus, although animals must experience paresthesia, as in Aujeszky's disease (pseudorabies) in cattle and sheep, the animal's response of licking or scratching does not make it possible to decide whether the diagnosis should be paresthesia or pruritus. Lesions of the peripheral sensory neurons cause hypersensitivity or decreased sensitivity of the area supplied by the nerve. Lesions of the spinal cord may affect only motor or only sensory fiber tracts or both, or may be unilateral.

Although it is often difficult to decide whether failure to respond to a normally painful stimulus is due to failure to perceive or inability to respond, certain tests may give valuable information. The test commonly used is pricking the skin with a needle, or pinching the skin with a pair of forceps, and observing the reaction. In exceptional circumstances light stroking may elicit an exaggerated response. The '**nibbling**' reaction stimulated by stroking the lumbar back of sheep affected with scrapie is a striking example of hypersensitivity.

In every test of sensitivity it must be remembered that there is considerable variation between animals and in an individual animal from time to time, and much discretion must be exercised when assessing the response. In any animal there are also cutaneous areas that are more sensitive than others. The face and the cranial cervical region are highly sensitive, the caudal cervical and shoulder regions less so, with sensitivity increasing over the caudal thorax and lumbar region to a high degree on the perineum. The proximal parts of the limbs are much less sensitive than the distal parts and sensitivity is highest over the digits, particularly on the medial aspect.

Absence of a response to the application of a painful stimulus to the limbs (**absence of the withdrawal reflex**) indicates interruption of the reflex arc; absence of the reflex with persistence of central perception, as demonstrated by groaning or body movement such as looking at the site of stimulus application, indicates interruption of motor pathways and that central perception of pain persists. In the horse the response can be much more subtle than in other species, with movements of the ears and eyelids being the best indicators of pain perception. Increased sensitivity is described as **hyperesthesia**, decreased as **hypoesthesia**, and complete absence of sensitivity is described as **anesthesia**. Special cutaneous reflexes include the anal reflex, in which spasmodic contraction of the anus occurs when it is touched, and the corneal reflex, in which there is closure of the eyelids on touching the cornea. The (cutaneous trunci) panniculus reflex is valuable in that the sensory pathways, detected by the prick of a pin, enter the cord at spinal cord segments T1–L3, but the motor pathways leave the cord only at spinal cord segments C8, T1, and T2. The quick twitch of the superficial cutaneous muscle along the whole back, which is the positive response (**panniculus reflex**), is quite unmistakable. Examination of the eye reflexes and hearing are discussed under examination of the cranial nerves (see below).

BLINDNESS

Blindness is manifested as a clinical abnormality by the animal walking into objects that it should avoid.

The menace or blink reflex is used to test the visual pathway. A threatening gesture of the hand (or even better by the index finger in a pointing manner) toward the eye elicits immediate closure of the eyelids. The hand must come close enough to the eye without touching the tactile hairs of the eyelids or creating a wind which can be felt by the animal. Some stoic, depressed or even excited animals may not respond to a menace reflex with closure of the eyelids; others may keep the eyelids partially or almost closed. It may be necessary to alert the patient to the risk of injury by touching the eyelids first. The menace reflex is a learned reflex that is absent in neonates.

The most definitive test is to make the animal walk an **obstacle course** and place objects in front of it so that it must step over the objects easily. A similar procedure is the only way to test for **night blindness (nyctalopia)**. The area should be dimly lit but the observer should be able to see the obstructions clearly. A decision that the animal is blind creates a need for examination of the visual pathways.

Central or peripheral blindness

Blindness may be central or peripheral. Animals with forebrain lesions are centrally blind, with depressed menace response in one or both eyes while the pupillary light reflexes are commonly intact. In peripheral blindness, such as hypovitaminosis-A, the menace reflex is absent, and the pupillary light reflexes are also absent.

Blindness can be caused by lesions along the visual pathway, from the eye to the cerebral cortex:

- **Diseases of the orbit** including keratoconjunctivitis, hypopyon, cataract, panophthalmia, mixed ocular defects inherited in white Shorthorn and Jersey cattle, night blindness in Appaloosa horses, sporadic cases of blindness due to idiopathic retinal degenerative disease in cattle
- **Diseases of the retina** including retinal dysplasia of goats, lenticular cataracts caused by poisoning with hygromycin in pigs,[9] congenital ocular malformations in calves after intrauterine infection with BVD virus (usually accompanied by cerebellar defects)
- **Diseases of the optic nerve and chiasma,** e.g. abscess of pituitary rete mirabile, constriction of optic nerve by diet deficient in vitamin A. Tumor of pituitary gland, injury to the optic

nerve, especially in horses after rearing and falling backwards. There is a sudden onset of unilateral or bilateral blindness with no ophthalmological change until 3–4 weeks after the injury, when the optic disc becomes paler and less vascular[10]

- **Metabolic or ischemic lesions of the cerebral cortex** as in polioencephalomalacia, cerebral edema, hydrocephalus
- **Localized infectious or parasitic lesions** caused by abscesses, migrating larvae
- **Functional blindness** in which there is complete, often temporary, blindness in the absence of any physical lesions. Causes are acetonemia, pregnancy toxemia and acute carbohydrate indigestion (hyper D-lactatemia) of ruminants
- **Specific poisonings** causing blindness include *Filix mas* (male fern), *Cheilanthes* spp. (rockfern) and rape. *Stypandra* spp. cause a specific degeneration of the optic nerves. Lead poisoning in cattle.

ABNORMALITIES OF THE AUTONOMIC NERVOUS SYSTEM

Lesions affecting the cranial parasympathetic outflow do so by involvement of the oculomotor, facial, vagus, and glossopharyngeal nerves or their nuclei and the effects produced are discussed under examination of the individual nerves.

In general, the lesions cause abnormality of pupillary constriction, salivation and involuntary muscular activity in the upper part of the alimentary and respiratory tracts. Lesions of the spinal sympathetic system interfere with normal function of the heart and alimentary tract. For the most part, affections of the autonomic nervous system are of minor importance in farm animals. Central lesions of the hypothalamus can cause abnormalities of heat exchange, manifested as neurogenic hyperthermia or hypothermia and obesity, but they are also of minor importance.

Some manifestations of autonomic disease are important. Autonomic imbalance is usually described as the physiological basis for spasmodic colic of horses; grass sickness of horses is characterized by degenerative lesions in the sympathetic ganglia; involvement of the vagus nerve in traumatic reticuloperitonitis of cattle can lead to impaired forestomach and abomasal motility and the development of vagus indigestion.

Defects of sphincter control and motility of the bladder and rectum may also be of importance in the diagnosis of defects of sacral parasympathetic outflow and the spinal sympathetic system. The sacral segments of the spinal cord are the critical ones, and loss of their function will cause incontinence of urine and loss of rectal tone. The parasympathetic nerve supply to the bladder stimulates the detrusor muscle and relaxes the sphincter; the sympathetic nerve supply has the reverse function. A spinal cord lesion may cause loss of the parasympathetic control and result in urinary retention. Incontinence, if it occurs, does so from overflow. When the sympathetic control is removed incontinence occurs but the bladder should empty. Similar disturbances of defecation occur. Both micturition and defecation are controlled by medullary and spinal centers but some measure of control is regained even when the extrinsic nerve supply to the bladder and rectum is completely removed.

Special examination of the nervous system

Veterinarians commonly include several components of a neurological examination in a complete clinical examination. Most often a diagnosis and differential diagnosis can be made from consideration of the history and the clinical findings. However, if the diagnosis is uncertain it may be necessary to conduct a complete neurological examination, which may uncover additional clinical findings necessary to make a diagnosis and give a prognosis.

The accuracy of clinical diagnosis of neurological diseases in the horse is high.[11] In a study of 210 horses in which a definitive pathological diagnosis was confirmed, the overall accuracy of clinical diagnosis for all diseases was 0.95; the accuracy ranged from 0.79–1.00, the sensitivity varied from 0.73–0.95 and the specificity varied from 0.88–1.00 for individual disease categories. Some neurological diseases are therefore underdiagnosed while others are overdiagnosed. The use of careful and thorough clinical examinations and diagnostic techniques, combined with confirmed pathological diagnoses, will result in more accurate diagnosis and therapy. Retrospective studies of series of ataxic horses, for example, will add to the body of knowledge and improve diagnosis.[12]

THE NEUROLOGICAL EXAMINATION

The primary aim of the neurological examination is to confirm whether or not a neurological abnormality exists and to determine the neuroanatomical location of the lesion.[13] A clinicoanatomical diagnosis is necessary before one can develop a list of differential diagnoses and decided whether or not treatment is possible. The format for a precise practical examination procedure that is logical in sequence, easy to remember with practice, and emphasizes the need for an anatomical diagnosis is outlined below. The rationale for the sequence is that the examination starts from a distance to assess posture and mentation, and then proceeds to a closer examination that may require placing the animal in stocks or a chute. The examination sequence is therefore suitable for minimally handled beef cattle, dairy cattle, horses, sheep, goats, and New World camelids. The results of the neurological examination should be documented and not left to memory. There are many standard examination forms available that outline each step in the examination and provide for documentation of the results.

SIGNALMENT AND EPIDEMIOLOGY

The age, breed, sex, use, and value of the animal are all important considerations in the diagnosis and prognosis of neurological disease. Some diseases occur more frequently under certain conditions: for example, lead poisoning in nursing beef calves turned out to pasture in the spring of the year. *Histophilus somni* meningoencephalitis occurs most commonly in feedlot cattle from 6–10 months of age and hypovitaminosis-A occurs most commonly in beef calves 6–8 months of age after grazing dry summer pastures. In the horse there are several clearly defined diseases that affect the spinal cord including cervical stenotic myelopathy, degenerative myeloencephalopathy, protozoal myelitis, equine rhinopneumonitis myelopathy, rabies polioencephalomyelitis and equine motor neuron disease.[14] Some of these diseases have distinguishing epidemiological characteristics that are useful in diagnosis and differential diagnosis.[9] The neurological examination of the newborn foal is fraught with hazards because of the different responses elicited from those in adults. The differences relate mostly to the temporary dysmetria of gait and exaggerated responses of reflexes.

HISTORY

Special attention should be given to the recording of an accurate history. The questioning of the owner should focus on the primary complaint and when it occurred and how it has changed over time (**the time–sign relationship**). The duration of signs, the mode of onset, particularly whether acute with later

subsidence, or chronic with gradual onset, the progression of involvement and the description of signs that occur only intermittently should be ascertained. When the disease is a herd problem the morbidity and mortality rates and the method of spread may indicate an intoxication when all affected animals show signs within a very short period. Diseases associated with infectious agents may have an acute or chronic onset. Neoplastic diseases of the nervous system may begin abruptly but are often slowly progressive. For some diseases, such as epilepsy, consideration of the history may be the only method of making a diagnosis.[15] Traumatic injuries have a sudden onset and then often stabilize or improve.

When obtaining a history of convulsive episodes an estimate should be made of their duration and frequency. The pattern is also of importance, and may be diagnostic, e.g. in salt poisoning in swine. The occurrence of pallor or cyanosis during the convulsion is of particular importance in the differentiation of cardiac syncope and a convulsion originating in the nervous system.

HEAD

Behavior

The owner should be questioned about the animal's abnormal behavior, which can include bellowing, yawning, licking, mania, convulsions, aggressiveness, head-pressing, wandering, compulsive walking and head-shaking.[16] Head-shaking may be photic in origin and can be tested by the application of blindfolds, covering the eyes with a face mask and observing the horse in total darkness outdoors.[17] In one horse, head-shaking ceased with blindfolding or night darkness outdoors, and became less with the use of gray lenses. Outdoor behavior suggested efforts to avoid light.

Mental status

Assessment of mental status is based on the animal's level of awareness or consciousness. Coma is a state of complete unresponsiveness to noxious stimuli. Other abnormal mental states include stupor, somnolence, deliriousness, lethargy and depression. Large animals that are recumbent because of spinal cord disease are commonly bright and alert unless affected with complications, which may cause fever and anorexia. Mature beef cattle that are recumbent with a spinal cord lesion and not used to being handled may be quite aggressive and apprehensive.

Head position and coordination

Lesions of the vestibular system often result in a head tilt. Lesions of the cerebrum often result in deviation of the head and neck. In cerebellar disease, there may be jerky movements of the head, which are exaggerated by increasing voluntary effort. These fine jerky movements of the head are called intention tremors. Animals with severe neck pain will hold their neck in a fixed position and be reluctant to move the head and neck. Head-shaking in horses has been associated with ear mite infestation, otitis externa, cranial nerve dysfunction, cervical injury, ocular disease, guttural pouch mycosis, dental periapical osteitis and vasomotor rhinitis.[16] However, idiopathic head-shaking in the horse is often associated with evidence of nasal irritation, sneezing and snorting, nasal discharge, coughing and excessive lacrimation.

Cranial nerves

Abnormalities of cranial nerve (CN) function assist in localizing a lesion near or within the brainstem. Some of the information on cranial nerve dysfunction is presented in tabular form (Tables 12.1–12.6) in addition to the more detailed examination described here.

Olfactory nerve (CN I)

Tests of smell are unsatisfactory in large animals because of their response to food by sight and sound.

Optic nerve (CN II)

The only tests of visual acuity applicable in animals are testing the eye preservation (menace) reflex: provoking closure of the eyelids and withdrawal of the head by stabbing the finger at the eye; and by making the animal run a contrived obstacle course. Both tests are often difficult to interpret and must be carried out in such a way that other senses are not used to determine the presence of the obstacles or threatened injury. In more intelligent species, a good test is to drop some light object such as a handkerchief or feather in front of the animal. It should gaze at the object while it is falling and continue to watch it on the ground. The same method can be applied to young ruminants, which demonstrate normal vision by following the examiner's moving hand at an age so early that they have not yet developed a

Table 12.1 Correlation between clinical findings and location of lesions in the nervous system of farm animals: abnormalities of mental state (behavior)

Principal sign	Secondary signs	Location of lesion	Example
Mania hysteria/hyperexcitability	Continuous, leading to paralysis; aggression, convulsions	Cerebrum-limbic system	Peracute lead poisoning, rabies, encephalitis
	Intermittent, acetonuria, signs of hepatic insufficiency	Cerebrum-limbic system	Hypoglycemia, hypoxia
Coma (recumbency with no response to stimuli; dilated pupils)	Gradual development. Hypothermia, peripheral vascular collapse. Clinicopathological tests	Cerebral-brainstem reticular formation (ascending reticular activating system)	Hepatic insufficiency, uremia, toxemia, septicemia
	Sudden onset. Normal temperature, pulse/heart rate slow to normal, nose bleed, skin laceration, bruising middle of forehead or poll	Cerebral-brainstem reticular formation (ascending reticular activating system)	Accidental, severe blunt trauma with edema, concussion, contusion of brain
Narcolepsy/catalepsy. Uncontrollable sleep	With or without sudden loss of consciousness, intermittent falling due to loss of voluntary motor function	Brainstem control of cerebral cortex	Inherited in Shetland ponies, American miniature horses, and Suffolk horses
Compulsive walking and head-pressing, aggressive behavior, grinding of teeth.	Apparent blindness, nystagmus	Cerebral-visual cortex and limbic system	Increased intracranial pressure in polioencephalomalacia
No ataxia	Apparent blindness, no nystagmus, hepatic insufficiency shown on clinical pathology tests	Cerebral-visual cortex and limbic system	Hepatic insufficiency (i.e. ammonia intoxication; in pyrrolizidine poisoning)
Imbecility in neonate; lack of response to normal stimuli; can walk, stand	Blindness	Cerebral cortex absent; hydrencephaly	Intrauterine infection with Akabane or bovine virus diarrhea (BVD) virus in calves

Table 12.2 Correlation between clinical findings and location of lesion in the nervous system of farm animals: involuntary movements

Principal sign	Secondary signs	Location of lesion	Example
Tremor (continuous repetitive movements of skeletal muscles)	Moderate tetany	No specific focal lesion. Generalized disease, e.g hypomyelinogenesis	Congenital tremor of Herefords. Hypomyelinogenesis, shaker pigs, lambs with Border disease
	Intention tremor, sensory ataxia	Cerebellum	Cerebellar hypoplasia
	With head rotation	Vestibular apparatus	Otitis media and interna. Fracture of petrous temporal bone
Nystagmus	Usually with tetraparesis, impaired consciousness, abnormal pupils, opisthotonos, facial palsy, dysphagia	Cerebellopontine and midbrain areas	Injury, increased intracranial pressure, polioencephalomalacia, listeriosis
	Pendular nystagmus	No lesion	Benign sporadic occurrence in dairy cattle, inherited in Finnish Ayrshire bulls
	Independent episodes	Focus of irritation in cerebral cortex or thalamus, with spread of excitation	Idiopathic or traumatic epilepsy
Convulsions	Continuous, leading to paralysis	Cerebral cortex	Increased intracranial pressure, encephalitis
	Intermittent, related to periods of metabolic stress	Cerebral cortex	Hypomagnesemia (lactation tetany); hypoglycemia (e.g. of baby pigs)
Tenesmus (straining)	Later paralysis of anus, sometimes tail head. Sexual precocity in male	Caudal cord segments and cauda equina, stimulation of nerve cells, later paralysis	Rabies, subacute local meningitis
Compulsive rolling	Disturbance of balance, cannot stand, must lie on one side. Nystagmus (See Table 12.1)	Vestibular apparatus	Brain abscess, otitis media
Compulsive walking and head-pressing			

menace reflex. Ophthalmoscopic examination is an integral part of an examination of the optic nerve.

Oculomotor nerve (CN III)

This nerve supplies the pupilloconstrictor muscles of the iris and all the extrinsic muscles of the eyeball except the dorsal oblique, the lateral rectus and the retractor muscles. Loss of function of the nerve results in pupillary dilatation and defective pupillary constriction when the light intensity is increased, abnormal position (ventrolateral deviation) or defective movement of the eyeballs and palpebral ptosis.

The pupillary light reflex is best tested by shining a bright point source of light into the eye, which causes constriction of the iris of that eye (direct pupillary reflex). Constriction of the opposite eye (consensual pupillary light reflex) will also occur. The consensual light reflex may be used to localize lesions of the optic pathways.

Examination of the menace reflex (eye preservation reflex to a menace) and the results of the pupillary light reflex can be used to distinguish between blindness due to a lesion in the cerebral cortex (central blindness) and that due to lesions in the optic nerve or other peripheral parts of the optic pathways (peripheral blindness).

As examples, in polioencephalomalacia (central blindness) the menace reflex is absent but the pupillary light reflex is present. In the ocular form of hypovitaminosis A (peripheral blindness) in cattle the menace reflex is also absent, the pupils are widely dilated and the pupillary light reflex is absent. In polioencephalomalacia, the optic nerve, oculomotor nucleus and oculomotor nerve are usually intact but the visual cortex is not; in hypovitaminosis A the optic nerve is usually degenerate, which interferes with both the menace and pupillary light reflexes.

Testing of ocular movements can be carried out by moving the hand about in front of the face. In paralysis of the oculomotor nerve there may also be deviation from the normal ocular axes and rotation of the eyeball. There will be an absence of the normal horizontal nystagmus reaction with a medial jerk of the eyeball in response to quick passive movement of the head. Failure to jerk laterally indicates a defect of the abducens nerve.

Trochlear nerve (CN IV)

This nerve supplies only the dorsal oblique muscle of the eye so that external movements and position of the eyeball are abnormal (dorsolateral fixation) when the nerve is injured. This is common in polioencephalomalacia in cattle, resulting in a dorsomedial fixation of the eyeball. In other words, the medial angle of the pupil is displaced dorsally when the head is held in normal extension.

Trigeminal nerve (CN V)

The sensory part of the trigeminal nerve supplies sensory fibers to the face and can be examined by testing the palpebral reflex and the sensitivity of the face. The motor part of the nerve supplies the muscles of mastication and observation of the act of chewing may reveal abnormal jaw movements and asymmetry of muscle contractions. There may also be atrophy of the muscles, which is best observed when the lesion is unilateral.

Abducent nerve (CN VI)

Because the abducent nerve supplies motor fibers to the retractor and lateral rectus muscles of the eyeball, injury to the nerve may result in protrusion and medial deviation of the globe. This is not readily observable clinically. An inherited exophthalmos and strabismus occurs in Jersey cattle.

Facial nerve (CN VII)

The facial nerve supplies motor fibers for movement of the ears, eyelids, lips, and nostrils, in addition to the motor pathways of the menace, palpebral, and corneal reflexes. The symmetry and posture of the ears, eyelids, and lips are the best criteria for assessing the function of the nerve. Ability to move the muscles in question can be determined by creating a noise or stabbing a finger at the eye. Absence of the eye preservation reflex may be due to facial nerve paralysis or blindness. Facial paralysis is evidenced by ipsilateral drooping of the ear, ptosis of the upper eyelid, drooping of the lips and pulling of the filtrum to the unaffected side. There may also be drooling of saliva from the

Table 12.3 Correlation between clinical findings and location of lesion in the nervous system of farm animals: abnormalities of posture

Principal sign	Secondary signs	Location of lesion	Example
Paresis (difficulty in rising, staggering gait, easily falling)	Persistent recumbency, muscle tone and reflexes variable depending on site of lesion	Loss of function in nervous tissue, e.g. spinal cord, may be upper or motor neuron lesion	Lymphosarcoma affecting spinal cord
	General loss of muscle tone including vascular, alimentary systems	Depression of synaptic or neuromuscular transmission for metabolic reasons or toxic reasons	Milk fever, botulism, peracute coliform mastitis, tick paralysis
Flaccid paralysis			
(1) Pelvic limbs only	Thoracic normal. Pelvic limbs flaccid, no tone, or reflexes, no anal reflex, urinary incontinence straining initially	Tissue destruction, myelomalacia at lumbosacral cord segments L4 to end osteomyelitis, fracture	Paralytic rabies. Spinal cord local meningitis, vertebral body
	Thoracic limbs normal. Pelvic limbs normal tone and reflexes, anal reflex normal. No withdrawal reflex caudally	Cord damage at thoracolumbar cord segments T3–L3	Spinal cord local meningitis as above, damage by vertebral fracture, lymphosarcoma
(2) Thoracic and pelvic limbs	Flaccid paralysis, normal tone and reflexes hindlimbs. Absent tone and reflexes in front limbs. Atrophy only in front. No withdrawal reflex caudally. Intact perineal reflex	Cord damage at cervicothoracic segments C6–T2	Fracture of vertebra lymphosarcoma, abscess
	Flaccid paralysis all four legs and neck. Unable to lift head off ground. Normal tone and reflexes all legs. Pain perception persists. No withdrawal reflex caudally	Cord damage at upper cervical segments C1–C5	Injury while running or falling, abscess or lymphosarcoma
Spastic paralysis (permanent, no variation, all four limbs in extension, increased tone, exaggerated reflexes, opisthotonos)	Cranial nerve deficits trigeminal to hypoglossal. Loss of central perception of pain. Depression	Medulla, pons and midbrain	Abscess, listeriosis
Tremor	Tremor (fine or coarse; no convulsions)	Red nucleus and reticular apparatus and midbrain/basal ganglia area tracts	Congenital disease of calves, e.g. hypomyelinogenesis, neuraxial edema
Tetany (all four limbs extended, opisthotonos). Variable intensity modifiable by treatment	Intense hyperesthesia, prolapse 3rd eyelid	Decreased synaptic resistance generally	Tetanus
	Exaggerated response to all external stimuli, i.e. hyperesthesia	Increased neuromuscular transmission	Hypomagnesemia
Paralysis of anus	No anal or perineal reflex. May be straining	Damage to spinal cord at segments S1–S3	Injury or local meningitis, early rabies
Paralysis of tail	Flaccid tail with anesthesia	Injury to caudal segments	Injury or local meningitis, early rabies
Opisthotonos	With spastic paralysis, tremor, nystagmus, blindness	Cerebrum, cerebellum and midbrain	Polioencephalomalacia, trauma
	Part of generalized tetanic state or convulsion	Neuromuscular transmission defect, tetanus, hypomagnesemia	Tetanus
Falling to one side	Mostly with circling (see below). Also with deviation of tail	No detectable lesion in spinal cord	*Xanthorrhea hastile* poisoning

commissures of the lips and in some cases a small amount of feed may remain in the cheeks of the affected side.

The common causes of damage to the nerve are fracture of the petrous temporal bone, guttural pouch mycosis and damage to the peripheral nerve at the mandible. A common accompaniment is injury to the vestibular nerve or center. A diagnosis of central, as compared to peripheral nerve involvement, can be made by identifying involvement of adjacent structures in the medulla oblongata. Signs such as depression, weakness and a head tilt would result, and are frequently present in ruminants and New World camelids with listeriosis.

Vestibulocochlear nerve (CN VIII)

The cochlear part of the vestibulocochlear nerve is not easily tested by simple clinical examination, but failure to respond to sudden sharp sounds, created out of sight and without creating air currents, suggests deafness. The cochlear portion can be tested electronically (the brainstem auditory evoked response, or BAER, test) to diagnose a lesion of the auditory nerve, eliminating the possibility of a central brain lesion. Abnormalities of balance and carriage of the head (rotation around the long axis and not deviation laterally) accompany lesions of the vestibular part of the vestibulocochlear nerve, and nystagmus is usually present.

In severe cases, rotation of the head is extreme, the animal is unable to stand and lies in lateral recumbency; moving to achieve this posture is compulsive and forceful. There is no loss of strength. In some species there is a relatively common occurrence of paralysis of the facial and the vestibular nerves as a result of otitis interna and otitis media. This does occur in the horse but less commonly than traumatic injury to the skull as a result of falling.

Pendular nystagmus should not be mistaken as a sign of serious neurological disease. Pendular nystagmus is characterized by oscillations of the eyeball that are always the same speed and amplitude and appear in response to a visual stimulus, e.g. a flashing light. Pendular nystagmus is observed most frequently in Holstein–Friesian cattle (prevalence of 0.51% in 2932 Holstein–Friesian and Jersey cows),[18] is not accompanied by other signs and there is no detectable histological lesion. A familial relationship was observed in Ayrshire bulls in Finland.[19]

Table 12.4 Correlation between clinical findings and location of lesion in the nervous system of farm animals: abnormalities of gait

Principal sign	Secondary signs	Location of lesion	Example
Circling			
(1) Rotation of the head	Nystagmus, circles, muscle weakness, falls easily, may roll, other cranial nerves affected	Vestibular nucleus	Brain abscess, listeriosis
	Nystagmus, walks in circles, falls occasionally, animal strong. Falls easily if blindfolded, sometimes facial paralysis	Inner ear (vestibular canals), 7th cranial nerve, facial nerve	Otitis media, otitis interna, fracture petrous temporal bone (horse)
(2) Deviation of the head	Deviation of head and gaze, compulsive walking, depression. Can walk straight. Balance may be normal	Cerebrum	Brain abscess in calf (infection from dehorning or umbilicus)
	Unable to walk straight. Facial paralysis, other cranial nerve deficits, head may be rotated	Medulla	Listeriosis
Cerebellar ataxia	Exaggerated strength and distance of movement, direction wrong. Hypermetria. Incoordination because of exaggerated movement. No paresis	Cerebellum	Inherited cerebellar hypoplasia in all species, especially Arabian horses; *Claviceps paspali* poisoning; Gomen disease a probable plant poisoning; destruction by a virus, especially BVD in cattle; hematoma in the fourth ventricle causes cerebellar displacement. Idiopathic cerebellar degeneration in adult cattle
Sensory ataxia	No loss of movement or strength but timing movement wrong, legs get crossed, feet badly placed when pivoting	Damage to sensory tracts in spinal cord	Cervical cord lesion, thoracolumbar if just pelvic limb
Sensorimotor ataxia	Weakness of movement, e.g. scuffing toes, knuckling, incomplete flexion, extension causes wobbly, wandering gait, falls down easily, difficulty in rising	Moderate lesion to spinal cord tracts	Plant poisonings, e.g. sorghum. Cervical vertebral compression of spinal cord. Degenerative myelopathy

BVD, bovine viral diarrhea.

Glossopharyngeal nerve (CN IX) and vagus nerve (CN X)

The glossopharyngeal nerve is sensory from the pharynx and larynx, and the vagus nerve is motor to these structures. Dysfunction of these nerves is usually accompanied by paralysis of these organs with signs of dysphagia or inability to swallow, regurgitation through the nostrils, abnormality of the voice and interference with respiration.

Because of the additional role of the vagus nerve in supplying nerve fibers to the upper alimentary tract, loss of vagal nerve function will lead to paralysis of the pharynx and esophagus. Parasympathetic nerve fibers to the stomach are also carried in the vagus and damage to them could cause hypomotility of that organ. The principal clinical finding in vagus nerve injury is laryngeal and pharyngeal paralysis.

Spinal accessory nerve (CN XI)

Damage to this nerve is extremely rare and the effects are not documented. Based on its anatomical distribution loss of function of this nerve could be expected to lead to paralysis of the trapezius, brachiocephalic and sternocephalic muscles and lack of resistance to lifting the head.

Hypoglossal nerve (CN XII)

As the motor supply to the tongue, the function of this nerve can be best examined by observing the motor activity of the tongue. There may be protrusion, deviation or fibrillation of the organ, all resulting in difficulty in prehending food and drinking water. The most obvious abnormality is the ease with which the tongue can be pulled out. The animal also has difficulty in getting it back into its normal position in the mouth, although diffuse cerebral disease can also produce this clinical sign. In lesions of some duration there may be obvious unilateral atrophy.

POSTURE AND GAIT

The examiner evaluates posture and gait to give a general assessment of brainstem, spinal cord and peripheral nerve and muscle function. Evaluation of posture and gait consists of determining which limbs are abnormal and looking for evidence of lameness suggesting a musculoskeletal gait abnormality. Weakness and ataxia are the essential components of gait abnormality. Each limb is examined for evidence of these abnormalities. This is done while the animal is standing still, walking, trotting, turning tightly (pivoting) and backing up. To detect subtle asymmetry in the length of the stride, the observer should walk parallel to or behind the animal, step for step. If possible, the gait should also be evaluated while the animal is walking up and down a slope, walking with the head and neck held extended, while blindfolded and while running free in an enclosure.

The best observations are made when the animal is running free, preferably at a fast gait, to avoid abnormalities resulting from being led. Also, slight abnormalities such as a high-stepping gait, slight incoordination of movement, errors of placement of feet, stumbling and failure to flex joints properly are all better observed in a free animal.

Weakness or paresis is evident when an animal drags its limbs, has worn hooves or has a low arc to the swing phase of the stride. When an animal bears weight on a weak limb, the limb often trembles and the animal may even collapse on that limb because of lack of support. While circling, walking on a slope and walking with the head held elevated, an animal frequently will stumble on a weak limb and knuckle over on the fetlock.

The presence of weakness in the limbs of horses or cattle can be determined by pulling the tail while the animal is walking forward. A weak animal is easily pulled to the side and put off stride. While the animal is circling, the examiner can pull on the lead rope and tail simultaneously to assess strength. Ease in pulling the animal to the side occurs because of weakness due to lesions of descending upper motor neuron pathway, the ventral

Table 12.5 Correlation between clinical findings and location of lesion in the nervous system of farm animals: abnormalities of the visual system

Principal sign	Secondary signs	Location of lesion	Example
Blindness (bumps into objects)	Pupillary dilatation. No pupillary light reflex. No menace reflex	Optic nerve (examine fundus of eye)	Vitamin A deficiency. Pituitary rete mirabile abscess. Congenital retinal dysplasia of goats
Peripheral blindness or night blindness		Retina	Nutritional deficiency of vitamin A Inherited defect of Appaloosa foals
Central blindness	Pupil normal size. Pupillary light reflexes normal	Cerebral cortex	Polioencephalomalacia, lead poisoning
Abnormal dilatation of pupils (mydriasis)	Absence of pupillary light reflex. Can see – does not bump into objects	Motor path of oculomotor nerve	Snakebite, atropine poisoning, milk fever
	Absent pupillary light reflex. No vision. Retinal damage on ophthalmoscopic examination	Retinal lesion	Toxoplasmosis, trauma, ophthalmitis
	Absent pupillary light reflex. No vision. Retina normal	Optic nerve atrophy and fibrosis	Avitaminosis A in cattle
Abnormal constriction of pupil (miosis)	Diarrhea, dyspnea	Failure to activate acetylcholine	Organophosphate poisoning
	Blindness, coma, semicoma, spastic paralysis	Diffuse lesion	Polioencephalomalacia, acute lead poisoning
Horner's syndrome. Drooping upper eyelid, miosis, enophthalmos	Hemilateral sweating and temperature rise side of face and upper neck. Unilateral exophthalmus; nasal obstruction	Damage to cranial thoracic and cervical sympathetic trunk	Mediastinal tumor, Guttural pouch mycosis. Neoplastic space-occupying lesions of the cranium involving the periorbit; perivascular injection around jugular vein or normal intravenous injection of xylazine hydrochloride in normal horses, melanoma at the thoracic inlet in a horse
Nystagmus	See Table 12.2		
Abnormal position of eyeball and eyelids	Dorsomedial deviation of eyeball	Trochlear (4th)	Polioencephalomalacia
	Eyelid	Facial (7th)	Listeriosis
	Ventrolateral fixation	Oculomotor (3rd)	
	Protrusion and medial deviation	Abducent (6th)	Abscess/tumor, e.g. bovine viral leukosis
No palpebral reflex		Deficit sensory branch of 5th nerve	Trauma
Absence of menace response		Facial nerve (provided vision is present)	Listeriosis
Absence of pupillary light reflex		Oculomotor (provided vision is present)	

Table 12.6 Correlation between clinical findings and location of lesion in the nervous system of farm animals: abnormalities of the head, neck and tongue

Principal sign	Secondary signs	Location of lesion	Example
Inability to prehend or inability to chew	Facial (nasal septal) hypalgesia	Sensory branch of trigeminal (5th) dysfunction	Poisoning by *Phalaris aquatica* in cattle. Local medullary lesion
	Inappropriate movements of tongue	Hypoglossal (12th) nerve dysfunction	Poisoning by *Phalaris aquatica* in cattle. Listeriosis, local medullary lesion
	Inappropriate movements of lips	Facial (7th) nerve dysfunction	Traumatic injury to petrous temporal bone, otitis media and interna, listeriosis, guttural pouch mycosis
	Inadequate chewing movements of jaw	Motor branch of the trigeminal (5th) nerve dysfunction	Poisoning by *Phalaris aquatica* in cattle, listeriosis
Inability to swallow (in absence of physical foreign body; in pharyngeal paresis or paralysis)	Regurgitation through nose and mouth, inhalation into lungs causing aspiration pneumonia	Glossopharyngeal (9th) nerve dysfunction. Also vagus (10th). Nuclei in medulla	Abscess or tumor adjacent to nerve. Listeriosis, abscess in medulla
	Inappropriate swallowing movements	Globus pallidus and substantia nigra	Poisoning *Centaurea* sp.

horn gray matter level with the limb or peripheral nerves or muscle. With lower motor neuron lesions, the weakness is often so marked that it is easy to pull an animal to the side while it is standing or walking. In contrast, a weak animal with a lesion of the upper motor neuron pathways will often fix the limb in extension, reflexly, when pulled to one side. It resists the pull and appears strong.

Severe weakness in all four limbs, but with no ataxia and spasticity, suggests neuromuscular disease. Obvious weakness in only one limb is suggestive of a peripheral nerve or muscle lesion in that limb.

Ataxia is an unconscious, general proprioceptive deficit causing poor coordination when moving the limbs and

the body. It results in swaying from side to side of the pelvis, trunk and sometimes the entire body. It may also appear as a weaving of the affected limb during the swing phase. This often results in abducted or abducted foot placement, crossing of the limbs or stepping on the opposite foot, especially when the animal is circling or turning tightly. Circumduction of the outside limbs when turning and circling is also considered a proprioceptive deficiency. Walking an animal on a slope, with the head held elevated, often exaggerates ataxia, particularly in the pelvic limbs. When a weak and ataxic animal is turned sharply in circles, it leaves the affected limb in one place while pivoting around it. An ataxic gait may be most pronounced when an animal is moving freely, at a trot or canter, especially when attempting to stop. This is when the limbs may be wildly abducted or adducted. Proprioceptive deficits are caused by lesions affecting the general proprioceptive sensory pathways, which relay information on limb and body position to the cerebellum (unconscious proprioception) and to the thalamus and cerebral cortex (conscious proprioception).

Knuckling the flexed foot while the animal stands on the dorsum to determine how long the animal leaves the foot in this state before returning it to a normal position is a test for conscious proprioception in dogs and cats. The test has not been useful in horses and adult cattle but is useful in sheep, goats, New World camelids, and calves. Depressed animals will often allow the foot to rest on the dorsum for prolonged periods. Crossing the limbs and observing how long the animal maintains a crosslegged stance has been used to test conscious proprioception.

Hypermetria is used to describe a lack of direction and increased range of movement, and is seen as an overreaching of the limbs with excessive joint movement. Hypermetria without paresis is characteristic of spinocerebellar and cerebellar disease.

Hypometria is seen as stiff or spastic movement of the limbs with little flexion of the joints, particularly the carpal and tarsal joints. This generally is indicative of increased extensor tone and of a lesion affecting the descending motor or ascending spinocerebellar pathways to that limb. A hypometric gait, particularly in the thoracic limbs, is best seen when the animal is backed up or when it is maneuvered on a slope with the head held elevated. The thoracic limbs may move almost without flexing.

Dysmetria is a term that incorporates both hypermetria and hypometria. Animals with severe cerebellar lesions may have a high-stepping gait but have limited movement of the distal limb joints, especially in thoracic limbs.

The degree of weakness, ataxia, hypometria and hypermetria should be graded for each limb. The types of gait abnormalities and the degree of weakness reflect various nervous and musculoskeletal lesions. Generally, with focal, particularly compressive, lesions in the cervical spinal cord or brainstem, neurological signs are one grade more severe in the pelvic limbs than in the thoracic limbs. Thus, with a mild, focal, cervical spinal cord lesion there may be more abnormality in the pelvic limbs with no signs in the thoracic limbs. The anatomical diagnosis in such cases may be a thoracolumbar, cervical, or diffuse spinal cord lesion.

A moderate or severe abnormality in the pelvic limbs, and none in the thoracic limbs, is consistent with a thoracolumbar spinal cord lesion. With a mild and a severe change in the thoracic and the pelvic limb gaits respectively, one must consider a severe thoracolumbar lesion plus a mild cervical lesion, or a diffuse spinal cord disease.

Lesions involving the brachial intumescence (spinal cord segments C6–T2) with involvement of the gray matter supplying the thoracic limbs, and diffuse spinal cord lesions may both result in severe gait abnormality in the thoracic limbs and the pelvic limbs.

A severely abnormal gait in the thoracic limbs, with normal pelvic limbs, indicates lower motor neuron involvement of the thoracic limbs; a lesion is most likely to be present in the ventral gray columns at spinal cord segments C6–T2 or thoracic limb peripheral nerves of muscle.

Gait abnormalities can occur in all four limbs, with lesions affecting the white matter in the caudal brainstem, when head signs, such as cranial nerve deficits, are used to define the site of the lesion. Lesions affecting the cerebrum cause no change in gait or posture.

NECK AND FORELIMBS

If a gait abnormality was evident in the thoracic limbs and there was no evidence of brain involvement, then examination of the neck and forelimbs can confirm involvement of the spinal cord, peripheral nerves (spinal cord segments C1–T2) or thoracic limb muscles. The neck and forelimbs are examined for evidence of gross skeletal defects, asymmetry of the neck and muscle atrophy. The neck should be manipulated from side to side and up and down to detect any evidence of resistance or pain. Localized unilateral sweating of the neck and cranial shoulder is evidence of **Horner's syndrome**,[20] in which there are varying degrees of ptosis, prolapse of the third eyelid, miosis, enophthalmos and increased temperature of the face, neck and shoulder. The syndrome is associated with lesions affecting the descending sympathetic fibers in the white matter of the spinal cord or gray matter in the cranial thoracic segments, thoracocervical sympathetic trunk, cervical vagosympathetic trunk or cranial cervical ganglion and its pre- and postganglionic fibers.

Sensory perception from the neck and forelimbs is assessed using a painful stimulus such as a blunt needle or forceps. The local responses as well as the cerebral responses are noted when the skin over the shoulders and down the limbs is pricked.

Gait deficits are evaluated by making the horse or halter-broken ruminant perform a series of movements. Such exercises should include walking and trotting in a straight line, in large circles, in tight circles, backing on a level ground and on a slight slope, walking and trotting over curbs or low obstacles, walking in straight lines and circles, and walking on a slope with the head held elevated. The sway reaction for the thoracic limb is assessed by pushing against the shoulders and forcing the animal first to resist and then to take a step laterally. This can be done while the animal is standing still and walking forward. Pulling the tail and lead rope laterally at the same time will assess the strength on each side of the body. Making the animal turn in a tight circle by pulling the lead rope and tail at the same time will indicate strength; an adult horse should be able to pull the examiner around and should not pivot on a limb or be pulled to the side. Pressing down with the fingers on the withers of a normal animal causes some arching, followed by resistance to the downward pressure. An animal with weakness in the thoracic limbs may not be able to resist this pressure by fixing its vertebral column but will arch its back more than normal and often buckle in the thoracic limbs.

In smaller farm animal species, other postural reactions can be performed. These include wheelbarrowing and the hopping response test. The spinal reflexes are assumed to be intact in animals that are ambulating normally.

If a large mature horse, cow or pig has a gait abnormality, it is very rare to cast the animal to assess the spinal reflexes. However, spinal reflexes are usually examined in calves, sheep, and goats.

A recumbent animal that can use its thoracic limbs to sit up in the dog-sitting position may have a lesion caudal to spinal cord segment T2. If a recumbent

animal cannot attain a dog-sitting position, the lesion may be in the cervical spinal cord. In lambs aged between 4 and 10 weeks with thoracic vertebral body abscesses extending into the epidural space causing spinal cord compression, the thoracic limbs are normal and the lambs frequently adopt a 'dog-sitting' position and move themselves around using the thoracic limbs only.[21] Lambs with a cervical spinal cord lesion are unable to maintain sternal recumbency and have paresis of all four limbs.

However, mature cattle with the downer cow syndrome secondary to hypocalcemia may be unable to use both the thoracic and pelvic limbs. If only the head, but not the neck, can be raised off the ground, there may be a severe cranial cervical lesion. With a severe caudal cervical lesion, the head and neck can usually be raised off the ground but thoracic limb function is decreased and the animal is unable to maintain sternal recumbency.

Assessment of limb function is done by manipulating each limb separately, in its free state, for muscle tone and sensory and motor activity. A limb that has been lain upon for some time cannot be properly evaluated because there will be poor tone from the compression. A flaccid limb, with no motor activity, indicates a lower motor lesion to that limb. A severe upper motor neuron lesion to the thoracic limbs causes decreased, or absent, voluntary effort, but there is commonly normal or increased muscle tone in the limbs. This is due to release of the lower motor neuron, which reflexly maintains normal muscle tone from the calming influence of the descending upper motor neuron pathways.

The tone of skeletal muscle may be examined by passively flexing and extending the limbs and moving the neck from side to side and up and down. Increased muscle tone, spasticity or tetany may be so great that the limb cannot be flexed without considerable effort. If the spastic-extended limb does begin to flex but the resistance remains, this is known as 'lead-pipe' rigidity, which is seen in tetanus. If after beginning to flex an extended spastic limb, the resistance suddenly disappears ('clasp-knife release') this suggests an upper motor neuron lesion, as occurs in spastic paresis in cattle.

Flaccidity, or decreased muscle tone, indicates the presence of a lower motor neuron lesion with interruption of the spinal reflex arc.

Localized atrophy of muscles may be myogenic or neurogenic and the difference can be determined only by electromyography, a technique not well suited to large-animal practice. If the atrophic muscle corresponds to the distribution of a peripheral nerve it is usually assumed that the atrophy is neurogenic. In addition, neurogenic atrophy is usually rapid (will be clinically obvious in a few days) and much more marked than either disuse or myogenic atrophy.

Spinal reflexes of the thoracic limbs

These include the flexor reflex, the biceps reflex and the triceps reflex. The flexor reflex is tested by stimulation of the skin of the distal limb and observing for flexion of the fetlock, knee, elbow, and shoulder. The reflex arc involves sensory fibers in the median and ulnar nerves, spinal cord segments C6–T2 and motor fibers in the axillary, musculocutaneous, median and ulnar nerves. Lesions cranial to spinal cord segment C6 may release this reflex from the calming effect of the upper motor neuron pathways and cause an exaggerated reflex with rapid flexion of the limb, and the limb may remain flexed for some time. A spinal reflex may be intact without cerebral perception. Cerebral responses to the flexor reflex include changes in the facial expression, head movement toward the examiner and vocalization. Conscious perception of the stimulus will be intact only as long as the afferent fibers in the median and ulnar nerves, the dorsal gray columns at spinal cord segments C6–T2 and the ascending sensory pathways in the cervical spinal cord and brainstem are intact.

The laryngeal adductory reflex is of special interest in the examination of ataxic horses. In normal horses a slap on the saddle region just caudal to the withers causes a flickering adductory movement of the contralateral arytenoid cartilage that is visible by an endoscope. Reflex muscle contraction can be palpated on the dorsolateral surfaces of the larynx. The reflex is absent when there is damage to afferent tracts up the spinal cord, when there is damage to the recurrent laryngeal nerves, and in tense or frightened horses. Elicitation of the reflex is called the **slap test**.

TRUNK AND HINDLIMBS

If examination of the posture, gait, head, neck or thoracic limbs reveals evidence of a lesion, then an attempt should be made to explain any further signs found during examination of the trunk and hindlimbs that could have been caused by the lesion. If there are only signs in the trunk and hindlimbs, then the lesion(s) must be either between spinal cord segments T2 and S2 or in the trunk and pelvic limb nerves or muscles. It must be remembered that a subtle neurological gait in the pelvic limbs may be anywhere between the midsacral spinal cord and the rostral brainstem.

The trunk and hindlimbs are observed and palpated for malformations and asymmetry. Diffuse or localized sweating, the result of epinephrine release and sympathetic denervation, is often present in horses affected with a severe spinal cord injury.

Gentle pricking of the skin over the trunk and over the lateral aspects of the body wall on both sides, including on either side of the thoracolumbar vertebral column, will test-stimulate the cutaneous trunci reflex. The sensory stimulus travels to the spinal cord in thoracolumbar spinal nerves at the level of the site of stimulation. These impulses are transmitted up the spinal cord to spinal cord segments C8–T1, where the lateral thoracic nerve is stimulated, causing contraction of the cutaneous trunci muscle, which is seen as a flicking of the skin over the trunk. Lesions anywhere along this pathway will result in suppression or absence of this reflex caudal to the site of the lesion. Degrees of hypalgesia and analgesia have been detected caudal to the sites of thoracolumbar spinal cord lesions, especially if they are severe. In mature cattle with fractured thoracolumbar vertebrae associated with traumatic injury or vertebral body abscesses in calves, the site of the lesion may be able to be localized with this reflex. Sensory perception of pinpricking the trunk and hindlimbs may also be absent caudal to the lesion.

The sway reaction for the pelvic limbs involves pushing against the pelvis and pulling on the tail with the animal standing still and walking forward. An animal which is weak in the pelvic limbs will be easily pulled and pushed laterally, especially while walking. Proprioceptive deficits can be observed as overabduction and crossing of the limbs when a step is taken to the side.

Pinching and pressing down on the thoracolumbar or sacral paravertebral muscles with the fingers causes a normal animal to extend slightly, then fix, the thoracolumbar vertebral column. It also resists the ventral motion and usually does not flex the thoracic or pelvic limbs. A weak animal usually is not able to resist the pressure by fixing the vertebral column and thus it overextends the back and begins to buckle in the pelvic limbs.

In the recumbent animal, examination of the pelvic limbs includes the pelvic limb spinal reflexes, the degree of voluntary effort and the muscle tone present. Observing the animal attempting to rise on its own or following some coaxing will help to assess the pelvic limbs. The **flexor spinal reflex** is performed by pricking the skin and observing the flexion of the limb; central perception of the painful stimulus is also noted. The afferent and efferent pathways for this

reflex are in the sciatic nerve and involve spinal cord segments L5–S3.

The **patellar reflex** is evaluated by placing the animal in lateral recumbency and supporting the limb in a partly flexed position. The intermediate patellar ligament (horses) or patellar ligament (ruminants, pigs, New World camelids) is then tapped with a heavy metal plexor. This results in extension of the stifle joint. The sensory and motor fibers for this reflex are in the femoral nerve, and the spinal cord segments are L4 and L5. The patellar reflex is hyperactive in newborn farm animals. The gastrocnemius reflex and the cranial tibial reflex are not evaluated because they cannot be reliably induced.

The spinal cord of the calf has more control of basic physical functions than in humans, dogs and horses. For example, calves are able to retain control of the pelvic limb in spite of experimentally induced lesions that cause hemiplegia in dogs and humans. Also transection of the spinothalamic tract in the calf cord does not produce an area of hypalgesia or analgesia on the contralateral side as such a lesion would do in a human.[22]

Skin sensation of the pelvic limbs should be assessed independently from reflex activity. The femoral nerve is sensory to the skin of the medial thigh region, the peroneal nerve to the dorsal tarsus and metatarsus, and the tibial nerve to the plantar surface of the metatarsus.

TAIL AND ANUS

Tail tone is evaluated by lifting the tail and noting the resistance to movement. A flaccid tail, with no voluntary movement, is indicative of a lesion of the sacrococcygeal spinal cord segments, nerves, or muscles. Decreased tone in tail can be detected with severe spinal cord lesions cranial to the coccygeal segment.

The perineal reflex is elicited by lightly pricking the skin of the perineum and observing reflex contraction of the anal sphincter and clamping down of the tail. The sensory fibers are contained within the perineal branches of the pudendal nerve (spinal cord segments S1–S3). Contraction of the anal sphincter is mediated by the caudal rectal branch of the pudendal nerve, and tail flexion is mediated by the sacral and coccygeal segments and nerves (spinal cord segments S1–Co). An animal with a flaccid tail and anus, due to lower motor neuron lesion, will not have an anal or tail reflex. However, it may still have normal sensation from the anus and tail provided that the sensory nerves and spinal cord and brainstem white matter nociceptive pathways are intact.

Observation of defecation and urination movements and postures contributes to knowledge of the state of the cauda equina. Thus neuritis of the cauda equina is characterized by flaccid paralysis and analgesia of the tail, anus and perineum, rectum and bladder. There is no paresis or paralysis of the hindlimbs unless lumbosacral segments of the cord are damaged.

PALPATION OF THE BONY ENCASEMENT OF THE CENTRAL NERVOUS SYSTEM

Palpable or visible abnormalities of the cranium or spinal column are not commonly encountered in diseases of the nervous system but this examination should not be neglected. There may be displacement, abnormal configuration or pain on deep palpation. These abnormalities are much more readily palpable in the vertebral column and if vertebrae are fractured. Abnormal rigidity or flexibility of the vertebral column, such as occurs in atlanto-occipital malformations in Arabian horses and cattle, may also be detectable by manipulation.

COLLECTION AND EXAMINATION OF CEREBROSPINAL FLUID

The collection and laboratory analysis of CSF from farm animals with clinical evidence of nervous system disease can provide useful diagnostic and prognostic information.[2]

CSF is formed mostly from the choroid plexuses of the lateral ventricles by the ultrafiltration of plasma and the active transport of selected substances across the blood–brain barrier. The CSF in the ventricular system flows caudally and diffuses out of the lateral aperture in the fourth ventricle to circulate around the brain and spinal cord. The presence of CSF in the subarachnoid space separates the brain and spinal cord from the bony cranium and vertebral column, which reduces trauma to the underlying delicate nervous tissue. CSF also has excretory functions with the removal of products of cerebral metabolism.

Collection of cerebrospinal fluid

CSF can be collected from **lumbosacral cistern** with sedation (horses) or restraint (ruminants) and the **atlanto-occipital cistern (cisterna magna)** using injectable general anesthesia. For collection it is necessary to puncture the subarachnoid space in either the lumbosacral space or cisterna magna. Although there is no substantial difference between the composition of lumbosacral or cisternal CSF samples unless there is a compressive lesion of the spinal cord, the general policy is to sample as close to the lesion as possible. CSF should be collected into a sterile tube and there is no need to add an anticoagulant, even in samples visibly contaminated with blood. Cytology should be performed as soon as possible after collection (ideally within 15 min) because the cells rapidly degenerate.

Collection from the lumbosacral cistern

The lumbosacral site is preferred because general anesthesia is not required. CSF can be collected from the lumbosacral cistern with relative ease provided that adequate restraint can be achieved and the anatomical landmarks can be identified. CSF can be collected from the standing or recumbent animal. If recumbent, the animal should be placed in sternal recumbency with hips flexed and the pelvic limbs extended alongside the abdomen. This widens the lumbosacral space to permit correct placement of the spinal needle.

The site for collection is the midpoint of the lumbosacral space, which can be identified as the midline depression between the last palpable dorsal lumbar spine (L6 in cattle, goats and horses; L6 or L7 in sheep and pigs; L7 in New World camelids) and the first palpable sacral dorsal spine (usually S2). In well conditioned animals, these landmarks cannot always be identified; in which case the site is identified as the midpoint of a line connecting the caudal aspect of the tuber coxae. The site is clipped, surgically prepared and 1–2 mL of local anesthetic is administered subcutaneously. Sterile surgical gloves should be worn. Hypodermic spinal needles with stilettes are recommended because ordinary needles commonly plug with tissue. The length and gauge of needle depends on the size of the animal, but 15 cm (6 in) 18-gauge needles are needed for adult horses and cattle. The following guide is recommended (Table 12.7).

Provided the animal is well restrained and care is exercised in introducing the needle, little difficulty should be encountered. For collection from the lumbosacral space the needle is slowly advanced

Table 12.7 Needle length gauge for lumbosacral cerebrospinal fluid collection

Species and body weight	Length (cm) and gauge of needle
Lambs <30 kg	2.5 and 20
Ewes 40–80 kg	4.0 and 20
Rams > 80 kg	5.0 and 20
Calves < 100 kg	4.0 and 20
Calves 100–200 kg	5.0 and 18
Cattle > 200 kg	10.0–15.0 and 18

perpendicular or up to 15° caudal to perpendicular to the plane of the vertebral column. The needle must be introduced in a perfectly vertical position relative to the plane of the animal's vertebral column because of the danger of entering one of the lateral blood vessels in the vertebral canal. Changes in tissue resistance can be felt as the needle point passes sequentially through the subcutaneous tissue, interarcuate ligament, then the sudden 'pop' due to the loss of resistance as the needle point penetrates the ligamentum flavum into the epidural space. Once the needle point has penetrated the dorsal subarachnoid space, CSF will well up in the needle hub within 2–3 seconds. Failure to appreciate the changes in resistance as the needle moves down may result in puncture of the conus medullaris, which may elicit an immediate pain response and some discomfort. Movement of the pelvic limbs may dislodge the needle point, with the risk of causing local trauma and hemorrhage in the leptomeninges, which results in blood in the sample. Repeated CSF taps of the lumbosacral space may make it more difficult to obtain an adequate sample volume because of fibrosis of epidural tissue.[23]

Careful aspiration with a syringe attached to the needle held between the thumb and index finger is usually required to obtain a sample of 2–3 mL, which is sufficient for laboratory analysis. This can be facilitated by firmly resting the forearms and wrists on the animal's back. Failure to obtain fluid is usually due to incorrect direction of the needle, in which the case the bony landmarks of the lumbosacral space (depression) must be rechecked and, with the needle correctly realigned, the procedure repeated. In animals with a vertebral body abscess and neurological disease confined to the hind limbs, CSF may be difficult to obtain from the lumbosacral space because flow is occluded. In these circumstances, if a sample is obtained, the CSF protein may be increased as a result of stagnation of CSF distal to the lesion with exudation or transudation of protein from the lesion (**Froin's syndrome**).[24]

Collection from the atlanto-occipital cistern (cisterna magna)

This site is preferred for intracranial lesions because the fluid is produced in the subarachnoid space and flows caudally down the spinal cord.[25] However, this site is rarely used because of the inherent risk of needle penetration of the brainstem. Xylazine at 0.20 mg/kg body weight (BW) intramuscularly is effective in providing adequate sedation and analgesia for this procedure in cattle. A general anesthetic (such as combined intravenous administration of xylazine and ketamine) is recommended for horses.

The site is prepared as with the lumbosacral cistern. Ventriflexion of the head and neck of cattle enlarges the space of the cisterna magna and allows easy entry using a stiletted spinal needle inserted at a point created by the transection of the transverse line of the cranial rim of the wing of the atlas and the dorsal midline. The needle is advanced carefully and steadily and the tip is directed rostrally towards the symphysis of the lower jaw. The needle point goes through the skin, ligamentum nuchae and leptomeninges. In most mature cattle of body weight over 500 kg, a 20-gauge, 10 cm (4 in) spinal needle will enter the cisterna magna at 5–7 cm after going through the ligamentum nuchae, which provides some increased resistance. When the needle point punctures the leptomeninges, the animal may move its head slightly. At that point the needle is advanced only 1–2 mm and the stilette is then removed. If the end of the needle is in the cisterna magna, CSF will flow out of the needle freely and the manometer can be attached and the pressure measured.

Cerebrospinal fluid pressure

The CSF pressure can be determined by the use of a manometer attached to the spinal needle. Normal CSF pressures of the cisterna magna in cattle and xylazine/ketamine-anesthetized horses range from 5–15 cm (uncertain reference point) and 28 ± 4 cm (referenced to the right atrium), respectively, using 0.9% NaCl solution in a manometer.[26] When the fluid system is properly connected, occlusion of both jugular veins causes a marked rise in CSF pressure; this is called **Queckenstedt's test**. The Queckenstedt test involves bilateral jugular vein compression; this results in a sudden increase in intracranial subarachnoid pressure that is transmitted to the cranial subarachnoid space. The resultant CSF pressure wave is transmitted to the lumbar area (when obtaining CSF from the lumbosacral space) in the absence of an obstruction in the spinal subarachnoid space, thereby resulting in an increased flow of CSF.

Variations in CSF pressure are not of much use in clinical diagnosis except in hypovitaminosis A, and measurement of CSF pressure is only indicated in animals with signs of cerebral disease (abnormal mentation). Care is needed in interpreting results because the pressure is greatly affected by voluntary movement such as tenesmus. CSF pressure is increased in a number of diseases, including polioencephalomalacia, bacterial meningitis, and hypovitaminosis A. Xylazine given intravenously causes a decrease in intracranial pressure in healthy conscious horses.[27] Epidural pressure of cattle changes with change in position from standing to lateral recumbency to dorsal recumbency, and epidural pressure is positive in laterally recumbent animals.[23] Although the effect of epidural pressure on CSF pressure has not been evaluated in large animals, it is likely that CSF pressure is also affected by position.

Analysis of cerebrospinal fluid

Analysis of CSF has greater diagnostic value than hematology in animals with nervous system disease. CSF can be examined for the presence of protein, cells and bacteria.[2] The white blood cell count in normal animals is usually less than 5 cells/μL but a report exists of higher counts (12–200 cells/μL) in sheep.[28] An increase in CSF leukocyte count above 5 cells/μL is termed a pleocytosis and is categorized as mild (6–49 cells/μL), moderate (50–200 cells/μL) or marked (> 200 cells/μL). The differential white cell count comprises mostly lymphocytes and monocytes; there are no erythrocytes in normal animals. Samples that show visible turbidity usually contain large numbers of cells (> 500 cells/μL) and much protein. In cattle, protein concentrations range from 23–6 mg/dL, sodium concentrations from 132–144 mmol/L, potassium 2.7–3.2 mmol/L, magnesium 1.8–2.1 mEq/L and glucose concentrations 37–51 mg/dL[29] In the horse, the reference values for CSF are similar.[30] Neonatal foals under 3 weeks of age have higher CSF protein concentrations than do adult horses. Glucose concentrations peak in the first 48 hours after birth, then decrease to adult values by the second week of life. Concentrations of sodium and potassium are not affected by age and are similar to values reported for adult horses and ponies.

With bacterial infections of the nervous system the CSF concentration of protein will be increased and the white blood cell count increased up to 2000 cells/μL with more than 70% neutrophils.[28] A neutrophilic pleocytosis is considered 95–100% indicative of an inflammatory process within the central nervous system.[28] Theoretically, the CSF glucose concentration will be decreased and CSF lactate concentration will be increased in animals with bacterial meningitis because of bacterial metabolism, but these are unreliable signs and usually do not provide additional information to that provided by determination of CSF leukocyte and protein concentrations. Bacteria may also be cultured from the CSF. Because meningoencephalitis may occur concurrently or following acute

diarrhea in calves under a few weeks of age, the evaluation of CSF should be considered in calves that remain depressed and inactive following rehydration and treatment.[31]

The creatine kinase and lactate dehydrogenase activities in CSF have been examined as an aid in the differentiation of some neurological diseases. However, creatine kinase activity is considered to be unreliable; contamination of the sample with epidural fat and dura may increase CSF creatine kinase activity in the horse.[32] Insufficient information is available to evaluate the clinical utility of CSF lactate dehydrogenase activity in large animals.

The CSF glucose concentration is usually 60–80% of serum glucose concentration; this steady state value reflects facilitated transport across the blood–brain barrier, absence of binding proteins for glucose in CSF and nervous tissue metabolism of glucose.[29] However, sudden changes in plasma glucose concentrations are not immediately reflected in CSF glucose concentrations, because CSF turns over at around 1% per minute. Typically, a lag time of up to 3 hours is needed for CSF glucose concentration to be in equilibrium with plasma glucose concentrations. Hyperglycemia as a result of the stress of handling and restraint may therefore not be reflected by an increased CSF glucose concentration.

Blood contamination of CSF can make interpretation difficult. A formula has been developed that 'corrects' the CSF values for the degree of blood contamination, based on the red blood cell count in CSF (RBC_{CSF}) and blood (RBC_{blood}), whereby the corrected value for substance X in CSF ($X_{corrected}$, where X is a concentration or activity) is derived from the measured value of X in CSF (X_{CSF}) and blood (X_{blood}) and applying the following formula:

$$X_{corrected} = X_{CSF} - (X_{blood} \times RBC_{CSF}/RBC_{blood}).$$[33]

Calculation of a 'corrected' value rarely provides additional insight into the CSF analysis and is not commonly practiced in large animals.

Protein fractionation of CSF is not routinely performed because it requires sensitive electrophoresis methodology or species-specific radial immunodiffusion assays. However, calculation of the **albumin quotient** and **IgG index** may be informative in specific neurologic diseases.[34,35] Theoretically, these calculations can differentiate four blood–brain permeability patterns; normal blood–brain barrier permeability (normal albumin quotient and IgG index); intrathecal IgG production with normal blood–brain barrier permeability (normal albumin quotient and increased IgG index); increased blood–brain barrier permeability without intrathecal IgG production (increased albumin quotient and normal IgG index) and increased blood–brain barrier permeability with intrathecal production of IgG (increased albumin quotient and increased IgG index). The albumin quotient is calculated from the albumin concentration in CSF (ALB_{CSF}) and serum (ALB_{serum}), whereby:

$$Albumin\ Quotient = (ALB_{CSF}) \times 100/(ALB_{serum}).$$

The normal value for albumin quotient in the adult horse is less than 2.2[34,36] but the mean is 0.4 to 0.5 in cattle and adult llamas.[29,35] Because CSF protein is most commonly derived by disturbance of the blood–brain barrier and inflammation (resulting in an increased CSF albumin concentration), an increased CSF protein concentration is usually accompanied by an increased albumin quotient.

In animals suspected to have increased immunoglobulin production in the central nervous system (a rare occurrence, and almost always accompanied by disturbance of the blood–brain barrier), the IgG index can be calculated from the IgG concentration in CSF (IgG_{CSF}) and serum (IgG_{serum}), and the albumin concentration in CSF (ALB_{CSF}) and serum (ALB_{serum}), whereby:

$$IgG\ Index = (IgG_{CSF}/(IgG_{serum}) \times (ALB_{serum}/ALB_{CSF}).$$

An IgG index of more than 0.3 is suspected to indicate intrathecal IgG production in the adult horse.[34]

This formula corrects the CSF IgG concentration for an increased permeability of the blood–brain barrier, and therefore theoretically provides a more sensitive method for detecting local production of IgG within the central nervous system. Calculating the albumin quotient and IgG index is expensive and rarely provides additional information to that provided by CSF protein concentration alone, and for this reason is not commonly performed in large animals.

In summary, collection and analysis of CSF from the lumbosacral region provides a practical, safe and informative diagnostic tool in conscious large animals with neurological disease. Analysis of CSF in animals with central nervous system disease has greater diagnostic value than analysis of the leukon or serum biochemical analysis. Routine assessment of CSF should include total protein concentration, erythrocyte count, leukocyte count and leukocyte differential count. Other analytical procedures on CSF can be performed in specific diseases related to the nervous system.

EXAMINATION OF THE NERVOUS SYSTEM WITH SERUM BIOCHEMICAL ANALYSIS

Arterial plasma ammonia concentration

In animals suspected of having hepatic encephalopathy, measurement of the arterial plasma ammonia concentration provides a clinically useful diagnostic test and a means of monitoring the response to treatment. In monogastrics, ammonia is produced by bacterial degradation of amines, amino acids, and purines in the gastrointestinal tract, by the action of bacterial and intestinal urease on urea in the gastrointestinal tract and by the catabolism of glutamine by enterocytes.[37] In ruminants, ammonia is derived predominantly from bacterial metabolism in the rumen and catabolism of amino acids in tissue. Absorbed ammonia is normally converted to urea by the liver and to glutamine by the liver, skeletal muscle, and brain. In the presence of hepatic dysfunction, ammonia is inadequately metabolized, resulting in high plasma ammonia concentrations. Ammonia is a direct neurotoxin that alters inhibitory and excitatory neurotransmission in the brain.

Hyperammonemia can be used as a specific indicator of hepatic dysfunction. Normal values for arterial plasma ammonia concentration are less than 29 μmol/L in adult cattle[37] but may reach higher values in the immediate periparturient period. Arterial values are higher than venous values, and are preferred for analysis.

Blood gas analysis and serum electrolyte determination should be routinely undertaken in animals with clinical signs of encephalopathy, in order to rule out metabolic causes of cerebral dysfunction.

EXAMINATION OF THE NERVOUS SYSTEM WITH IMAGING TECHNIQUES

Radiography

Examination of the bony skeleton of the head and vertebral column to detect abnormalities which are affecting the nervous system of large animals is being used more commonly in referral centers. Conventional diagnostic radiography remains the best method for the initial evaluation of trauma to the brain and spinal cord. The injection of contrast media into the CSF system (**myelography**) is used for the detection of spinal cord compression but is rarely indicated in large animals because spinal cord depression surgery is rarely performed. In cases of peripheral nerve injury the radiograph of the appropriate limb may reveal the presence of a fracture or space-occupying lesion that has caused dysfunction of the peripheral nerve.

Computed tomography

Computed tomography (CT) of the skull has several advantages over radiography because structures are viewed in cross section without superimposition.[38] The development of computer software and technology allows a large amount of information to be obtained from a CT examination. Numerous diseases of the head of the horse, including those of the brain, can be diagnosed using this technique, but the limiting factors are the weight of the patient, accessibility for large animals and the need for general anesthesia. In general, CT provides an excellent image of skeletal defects. CT has been used for the antemortem diagnosis of many conditions in foals and horses, and otitis interna in calves.[39]

Magnetic resonance imaging

Magnetic resonance imaging (MRI) scanning uses nuclear magnetic resonance to create cross sectional images based on the magnetic properties of tissues. In general, MRI provides an excellent image of soft tissue defects, but the limiting factors are the weight of the patient, accessibility for large animals and the need for general anesthesia. MRI has been used for the antemortem diagnosis of many neurological conditions in foals and horses[40] and cerebellar hypoplasia in a calf.[41]

RHINOLARYNGOSCOPY (ENDOSCOPY) AND OPHTHALMOSCOPY

Endoscopy (rhinolaryngoscopy) is now a routine technique for the examination of horses with suspected laryngeal hemiplegia.[3] Ophthalmoscopy for the examination of the structures of the eye is important in the diagnosis of diseases affecting the optic nerve such as in vitamin A deficiency, and the optic disc edema (**papilledema**) associated with diffuse cerebral edema.

ELECTROENCEPHALOGRAPHY

Electroencephalography (EEG) has not been utilized to any significant degree in large animals. The EEG requires sophisticated equipment, a quiet dim environment free from electrical interference and a quiet patient that has minimal muscular activity. Because of the difficulty in obtaining quality recordings in a conscious large animal, it is preferred that the animal is anesthetized for the recording, which may confound interpretation of the EEG pattern depending on the anesthetic protocol. Electroencephalography has therefore been primarily used as an antemortem or research tool in large animals, and its use will probably remain as a complementary test to other neurological examinations and diagnostic tests at referral institutions.[42]

Recommendations have been made in order to standardize EEG techniques for animals; these typically involve meticulous preparation of the recording sites on the scalp, and placement of electrodes over the left and right frontal areas, the left and right occipital areas, the vertex area and a reference electrode is placed behind the tip of the nose.[20] However, the addition of other recording sites increases the ability to localize a focal lesion.[42] Neurological disease is associated with changes in either EEG frequency or amplitude, or both, with frequency changes being a more reliable indicator of disease. In general, focal EEG abnormalities indicate a focal lesion in the cortex, whereas diffuse EEG abnormalities indicate diffuse cortical or subcortical lesions or focal subcortical lesions.

Electroencephalography has been used to study epilepsy in goats and cattle, congenital hydranencephaly and hydrocephalus in cattle, scrapie in sheep, thiamine-responsive polioencephalomalacia in cattle[43] and bovine spongiform encephalopathy in cattle. When performed under controlled conditions, EEG has been shown to be a useful diagnostic tool for the early diagnosis of equine intracranial diseases,[42] with adequate sensitivity and specificity.

ELECTROMYOGRAPHY

Electromyographic needle examination (EMG) is a technique that records the electrical activity generated by single muscle fibers and the summated electrical activity of muscle fibers in individual motor units.[44] The technique involves inserting a recording needle into the muscle of interest and recording the resultant EMG. Typically, animals are unsedated and restrained in stocks or a chute. Abnormal EMG signals include short-duration and low-amplitude motor unit action potentials, which indicate diseased muscle fibers of early or incomplete reinnervation after denervation. Other abnormalities include the presence of fibrillation potentials, positive sharp waves and complex repetitive discharges that occur when the skeletal cell membrane becomes unstable because of denervation or myopathy.[44]

Electromyography provides a more practical diagnostic test than EEG, and is especially useful for evaluating peripheral nerve injury and diagnosing hyperkalemic periodic paresis in horses. Electromyography can discriminate between neurogenic or myogenic disorders, and nerve conduction studies can differentiate axonal loss from demyelination. In addition, repetitive stimulation can provide information regarding neuromuscular transmission.

Electromyography has been coupled with transcranial magnetic stimulation to induce magnetic motor evoked potentials in the horse.[45] This provides a useful non-invasive evaluation of cervical spinal cord dysfunction in horses that evaluates the integrity of the descending motor tracts.

BRAINSTEM AUDITORY EVOKED POTENTIALS

The brainstem auditory evoked potential (BAEP) is a recording of the electrical activity of the brainstem following an acoustic stimulation.[46] The use of the BAEP is well documented in human medicine as a diagnostic aid and has been used in dogs to evaluate deafness. The BAEP is obtained by recording neuroelectrical activity from generators in the auditory pathway immediately following an acoustic click stimulus, and BAEP waveforms for horses and ponies have been recorded.[47] Such recordings can be useful in evaluating horses suspected to have deafness, vestibular disease or brainstem disease, and to monitor the response to treatment.[48]

INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION PRESSURE

Intracranial pressure has been measured in neonatal foals,[49] although the clinical utility of such measurements has not been demonstrated. Increases in intracranial pressure can cause decreases in cerebral perfusion pressure and irreversible injury to the central nervous system.

Principles of treatment of diseases of the nervous system

Treatment of disease of the nervous system presents some particular problems because of the failure of nervous tissue in the brain and spinal cord to regenerate and because of the impermeability of the blood–brain barrier to many antimicrobial agents, antiprotozoal agents, and anthelmintics.

When peripheral nerves are severed, regeneration occurs if the damage is not extensive but no specific treatment, other than surgical intervention, can be provided to facilitate repair. When neurons are destroyed in the brain and spinal cord no regeneration occurs and the provision of nervous system stimulants can have no effect on the loss of function that occurs. The emphasis in the treatment of diseases

of the nervous system must be on prevention of further damage. On occasion this can be done by providing specific or ancillary treatments.

ELIMINATION AND CONTROL OF INFECTION

Most of the viral infections of the nervous system are not susceptible to chemotherapeutics. Some of the larger organisms such as *Chlamydia* spp. are susceptible to broad-spectrum antimicrobial agents such as the tetracyclines and chloramphenicol.

Bacterial infections of the central nervous system are usually manifestations of a general systemic infection as either bacteremia or septicemia. Treatment of such infections is limited by the existence of the blood–brain and blood–CSF barriers, which prevent penetration of some substances into nervous tissue and into the CSF. Very little useful data exist on the penetration of parenterally administered antibiotics into the central nervous system of either normal farm animals or those in which there is inflammation of the nervous system.

In humans it is considered that most antimicrobials do not enter the subarachnoid space in therapeutic concentrations unless inflammation is present, and the degree of penetration varies among drugs. Chloramphenicol is an exception; levels of one-third to one-half of the blood level are commonly achieved in normal individuals. The relative diffusion of Gram-negative antimicrobial agents from blood into CSF in humans is shown in Table 12.8.

The most promising antimicrobial agents for the treatment of bacterial meningitis in farm animals are the third-generation cephalosporins, trimethoprim–sulfonamide combinations and gentamicin.[50]

In most instances of bacterial encephalitis or meningitis in farm animals it is likely that the blood–brain barrier is not intact and that parenterally administered drugs will diffuse into the nervous tissue and CSF. Certainly, the dramatic beneficial response achieved by the early parenteral treatment of *Histophilus somni* meningoencephalitis in cattle using intravenous oxytetracycline, intramuscular penicillin or a broad-spectrum antibiotic suggests that the blood–brain barrier may not be a major limiting factor when inflammation is present. Another example of an antibiotic that does not normally pass the blood–brain barrier well but is able to do so when the barrier is damaged is penicillin in the treatment of listeriosis. When cases of bacterial meningoencephalitis fail to respond to antimicrobial agents, to which the organisms are susceptible, other reasons should also be considered. Often the lesion is irreversibly advanced or there is a chronic suppurative process which is unlikely to respond.

Intrathecal injections of antimicrobial agents have been suggested as viable alternatives when parenteral therapy appears to be unsuccessful. However, there is no evidence that such treatment is superior to appropriate parenteral therapy. In addition, intrathecal injections can cause rapid death and therefore are not recommended.

Table 12.8 Relative diffusion of Gram-negative antimicrobials

Excellent with or without inflammation	Good only with inflammation
Sulfonamides Third-generation cephalosporins (cefoperazone, cefotaxime)	Ampicillin Carbenicillin Cephalothin Cephaloridine
Minimal or not good with inflammation	**No passage with inflammation**
Tetracycline Streptomycin Kanamycin Gentamicin	Polymyxin B Colistin

DECOMPRESSION

Increased intracranial pressure probably occurs in most cases of inflammation of the brain but it is only likely to be severe enough to cause physical damage in acute cerebral edema, space-occupying lesions such as abscesses, and hypovitaminosis A. In these circumstances some treatment should be given to withdraw fluid from the brain tissue and decrease the intracranial pressure.

One treatment that may be attempted is the combination of mannitol and corticosteroids used in man and in small animals. Mannitol given as a 20% solution intravenously over a 30–60-minute period is a successful intracranial decompressant with an effect lasting about 4 hours; the effect can be prolonged by the intravenous administration of dexamethasone 3 hours after the mannitol. The treatment has been used in calves with polioencephalomalacia, combined with thiamin, with excellent results to relieve the effects of acute cerebral edema. The dose rates have been those recommended for dogs and are very expensive: mannitol 2 g/kg BW, dexamethasone 1 mg/kg BW, both intravenously. There are dangers with mannitol: it should not be repeated often; it must not be given to an animal in shock; it should be given intravenously slowly. Dexamethasone on its own is safe and has a good effect but does not decompress sufficiently. Hypertonic glucose given intravenously is dangerous because an initial temporary decompression is followed after a 4–6-hour interval by a return to pretreatment CSF pressure when the glucose is metabolized.

TREATMENT OF BRAIN INJURY AFTER HEAD TRAUMA

The principles of treatment of animals exhibiting neurological abnormalities after a traumatic event are derived from the results of large, controlled, multicenter clinical trials in human beings. Similar studies have not been performed in large animals. The general principles are: 1) stabilize the patient by ensuring a patent airway, obtaining vascular access and attending to wounds, 2) specific treatment for hyperthermia as brain defects may result in an inability to regulate core temperature, 3) prevent or treat systemic arterial hypotension, 4) optimize oxygen delivery, 5) ensure adequate ventilation by placing in sternal recumbency whenever possible, 6) decrease pain, 7) monitor plasma glucose concentration and maintain euglycemia, and 8) prevent or treat cerebral edema by having the head elevated or by the intravenous administration of a hyperosmolar agent (hypertonic saline, 7.2% NaCl, 2 mL/kg BW every 4 hours for 5 infusions; 20% mannitol as a series of bolus infusions of 0.25 to 1 g/kg BW every 4–6 hours, the latter is an expensive treatment). Intravenous catheterization should be confined to one jugular vein and the neck should not be bandaged in an attempt to minimize promotion of cerebral edema by jugular venous hypertension. Seizures should be treated when they occur by administering diazepam, midazolam, phenobarbital, or pentobarbital.

Many anecdotal treatments have been used in large animals, but evidence attesting to their efficacy is clearly lacking. Amongst the more popular empiric antioxidant treatments are dimethyl sulfoxide (1 g/kg BW as a 10% solution in 0.9% NaCl) administered intravenously or by nasogastric tube every 12 h, vitamin E (α-tocopherol, 50 IU/kg BW administered orally every day), vitamin C (ascorbic acid, 20 mg/kg BW administered orally every day), and allopurinol (5 mg/kg BW administered orally every 12 h). Corticosteroids have also been advocated; promoted treatments include an anti-inflammatory dose of dexamethasone (0.05 mg/kg BW every day) or a high dose of methylprednisolone sodium succinate (30 mg/kg BW initial bolus, followed by continuous infusion of 5.4 mg/kg BW per hour for

24–48 h); the latter treatment is prohibitively expensive in large animals and must be given within 8 hours of the traumatic event to be effective. Intravenous magnesium sulfate (50 mg/kg BW) in the first 5–10 L of intravenous fluids has also been advocated on the basis that it inhibits several aspects of the secondary injury cascade.

CENTRAL NERVOUS SYSTEM STIMULANTS

These substances are used to excess in many instances. They exert only a transitory improvement in nervous function and are indicated only in nervous shock and after anesthesia or other short-term reversible anoxias such as cyanide or nitrate poisoning. It is unlikely that terminal respiratory failure caused by anoxia over a long period, and in which anoxia is likely to continue, will respond permanently to their use.

CENTRAL NERVOUS SYSTEM DEPRESSANTS

Animals with convulsions should be sedated to avoid inflicting traumatic injuries on themselves. Most of the general anesthetic agents in common use will satisfactorily control convulsions, and allow some time to examine the animal properly, assess the diagnosis and institute specific therapy if possible.

Pathophysiological mechanisms of nervous system disease

Etiology of nervous system disease

There are many different causes of nervous system disease in large domestic animals.

- Infectious causes include bacteria, viruses, fungi, and helminth, arthropod and protozoan parasites
- Exogenous substances such as lead, salt, selenium, organophosphate insecticides, feed additives such as urea, poisonous plants and many other chemicals are common causes
- Endogenous substances such as products of disease in other body systems or of abnormal metabolism such as bacterial toxins, ammonia and carbon dioxide can cause abnormalities of the nervous system
- Metabolic and nutritional causes include ischemia secondary to cardiopulmonary disease, hypoglycemia, hypomagnesemia, copper deficiency in pregnant animals, and hyper D-lactatemia in calves with neonatal diarrhea and adult ruminants with grain overload
- Acidemia associated with diarrhea can cause mental depression and ataxia
- Traumatic and physical injuries to the brain or spinal cord are common
- Neoplasms of the nervous system in large animals are uncommon, with the exception of spinal lymphosarcoma in adult cattle due to enzootic bovine leukosis
- Idiopathic diseases account for several diseases of the spinal cord of horses
- Malformation occurs primarily in the developing fetus and results in congenital nervous system disease, which is usually present at birth. Many different teratogens can cause congenital defects. In some cases of inherited disease, the clinical signs are not manifest until some time after birth.

Responses of central nervous system to injury

The central nervous system may respond to injury by morphological changes that include cerebral edema and brain swelling, inflammation, and demyelination. Malformations occur when the central nervous system is affected during fetal life.

The remainder of this chapter will present the general clinical aspects of the diseases of the nervous system according to anatomical sites. The salient features of the etiology, pathogenesis, clinical findings, diagnosis, and treatment of these clinicoanatomical diseases are described. The objective is to generalize about the clinical findings that are common or typical of diseases affecting each of the major anatomical sites of the brain and spinal cord. Cerebral hypoxia and ischemia, hydrocephalus and cerebral edema are common to many diseases of the nervous system, and are described here.

Diffuse diseases of the brain*

CEREBRAL HYPOXIA

Cerebral hypoxia occurs when the supply of oxygen to the brain is reduced for any reason. An acute or chronic syndrome

* In the following discussion of diseases of the brain, the terms 'irritation', 'release', 'paralysis' and 'nervous shock' are used to describe groups of signs. These terms are used in accordance with their definitions under the principles of nervous dysfunction.

develops depending on the acuteness of the deprivation. Initially there are irritation signs followed terminally by signs of loss of function.

ETIOLOGY

All forms of hypoxia, including anemic, anoxic, histotoxic, and stagnant forms cause some degree of cerebral hypoxia but signs referable to cerebral dysfunction occur only when the hypoxia is severe. The hypoxia of the brain may be secondary to a general systemic hypoxia or be caused by lesions restricted to the cranial cavity.

Cerebral hypoxia secondary to general hypoxia

- Poisoning by hydrocyanic acid or nitrite
- Acute heart failure in severe copper deficiency in cattle
- Anesthetic accidents
- Terminally in pneumonia, congestive heart failure
- During or at birth in foals, neonatal maladjustment syndrome in foals, or intrapartum hypoxia in calves and lambs due to prolonged parturition.

Cerebral hypoxia secondary to intracranial lesion

- In increased intracranial pressure
- In brain edema.

PATHOGENESIS

The central nervous system is extremely sensitive to hypoxia, and degeneration occurs if the deprivation is extreme and prolonged for more than a few minutes. The effects of the hypoxia vary with the speed of onset and with the severity. When the onset is sudden there is usually a transitory period during which excitation phenomena occur and this is followed by a period of loss of function. If recovery occurs, a second period of excitation usually develops as function returns. In more chronic cases the excitation phase is not observed, the signs being mainly those of loss of function. These signs include dullness and lethargy when deprivation is moderate, and unconsciousness when it is severe. All forms of nervous activity are depressed but the higher centers are more susceptible than medullary centers and the pattern of development of signs may suggest this.

CLINICAL FINDINGS

Acute and chronic syndromes occur depending on the severity of the hypoxia. Acute cerebral hypoxia is manifested by a sudden onset of signs referable to paralysis of all brain functions, including tetraparesis and unconsciousness. Muscle tremor, beginning about the head and spreading to the trunk and limbs, followed by recumbency, clonic convulsions and death or recovery after further clonic convulsions is the most common pattern, although affected animals may fall to the ground without premonitory signs. In chronic hypoxia there is lethargy, dullness, ataxia, weakness, blindness and in some cases muscle tremor or convulsions. In both acute and chronic hypoxia the signs of the primary disease will also be evident. Cerebral hypoxia of fetal calves is thought to be a cause of weakness and failure to suck after birth, leading to the eventual death of the calf from starvation. Such hypoxia can occur during the birth process, especially if it is difficult or delayed, or during late pregnancy.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

There is no distinctive clinical pathology or characteristic necropsy lesion other than those of the primary disease.

DIFFERENTIAL DIAGNOSIS

Clinically there is little to differentiate cerebral hypoxia from hypoglycemia or polioencephalomalacia in which similar signs occur. Irritation and paralytic signs follow one another in many poisonings including lead and arsenic and in most diffuse diseases of the brain including encephalitis and encephalomalacia. The differential diagnosis of cerebral hypoxia depends upon the detection of the cause of the hypoxia.

TREATMENT

An increase in oxygen delivery is essential and can usually only be provided by removing the causative agent. A respiratory stimulant (such as doxapram) may be advantageous in acute cases and artificial respiration may be necessary and effective.

INCREASED INTRACRANIAL PRESSURE, CEREBRAL EDEMA, AND BRAIN SWELLING

Diffuse cerebral edema and brain swelling usually occur acutely and cause a general increase in intracranial pressure. Cerebral edema is rarely a primary disease, but commonly an accompaniment of other diseases. Cerebral edema is commonly a transient phenomenon and may be fatal but complete recovery or recovery with residual nervous signs also occurs. It is manifested clinically by blindness, opisthotonos, muscle tremor, paralysis, and clonic convulsions.

ETIOLOGY

Diffuse cerebral edema and brain swelling may be **vasogenic**, when there is increased permeability of capillary endothelium, **cytotoxic** when all the elements of brain tissue, glia, neurons and endothelial cells undergo swelling. Causes include the following.

Vasogenic edema

- Brain abscess, neoplasm, hemorrhage, lead encephalopathy, purulent meningitis
- Minor edema after most traumatic injuries, in many encephalitides and many poisonings, including propylene glycol in the horse; probably contributes to the pathogenesis
- Accidental intracarotid injection of promazine in horses
- Leukoencephalomalacia in horses due to fumonisin consumption[1,2]
- Septicemia in neonatal foals.[3]

Cytotoxic edema

- Hypoxia
- Polioencephalomalacia of ruminants (thiamine deficiency or sulfur toxicosis)
- Salt poisoning of swine.

Interstitial edema

- Hydrocephalus.

PATHOGENESIS

Cerebral edema and brain swelling

This disease is potentially life-threatening because of the limited ability for accommodation of increased volume within the confines of the dura and the cranium. The central nervous system parenchyma does not possess a lymphatic system, and the interstitial space between cells, especially in the gray matter, is much narrower than in other tissues. When central nervous system edema develops, of necessity it largely accumulates within cells, although interstitial fluid will form if cells lyse or if the edema is severe.

Cerebral edema commonly occurs to some degree in all pathological states, whether degenerative or inflammatory, traumatic or neoplastic. Edema around chronic, focal lesions such as abscesses, parasitic cysts and primary or metastatic tumors in white matter often produces marked swelling. Cerebral hemispheric swelling compresses the underlying brainstem, flattening the rostral colliculi and distorting the aqueduct. As the swollen brain expands and fills the confines of the calvaria, some regions are prone to herniation. If this occurs, the accompanying blood vessels are likely to become occluded, which may result in hemorrhage or infarction. Commonly with brain swelling, the caudal lobe of the cerebellar vermis protrudes as a flattened lip over the medulla oblongata toward the foramen magnum.

In vasogenic edema the primary insult is to the wall of cerebral capillaries, allowing the escape of plasma fluid and proteins under the hydrostatic pressure of the circulation. The inciting vascular

injury may be brain or spinal cord trauma, vasculitis, a neoplasm or a cerebrovascular accident. Vasogenic edema affects predominantly the white matter, where fluid accumulates within the cytoplasm of astrocytes and spreads in the interstitial spaces. Vasogenic edema moves over very long distances and from one hemisphere to the other via the corpus callosum. A chronic epidural abscess involving the frontal lobe can produce sufficient brain swelling from vasogenic edema to induce herniation of the occipital cortex beneath the tentorium cerebelli.

Cytotoxic edema results from an injury to a glial cell that disturbs osmoregulation of that cell by depletion of energy stores and failure of energy-dependent ionic pumps. This leads to cell swelling with fluid, and differs from edema in other tissues in which fluid accumulation is interstitial. Cytotoxic edema reflects a specific cellular insult and may result from ischemia or hypoxia, nutritional deficiency, an intoxication or an inherited metabolic abnormality. Brain swelling from cytotoxic edema is less dramatic than that seen in vasogenic edema. It may affect just the gray matter, just the white matter, or both.

The extracellular fluid volume in vasogenic edema is increased by the edema fluid, which is a plasma filtrate containing plasma protein. In cytotoxic edema it is the cellular elements themselves that increase in size. In hypoxia this is because of failure of the adenosine triphosphate (ATP)-dependent sodium pump within the cells. As a result sodium accumulates within the cells and water follows to maintain osmotic equilibrium. In polioencephalomalacia and salt poisoning the edema of the brain is primary. In salt poisoning in pigs there is an increase in concentration of cations in brain tissue with a sudden passage of water into the brain to maintain osmotic equilibrium. The cause of the edema in polioencephalomalacia of ruminants, associated with a thiamin inadequacy, is unknown. When promazine is injected accidentally into the carotid artery of the horse it produces a vasogenic edema and infarction generally, but especially in the thalamus and corpora quadrigemina on the injected side. The vasogenic edema surrounding an abscess is localized and is not evident in the white matter.

Cerebral edema and cerebellar herniation has been described in four neonatal foals admitted to an intensive care unit for treatment.[3] All foals had septicemia. It was suggested that hypoglycemia, hypoxia, or the alterations in cerebral blood flow associated with septicemia might have initiated injury to cell membranes, resulting in vascular damage and subsequent edema. It is hypothesized that cerebellar herniation occurs in neonatal foals with sepsis because of the inelastic nature of the dural folds and the anatomical rigidity of the neonatal equine skull. This is in contrast to the human infant, in whom cerebral edema occurs in bacterial meningitis but cerebral or cerebellar herniation is not normally a feature. The relatively small brain of the newborn foal is only 1% of total body mass compared to the human infant which is 12% and in which the brain is enclosed within a large but relatively thin calvarium with sutures that, in the preterm infant at least, can be separated by excess internal pressure.[4]

An increase in intracranial pressure occurs suddenly and, as in hydrocephalus, there is a resulting ischemic anoxia of the brain due to compression of blood vessels and impairment of blood supply. This may not be the only factor that interferes with cerebral activity in polioencephalomalacia and salt poisoning. The clinical syndrome produced by the rapid rise in intracranial pressure is manifested by involuntary movements such as tremor and convulsions followed by signs of weakness. If the compression of the brain is severe enough and of sufficient duration, ischemic necrosis of the superficial layers of the cortical gray matter may occur, resulting in permanent nervous defects in those animals that recover. Opisthotonos and nystagmus are commonly observed and are probably due to the partial herniation of the cerebellum into the foramen magnum.

CLINICAL FINDINGS

Although the rise of intracranial pressure in diffuse edema of the brain is usually more acute than in hydrocephalus, the development of clinical signs takes place over a period of 12–24 hours and nervous shock does not occur. There is central blindness, and periodic attacks of abnormality occur in which **opisthotonos**, **nystagmus**, **muscle tremor**, and **convulsions** are prominent.

In the intervening periods the animal is dull, depressed, and blind, and optic disc edema may be present. The involuntary signs of tremor, convulsions, and opisthotonos are usually not extreme but this varies with the rapidity of onset of the edema. Because of the involvement of the brainstem, in severe cases muscle weakness appears, the animal becomes ataxic, goes down and is unable to rise, and the early signs persist. Clonic convulsions occur terminally and animals that survive may have residual defects of mentality and vision.

CLINICAL PATHOLOGY

Clinicopathological observations will depend on the specific disease causing the edema.

NECROPSY FINDINGS

Microscopically the gyri are flattened and the cerebellum is partially herniated into the foramen magnum with consequent distortion of its caudal aspect. The brain has a soft, swollen appearance and tends to sag over the edges of the cranium when the top has been removed. Caudal portions of the occipital lobes herniate ventral to the tentorium cerebelli.

DIFFERENTIAL DIAGNOSIS

Diffuse brain edema causes a syndrome not unlike that of encephalitis although there are fewer irritation phenomena. Differentiation from encephalomalacia and vitamin A deficiency may be difficult if the history does not give a clue to the cause of the disease. Metabolic diseases, particularly pregnancy toxemia, hypomagnesemic tetany of calves and lactation tetany, resemble it closely, as do some cases of acute ruminal impaction. In the history of each of these diseases there are distinguishing features that aid in making a tentative diagnosis. Some of the poisonings, particularly lead, organic mercurials and arsenicals and enterotoxemia associated with *Clostridium perfringens* type D produce similar nervous signs and gut edema of swine may be mistaken for diffuse cerebral edema.

TREATMENT

Decompression of the brain is desirable in acute edema. The treatment will depend in part on the cause; the edema associated with polioencephalomalacia will respond to early treatment with thiamin. In general terms, edema of the brain responds to parenteral treatment with hypertonic solutions and corticosteroids. Hypertonic solutions are most applicable to cytotoxic edema and corticosteroids to vasogenic edema. This is in addition to treatment for the primary cause of the disease. Mannitol at 2 g/kg BW and dexamethasone at 1 mg/kg BW, both intravenously, are recommended. The mannitol is given intravenously as a 20% solution followed 3 hours later by the dexamethasone, also intravenously. Diuretics usually produce tissue dehydration too slowly to be of much value in acute cases, but they may be of value as an adjunct to hypertonic solutions or in early or chronic cases. The removal of CSF from the cisterna magna in an attempt to provide relief may cause complications. In some cases the removal of 25–75 mL of CSF provides some temporary relief but the condition becomes worse later because portions of the swollen brain herniate into the foramen magnum. There is no published information available on how much fluid can be safely removed and recommendations cannot therefore be made.

HYDROCEPHALUS

Obstructive hydrocephalus may be congenital or acquired and is manifested in both cases by a syndrome referable to a general increase in intracranial pressure. Irritation signs of mania, head-pressing, muscle tremor and convulsions occur when the onset is rapid, and signs of paralysis including dullness, blindness and muscular weakness are present when the increased pressure develops slowly.

ETIOLOGY

Obstructive hydrocephalus may be congenital or acquired but in both instances it is due to defective drainage or absorption of CSF. In the congenital disease there is an embryological defect in the drainage canals and foramina between the individual ventricles or between the ventricles and the subarachnoid space, or in the absorptive mechanism, the arachnoid villi.

Congenital hydrocephalus

Causes are:

- Alone, with lateral narrowing of the mesencephalon
- Inherited defects of Hereford, Holstein, Ayrshire and Jersey cattle
- Inherited combined defects with chondrodysplasia, or in white Shorthorn cattle combined with hydrocephalus, microphthalmia and retinal dysplasia
- Virus infections of the fetus suggest themselves as possible causes of embryological defects in the drainage system, but there are no verified examples of this. The cavitation of brain tissue and subsequent accumulation of fluid, hydranencephaly, which occurs after infection with bluetongue virus in lambs and Akabane virus in calves, is compensatory, not obstructive
- Vitamin A deficiency may contribute
- Other occurrences, sometimes at high levels of prevalence, but without known cause.

Acquired hydrocephalus

Causes include:

- Hypovitaminosis A in young growing calves causing impaired absorption of fluid by the arachnoid villi
- Cholesteatoma in choroid plexuses of the lateral ventricles in the horse. These may produce an acute, transient hydrocephalus on a number of occasions before the tumor reaches sufficient size to cause permanent obstruction
- Other tumor or chronic inflammatory lesion obstructing drainage from the lateral ventricles.

PATHOGENESIS

Increased intracranial pressure in the fetus and before the syndesmoses of the skull have fused causes hydrocephalus with enlargement of the cranium. After fusion of the suture lines the skull acts as a rigid container and an increase in the volume of its contents increases intracranial pressure. Although the increase in volume of the contents may be caused by the development of a local lesion such as an abscess, tumor, hematoma or cestode cyst, which interferes with drainage of the CSF, the more common lesion is a congenital defect of CSF drainage.

Clinical and pathological hydrocephalus has been produced experimentally in animals by creating granulomatous meningitis. The clinical signs included depression, stiffness of gait, recumbency and opisthotonus with paddling convulsions. The general effects in all cases are the same, the only difference being that local lesions may produce localizing signs as well as signs of increased intracranial pressure. These latter signs are caused by compression atrophy of nervous tissue and ischemic anoxia due to compression of blood vessels and impairment of blood supply to the brain.

In congenital hydrocephalus the signs observed are usually those of paralysis of function, while acquired hydrocephalus, being more acute, is usually manifested first by irritation phenomena followed by signs of paralysis. Edema of the optic papilla is a sign of increased intracranial pressure and may be detected ophthalmoscopically. Bradycardia occurs inconstantly and cannot be considered to be diagnostic.

CLINICAL FINDINGS

In acquired hydrocephalus there is, in most cases, a gradual onset of general paresis. Initially there is depression, disinclination to move, central blindness, an expressionless stare and a lack of precision in acquired movements. A stage of somnolence follows and is most marked in horses. The animal stands with half-closed eyes, lowered head and a vacant expression and often leans against or supports itself upon some solid object. Chewing is slow, intermittent and incomplete and animals are often observed standing with food hanging from their mouths. The reaction to cutaneous stimulation is reduced, and abnormal postures are frequently adopted. Frequent stumbling, faulty placement of the feet and incoordination are evidenced when the animal moves, and circling may occur in some cases. Bradycardia and cardiac arrhythmia have been observed.

Although the emphasis is on depression and paresis, signs of brain irritation may occur, particularly in the early stages. These signs often occur in isolated episodes during which a wild expression, charging, head-pressing, circling, tremor and convulsions appear. These episodes may be separated by quite long intervals, sometimes of several weeks' duration. In vitamin A deficiency in calves blindness and papilledema are the early signs and an acute convulsive stage occurs terminally.

Congenitally affected animals are usually alive at birth but are unable to stand and most die within 48 hours. The cranium is sometimes domed, the eyes protrude and nystagmus is often evident. Meningocele is an infrequent accompaniment.

CLINICAL PATHOLOGY

Examination of the composition and pressure of the CSF will be of value. The fluid is usually normal biochemically and cytologically but the pressure is increased. A marked increase in serum muscle enzyme activity has been observed in calves with congenital hydrocephalus, due probably to an accompanying muscular dystrophy. Convulsions, if they occur, may contribute to this increase.

NECROPSY FINDINGS

The cranium may be enlarged and soft in congenital hydrocephalus. The ventricles are distended with CSF under pressure and the overlying cerebral tissue is thinned if the pressure has been present for some time.

DIFFERENTIAL DIAGNOSIS

Congenital hydrocephalus resembles vitamin A deficiency in newborn pigs, toxoplasmosis and hydranencephaly if there is no distortion of the cranium. Acquired hydrocephalus needs to be differentiated from other diffuse diseases of the brain, including encephalitis and encephalomalacia, and from hepatic dystrophies, which resemble it very closely. In these latter diseases there may be other signs of diagnostic value, including fever in encephalitis and jaundice in hepatic dystrophy. In most cases it is necessary to depend largely on the history and recognition of individual disease entities.

ENCEPHALITIS

Encephalitis is, by definition, inflammation of the brain but in general usage it includes those diseases in which inflammatory lesions occur in the brain, whether there is inflammation of the nervous tissue or primarily of the vessel walls. Clinically, encephalitis is characterized initially

by signs of involuntary movements, followed by signs caused by loss of nervous function. The meninges and spinal cord may be involved in an encephalitis, causing varying degrees of meningoencephalomyelitis.

ETIOLOGY

Many encephalitides of large animals are associated with viruses but other infectious agents are also common. Some causes are as follows.

All species
- Viral infections – rabies, pseudorabies, Japanese B encephalitis, West Nile virus encephalomyelitis
- Bacterial infections of neonatal farm animals
- Toxoplasmosis, which is not a common cause in any species
- Sarcocystosis
- Verminous encephalomyelitis – migration of larvae of parasitic species that normally have a somatic migration route, e.g. *Micronema deletrix*, *Setaria* spp. *Paraelaphostrongylus tenuis*

Cattle
- Bovine spongiform encephalopathy
- Viral infections – bovine malignant catarrh, sporadic bovine encephalomyelitis and bovine herpes virus
- Bacterial infections including *Listeria monocytogenes*, *Histophilus somni* (formerly *Haemophilus somnus*),[1] heartwater, clostridial infections following dehorning of calves[2]
- Migration of *Hypoderma bovis* occasionally to brain and spinal cord

Sheep
- Scrapie
- Viral infections – louping ill, visna (associated with Maedi-visna virus)[3]
- Thrombotic meningoencephalitis associated with *H. somni* (formerly *Histophilus ovis*) in lambs[1,4]
- Bacterial meningoencephalitis in lambs 2–4 weeks of age[5]
- Migration of *Oestrus ovis*

Goats
- Scrapie
- Caprine arthritis–encephalitis virus

New World camelids
- Bacterial infection due to *L. monocytogenes*

Pigs
- Bacterial infections – as part of systemic infections with *Salmonella* and *Erysipelas* spp., rarely *L. monocytogenes*
- Viral infections – hog cholera, African swine fever, encephalomyocarditis, swine vesicular disease, hemagglutinating encephalomyelitis virus, porcine encephalomyelitis virus

Horses
- Viral infections – infectious equine encephalomyelitis, Borna disease, equine herpes virus, equine infectious anemia, eastern, western and West Nile equine encephalomyelitides, rarely louping ill virus
- Protozoal encephalomyelitis[6]
- Verminous encephalomyelitis due to *Strongylus vulgaris* in horses and *Draschia megastoma*. *Angiostrongylus cantonensis*, which normally migrates through the central nervous system of the rat, has been found as a cause of verminous encephalomyelitis in foals[7]

PATHOGENESIS

Compared to other extraneural tissues, the inflammatory response mounted by the nervous system is unique. The central nervous system is in a sequestered and immunologically dormant state within the body. The capillary endothelial blood–brain barrier restricts free access by blood constituents. The central nervous system lacks specialized dendritic antigen-presenting cells, and the intrinsic expression by central nervous system cells of major histocompatibility complex molecules, especially class II, is low. There is no lymphatic system within nervous tissue, but cells and antigens within the central nervous system drain into the circulation and to the cervical lymph nodes.

The central nervous system has unique populations of cells consisting of parenchymal cells, which are **neurons**, and **neuroglia**. The neuroglia are supporting cells and are subdivided into macroglia and microglia: the macroglia are **astrocytes** and **oligodendrocytes**; the third glial cell type is a **microglial cell**. The brain and spinal cord are enclosed by meninges (**dura**, **arachnoid** and **pia**), which provide protection, a compartment for CSF circulation (the subarachnoid space), support for blood vessels and a sheath for the cranial and spinal nerves. Within the brain and spinal cord are the ventricular system and central canal, which are lined by **ependymal cells** and the **choroid plexuses**, which produce the CSF. Circulation of the CSF moves from the lateral, third and fourth ventricles into the central canal or through lateral apertures at the cerebellomedullary angle into the subarachnoid space of the brain. CSF in the subarachnoid space drains via specialized **arachnoid granulations** into intracranial venous sinuses, with some draining into venous plexuses associated with cranial and spinal nerves. CSF may also cross the ventricular surface into the adjacent parenchyma.

The histological characteristics of central nervous system inflammation are:
- **Perivascular cuffing**
- **Gliosis**
- **Neuronal satellitosis and neuronophagia.**

A perivascular compartment, actual or potential, exists around all central nervous system arteries, arterioles, venules and veins. A characteristic feature of central nervous system inflammation is perivascular cuffing, the accumulation of leukocytes of one or multiple types in the perivascular space. All perivascular cuffing results in vasculitis of some degree. In bacterial diseases, polymorphonuclear cells predominate with a minor component of mononuclear cells. In general, viral diseases are characterized by lymphocyte-rich cells with some plasma cells and monocytes; some arbovirus infections cause a polymorphonuclear cell response. In immune-mediated diseases, there are mixtures of polymorphonuclear and mononuclear cells. In thrombogenic diseases such as thrombotic meningoencephalitis, vascular occlusion precludes the development of cuffing around injured vessels.

Gliosis is the increased prominence of glial cells, resulting from cytoplasmic swelling and the acquisition of more cell processes, from cell proliferation, or both. Either of the macroglia (oligodendrocytes or astrocytes) or microglia may participate in gliosis.

Neuronal satellitosis occurs when oligodendrocytes react and proliferate in response to degenerating neurons which may be infected by a virus.

Neuronophagia is the progressive degeneration of the neuron characterized by its piecemeal division and phagocytosis, eventually leaving a dense nodule of glial cells and fragments of the former neuron. Details of the form, functions and roles of astrocytes in neurological disease have been reviewed.[8]

Primary demyelination is characteristic of only a small number of inflammatory neurological diseases and is associated with only a few viruses. The inflammatory neuraxial diseases of large animals include visna in sheep and caprine arthritis–encephalitis. The demyelinating process may be initiated directly by the infectious agent alone or by an immunological response initiated by the agent.

With the exception of the viruses of bovine malignant catarrh and equine herpesvirus 1, which exert their effects principally on the vasculature, those viruses that cause encephalitis do so by invasion of cellular elements, usually the neurons, and cause initial stimulation and then death of the cells. Those bacteria that

cause diffuse encephalitis also exert their effects primarily on vascular endothelium. *L. monocytogenes* does so by the formation of microabscesses. In some diseases, such as meningoencephalitis in cattle associated with *H. somni*, the lesions may be present in the brain and throughout the spinal cord.[9]

Entrance of the viruses into the nervous tissue occurs in several ways. Normally the blood–brain barrier is an effective filtering agent but when there is damage to the endothelium infection readily occurs. The synergistic relationship between the rickettsias of tick-borne fever and the virus of louping ill probably has this basis. Entry may also occur by progression of the agent up a peripheral nerve trunk, as occurs with the viruses of rabies and pseudorabies and with *L. monocytogenes*. Entry via the olfactory nerves is also possible.

The clinical signs of encephalitis are usually referable to a general stimulatory or lethal effect on neurons in the brain. This may be in part due to the general effect of inflammatory edema and in part to the direct effects of the agent on nerve cells. In any particular case one or other of these factors may predominate but the tissue damage and therefore the signs are generalized. Clinical signs are often diverse and can be acute or chronic, localized or diffuse, and progressive or reversible. Because of diffuse inflammation in encephalitis, the clinical signs are commonly multifocal and asymmetric. This is not the case in listeriosis, in which damage is usually localized in the pons–medulla. Localizing signs may appear in the early stages of generalized encephalitis and remain as residual defects during the stage of convalescence. In calves with thromboembolic meningoencephalitis due to *H. somni*, prolonged recumbency may be associated with widespread lesions of the spinal cord. Visna is a demyelinating encephalitis, and caprine leukoencephalomyelitis is both demyelinating and inflammatory and also invades other tissues including joints and lung.

In verminous encephalomyelitis, destruction of nervous tissue may occur in many parts of the brain and in general the severity of the signs depends upon the size and mobility of the parasites and the route of entry. One exception to this generalization is the experimental 'visceral larva migrans' produced by *Toxocara canis* in pigs when the nervous signs occur at a time when lesions in most other organs are healing. The signs are apparently provoked by a reaction of the host to static larvae rather than trauma due to migration. Nematodes not resident in nervous tissues may cause nervous signs due possibly to allergy or to the formation of toxins.

CLINICAL FINDINGS

Because the encephalitides are associated with infectious agents they are often accompanied by fever, anorexia, depression and increased heart rate. This is not the case in the very chronic diseases such as scrapie and bovine spongiform encephalopathy. In those diseases associated with agents that are not truly neurotropic, there are characteristic signs, which are not described here.

The clinical findings that can occur in encephalitis are combinations of:

- **Subtle to marked changes in behavior**
- **Depression**
- **Seizures**
- **Blindness**
- **Compulsive walking**
- **Leaning on walls or fences**
- **Circling**
- **Ataxia.**

Bacterial meningoencephalitis in lambs 2–4 weeks of age is characterized by lack of suck reflex, weakness, altered gait and depression extending to stupor, but hyperesthesia to auditory and tactile stimuli.[5] Opisthotonus is common during the terminal stages.

There may be an initial period of **excitement or mania**. The animal is easily startled and responds excessively to normal stimuli. It may exhibit viciousness and uncontrolled activity including blind charging, bellowing, kicking and pawing. Self-mutilation may occur in diseases such as pseudorabies. Mental depression, including head-pressing, may occur between episodes.

Involuntary movements are variable in their occurrence or may not appear at all. When they do occur they include convulsions, usually clonic, and may be accompanied by nystagmus, champing of the jaws, excessive frothy salivation and muscle tremor, especially of the face and limbs. In cattle with malignant catarrhal fever, there is severe depression for a few days followed by the onset of tremors associated with the terminal encephalitis. Unusual irritation phenomena are the paresthesia and hyperesthesia of pseudorabies and scrapie.

Signs caused by loss of nervous function follow and may be the only signs in some instances. Excessive drooling and pharyngeal paralysis are common in rabies. In horses with equine encephalomyelitis, feed may be left hanging from the mouth, although swallowing may not be impaired. The loss of function varies in degree from paresis with knuckling at the lower limb joints, to spasticity of the limbs with resultant ataxia, to weakness and recumbency. Recumbency and inability to rise may be the first clinical finding encountered as in many cases of meningoencephalitis associated with *H. somni*. Hypermetria, a staggering gait and apprehensiveness progressing to belligerency may occur in a disease such as bovine spongiform encephalopathy.

Clinical signs referable to certain anatomical sites and pathways of the brain and spinal cord are manifested by deviation of the head, walking in circles, abnormalities of posture, ataxia and incoordination but these are more commonly residual signs after recovery from the acute stages. Progressive ascending spinal cord paralysis, in which the loss of sensation and weakness occur initially in the hindlimbs followed by weakness in the forelimbs, occurs commonly in rabies. Residual lesions affecting the cranial nerves do not commonly occur in the encephalitides, except in listeriosis and protozoal encephalitis of horses, both infections predominating in the caudal brainstem.

An acute hemorrhagic necrotizing encephalitis following dehorning calves has been described.[2] Affected calves were found dead or moribund within a few days following dehorning using a gouge. A secondary clostridial infection was suspected.

In the horse with cerebral nematodiasis due to *S. vulgaris* the clinical signs are referable to migration of the parasite in the thalamus, brainstem and cerebellum. There is incoordination, leaning and head-pressing, dysmetria, intermittent clonic convulsions, unilateral or bilateral blindness and paralysis of some cranial nerves. The onset may be gradual or sudden. The clinical diagnosis is extremely difficult because examination of CSF and hematology are of limited value. A pathological diagnosis is necessary. In foals with neural angiostrongylosis, tetraparesis was the end result of progressive and multifocal neurological disease.[7]

CLINICAL PATHOLOGY

Clinical pathology may be of considerable assistance in the diagnosis of encephalitis but the techniques used are for the most part specific to the individual diseases.

Hemogram

In the horse, complete and differential blood counts and serum chemistry profiles are recommended for most neurological cases.

Serology

Acute and convalescent sera can be submitted when a specific infectious disease is suspected for which a serologic diagnosis is possible.

Cerebrospinal fluid

Laboratory examination of CSF for cellular content and pathogens may also be indicated. In bacterial meningoencephalitis of young lambs, analysis of CSF obtained from the lumbosacral space reveals a highly significant increase in protein concentration with neutrophilic pleocytosis.[5]

NECROPSY FINDINGS

In some of the commonly occurring encephalitides there are no gross lesions of the brain apart from those that occur in other body systems and that are typical of the specific disease. In other cases, on transverse section of the brain, extensive areas of hemorrhagic necrosis may be visible, as in meningoencephalitis in cattle due to *H. somnus*. Histological lesions vary with the type and mode of action of the causative agent. Material for laboratory diagnosis should include the fixed brain and portions of fresh brain material for culture and for transmission experiments.

DIFFERENTIAL DIAGNOSIS

The diagnosis of encephalitis cannot depend entirely on the recognition of the typical syndrome because similar syndromes may be caused by many other brain diseases. Acute cerebral edema and focal space-occupying lesions of the cranial cavity, and a number of poisonings, including salt, lead, arsenic, mercury, rotenone and chlorinated hydrocarbons all cause similar syndromes, as do hypovitaminosis A, hypoglycemia, encephalomalacia and meningitis.

Fever is common in encephalitis but is not usually present in rabies, scrapie, or bovine spongiform encephalopathy; but it may occur in the noninflammatory diseases if convulsions are severe.

Generally, the clinical diagnosis rests upon the recognition of the specific encephalitides and the elimination of the other possible causes on the basis of the history and clinical pathology, especially in poisonings, and on clinical findings characteristic of the particular disease. In many cases a definite diagnosis can only be made on necropsy. For differentiation of the specific encephalitides reference should be made to the diseases listed under Etiology, above.

Infestation with nematode larvae causes a great variety of signs depending on the number of invading larvae and the amount and location of the damage.

TREATMENT

Specific treatments are dealt with under each disease. Antimicrobials are indicated for bacterial meningoencephalomyelitis. Generally the aim should be to provide supportive treatment by intravenous fluid and electrolyte therapy or stomach tube feeding during the acute phase. Sedation during the excitement stage may prevent the animal from injuring itself, and nervous system stimulants during the period of depression may maintain life through the critical phase. Although there is an increase in intracranial pressure, the removal of CSF is contraindicated because of the deleterious effects of the procedure on other parts of the brain.

ENCEPHALOMALACIA OR THE DEGENERATIVE DISEASES OF THE CENTRAL NERVOUS SYSTEM

The degenerative diseases of the brain are grouped together under the name encephalomalacia. By definition encephalomalacia means softening of the brain. It is used here to include all degenerative changes. Leukoencephalomalacia and polioencephalomalacia refer to softening of the white and gray matter respectively. Abiotrophy is the premature degeneration of neurons due to an inborn metabolic error of development and excludes exogenous insults of neurons. The underlying cellular defect in most abiotrophies is inherited. The syndrome produced in most degenerative diseases of the nervous system is essentially one of loss of function.

ETIOLOGY

Some indication of the diversity of causes of encephalomalacia and degenerative diseases of the nervous system can be appreciated from the examples which follow but many sporadic cases occur in which the cause cannot be defined.

All species

- Hepatic encephalopathy thought to be due to high blood levels of ammonia associated with advanced liver disease.[1] This is recorded in experimental pyrrolizidine alkaloid poisoning in sheep, in hepatic arteriovenous anomaly and thrombosis of the portal vein in the horse. Congenital portocaval shunts are also a cause
- Abiotrophy involving multisystem degenerations in the nervous system as focal or diffuse lesions involving the axons and myelin of neuronal processes.[2] These include a multifocal encephalopathy in the Simmental breed of cattle in New Zealand and Australia,[2] and progressive myeloencephalopathy in Brown Swiss cattle, known as 'weavers' because of their ataxic gait (see below and Chapter on Inherited Defects)
- Poisoning by organic mercurials and, in some instances, lead; possibly also selenium poisoning; a bilateral multifocal cerebrospinal poliomalacia of sheep in Ghana
- Cerebrovascular disorders corresponding to the main categories in humans are observed in animals, but their occurrence is chiefly in pigs and their clinical importance is minor
- Congenital hypomyelinogenesis and dysmyelinogenesis are recorded in lambs (hairy shakers), piglets (myoclonia congenita) and calves (hypomyelinogenesis congenita). All are associated with viral infections in utero. Equine herpesvirus-1 infections in horses cause ischemic infarcts
- Cerebellar cortical abiotrophy in calves and lambs.[2–4]

Ruminants

- Bovine spongiform encephalopathy
- Plant poisons, e.g. *Astragalus* spp., *Oxytropis* spp., *Swainsona* spp., *Vicia* spp., *Kochia scoparia*
- Focal symmetrical encephalomalacia of sheep, thought to be a residual lesion after intoxication with *Clostridium perfringens* type D toxin
- Polioencephalomalacia caused by thiamin inadequacy in cattle and sheep and sulfur toxicosis in cattle; poliomalacia of sheep caused possibly by an antimetabolite of nicotinic acid
- Progressive spinal myelopathy of Murray Grey cattle in Australia[2]
- Spongiform encephalopathy in newborn polled Hereford calves similar to maple syrup urine disease[2]
- Neuronal dystrophy in Suffolk sheep[2]
- Shakers in horned Hereford calves associated with neuronal cell body chromatolysis[2]
- The abiotrophic lysosomal storage diseases – progressive ataxia of Charolais cattle, mannosidosis, gangliosidosis, globoid cell leukodystrophy of sheep
- The inherited defect of Brown Swiss cattle known as 'weavers', and presented elsewhere, is a degenerative myeloencephalopathy[5]
- Swayback and enzootic ataxia due to nutritional deficiency of copper in lambs
- Prolonged parturition of calves causing cerebral hypoxia and the weak calf syndrome

- Idiopathic brainstem neuronal chromatolysis in cattle[6]
- Bovine bonkers due to the consumption of ammoniated forages
- Inherited neuronal degeneration in Angora goats.[2]

Horses

- Leukoencephalomalacia caused by feeding moldy corn infested with *Fusarium moniliforme*, which produces primarily fumonisin B_1 and, to a lesser extent, fumonisin B_2[7–10]
- Nigropallidal encephalomalacia caused by feeding on yellow star thistle (*Centaurea solstitialis*)
- Poisoning by bracken and horsetail causing a conditioned deficiency of thiamin
- Ischemic encephalopathy of neonatal maladjustment syndrome of foals
- Equine degenerative myeloencephalopathy;[11] may be associated with a vitamin E deficiency.

Ruminants and horses

Neurotoxic mycotoxins

Swainsonine and slaframine produced by *Rhizoctonia leguminicola* cause mannose accumulation and parasympathomimetic effects. Lolitrems from *Acremonium lolii* and paspalitrems from *Claviceps paspali* are tremorgens found in grasses.[7]

Pigs

- Leukoencephalomalacia in mulberry heart disease
- Subclinical attacks of enterotoxemia similar to edema disease
- Poisoning by organic arsenicals, and salt.

PATHOGENESIS

The pathogenesis of the degenerative diseases can be subdivided into:

- **Metabolic and circulatory disorders**
- **Intoxications and toxic–infectious diseases**
- **Nutritional diseases**
- **Hereditary, familial, and idiopathic degenerative diseases.**[12]

Metabolic and circulatory

Hepatic encephalopathy is associated with acquired liver disease and the resultant hyperammonemia and other toxic factors are considered to be neurotoxic. Disorders of intermediary metabolism result in the accumulation of neurotoxic substances such as in maple syrup urine disease of calves. Lysosomal storage diseases are caused by a lack of lysosomal enzymes which results in an accumulation of cellular substrates and affecting cell function. Central nervous system hypoxia and ischemia impair the most sensitive elements in brain tissue especially neurons. Severe ischemia results in necrosis of neurons and glial elements and areas of infarcts. Gas-anesthesia-related neurological disease occurs in animals that have been deprived of oxygen for more than 5 minutes.

The hypoxia is lethal to neurons and upon recovery from the anesthetic affected animals are blind and seizures may occur. The typical lesion consists of widespread neuronal damage. Post-anesthetic hemorrhagic myelopathy and postanesthetic cerebral necrosis in horses are typical examples. Hypoglycemia occurs in neonates deprived of milk and in acetonemia and pregnancy toxemia and clinical signs of lethargy, dullness progressing to weakness, seizures and coma have been attributed to hypoglycemia. However, there are no studies of the central nervous system in farm animals with hypoglycemia and the effects, if any, on the nervous tissue are unknown.

Intoxications and toxic-infectious diseases

A large number of poisonous substances including poisonous plants, heavy metals (lead, arsenic, mercury), salt poisoning, farm chemicals, antifreeze, herbicides and insecticides can directly affect the nervous system when ingested by animals. They result in varying degrees of edema of the brain, degeneration of white and gray matter and hemorrhage of both the central and peripheral nervous system. Toxic-infectious diseases such as edema disease of swine and focal symmetrical encephalomalacia of sheep are examples of endotoxins and exotoxins produced by bacterial infections which have a direct effect on the nervous system resulting in encephalomalacia.

Nutritional diseases

Several nutritional deficiencies of farm animals can result in neurological disease:

- **Vitamin A deficiency** affects bone growth, particularly remodeling of the optic nerve tracts, and CSF absorption. The elevated CSF pressure and constriction of the optic nerve tracts results in edema of the optic disc and wallerian-type degeneration of the optic nerve resulting in blindness
- **Copper deficiency** in pregnant ewes can result in swayback and enzootic ataxia of the lambs. Copper is an integral element in several enzyme systems such as ceruloplasmin and lysyl oxidase, and copper deficiency affects several organ systems. The principal defect in swayback appears to be one of defective myelination probably caused by interference with phospholipid formation. However, some lesions in the newborn are more extensive, and show cavitation with loss of axons and neurons rather than simply demyelination. In the brain, there is a progressive gelatinous transformation of the white matter, ending in cavitation that resembles porencephaly or hydranencephaly. In the spinal cord the lesions are bilateral and it is suggested that the copper deficiency has a primary axonopathic effect
- **Thiamine deficiency** in ruminants can result in **polioencephalomalacia** or **cerebrocortical necrosis**. Thiamine, mainly as thiamine diphosphate (pyrophosphate), has an important role as a coenzyme in carbohydrate metabolism especially the pentose pathway. Diffuse encephalopathy may occur characterized by brain edema and swelling, resulting in flattening of the gyri, tentorial herniation and coning of the cerebellar vermis. Bilateral areas of cerebral cortical laminar necrosis are widespread.

Hereditary, familial, and idiopathic degenerative diseases

A large number of neurological diseases of farm animals are characterized by abnormalities of central myelinogenesis. In most instances the underlying abnormality directly or indirectly affects the oligodendrocyte and is reflected in the production of central nervous system myelin of diminished quantity or quality or both. Many of these are inherited and are manifest from or shortly after birth. They include leukodystrophies, hypomyelinogenesis, spongy degeneration, and related disorders.[12] Neuronal abiotrophy, motor neuron diseases, neuronal dystrophy and degenerative encephalomyelopathy of horses and cattle are included in this group.

Polioencephalomalacia and leukoencephalomalacia

Polioencephalomalacia appears to be, in some cases at least, a consequence of acute edematous swelling of the brain and cortical ischemia. The pathogenesis of leukoencephalomalacia appears to be related to vasogenic edema as a result of cardiovascular dysfunction and an inability to regulate cerebral blood flow. Whether the lesion is in the gray matter (polioencephalomalacia) or in the white matter (leukoencephalomalacia) the syndrome is largely one of loss of function although as might be expected irritation signs are more likely to occur when the gray matter is damaged.

CLINICAL FINDINGS

Weakness of all four limbs is accompanied by:

- **Dullness or somnolence**
- **Blindness**

- **Ataxia**
- **Head-pressing**
- **Circling**
- **Terminal coma.**

In the early stages, particularly in ruminant **polioencephalomalacia**, there are involuntary signs including muscle tremor, opisthotonos, nystagmus, and convulsions.

In equine leukoencephalomalacia, which may occur in outbreaks, initial signs include anorexia and depression.[3] In the neurotoxic form, which is most common, the anorexia and depression progresses to ataxia, circling, apparent blindness, head-pressing, hyperesthesia, agitation, delirium, recumbency, seizures, and death. An early and consistent sign in affected horses is reduced proprioception of the tongue, manifest as delayed retraction of the tongue to the buccal cavity after the tongue has been extended.[10] In the hepatotoxicosis form, clinical findings include icterus, swelling of the lips and nose, petechiation, abdominal breathing and cyanosis. Horses with either syndrome may be found dead without any premonitory signs.

In many of the leukoencephalomalacias, the course may be one of gradual progression of signs, or more commonly a level of abnormality is reached and maintained for a long period, often necessitating euthanasia of the animal. For example, equine degenerative myeloencephalopathy is a diffuse degenerative disease of the equine spinal cords and caudal portion of the brainstem and primarily affects young horses. There is an insidious onset of symmetrical spasticity, ataxia, and paresis. Clinical signs may progress slowly to stabilize for long periods. All four limbs are affected, but the pelvic limbs are commonly more severely affected than the thoracic limbs. There is no treatment for the disease, no spontaneous recovery and, once affected, horses remain atactic and useless for any athletic function.

CLINICAL PATHOLOGY

There are no clinicopathological tests specific for encephalomalacia but various tests may aid in the diagnosis of some of the specific diseases mentioned above under Etiology.

NECROPSY FINDINGS

Gross lesions including areas of softening, cavitation and laminar necrosis of the cortex may be visible. The important lesions are described under each of the specific diseases.

TREATMENT

The prognosis depends on the nature of the lesion. Early cases of thiamine-deficiency-induced polioencephalomalacia can recover completely if treated with adequate levels of thiamin. Encephalomalacia due to sulfur-induced polioencephalomalacia and lead poisoning is more difficult to treat. Young calves with acquired in utero hypomyelinogenesis and horses with myelitis associated with equine herpesvirus-1 infection can make complete recoveries.

DIFFERENTIAL DIAGNOSIS

The syndromes produced by encephalomalacia resemble very closely those caused by most lesions that elevate intracranial pressure. The onset is quite sudden and there is depression of consciousness and loss of motor function. One major difference is that the lesions tend to be nonprogressive and affected animals may continue to survive in an impaired state for long periods.

TRAUMATIC INJURY TO THE BRAIN

The effects of trauma to the brain vary with the site and extent of the injury but initially nervous shock is likely to occur followed by death, recovery, or the persistence of residual nervous signs.

ETIOLOGY

Traumatic injury to the brain may result from direct trauma applied externally, by violent stretching or flexing of the head and neck or by migration of parasitic larvae internally. Recorded causes include the following:

- Direct trauma, an uncommon cause because of the force required to damage the cranium. Accidental collisions, rearing forwards, falling over backwards after rearing are the usual reasons
- Periorbital skull fractures in horses caused by direct traumatic injury commonly from collision with gate posts[1]
- Cerebral injury and cranial nerve injury, accounted for in a large percentage of neurological disease in horses.[2] Young horses under 2 years of age seem most susceptible to injuries of the head
- Injury by heat in goat kids achieved with prolonged application of a hot iron used for debudding
- Pulling back violently when tethered causing problems at the atlanto-occipital junction
- Animals trapped in bogs, sumps, cellars, and waterholes and dragged out by the head; recumbent animals pulled on to trailers suffering dire consequences to the medulla and cervical cord, although the great majority of them come to surprisingly little harm
- The violent reaction of animals to lightning stroke and electrocution causing damage to central nervous tissue; the traumatic effect of the electrical current itself also causing neuronal destruction
- Spontaneous hemorrhage into the brain – rare but sometimes occurring in cows at parturition, causing multiple small hemorrhages in the medulla and brainstem
- Brain injury at parturition, recorded in lambs, calves, and foals and possibly a significant cause of mortality in the former.

PATHOGENESIS

The initial reaction in severe trauma or hemorrhage is nervous shock. Slowly developing subdural hematoma, a common development in humans, is accompanied by the gradual onset of signs of a space-occupying lesion of the cranial cavity but this seems to be a rare occurrence in animals. In some cases of trauma to the head, clinical evidence of injury to the brain may be delayed for a few days until sufficient swelling, callus formation or displacement of the fracture fragments has occurred. Trauma to the cranial vault may be classified, from least to most severe, as **concussion**, **contusion**, **laceration**, and **hemorrhage**.

Concussion

Concussion is usually a brief loss of consciousness which results from an abrupt head injury which produces an episode of rapid acceleration/deceleration of the brain.

Contusion

With a more violent force, the brain is contused. There is maintenance of structure

but loss of vascular integrity, resulting in hemorrhage into the parenchyma and meninges relative to the point of impact. Bony deformation or fracture of the calvaria result in two different kinds of focal lesions:

- Direct (**coup**) contusions immediately below the impact site
- Indirect (**contrecoup**) contusions to the brain at the opposite point of the skull. Contrecoup hemorrhages result from tearing of leptomeningeal and parenchymal blood vessels.

Laceration

The most severe contusion is laceration where the central nervous system tissue is physically torn or disrupted by bony structures lining the cranium or by penetrating objects such as bone fragments. Focal meningeal hemorrhage is a common sequel to severe head injury. Subdural hematomas usually follow disruption of bridging cerebral veins that drain into the dural venous sinuses but subarachnoid hemorrhages are more common. The importance of these hemorrhages is that they develop into space-occupying masses that indent and compress the underlying brain. Progressive enlargement of the hematoma can result in secondary effects such as severe, widespread brain edema, areas of ischemia, herniations, midline shift, and lethal brainstem compression.

In birth injuries the lesion is principally one of hemorrhage subdurally and under the arachnoid.

Experimental traumatic craniocerebral missile injury

Traumatic insult of the brains of sheep with a .22 caliber firearm results in a primary hemorrhagic wound track with indriven bone fragments and portions of muscle and skin.[3] There is crushing and laceration of tissues during missile penetration, secondary tracks due to bone and bullet fragments, widely distributed stretch injuries to blood vessels, nerve fibers and neurons as a consequence of the radial forces of the temporary cavity that develops as a bullet penetrates tissue, marked subarachnoid and intraventricular hemorrhage, and distortion and displacement of the brain. The lesions are consistently severe and rapidly fatal.

CLINICAL FINDINGS

The syndrome usually follows the pattern of greatest severity initially with recovery occurring quickly but incompletely to a point where a residual defect is evident, this defect persisting unchanged for a long period and often permanently. This failure to improve or worsen after the initial phase is a characteristic of traumatic injury.

With severe injury there is cerebral shock in which the animal falls unconscious with or without a transient clonic convulsion. Consciousness may never be regained but in animals that recover it returns in from a few minutes up to several hours. During the period of unconsciousness, clinical examination reveals dilatation of the pupils, absence of the eye preservation and pupillary light reflexes, and a slow, irregular respiration, the irregularity being phasic in many cases. There may be evidence of bleeding from the nose and ears and palpation of the cranium may reveal a site of injury. Residual signs vary a great deal, blindness is present if the optic cortex is damaged; hemiplegia may be associated with lesions in the midbrain; traumatic epilepsy may occur with lesions in the motor cortex.

Fracture of the petrous temporal bone is a classic injury in horses caused by rearing and falling over backwards. Both the facial and the vestibular nerves are likely to be damaged so that at first the animal may be unable to stand and there may be blood from the ear and nostril of the affected side. When the animal does stand the head is rotated with the damaged side down. There may be nystagmus, especially early in the course of the disease. The ear, eyelid, and lip on the affected side are also paralyzed and sag. Ataxia with a tendency to fall is common. Some improvement occurs in the subsequent 2 or 3 weeks as the horse compensates for the deficit, but there is rarely permanent recovery. An identical syndrome is recorded in horses in which there has been a stress fracture of the petrous temporal bone resulting from a pre-existing inflammation of the bone. The onset of signs is acute but unassociated with trauma.

Fracture of the basisphenoid and/or **basioccipital bones** is also common. These fractures can seriously damage the jugular vein, carotid artery and glossopharyngeal, hypoglossal and vagus nerves. The cavernous sinus and the basilar artery may also be damaged and lead to massive hemorrhage within the cranium. Large vessels in the area are easily damaged by fragments of the fractured bones, causing fatal hemorrhage. A midline fracture of the frontal bones can also have this effect.

Other signs of severe trauma to the brain include opisthotonos with blindness and nystagmus and, if the brainstem has been damaged, quadriplegia. There may also be localizing signs, including head rotation, circling and falling backwards. Less common manifestations of resulting hemorrhage include bleeding into the retropharyngeal area, which may cause pressure on guttural pouches and the airways and lead to asphyxia. Bleeding may take place into the guttural pouches themselves.

Newborn lambs affected by birth injury to the brain are mostly dead at birth, or die soon afterwards. Surviving lambs drink poorly and are very susceptible to cold stress. In some flocks it may be the principal mechanism causing perinatal mortality.

CLINICAL PATHOLOGY

Radiography of the skull is important to detect the presence and severity of fractures, which may have lacerated nervous tissue. CSF should be sampled from the cerebellomedullary cistern and examined for evidence of red blood cells. Extreme care must be taken to ensure that blood vessels are not punctured during the sampling procedure as this would confound the interpretation of the presence of red blood cells. The presence of heme pigments in the CSF suggests the presence of pre-existing hemorrhage; the presence of eosinophils or hypersegmented neutrophils suggests parasitic invasion.

NECROPSY FINDINGS

In most cases a gross hemorrhagic lesion will be evident but in concussion and nematodiasis the lesions may be detectable only on histological examination.

DIFFERENTIAL DIAGNOSIS

Unless a history of trauma is available diagnosis may be difficult.

TREATMENT

In those animals that recover consciousness within a few hours or earlier, the prognosis is favorable and little or no specific treatment may be necessary other than nursing care. When coma lasts for more than 3–6 hours the prognosis is unfavorable and slaughter for salvage or euthanasia is recommended. Treatment for edema of the brain as previously outlined may be indicated when treatment for valuable animals is requested by the owner. Animals that are still in a coma 6–12 hours following treatment are unlikely to improve and continued treatment is not warranted.

Focal diseases of the brain

BRAIN ABSCESS

Abscesses of the brain occur most commonly in young farm animals under 1 year of age and rarely in older animals. Brain abscesses produce a variety of clinical signs depending on their location and size. Basically the syndrome produced is one of a space-occupying lesion of the cranial cavity with some motor irritation signs. Localized or diffuse meningitis is also common, along with the effects of the abscess.

ETIOLOGY

Abscesses in the brain originate in a number of ways. Hematogenous infections are common, but direct spread from injury to the cranium or via the nasopharynx may also occur.

Hematogenous spread

The lesions may be single, but are often multiple, and are usually accompanied by meningitis. The infection usually originates elsewhere.

- *Actinobacillus mallei* from glanders lesions in lung
- *Streptococcus zooepidemicus* var. *equi* as a complication of strangles in horses
- *Corynebacterium pseudotuberculosis* in a goat causing an encapsulated abscess in the left cerebellar peduncles[1]
- *Actinomyces bovis* and *Mycobacterium bovis* from visceral lesions in cattle
- *Fusobacterium necrophorum* from lesions in the oropharynx of calves
- *Pseudomonas pseudomallei* in melioidosis in sheep
- *Staphylococcus aureus* in tick pyemia of lambs
- Systemic fungal infections such as cryptococcosis may include granulomatous lesions in brain.[2]

Local spread

- Via peripheral nerves from oropharynx, the one specific disease is listeriosis in ruminants and New World camelids
- Multifocal meningoencephalitis associated with lingual arteritis induced by barley spikelet clusters[3]
- Space-occupying lesions of facial and vestibulocochlear nerves and geniculate ganglion secondary to otitis media in calves[4]
- Abscesses of rete mirabile of pituitary gland secondary to nasal septal infection after nose-ringing in cattle.[5] *Arcanobacterium (Actinomyces* or *Corynebacterium) pyogenes* is the most common isolate and several other species of bacteria that cause chronic suppurative lesions have been recovered.[5] Similar abscesses, usually containing *A. pyogenes*, occur in the pituitary gland itself
- Extensions from local suppurative processes in cranial signs after dehorning, from otitis media. The lesions are single, most commonly contain *A. pyogenes* and are accompanied by meningitis.

PATHOGENESIS

Infectious agents can invade the central nervous system by four routes:

- **Retrograde infection via peripheral nerves**
- **Direct penetrating injuries**
- **Extension of adjacent suppurative lesions**
- **By way of the systemic circulation.**

Single abscesses cause local pressure effects on nervous tissue and may produce some signs of irritation, including head-pressing and mania, but the predominant effect is one of loss of function due to destruction of nerve cells. Multiple abscesses have much the same effect but whereas in single abscesses the signs usually make it possible to define the location of the lesion, multiple lesions present a confusing multiplicity of signs and variation in their severity from day to day, suggesting that damage has occurred at a number of widely distributed points and at different times.

The pituitary abscess syndrome has an uncertain pathogenesis. The pituitary gland is surrounded by a complex mesh of intertwined arteries and capillary beds known as the rete mirabile, which has been identified in cattle, sheep, goats, and pigs but not horses. This extensive capillary network surrounding the pituitary gland makes it susceptible to localization by bacteria that originate from other sources of infection. Nose-ringing of cattle may result in septic rhinitis, which could result in infection of the dural venous sinus system, which communicates with the subcutaneous veins of the head. Bacteria may also reach the rete mirabile by way of lymphatics of the nasal mucosa and cribriform plate. Cranial nerve deficits occur as a result of the extension of the abscess into the adjacent brainstem.

CLINICAL FINDINGS

General signs include mental depression, clumsiness, head-pressing, and blindness, often preceded or interrupted by transient attacks of motor irritation including excitement, uncontrolled activity, and convulsions. A mild fever is usually present but the temperature may be normal in some cases.

The degree of blindness varies depending on the location of the abscess and the extent of adjacent edema and meningoencephalitis. The animal may be blind in one eye and have normal eyesight in the other eye or have normal eyesight in both eyes. Unequal pupils and abnormalities in the pupillary light reflex, both direct and consensual, are common. Uveitis, iris bombé, and a collection of fibrin in the anterior chamber of an eye may be present in some cases of multiple meningoencephalitis in cattle.[3] Nystagmus is common when the lesion is near the vestibular nucleus; strabismus may also occur.

Localizing signs depend on the location of lesions and may include cerebellar ataxia, deviation of the head with circling and falling, hemiplegia or paralysis of individual or groups of cranial nerves often in a unilateral pattern. In the later stages there may be papilledema. In calves with lesions of the facial and vestibulocochlear nerves and geniculate ganglion, clinical signs may include drooping of the ears and lips, lifting of the nose, slight unilateral tilting of the head and uncontrolled saliva flow. Inability to swallow may follow and affected calves become dehydrated.

These localizing signs may be intermittent, especially in the early stages, and may develop slowly or acutely.

Pituitary gland abscesses are most common in ruminants, primarily cattle 2–5 years of age,[5] but are relatively rare. The most common history includes anorexia, ataxia, depression, and drooling from the mouth with inability to chew and swallow. The most common clinical findings are depression, dysphagia, dropped jaw, blindness, and absence of pupillary light reflexes. Terminally, opisthotonos, nystagmus, ataxia, and recumbency are common. Characteristically, the animal stands with a base-wide stance, with its head and neck extended and its mouth not quite closed; there is difficulty in chewing and swallowing, and drooling of saliva. Affected animals are usually nonresponsive to external stimuli. Cranial nerve deficits are common, usually asymmetrical, multifocal and progressive. These include reduced tone of the jaw, facial paralysis, strabismus, and a head tilt. There may also be ptosis and prolapse of the tongue. Bradycardia has been recorded in about 50% of cases.[5] Terminally there is opisthotonos, nystagmus, and loss of balance, followed by recumbency.

CLINICAL PATHOLOGY

Cerebrospinal fluid

Leukocytes, protein, and bacteria may be present in the CSF, but only when the abscess is not contained.

Hematology

In pituitary gland abscessation there may be hematological evidence of chronic infection including neutrophilia, hyperproteinemia, and increased fibrinogen,[5]

although it is unlikely that a pituitary abscess itself is sufficiently large enough to induce these changes.

Imaging

Radiographic examination will not detect brain abscesses unless they are calcified or cause erosion of bone. Computed tomography has been used to diagnose a brain abscess in the horse.[6]

Electroencephalography

Electroencephalographic assessment of central blindness due to brain abscess in cattle has been reported.[7]

NECROPSY FINDINGS

The abscess or abscesses may be visible on gross examination and if superficial are usually accompanied by local meningitis.[8] Large abscesses may penetrate to the ventricles and result in a diffuse ependymitis. Microabscesses may be visible only on histological examination. A general necropsy examination may reveal the primary lesion.

DIFFERENTIAL DIAGNOSIS

Brain abscess is manifested by signs of involuntary movements and loss of function, which can occur in many other diseases of the brain, especially when local lesions develop slowly. This occurs more frequently with tumors and parasitic cysts but it may occur in encephalitis. The characteristic clinical findings are those of a focal or multifocal lesion of the brain, which include:

- Localizing signs of hemiparesis and ataxia
- Postural reaction deficit
- Vestibular signs, including head tilt and positional nystagmus
- Cranial nerve deficits.

There may be evidence of the existence of a suppurative lesion in another organ, and a high cell count and detectable infection in the CSF to support the diagnosis of abscess. Fever may or may not be present. The only specific disease in which abscess occurs is listeriosis, in which the lesions are largely confined to the medulla oblongata and the characteristic signs include circling and unilateral facial paralysis. Occasional cases may be associated with fungal infections, including cryptococcosis. Toxoplasmosis is an uncommon cause of granulomatous lesions in the brain of most species.

Many cases of brain abscess are similar to otitis media but there is, in the latter, rotation of the head, a commonly associated facial paralysis and an absence of signs of cerebral depression.

The pituitary gland syndrome in cattle must be differentiated from listeriosis, polioencephalomalacia, lead poisoning, other brain abscesses and thrombomeningoencephalitis. In sheep and goats, *Paraelaphostrongylus tenuis* infection and caprine arthritis encephalomyelitis syndrome may resemble the pituitary gland abscess syndrome.

TREATMENT

Parenteral treatment with antimicrobials is indicated but the results are generally unsatisfactory because of the inaccessibility of the lesion, with the clear exception being listeriosis. Treatment of pituitary gland abscess is not recommended, and an antemortem diagnosis is rarely obtained.

OTITIS MEDIA/INTERNA

Infection of the middle ear (**otitis media**) occurs in young animals of all species but especially dairy calves and pigs, to a lesser extent feedlot cattle and lambs, and rarely foals. The infection may gain entrance from the external ear (e.g. caused by ear mite infestation) or hematogenously, but the spread is chiefly an ascending infection of the eustachian tubes in a young animal from a respiratory tract infection. Extension of infection into the inner ear leads to **otitis interna**.

Pigs

Otitis media was present in 68% of 237 pigs that were slaughtered because of illness.[1] It is suggested that otitis media in pigs develops first as an acute inflammation in the auditory tube and then extends to other parts of the ear and brain. When abscesses form at the ventrum of the brainstem, the vestibulocochlear nerve is usually involved in the lesion.[1] Infection in the ear may extend into the brain by following the auditory nerve. Perilymph filling the scala vestibuli and scala tympani is also a possible tract for the extension of the infection because there is a communication between the perilymph-filled spaces of the bony labyrinth and the subarachnoid space.

Calves and lambs

The peak of occurrence in calves and lambs is 1–4 weeks of age. The highest prevalence is in suckling dairy calves and weaned cattle and sheep in feedlots, where the disease is probably secondary to respiratory tract infection. Outbreaks of otitis media/interna have occurred in beef calves from 6–10 weeks of age on pasture with their dams; mixed cultures of *Escherichia coli*, *Pseudomonas* spp., and *Acinetobacter* spp. were isolated.[2] Otitis media/interna in suckling dairy calves can also occur in outbreaks, and *Mycoplasma bovis* is frequently isolated from the middle and inner ears of affected calves.[3]

The onset of clinical signs commonly includes dullness, fever, inappetence, tachypnea, and a purulent discharge from the affected ear accompanied by rotation of the head (in otitis interna) and drooping of the ear a few days later due to involvement of the facial nerve in the inflammation.[2] Deep palpation at the base of the ears may elicit a pain response.[3]

Rotation of the head, with the affected side down and facial paralysis may occur on the same side, and walking in circles with a tendency to fall to the affected side is common. In most cases the animals are normal in other respects, although depression and inappetence can occur in advanced cases.

Horses

Otitis media/interna occurs in horses[4,5] and two clinical syndromes have been described.

The first syndrome is primary otitis media characterized by abnormal behavior, including head tossing, head shaking, and ear rubbing.[4] Violent, uncontrollable behavior includes throwing themselves on the ground, rolling, and thrashing. This may progress to involve the bony structures of the temporal and proximal stylohyoid bones, resulting in a degenerative arthritis and eventual fusion of the temporohyoid bone.

The second syndrome is characterized by an acute onset of neurologic deficits. Commonly, there is vestibulocochlear nerve and often facial nerve dysfunction characterized by head tilt to the side of the lesion, nystagmus with the slow component to the affected side and weakness of the extensor muscles on the affected side resulting in an ataxia or reluctance or refusal to stand. Horses that can stand often will lean on walls for support of the affected side.

Definitive diagnosis is dependent on either a positive tympanocentesis or, in the majority of cases, bony proliferation of the temporal bone and proximal part of the stylohyoid bone, or lysis of the tympanic bulla, as determined by radiography[4] or computed tomography.[3] This can be visualized using endoscopy of

the auditory tube diverticula in horses with otitis media/interna.[5] In some cases, the tympanic membrane is ruptured, which can be seen using an otoscope.[5]

Tympanocentesis is done under general anesthesia in horses or sedation in ruminants by directing a 15 cm needle through the tympanic membrane visualized with the aid of an otoscope. The technique is somewhat difficult because of the long and angled external auditory canal. Sterile 0.9% NaCl (0.5–1 mL) is injected into the tympanic cavity and then, after a few seconds, withdrawn. A positive tap consists of withdrawal of a cloudy or yellow fluid, which on analysis may contain evidence of pus and can be sampled for culture and antimicrobial susceptibility.

DIFFERENTIAL DIAGNOSIS

The disease needs to be differentiated from otitis externa, in which the head may be carried in a rotated position, but usually intermittently, and this is accompanied by head shaking and the presence of exudate and an offensive smell in the ear canal, and from cerebral injury or abscess, and similar lesions of the upper cervical cord. All of these are characterized by deviation of the head, not rotation. At necropsy the tympanic bulla contains pus, and a variety of organisms, such as staphylococci, streptococci, *Pasteurella haemolytica*, and *Neisseria catarrhalis*, may be isolated.

TREATMENT

Treatment consists of broad-spectrum antimicrobials daily for 4 weeks, and anti-inflammatory agents. The prognosis with treatment with fluoroquinolones is very good in calves, although a 50% mortality rate has been reported in calves that were not treated with other antimicrobial agents.[6] The use of lincomycin at 6.5 mg/kg BW combined with spectinomycin at 10 mg/kg BW intravenously twice daily for 5 days has been reported to be successful for the treatment of otitis media in beef calves.[2] Anecdotal reports exist in cattle of the use of a knitting needle to rupture the tympanic membrane, with rapid resolution of the head tilt because of the decreased pressure in the middle ear. Bilateral tympanic bulla osteotomy has been performed in an affected calf, resulting in a rapid resolution of the head tilt.[3]

TUMORS OF THE CENTRAL NERVOUS SYSTEM

Primary tumors of the central nervous system are extremely rare in farm animals. They produce a syndrome indicative of a general increase in intracranial pressure and local destruction of nervous tissue. Tumors of the peripheral nervous system are more common.

ETIOLOGY

The reader is referred to the review literature for a summary of available references on the tumors of the central nervous system of farm animals, which include:

- Meningeal tumors in cattle[1]
- Equine papillary ependymoma.[2]

PATHOGENESIS

The development of the disease parallels that of any space-occupying lesion, with the concurrent appearance of signs of increased intracranial pressure and local tissue destruction. Many lesions found incidentally at necropsy may not have had any related clinical findings.

CLINICAL FINDINGS

The clinical findings are similar to those caused by a slowly developing abscess and localizing signs depend on the location, size, and speed of development of the tumor. Clinical signs are usually representative of increased intracranial pressure, including opisthotonos, convulsions, nystagmus, dullness, head-pressing, and hyperexcitability. Common localizing signs include circling, deviation of the head, disturbance of balance. Lesions close to the pituitary gland may cause diabetes insipidus and Cushing's syndrome.[3] A 17-year-old horse with an ependymoma had an 18-month history of slowly progressive ataxia culminating in a sudden loss of ability to control the pelvic limbs, with dog-sitting, spinning, and falling.[4]

CLINICAL PATHOLOGY

There are no positive findings in clinicopathological examination which aid in diagnosis.

NECROPSY FINDINGS

The brain should be carefully sectioned after fixation if the tumor is deep-seated.

TREATMENT

There is no treatment.

REVIEW LITERATURE

Summers BA, Cummings JF, de Lahunta A. Veterinary neuropathology. St Louis, MO: Mosby, 1995.

DIFFERENTIAL DIAGNOSIS

Differentiation is required from the other diseases in which space-occupying lesions of the cranial cavity occur. The rate of development is usually much slower in tumors than with the other lesions.

CENTRAL-NERVOUS-SYSTEM-ASSOCIATED TUMORS

The pituitary gland (hypophysis) consists of the adenohypophysis (pars distalis, intermedia, tuberalis) and the neurohypophysis (pars nervosa). Tumors of the pituitary gland occur in the horse.[1] Cushing's syndrome in horses almost invariably originates from an adenoma of the pars intermedia of the pituitary gland.[1] Initially, these animals exhibit only one remarkable sign, namely, hirsutism. Horses with Cushing's disease only do not manifest polyuria and polydipsia. Major sequelae of an adenoma of the pars intermedia of the pituitary gland are type 2 diabetes mellitus and laminitis. Diagnosis of an adenoma of the pars intermedia of the pituitary gland in the horse mainly depends on dynamic endocrinological function tests. The sensitivity of the adrenocorticotropin (ACTH) test is about 80%.[1]

METASTATIC TUMORS OF THE CENTRAL NERVOUS SYSTEM

Many primary tumors of non-nervous tissue have the potential for metastasis to the central nervous system.

Ocular squamous cell carcinoma of cattle may invade the cranium through the cribriform plate

Lymphomas of cattle may metastasize to the central nervous system with either a multicentric distribution or occasionally as the only lesion. Most commonly bovine lymphoma occurs as an epidural mass in the vertebral canal. Intracranial lymphoma usually involves the leptomeninges or the choroid plexus. Clinical signs are related to the progressive compression of the

nervous tissue at the site of the mass. Lymphoma in the horse has occurred in the epidural space with spinal cord compression.

CENTRAL-NERVOUS-SYSTEM-ASSOCIATED MASSES

Cholesterinic granulomas, also known as cholesteatomas may occur in up to 20% of older horses without any clinical effects.[1] However, they can be associated with significant neurological disease. Affected horses are commonly obese.[1] Cholesterinic granulomas occur in the choroid plexus of the fourth ventricle or in the lateral ventricles and mimic cerebrocortical disease. It has been suggested that cholesterol granulomas result from chronic hemorrhage into the plexus stroma but the underlying pathogenesis is unknown.

Brownish nodular thickening of the plexuses with glistening white crystals is a common incidental finding in mature and aged horses. Occasionally, deposits in the plexuses of the lateral ventricles are massive and fill the ventricular space and cause secondary hydrocephalus due to the build up of CSF behind the mass. CSF may be xanthochromic with an elevated total protein.[1]

Clinical findings include episodes of abnormal behavior such as depression and bolting uncontrollably, running into fences and walls.[2] Some horses exhibit profound depression, somnolence, and reluctance to move.[1] Seizures have also been reported.[1] Other clinical findings reported include decreased performance, aggression, head tilt, incoordination, intermittent convulsions, hindlimb ataxia progressing to recumbency, intermittent circling in one direction, and spontaneous twitching along the back and flank. There are often serious changes in temperament, with previously placid animals becoming violent and aggressive. In others there are outbursts of frenzied activity followed by coma. The horse may be normal between attacks and these may be precipitated by moving the head rapidly.

These signs are referable to cerebrocortical disease and the differential diagnosis of cholesterol granulomas must include diffuse cerebral encephalopathy due to abscess, tumor, toxicosis, metabolic disease, encephalomyelitis, trauma, and hydrocephalus. At necropsy, large cholesterol granulomas are present in the choroid plexus.

COENUROSIS (GID, STURDY)

Coenurosis is the disease caused by invasion of the brain and spinal cord by the intermediate stage of *Taenia multiceps.* The syndrome produced is one of localized, space-occupying lesions of the central nervous system. In most countries the disease is much less common than it used to be and relatively few losses occur.

ETIOLOGY

The disease is associated with *Coenurus cerebralis,* the intermediate stage of the tapeworm *T. multiceps,* which inhabits the intestine of dogs and wild Canidae. The embryos, which hatch from eggs ingested in feed contaminated by the feces of infested dogs, hatch in the intestine and pass into the bloodstream. Only those embryos that lodge in the brain or spinal cord survive and continue to grow to the coenurid stage. *C. cerebralis* can mature in the brain and spinal cords of sheep, goats, cattle, horses, and wild ruminants, and occasionally humans, but clinical coenurosis is primarily a disease of sheep and occasionally cattle. Infection in newborn calves, acquired prenatally, has occasionally been observed.

PATHOGENESIS

The early stages of migration through nervous tissue usually passes unnoticed, but in heavy infections an encephalitis may be produced. Most signs are caused by the mature coenurus, which may take 6–8 months to develop to its full size of about 5 cm. The cyst-like coenurus develops gradually and causes pressure on nervous tissue, resulting in its irritation and eventual destruction. It may cause sufficient pressure to rarefy and soften cranial bones.

CLINICAL FINDINGS

In acute outbreaks due to migration of larval stages, sheep show varying degrees of blindness, ataxia, muscle tremors, nystagmus, excitability, and collapse. Sheep affected with the mature coenurus show an acute onset of irritation phenomena including a wild expression, salivation, frenzied running and convulsions. Deviation of the eyes and head may also occur. Some animals may die in this stage but the greater proportion go on to the second stage of loss of function phenomena, the only stage in most affected animals. The most obvious sign is slowly developing partial or complete blindness in one eye. Dullness, clumsiness, head-pressing, ataxia, incomplete mastication and periodic epileptiform convulsions are the usual signs. Papilledema may be present. Localizing signs comprise chiefly deviation of the head and circling; there is rotation of the head with the blind eye down, and deviation of the head with circling in the direction of the blind eye.[1]

In young animals local softening of the cranium may occur over a superficial cyst and rupture of the cyst to the exterior may follow, with final recovery. When the spinal cord is involved there is a gradual development of paresis and eventually inability to rise. Death usually occurs after a long course of several months.

CLINICAL PATHOLOGY

Clinicopathological examinations are not generally used in diagnosis in animals and serological tests are not sufficiently specific to be of value. Radiological examinations are helpful in defining the location of the cyst, especially if there is a prospect of surgical intervention.[1]

NECROPSY FINDINGS

Thin-walled cysts may be present anywhere in the brain but are most commonly found on the external surface of the cerebral hemispheres. In the spinal cord the lesions are most common in the lumbar region but can be present in the cervical area. Local pressure atrophy of nervous tissue is apparent and softening of the overlying bone may occur.

DIFFERENTIAL DIAGNOSIS

The condition needs to be differentiated from other local space-occupying lesions of the cranial cavity and spinal cord, including abscess, tumor, and hemorrhage. In the early stages the disease may be confused with encephalitis because of the signs of brain irritation. Clinically there is little difference between them and, while clinical signs and local knowledge may lead to a presumptive diagnosis, demonstration of the metacestode is essential.

TREATMENT AND CONTROL

Surgical drainage of the cyst may make it possible to fatten the animal for slaughter, and surgical removal with complete recovery is possible in a majority of cases. The life cycle can be broken most satisfactorily by control of mature tapeworm infestation in dogs. Periodic treatment of all farm dogs with a tenicide is essential for control of this and other more pathogenic tapeworms. Carcasses of livestock infested with the intermediate stages should not be available to dogs.

Diseases of the meninges

MENINGITIS

Inflammation of the meninges occurs most commonly as a complication of

a pre-existing disease. Meningitis is usually associated with a bacterial infection and is manifested clinically by fever, cutaneous hyperesthesia, and rigidity of muscles. Although meningitis may affect the spinal cord or brain specifically, it commonly affects both and is dealt with here as a single entity. Meningoencephalitis is common in neonatal farm animals. Primary bacterial meningitis is extremely rare in adult farm animals, with the exception of listeriosis and *Histophilus somni* (formerly *Haemophilus somnus*) infection, although the latter is more a vasculitis than a primary meningitis. The possibility of immunodeficiency should be considered in adult horses with bacterial meningitis.[1]

ETIOLOGY

Most significant meningitides are bacterial, although most viral encephalitides have some meningitic component.

Cattle

- Viral diseases – bovine malignant catarrh, sporadic bovine encephalomyelitis
- Bacterial diseases – listeriosis, *H. somni*, chronic lesions elsewhere in the body possibly associated with meningitis in adult animals;[2] rarely tuberculosis.

Horses

- Strangles, *Pasteurella haemolytica* (also donkeys and mules), *Streptococcus suis*, *Streptococcus equi*, *Actinomyces* spp. *Klebsiella pneumonia*, coagulase-negative staphylococci, *Sphingobacterium multivorum*, *Cryptococcus neoformans*.

Sheep

- Melioidosis, *S. aureus* (tick pyemia) in newborn lambs
- *Pasteurella multocida* in lambs *Mannhemia (Pasteurella) haemolytica* in lambs.

Pigs

Glasser's disease, erysipelas, salmonellosis; *S. suis* type 2 in weaned and feeder pigs.

Young animals generally

Streptococcal and coliform septicemias are probably the commonest causes of meningitis in neonatal farm animals. The infection may originate from an omphalophlebitis, bacteremia,[3] or bacterial translocation across the gastrointestinal tract in neonates less than 24 h of age or with enteritis. Septicemia occurs in all species, especially calves, and may be accompanied by polysynovitis, endocarditis, and hypopyon. The causative bacteria are usually a mixed flora.[4]

Hematogenous infection occurs from other sites also. In neonatal animals, some of the common infections are:

- **Calf** – *E. coli*. The disease occurs most commonly in calves under several days of age and can occur in less than 24 hours after birth. Failure of transfer of colostral immunoglobulins is a common contributing factor
- **Piglet** – *Streptococcus zooepidemicus*, *S. suis* type 1
- **Lamb** – *S. zooepidemicus*.

PATHOGENESIS

Inflammation of the meninges causes local swelling and interference with blood supply to the brain and spinal cord but as a rule penetration of the inflammation along blood vessels and into nervous tissue is of minor importance and causes only superficial encephalitis. Failure to treat meningitis associated with pyogenic bacteria often permits the development of a fatal choroiditis, with exudation into CSF, and ependymitis. There is also inflammation around the nerve trunks as they pass across the subarachnoid space. The signs produced by meningitis are thus a combination of those resulting from irritation of both central and peripheral nervous systems. In spinal meningitis there is muscular spasm with rigidity of the limbs and neck, arching of the back and hyperesthesia with pain on light touching of the skin. When the cerebral meninges are affected, irritation signs, including muscle tremor and convulsions, are the common manifestations. Since meningitis is usually bacterial in origin, fever and toxemia can be expected if the lesion is sufficiently extensive.

Defects of drainage of CSF occur in both acute and chronic inflammation of the meninges and produce signs of increased intracranial pressure. The signs are general although the accumulation of fluid may be localized to particular sites such as the lateral ventricles.

CLINICAL FINDINGS

Acute meningitis usually develops suddenly and is accompanied by fever and toxemia in addition to nervous signs. Vomiting is common in the early stages in pigs. There is trismus, opisthotonos, and rigidity of the neck and back. Motor irritation signs include tonic spasms of the muscles of the neck causing retraction of the head, muscle tremor and paddling movements. Cutaneous hyperesthesia is present in varying degrees, even light touching of the skin causing severe pain in some cases. There may be disturbance of consciousness manifested by excitement or mania in the early stages, followed by drowsiness and eventual coma.

Blindness is common in cerebral meningitis but not a constant clinical finding. In young animals, ophthalmitis with hypopyon may occur, which supports the diagnosis of meningitis. The pupillary light reflex is usually much slower than normal. Examination of the fundus of the eyes may reveal evidence of optic disk edema, congestion of the retinal vessels and exudation.

In uncomplicated meningitis the respiration is usually slow and deep, and often phasic in the form of **Cheyne–Stokes breathing** (a breathing pattern characterized by a period of apnea followed by a gradual increase in the depth and rate of respiration) or **Biot's breathing** (a breathing pattern characterized by unpredictable irregularity). Terminally there is quadriplegia and clonic convulsions.

The major clinical finding of meningoencephalitis in calves under 2 weeks of age was depression which progressed rapidly to stupor but the mental state changed to hyperesthesia, opisthotonos and seizures in unresponsive terminal cases.[3] Meningoencephalitis should be considered in calves that have been treated for the effects of diarrhea with fluid therapy but fail to respond and remain depressed.

In a series of 32 cases of meningitis in neonatal calves, the mean age at admission was 6 days (range, 11 hours–30 days). The major clinical findings were lethargy (32/32), recumbency (32/32), anorexia and loss of the suck reflex (26/32), and stupor and coma (21/32).[5] The frequency of other clinical findings were as follows: opisthotonos (9/32), convulsions (7/32), tremors (6/32), and hyperesthesia (6/32). The case fatality rate was 100%.

Although meningitis in farm animals is usually diffuse, affecting particularly the brainstem and upper cervical cord, it may be quite localized and produce localizing signs, including involvement of the cranial or spinal nerves. Localized muscle tremor, hyperesthesia and rigidity may result. Muscles in the affected area are firm and board-like on palpation. Anesthesia and paralysis usually develop caudal to the meningitic area. Spread of the inflammation along the cord is usual. Reference should be made to the specific diseases cited under Etiology for a more complete description of their clinical manifestations.

In newborn calves, undifferentiated diarrhea, septic arthritis, omphalophlebitis and uveitis are frequent concurrent clinical findings. Bacterial meningitis has been reproduced experimentally in calves, resulting in typical clinical signs consisting of convulsions, depression, circling and falling to one side, ataxia, propulsive walking, loss of saliva, tremors, recumbency, lethargy, and nystagmus.[6]

CLINICAL PATHOLOGY

Cerebrospinal fluid

CSF collected from the lumbosacral space or cisterna magna in meningitis contains elevated protein concentrations, has a high cell count and usually contains bacteria.[4,7] The collection of CSF from the lumbosacral space of calves has been described under the section on Special examination of the nervous system.[7] Culture and determination of drug sensitivity of the bacteria is advisable because of the low concentrations of antimicrobial agents achieved in CSF. In a series of meningitis in neonatal calves, the CSF revealed pleocytosis (mean 4000 leukocytes/μL; range, 130–23 270 leukocytes/μL), xanthochromia, turbidity and a high total protein concentration.[5]

Hematology

The hemogram usually reveals a marked leukocytosis, reflecting the severity of the systemic illness secondary to septicemia.

NECROPSY FINDINGS

Hyperemia, the presence of hemorrhages, and thickening and opacity of the meninges, especially over the base of the brain, are the usual macroscopic findings. The CSF is often turbid and may contain fibrin. A local superficial encephalitis is commonly present. Additional morbid changes are described under the specific diseases and are often of importance in differential diagnosis. In neonatal calves with meningitis, lesions of septicemia are commonly present at necropsy and *E. coli* is the most commonly isolated organism.

DIFFERENTIAL DIAGNOSIS

Hyperesthesia, severe depression, muscle rigidity, and blindness are the common clinical findings in cerebral meningitis but it is often difficult to differentiate meningitis from encephalitis and acute cerebral edema. Examination of the CSF is the only means of confirming the diagnosis before death. Analysis of CSF is very useful in the differential diagnosis of diseases of the nervous system of ruminants.[7,8] Details are presented under Examination of CSF in the section on Special examination of the nervous system. Subacute or chronic meningitis is difficult to recognize clinically. The clinical findings may be restricted to recumbency, apathy, anorexia, slight incoordination if forced to walk and some impairment of the eyesight. Spinal cord compression is usually more insidious in onset and is seldom accompanied by fever; hyperesthesia is less marked or absent and there is flaccidity rather than spasticity.

TREATMENT

The infection is usually bacterial, and parenteral treatment with antimicrobial agents is necessary. Large doses daily for several days are required. The levels of antimicrobial agents that are achieved in the meninges and CSF following parenteral administration to farm animals are not known. Presumably, the blood–brain and blood–CSF barriers are not intact in meningitis and minimum inhibitory concentrations of some drugs may be achieved.

Antimicrobial agents

The injection of antimicrobial agents into the cerebromedullary cistern or into the lumbosacral space is not recommended. If parenteral treatment with the antimicrobial of choice, determined by a susceptibility test, does not result in a beneficial response in 3–5 days the prognosis is unfavorable.

The choice of antimicrobial agent will depend on the suspected cause of the meningitis. The common antibiotics, such as penicillin and oxytetracycline, are effective for the treatment of meningoencephalitis in cattle due to *H. somni* when treatment is begun early. Neonatal streptococcal infections also respond beneficially to penicillin when treated early before irreparable injury has occurred.

The response to therapy will depend on the causative pathogen and the severity of the inflammation present. Some cases of meningitis, such as that in swine associated with *S. suis* type 2, commonly do not respond to treatment when clinical signs are obvious. Conversely, the meningoencephalitis in cattle associated with *H. somni* will respond dramatically if treatment is begun as soon as clinical signs are apparent. The prognosis in meningitis associated with infection with *E. coli* is unfavorable. In a series of 32 cases admitted to a veterinary teaching hospital, even after intensive therapy the case fatality rate was 100%.[5]

Cephalosporins

Based on recent experiences in human medicine, the most promising antimicrobials for the treatment of meningitis in farm animals, particularly the neonates, may be the new third-generation cephalosporins, which resist hydrolysis by beta-lactamases, have enhanced penetration into the CSF and are bactericidal at very low concentrations.[4] Clinical experience with these agents in the treatment of neonatal meningitis has been very encouraging. The aminoglycosides are also indicated in the treatment of meningitis in newborn animals.[5] Moxalactam and cefotaxime are used widely for the treatment of Gram-negative bacillary meningitis in human and ceftazidime is equally effective.[4] Trimethoprim–sulfonamide combinations, with or without gentamicin, which is synergistic with the former, are also recommended. The principles of the pharmacotherapeutics of bacterial meningitis in farm animals have been reviewed.[4]

Toxic and metabolic encephalomyelopathies

A very large number of poisons, especially poisonous plants and farm chemicals, and some metabolic defects cause abnormalities of function of the nervous system. Those plants that cause degenerative nervous system disease are listed under encephalomalacia; those that cause no detectable degenerative change in tissue are listed here.

A partial list of toxins and metabolic errors or imbalances that can cause nervous system dysfunction are as follows.

Abnormalities of consciousness and behavior

- Hypoglycemia and ketonemia of pregnancy toxemia (with degenerative lesions in some) and acetonemia
- Depression due to strong ion (metabolic) acidosis associated with diarrhea and dehydration, particularly in neonatal animals
- Hypomagnesemia of lactation tetany
- Hyper-D-lactatemia in neonatal calves with diarrhea and adult ruminants with grain overload
- High blood levels of ammonia in hepatic insufficiency
- Unspecified toxic substances in uremic animals
- Exogenous toxins, including carbon tetrachloride, hexachloroethane, and trichloroethylene
- Plants causing anemic and histotoxic hypoxia, especially plants causing cyanide or nitrite poisoning
- Poison plants, including *Helichrysum* spp., tansy mustard, male fern, kikuyu grass (or a fungus, *Myrothecium* sp. on the grass).

Abnormality characterized by tremor and ataxia

- Weeds, including *Conium* spp. (hemlock), *Eupatorium* spp. (snakeroot), *Sarcostemma* spp., *Euphorbia* spp. and *Karwinskia* spp.
- Bacterial toxins in shaker foal syndrome (probably)
- Fungal toxins, e.g. *Acremonium lolii*, the fungus of ryegrass staggers.

Convulsions

- Metabolic deficits, including hypoglycemia (piglets, ewes with pregnancy toxemia), hypomagnesemia (of whole milk tetany of calves, lactation tetany, cows and mares)
- Nutritional deficiencies of vitamin A (brain compression in calves and pigs), pyridoxine (experimentally in calves)
- Inorganic poisons, including lead (calves), mercury (calves), farm chemicals such as organic arsenicals (pigs), organophosphates, chlorinated hydrocarbons, strychnine, urea, metaldehyde
- Bacterial toxins, including *Clostridium tetani*, *Clostridium perfringens* type D
- Fungal toxins, e.g. *Claviceps purpurea*
- Grasses, including Wimmera ryegrass (*Lolium rigidum*) or the nematode on it, *Echinopogon ovatus*
- Pasture legumes – lupines
- Weeds – *Oenanthe* spp. (hemlock water dropwort), *Indigophera* spp. (in horses), *Cicuta* spp. (water hemlock), *Albizia tanganyinicus*, *Sarcostemma* spp. and *Euphorbia* spp.
- Trees – laburnum, oleander, supplejack (*Ventilago* spp.).

Ataxia apparently due to proprioceptive defect

- Grasses – *Phalaris tuberosa (aquatica)* (and other *Phalaris* spp.), *Lolium rigidum*, *Echinopogon ovatus*
- Weeds – *Romulea bulbocidum*, sneezeweed (*Helenium* spp.), *Indigophera* spp., Iceland poppy (*Papaver nudicaule*), *Gomphrena* spp., *Malva* spp., *Stachys* spp., *Ipomoea* spp., *Solanum esuriale*
- Trees – *Kalmia* spp., *Erythrophloeum* spp., *Eupatorium rugosum*
- Ferns – *Xanthorrhea* spp., *Zamia* spp. Induced thiamin deficiency caused by bracken and horsetail poisoning.

Involuntary spastic contraction of large muscle masses

This includes, for example, Australian stringhalt caused by *Arctotheca calendula* (flatweed).

Tremor, incoordination, and convulsions

There is an additional long list of plants that cause diarrhea and nervous signs, especially ataxia, together, but whether the latter are due to the former or caused by neurotoxins is not identified.

The nervous signs include tremor, incoordination, and convulsions.

Paresis or paralysis

Many of the toxic substances and metabolic defects listed above cause paresis when their influence is mild and paralysis when it is severe. Some of the items appear in both lists. Because an agent appears in one list and not the other is not meant to suggest that it does not cause the other effect. It is more likely that it occurs in circumstances that are almost always conducive to the development of a mild syndrome (or a severe one, as the case may be).

- **Disturbance of function** at neuromuscular junctions e.g.: hypocalcemia, hypomagnesemia, hypokalemia (as in downer cows), tetanus, botulism and hypoglycemia of pregnancy toxemia in cows and ewes, and tick paralysis. Hypophosphatemia has not been demonstrated to be a definitive cause of weakness in cattle
- **Nutritional deficiency**, but including only experimentally induced deficiency of nicotinic and pantothenic acids: biotin and choline, cause posterior paresis and paralysis in pigs and calves
- **Toxic diseases** of the nervous system, including disease associated with many chemicals used in agriculture, e.g.: piperazine, rotenone, 2,4-D and 2,4,5-T, organophosphates, carbamates, chlorinated hydrocarbons, propylene glycol, metaldehyde, levamisole, toluene, carbon tetrachloride, strychnine, and nicotine sulfate.

Psychoses or neuroses

Psychoses or neuroses are extremely rare in farm animals, although the vices of crib-biting and weaving in horses could be included in this category.

Crib-biting and windsucking

Crib-biting is an acquired habit in which the horse grasps an object, usually the feed box or any solid projection, with the incisor teeth, then arches the neck and, by depressing the tongue and elevating the larynx, pulls upwards and backwards and swallows air, emitting a loud grunt at the same time. This results in erosion of the incisor teeth, intermittent bouts of colic and flatulence. Crib-biting must be distinguished from chewing wood due to boredom and from pica due to a mineral deficiency. Some horses perform similarly but do not actually seize the object with their teeth; they just rest their teeth or their chin on it.

Wind sucking is the vice in which the horse flexes and arches the neck and swallows air and grunts but there is no grasping of objects.

Grasping is the seizing of an object with the teeth but without swallowing of air.

Kicking, pawing, circling, weaving

Persistent kicking of the stall, in the absence of pruritic lesions of the lower limbs, continuous circling of a stall, pawing of the floor with a forefoot and weaving, standing at the window looking out while rocking from one forefoot to the other and swinging the head and neck to the same side, are all neurotic vices caused by boredom in active horses. The extreme case is the animal that bites itself and causes cutaneous and subcutaneous mutilation.

Farrowing hysteria

Hysteria in sows at farrowing is a common occurrence. This syndrome occurs most commonly in gilts. Affected animals are hyperactive and restless and they attack and savage their piglets as they approach the head during the initial teat sucking activity after birth. Serious and often fatal injuries result. Cannibalism is not a feature.

When the syndrome occurs, the remaining piglets and freshly born piglets should be removed from the sow and placed in a warm environment until parturition is finished. The sow should then be tested to see if she will accept the piglets. If not, ataractic or neuroleptic drugs should be administered to allow initial sucking, after which the sow will usually continue to accept the piglets.

Azaperone (2 mg/kg BW) is usually satisfactory and pentobarbital sodium administered intravenously until the pedal reflex is lost has been recommended. Promazine derivatives are effective but subsequent incoordination may result in a higher crushing loss of piglets. The piglets' teeth should be clipped.

Affected gilts should be culled subsequently as the syndrome may recur at subsequent farrowing. Where possible, gilts should be placed in their farrowing accommodation 4–6 days before parturition and the farrowing environment should be kept quiet at the time of parturition.

Tail-biting, ear-chewing, snout-rubbing

The incidence of cannibalism has increased with intensification of pig rearing

and it is now a significant problem in many pig-rearing enterprises. Tail-biting is the most common and occurs in groups of pigs, especially males, from weaning to market age. Ear-chewing is less common and is generally restricted to pigs in the immediate postweaning and early growing period, although both syndromes may occur concurrently. The incidence of ear-chewing has increased with the practice of docking piglet tails at birth.

Tail-biting usually begins with one or two pigs sucking or chewing the tails of pen mates. Initially the practice causes no resentment but as the tail becomes raw and eroded, pain is shown. Rarely, if the offending agonists are removed at this stage, the problem will not progress. Generally the raw eroded tail becomes attractive to other individuals within the group and the vice spreads within the group to involve the majority of pigs. Most of the tail may eventually be removed, leaving a raw bleeding stump.

Productivity is affected by severe lesions and sequelae such as spinal abscessation with paralysis and abscessation or pyemia with partial or total carcass condemnation are not uncommon.

Ear-biting occurs in similar fashion. The lesions are usually bilateral and most commonly involve the ventral part of the ear. Lesions from bite wounds may also occur on the flanks of pigs. There is frequently an association with mange infestation with both of these vices.

A syndrome of snout-rubbing to produce eroded necrotic areas on the flanks of pigs has been described. Affected pigs were invariably colored, although both white and colored pigs acted as agonists.

The causes of these forms of cannibalism in pigs are poorly understood but they are undoubtedly related to an inadequate total environment. Affected groups are usually more restless and have heightened activity. Factors such as a high population density, both in terms of high pen density and large group size, limited food and competition for food, low protein and inadequate nutrition, boredom and inadequate environment in terms of temperature, draft and ventilation have been incriminated in precipitating the onset of these vices.

When a problem is encountered each of these factors should be examined and corrected or changed if necessary. **Prevention** is through the same measures. Chains or tires are frequently hung for displacement activity but are not particularly effective.

The problem may recur despite all attempts at prevention. Also for economic reasons it is not always possible to implement the radical changes in housing and management that may be necessary to avoid the occurrence of these vices. Because of this, the practice of tipping or docking the piglets' tails at birth has become common as a method of circumventing the major manifestation of cannibalism.

Epilepsy

Seizures occur most frequently in conjunction with other signs of brain disease. The syndrome of inherited, recurrent seizures, which continues through life with no underlying morphological disease process, is true epilepsy, which is extremely rare in farm animals. Familial epilepsy has been recorded in Brown Swiss cattle and is described under that heading in Chapter 12.

Residual lesions after encephalitis may cause symptomatic epileptiform seizures but there are usually other localizing signs. A generalized seizure is manifested by an initial period of alertness, the counterpart of the aura in human seizures, followed by falling in a state of tetany, which gives way after a few seconds to a clonic convulsion with paddling, opisthotonos and champing of the jaws. The clonic convulsions may last for some minutes and are followed by a period of relaxation. The animal is unconscious throughout the seizure, but appears normal shortly afterwards.

Some seizures may be preceded by a local motor phenomenon such as tetany or tremor of one limb or of the face. The convulsion may spread from this initial area to the rest of the body. This form is referred to as jacksonian epilepsy and the local sign may indicate the whereabouts of the local lesion or point of excitation. Such signs are recorded very rarely in dogs and not at all in farm animals. The seizures are recurrent and the animal is normal in the intervening periods.

Diseases of the spinal cord

TRAUMATIC INJURY

Sudden severe trauma to the spinal cord causes a syndrome of immediate, complete, flaccid paralysis caudal to the injury because of spinal shock. This is so brief in animals as to be hardly recognizable clinically. Spinal shock is soon followed by flaccid paralysis in the area supplied by the injured segment and spastic paralysis caudal to it.

ETIOLOGY

Trauma is the most common cause of monoplegia in large animals. There are varying degrees of loss of sensation, paresis, paralysis, and atrophy of muscle.

Physical trauma

- Animals falling off vehicles, through barn floors
- Osteoporotic or osteodystrophic animals, especially aged brood mares and sows, spontaneously while jumping or leaning on fences
- Spondylosis and fracture of thoracolumbar vertebrae in old bulls in insemination centers
- Cervical vertebral fractures account for a large percentage of spinal cord injuries in horses[1]
- Trauma due to excessive mobility of upper cervical vertebrae may contribute to the spinal cord lesion in wobbles in horses
- Dislocations of the atlanto-occipital joint are being reported increasingly
- Stenosis of the cervical vertebral canal at C2–C4 in young rams, probably as a result of head-butting[2]
- Fracture of T1 vertebra in calves turning violently in an alleyway wide enough to admit cows
- Vertebral fractures in 7–10-month-old calves escaping under the head gate of chute and forcefully hitting their backs (just cranial to the tuber coxae) on the bottom rail of the gate[3]
- Vertebral fractures in neonatal calves associated with forced extraction during dystocia[2,4]
- Lightning strike may cause tissue destruction within the vertebral canal.

Parasitic invasion

- Cerebrospinal nematodiasis, e.g. *Paraelaphostrongylus tenuis, Setaria* spp. in goats and sheep, *Stephanurus dentatus* in pigs. *P. tenuis* in moose, causing moose sickness
- *Toxocara canis* experimentally in pigs
- *Strongylus vulgaris* in horses and donkeys
- *Hypoderma bovis* larvae in cattle.

Local ischemia of the spinal cord

- Obstruction to blood flow to the cord by embolism, or of drainage by compression of the caudal vena cava, e.g. in horses during prolonged dorsal recumbency under general anesthesia;[5] in pigs due to fibrocartilaginous emboli, probably originating in injury to the nucleus pulposus of an intervertebral disk.[5]

PATHOGENESIS

The lesion may consist of disruption of nervous tissue or its compression by displaced bone or hematoma. Minor degrees of damage may result in local edema or hyperemia or, in the absence of macroscopic lesions, transitory injury to nerve cells, classified as concussion. The initial

response is that of spinal shock, which affects a variable number of segments on both sides of the injured segment and is manifested by complete flaccid paralysis. The lesion must affect at least the ventral third of the cord before spinal shock occurs. When the shock wears off the effects of the residual lesion remain. These may be temporary in themselves and completely normal function may return as the edema or the hemorrhage is resorbed. In sheep, extensive experimental damage to the cord may be followed by recovery to the point of being able to walk, but not sufficiently to be of any practical significance.

Traumatic lesions usually affect the whole cross-section of the cord and produce a syndrome typical of complete transection. Partial transection signs are more common in slowly developing lesions. Most of the motor and sensory functions can be maintained in 3-month-old calves with experimental left hemisection of the spinal cord.[6]

In a retrospective study of dystocia-related vertebral fractures in neonatal calves, all the fractures were located between the 11th thoracic vertebra and the fourth lumbar vertebra, with 77% occurring at the thoracolumbar junction.[4] All but one case was associated with a forced extraction using unspecified (53%), mechanical (28%) or manual (17%) methods of extraction. Traction is most commonly applied after the fetus has entered the pelvic canal. Manual traction varies from 75 kg pressure applied by one man to 260 kg applied by three or more men. The forces applied in mechanical traction vary from 400 kg for a calf puller to over 500 kg for a tractor. The transfer of these forces to the vertebrae and to the physeal plates at the thoracolumbar junction could readily cause severe tissue damage. In a prospective study of vertebral fractures in newborn calves, all fractures were located at the thoracolumbar area, especially the posterior epiphysis of T13.[2]

CLINICAL FINDINGS

Spinal shock develops immediately after severe injury and is manifested by flaccid paralysis (reflex loss) caudal to a severe spinal cord lesion. There is a concurrent fall in local blood pressure due to vasodilatation and there may be local sweating. Stretch and flexor reflexes and cutaneous sensitivity disappear but reappear within a half to several hours, although hypotonia may remain. The extremities are affected in most cases and the animal is unable to rise and may be in sternal or lateral recumbency. The muscles of respiration may also be affected, resulting in interference with respiration. The body area supplied by the affected segments will eventually show flaccid paralysis, disappearance of reflexes and muscle wasting – a lower motor neuron lesion.

When the injury is caused by invasion by parasitic larvae there is no stage of spinal shock but the onset is acute, although there may be subsequent increments of paralysis as the larva moves to a new site.

Neonatal calves with dystocia-related vertebral fractures are weak immediately after birth or remain recumbent and make no effort to rise.

Sensation may be reduced at and caudal to the lesion and hyperesthesia may be observed in a girdle-like zone at the cranial edge of the lesion as a result of irritation of sensory fibers by local inflammation and edema. Because of interference with the sacral autonomic nerve outflow there may be paralysis of the bladder and rectum, although this is not usually apparent in large animals. The vertebral column should be examined carefully for signs of injury. Excessive mobility, pain on pressure, and malalignment of spinous processes may indicate bone displacements or fractures. Rectal examination may also reveal damage or displacement particularly in fractures of vertebral bodies and in old bulls with spondylosis.

Residual signs may remain when the shock passes off. This usually consists of paralysis, which varies in extent and severity with the lesion. The paralysis is apparent caudal to and at the site of the lesion. The reflexes return except at the site of the lesion. There is usually no systemic disturbance but pain may be sufficiently severe to cause an increase in heart rate and prevent eating.

Recovery may occur in 1–3 weeks if nervous tissue is not destroyed but when extensive damage has been done to a significantly large section of the cord there is no recovery and disposal is advisable. In rare cases animals that suffer a severe injury continue to be ambulatory for up to 12 hours before paralysis occurs. In such instances it may be that a fracture occurs but displacement follows at a later stage during more active movement. Recovered animals may be left with residual nervous deficits or with postural changes such as torticollis.

Fracture of the cervical vertebrae in horses

In horses fracture/dislocation of cranial cervical vertebrae occurs fairly commonly. Affected animals are recumbent and unable to lift the head from the ground. However, they may be fully conscious and able to eat and drink. It may be possible to palpate the lesion, but a radiograph is usually necessary. Lesions of the caudal cervical vertebrae may permit lifting of the head but the limbs are not moved voluntarily. In all cases the tendon and withdrawal reflexes in the limbs are normal to supernormal.

Spondylosis in bulls

Old bulls in artificial insemination centers develop calcification of the ventral vertebral ligaments and subsequent spondylosis or rigidity of the lumbar area of the vertebral column. When the bull ejaculates vigorously the calcified ligaments may fracture and this discontinuity may extend upward through the vertebral body. The ossification is extensive, usually from about T2–L3, but the fractures are restricted to the midlumbar region. There is partial displacement of the vertebral canal and compression of the cord. The bull is usually recumbent immediately after the fracture occurs but may rise and walk stiffly several days later. Arching of the back, slow movement, trunk rigidity and sometimes unilateral lameness are characteristic signs. Less severe degrees of spondylosis have been recorded in a high proportion of much younger (2–3-year old) bulls, but the lesions do not appear to cause clinical signs.

CLINICAL PATHOLOGY

Radiologic examination may reveal the site and extent of the injury. CSF obtained from the lumbosacral space may reveal the presence of red blood cells, suggesting pre-existing hemorrhage.

NECROPSY FINDINGS

The abnormality is always visible on macroscopic examination. In neonatal calves with dystocia-related vertebral fractures, hemorrhage around the kidneys, around the adrenal glands and in the perivertebral muscles is a common finding and a useful indicator that a thoracolumbar fracture is present. In addition to the vertebral fracture, subdural and epidural hemorrhage, myelomalacia, spinal cord compression, severed spinal cord, and fractured ribs are common findings.

DIFFERENTIAL DIAGNOSIS

Differentiation from other spinal cord diseases is not usually difficult because of the speed of onset and the history of trauma, although spinal myelitis and meningitis may also develop rapidly. Other causes of recumbency may be confused with trauma especially if the animal is not observed in the immediate preclinical period. In most diseases characterized by recumbency, such as azoturia, acute rumen impaction and acute coliform mastitis, there are other signs to indicate the existence of a lesion other than spinal cord trauma. White muscle disease in foals is characterized by weakness and the serum creatine kinase activity will be increased.

TREATMENT

Treatment is expectant only, surgical treatment rarely being attempted. Large doses of corticosteroids or nonsteroidal anti-inflammatory agents are recommended to minimize the edema associated with the spinal cord injury. Careful nursing on deep bedding with turning at 3-hourly intervals, massage of bony prominences and periodic slinging may help to carry an animal with concussion or other minor lesion through a long period of recumbency. In cattle especially, recumbency beyond a period of about 48 hours is likely to result in widespread necrosis of the caudal muscles of the thigh and recovery in such cases is improbable. A definitive diagnosis of a vertebral fracture with paralysis usually warrants a recommendation for euthanasia.

SPINAL CORD COMPRESSION

The gradual development of a space-occupying lesion in the vertebral canal produces a syndrome of progressive weakness and paralysis. A pre-existing inflammatory or neoplastic lesion of the vertebral body may result in spontaneous fracture of the vertebral body and compression of the spinal cord.

ETIOLOGY

Compression of the spinal cord occurs from space-occupying lesions in the vertebral canal, the common ones being as follows.

Tumors

The most commonly occurring tumor in animals is lymphomatosis, which the nerve trunks and invades the vertebral canal, usually in the lumbosacral region and less commonly in the brachial and cervical areas This tumor is particularly common in adult cattle with multicentric lymphosarcoma due to bovine leukosis virus infection.

Rare tumors include: fibrosarcomas, metastases, plasma cell myeloma, angioma, melanoma in a horse,[1] hemangiosarcoma in a horse,[2] neurofibroma and lymphosarcoma, e.g. in horses, vascular hamartoma in a goat.[3]

Vertebral body or epidural abscess

Vertebral body abscesses (osteomyelitis) occur most commonly in neonatal farm animals generally in association with a chronic suppurative lesion elsewhere in the body.

- Docking wounds in lambs, bite wounds in pigs and chronic suppurative pneumonia in calves are common occurrences
- Polyarthritis and endocarditis may also be present
- Compression of the spinal cord is caused by enlargement of the vertebral body abscess into the vertebral canal and there may or may not be deviation of the vertebral canal and its contents
- The original site of infection may have resolved when the clinical signs referable to the spinal cord abscess appear
- Hematogenous spread may also occur from *Arcanobacterium (Actinomyces or Corynebacterium) pyogenes* in cattle, *Actinomyces bovis* in cattle with lumpy jaw, *Corynebacterium pseudotuberculosis* in sheep
- Epidural abscesses causing compression of the spinal cord and not associated with vertebral bodies also occur in lambs.[4]

Bony lesions of vertebra

- Exostoses over fractures with no displacement of vertebral bodies
- Similar exostoses on vertebral bodies of lambs grazing around old lead mines
- Hypovitaminosis A in young growing pigs causing compression of the nerve roots passing through the vertebral foramina
- Congenital deformity or fusion of the atlanto-occipital-axial joints in calves, foals and goats (see Congenital defects, below)
- Congenital spinal stenosis of calves.[5]

Rarely there is protrusion of an intervertebral disc, identifiable by myelogram, and progressive paresis and ataxia also occur rarely in diskospondylitis in horses. Cervical pain is a more common sign in the latter. The degenerative lesions in disks in the neck of the horse resemble the Hansen type 2 disk prolapses in dogs.

Adult sows and boars may have degeneration of intervertebral disks and surrounding vertebral osteophytes. Less commonly ankylosing spondylosis, arthrosis of articular facets, defects in annulus fibrosus and vertebral end plates, and vertebral osteomyelitis or fracture. These lesions of diskospondylitis cause lameness in boars and sows rather than compression of cord and paresis/ paralysis.

These are not to be confused with the many extravertebral causes of posterior lameness or paralysis in adult pigs, which are discussed in Chapter 13 on the musculoskeletal system.

Vertebral subluxation

Cervicothoracic vertebral subluxation in Merino sheep in Australia.[6]

Ataxia in horses

This is a major problem and is dealt with more extensively under the heading of enzootic incoordination of horses. For purposes of comparison the diseases involved are listed here:

- Nonfatal fractures of the skull (basisphenoid, basioccipital, and petrous temporal bones)
- Nonfatal cervical fractures
- Atlanto-occipital instability
- Stenosis of cranial vertebral orifice of C3–C7;[7] this may be effective as a compression mechanism only if the vertebrae adopt exaggerated positions
- Abnormal growth of interarticular surfaces
- Dorsal enlargement of caudal vertebral epiphyses and bulging of intervertebral disks
- Formation and protrusion of false joint capsules and extrasynovial bursae
- Spinal myelitis due to parasitic invasion or equine herpesvirus-1 virus, even louping-ill virus and probably others
- Spinal abscess usually in a vertebral body
- Cerebellar hypoplasia – most commonly the inherited version in Arabian foals
- Degenerative myelomalacia/ myelopathy – cause unknown
- Fusion of occipital bone with the atlas, which is fused with the axis
- Hypoxic–ischemic neuromyopathy in aortic–iliac thrombosis
- Tumors of the meninges.

PATHOGENESIS

The development of any of the lesions listed above results in the gradual appearance of motor paralysis or hypoesthesia, depending on whether the lesion is ventrally or dorsally situated. In most cases there is involvement of all motor and sensory tracts but care is necessary in examination if the more bizarre lesions are to be accurately diagnosed. There may be hemiparesis or hemiplegia if the lesion is laterally situated. Paraparesis or paraplegia is caused by a bilateral lesion in the thoracic or lumbar cord and monoplegia by a unilateral lesion in the same area. Bilateral lesions in the cervical region cause tetraparesis to tetraplegia (quadriplegia).

In horses with chronic compressive myelopathy (wobbles), compression of the spinal cord results in necrosis of white

matter, and some focal loss of neurons.[8,9] With time, secondary wallerian-like neuron fiber degeneration in ascending white matter tracts cranial to the focal lesion and in descending white matter tracts caudal to the lesion occurs. Astrocytic gliosis is a prominent and persistent alteration of the spinal cord of horses with chronic cervical compressive myelopathy and is associated with nerve fiber degeneration at the level of the compression and in well-delineated areas of ascending and descending nerve fiber tracts. It is possible that the persistent astrocytic gliosis may prevent, or slow, recovery of neurological function in affected horses.

Vertebral osteomyelitis in young calves occurs most commonly in the thoracolumbar vertebrae and less commonly in the cervical vertebrae. The abscess of the vertebral body gradually enlarges and causes gradual compression of the spinal cord, which causes varying degrees of paresis of the pelvic limbs and ataxia.[10] The abscess may extend into adjacent intervertebral spaces and result in vertebral arthritis with lysis of the articular facets. The onset of paresis and paralysis may be sudden in cases of abscessation or osteomyelitis of the vertebrae, which may fracture and cause displacement of bony fragments into the vertebral canal with compression and traumatic injury of the spinal cord. Vertebral body abscesses between T2 and the lumbar plexus will result in weakness of the pelvic limbs and normal flexor withdrawal reflexes of the pelvic limbs. Lesions at the site of the lumbar plexus will result in flaccid paralysis of the pelvic limbs.

CLINICAL FINDINGS

Varying degrees of progressive weakness of the thoracic limbs or pelvic limbs may be the initial clinical findings. With most lesions causing gradual spinal cord compression, difficulty in rising is the first sign, then unsteadiness during walking due to weakness, which may be more marked in one of a pair of limbs. The toes are dragged along the ground while walking and the animal knuckles over on the fetlocks when standing. Finally the animal can rise only with assistance and then becomes permanently recumbent. These stages may be passed through in a period of 4–5 days.

The paralysis will be flaccid or spastic depending on the site of the lesion and reflexes will be absent or exaggerated in the respective states. The 'dog-sitting' position in large animals is compatible with a spinal lesion caudal to the second thoracic vertebral segment. Calves with vertebral osteomyelitis caudal to T2 are usually able to sit up in the 'dog-sitting' position, they are bright and alert and will suck the cow if held up to the teat. In some cases, extensor rigidity of the thoracic limbs resembles the Schiff–Sherrington syndrome and indicates a lesion of the thoracic vertebrae.

Lesions involving the lumbar plexus will result in flaccid paralysis of the pelvic limbs and an absence of the flexor withdrawal reflexes. Lesions involving the sacrococcygeal vertebrae will cause a decrease in tail tone, decreased or absent perineal reflex and urinary bladder distension.

Pain and hyperesthesia may be evident before motor paralysis appears. The pain may be constant or occur only with movement. In vertebral body osteomyelitis in the horse, vertebral column pain and a fever may be the earliest clinical abnormalities. With neoplasms of the epidural space, the weakness and motor paralysis gradually worsen as the tumor enlarges.

Considerable variation in signs occurs depending on the site of the lesion. There may be local hyperesthesia around the site of the lesion and straining to defecate may be pronounced. Retention of the urine and feces may occur. There is usually no detectable abnormality of the vertebrae on physical examination.

In the wobbler horse, circumduction of the limbs with ataxia is typical. The ataxia is usually pronounced in the pelvic limbs, and weakness is evident by toe dragging and the ease with which the horse can be pulled to one side while walking. Ataxia with hypometria is often evident in the thoracic limbs, especially while walking the horse on a slope and with the head elevated.

Calves with congenital spinal stenosis are usually unable to stand or can do so only if assisted. There are varying degrees of weakness and ataxia of the pelvic limbs. They are bright and alert and will suck the cow if assisted. Those that survive for several weeks will sometimes assume the 'dog-sitting' position.

CLINICAL PATHOLOGY

Radiographic examination of the vertebral column should be carried out if the animal is of a suitable size. Myelography is necessary to demonstrate impingement on the spinal cord by a stenotic vertebral canal. Myelography using the contrast medium Iopamidol has been done in neonatal calves for the detection of spinal cord compression causing paresis.[11] The contrast medium was introduced through the foramen magnum under general anesthesia.

The cerebrospinal fluid may show a cellular reaction if there is some invasion of the spinal canal.

NECROPSY FINDINGS

Gross abnormalities of the vertebrae and the bony spinal canal are usually obvious. Those diseases of the spinal cord characterized by degeneration without gross changes require histological techniques for a diagnosis.

DIFFERENTIAL DIAGNOSIS

Differentiation between abscess, tumor and exostosis in the vertebral canal is usually not practicable without radiographic examination. Vertebral osteomyelitis is difficult to detect radiographically, particularly in large animals, because of the overlying tissue. In bovine lymphosarcoma there are frequently signs caused by lesions in other organs. A history of previous trauma may suggest exostosis. The history usually serves to differentiate the lesion from acute trauma.

- Spinal myelitis, myelomalacia and meningitis may resemble cord compression but are much less common. They are usually associated with encephalitis, encephalomalacia and cerebral meningitis respectively
- Meningitis is characterized by much more severe hyperesthesia and muscle rigidity
- Rabies in the dumb form may be characterized by a similar syndrome but ascends the cord and is fatal within a 6-day period.

In the newborn there are many congenital defects in which there is defective development of the spinal cord. Most of them are not characterized by compression of the cord, the diminished function being caused in most cases by an absence of tissue. **Spina bifida**, **syringomyelia** and **dysraphism** are characterized by hindquarter paralysis or, if the animal is able to stand, by a wide-based stance and overextension of the legs when walking. Some animals are clinically normal.

A generalized degeneration of peripheral nerves such as that described in pigs and cattle causes a similar clinical syndrome; so does **polyradiculoneuritis**. A nonsuppurative **ependymitis**, **meningitis** and **encephalomyelitis**, such as occurs in equine infectious anemia, may also cause an ataxia syndrome in horses.

Paresis or paralysis of one limb (monoplegia) is caused by lesions in the ventral gray matter, nerve roots, brachial and lumbosacral plexus, and peripheral nerves and muscles of the limbs.

TREATMENT

Successful treatment of partially collapsed lumbar vertebra by dorsal laminectomy has been performed in a calf and in horses, but in farm animals treatment is usually not possible and in most cases slaughter for salvage is recommended.

BACK PAIN IN HORSES

The subject of back pain, and its relationship to lameness, is a very important one in horses. There is often a lesion in the vertebral canal and by pressing on the cord or peripheral nerves it causes gait abnormalities that suggest the presence of pain, or they actually cause pain. Spondylosis, injury to dorsal spinous processes, and sprain of back muscles are common causes of the same pattern of signs. Because these problems are largely orthopedic ones, and therefore surgical, their exposition is left to other authorities.

It is necessary in horses to differentiate spinal cord lesions from acute nutritional myodystrophy, and subacute tying-up syndrome. Those diseases are characterized by high serum creatine kinase and aspartate aminotransferase activities.

MYELITIS

Inflammation of the spinal cord is usually associated with viral encephalitis. The signs are referable to the loss of function, although there may be signs of irritation. For example, hyperesthesia or paresthesia may result if the dorsal root ganglia are involved. This is particularly noticeable in pseudorabies and to a lesser extent in rabies. Paralysis is the more usual result. There are no specific myelitides in farm animals. Listeriosis is sometimes confined in its lesion distribution to the spinal cord in sheep. Viral myelitis associated with equine herpesvirus-1 (the equine rhinopneumonitis virus) is now commonplace and equine infectious anemia and dourine include incoordination and paresis in their syndromes. In goats, caprine arthritis encephalitis is principally a myelitis, involving mostly the white matter.

Equine protozoal myeloencephalitis causes multifocal lesions of the central nervous system, mostly the spinal cord.[1] The most accurate diagnosis is based on histological findings:

- Necrosis and mild to severe, nonsuppurative myeloencephalitis
- Infiltration of neural tissue by mononuclear cells
- Sometimes giant cells, neutrophils, and eosinophils
- Infiltration of perivascular tissue by mononuclear cells including lymphocytes and plasma cells.

Equine protozoal myeloencephalitis is caused primarily by *Sarcocystis neurona*, which has the opossum (*Didelphis virginiana*) as the definitive host, raccoons as the most likely intermediate host, with the horse acting as a dead end host.[1] Occasional cases of protozoal myeloencephalitis in horses are associated with *Neospora hughesi*.

Myelitis associated with *Neosporum caninum* infection in newborn calves has been described.[2] Affected calves were recumbent and unable to rise but were bright and alert. Histologically there was evidence of protozoal myelitis.

MYELOMALACIA

Myelomalacia occurs rarely as an entity separate from encephalomalacia. One recorded occurrence is focal spinal poliomalacia of sheep and in enzootic ataxia the lesions of degeneration are often restricted to the spinal cord. In both instances there is a gradual development of paralysis without signs of irritation and with no indication of brain involvement. Progressive paresis in young goats may be associated with the virus of caprine arthritis encephalitis and other unidentified, possibly inherited causes of myelomalacia.[3]

Degeneration of spinal cord tracts has also been recorded in **poisoning** by *Phalaris aquatica* in cattle and sheep, by sorghum in horses, by 3-nitro-4-hydroxyphenylarsonic acid in pigs and by selenium in ruminants; the lesion is a symmetrical spinal poliomalacia. Poisoning of cattle by plants of *Zamia* spp. produces a syndrome suggestive of injury to the spinal cord but no lesions have been reported. Pantothenic acid or pyridoxine deficiencies also cause degeneration of spinal cord tract in swine.

A disease of obscure etiology in sheep with spinal cord degeneration is Murrurrundi disease. A spinal myelinopathy, possibly of genetic origin is recorded in Murray Grey calves.[4] Affected animals develop ataxia of the hindlegs, swaying of the hindquarters and collapse of one hindleg with falling to one side. Clinical signs become worse over an extended period.

Sporadic cases of degeneration of spinal tracts have been observed in pigs. One outbreak is recorded in the litters of sows on lush clover pasture. The piglets were unable to stand, struggled violently on their sides with rigid extension of the limbs and, although able to drink, usually died of starvation. Several other outbreaks in pigs have been attributed to selenium poisoning.

An inherited lower motor neuron disease of pigs has been recorded.[5] Clinical findings of muscular tremors, paresis or ataxia developed at 12–59 days of age. There is widespread degeneration of myelinated axons in peripheral nerves and in the lateral and ventral columns of lumbar and cervical segments of the spinal cord. Axonal degeneration is present in ventral spinal nerve roots and absent in dorsal spinal nerve roots when sampled at the same lumbar levels.

Equine degenerative myeloencephalopathy of unknown etiology affects young horses and has been recorded in the USA, Canada, the UK, and Australia.[6] The major clinical signs are referable to bilateral leukomyelopathy involving the cervical spinal cord. There is abnormal positioning and decreased strength and spasticity of the limbs as a result of upper motor neuron and general proprioceptive tract lesions. Hypalgesia, hypotonia, hyporeflexia, muscle atrophy, or vestibular signs are not present and there is no evidence of cranial nerve, cerebral or cerebellar involvement clinically. Abnormal gait and posture are evident, usually initially in the pelvic but eventually also in the thoracic limbs. There are no gross lesions but histologically there is degeneration of neuronal processes in the white matter of all spinal cord funiculi, especially the dorsal spinocerebellar and sulcomarginal tracts. The lesion is most severe in the thoracic segments. The disease is progressive and there is no known treatment.

Equine motor neuron disease affects horses from 15 months to 25 years of age of many different breeds.[7,8] Progressive weakness, short-striding gait, trembling, long periods of recumbency, and trembling and sweating following exercise are characteristic clinical findings. The weakness is progressive and recumbency is permanent. Appetites remain normal or become excessive. At necropsy, degeneration and/or loss of somatic motor neurons in the spinal ventral horns and angular atrophy of skeletal muscle fibers are characteristic.[7]

Sporadic cases of spinal cord damage in horses include hemorrhagic myelomalacia following general anesthesia[9] and acute spinal cord degeneration following general anesthesia and surgery.[10] Following recovery from the anesthesia, the horse is able to assume sternal recumbency but not able to stand.[10] A hemorrhagic infarct assumed to be due to cartilage emboli, and a venous malformation causing spinal cord destruction have also occurred in the horse. The disease must be differentiated from myelitis and spinal cord compression caused by space-occupying lesions of the vertebral canal, and cervical, vertebral malformation/malarticulation.

Diseases of the peripheral nervous system

The **peripheral nervous system** consists of cranial and spinal nerve components. As such, the peripheral nervous system includes the dorsal and ventral nerve roots, spinal ganglia, spinal and specific peripheral nerves, cranial nerves and their sensory ganglia, and the peripheral components of the autonomic nervous system.[1]

ETIOLOGY

There are several different causes of peripheral nervous system disease.

Inflammatory

Polyneuritis equi, also known as **neuritis of the cauda equina** or **cauda equina syndrome**, is a rare and slowly progressive demyelinating granulomatous disease affecting peripheral nerves in the horse.[2] Polyneuritis equi is characterized by signs of lower motor neuron lesions, primarily involving the perineal region but also affecting other peripheral nerves, especially the 5th and 7th cranial nerves. The 8th, 9th, 10th and 12th cranial nerves also may be involved. Clinical signs of perineal region paresis/paralysis predominate, manifest as varying degrees of hypotonia, hypalgesia and hyporeflexia of the tail, anus and perineal region. Degrees of urinary bladder paresis and rectal dilatation are also present. Differential diagnoses include sacral or coccygeal trauma, equine herpes myeloencephalopathy, equine protozoal myeloencephalitis, rabies and equine motor neuron disease [2]

Cranial neuritis with guttural pouch mycosis and empyema in the horse may cause abnormalities of swallowing, laryngeal hemiplegia and Horner's syndrome if the glossopharyngeal and vagal nerves are involved in the inflammatory process of the guttural pouch.[1]

Degenerative

Equine laryngeal hemiplegia, often called roaring, is a common disease of the horse in which there is paralysis of the left cricoarytenoid dorsalis muscle resulting in an inability to abduct the arytenoid cartilage and vocal fold, which causes an obstruction in the airway during inspiration. Endoscopic examination reveals asymmetry of the glottis. On exercise, inspiratory stridor develops as the airflow vibrates a slack and adducted vocal fold. The abnormality is due to idiopathic distal degeneration of axons in the left recurrent laryngeal nerve (see more details in Chapter 10).

Traumatic

Injection injuries to peripheral nerves may result from needle puncture, the drug deposited, pressure from an abscess or hematoma, or fibrous tissue around the nerve.[1] The sciatic nerve has been most commonly affected in cattle because historically most intramuscular injections were given deep in the hamstring muscles. Young calves were particularly susceptible because of the small muscle masses. Current recommendations in cattle are that intramuscular injections should be administered cranial to the shoulder.

Femoral nerve paralysis in calves occurs in large calves born to heifers with dystocia. The injury occurs when calves in anterior presentation fail to enter the birth canal because their stifle joints become engaged at the brim of the pelvis. Traction used to deliver these calves causes hyperextension of the femur and stretching of the quadriceps muscle and its neural and vascular supplies. In most cases the right femoral nerve is affected. Such calves are unable to bear weight on the affected leg within days after birth, the quadriceps muscle is atrophied and the patella can be luxated easily. The patellar reflex is absent or markedly reduced in the affected limb because this reflex requires an intact femoral nerve and functional quadriceps muscle. Varying degrees of rear limb paresis result, accompanied by varying degrees of hind limb gait abnormality.[3,4] Skin analgesia maybe present over the proximal lateral to cranial to medial aspect of the tibia.[3] At rest, the affected leg is slightly flexed and the hip on the affected side is held slightly lower.[4] During walking, the animal has difficulty in advancing the limb normally because the limb collapses when weight-bearing. In severe cases of muscle atrophy, the patella is easily luxated both medially and laterally. Injury to the femoral nerve is relatively easy to clinically identify, and there is usually no need to perform electromyographic studies of atrophied quadriceps muscle in order to document denervation.

Calving paralysis is common in heifers that have experienced a difficult calving. Affected animals are unable to stand without assistance; if they do stand, the hind limbs are weak and there is marked abduction and inability to adduct. It has always been erroneously thought that traumatic injury of the obturator nerves during passage of the calf in the pelvic cavity was the cause of the paresis; however, detailed pathological and experimental studies have demonstrated that most calving paresis/paralysis is due to damage to the sciatic nerve.[5–8] Experimental transection of the obturator nerves does not result in paresis. The term obturator nerve paralysis should only be used for post-parturient cattle with an inability to adduct one or both hindlimbs, and calving paralysis in the preferred descriptive term for hind limb paresis/paralysis occurring in the immediate postparturient period.

Damage to the sciatic nerve results in rear limb weakness and knuckling of the fetlocks; the latter clinical sign is an important means for differentiating sciatic nerve damage from obturator nerve damage. The patellar reflex in ruminants with sciatic nerve damage is normal or increased, because the reflex contraction of the quadriceps muscle group by the femoral nerve is unopposed by the muscles of the hindlimb innervated by the sciatic nerve.

The peroneal nerve is most frequently damaged by local trauma to the lateral stifle, where the peroneal nerve runs in a superficial location lateral to the head of the fibular bone. Damage to the peroneal nerve leads to knuckling over of the fetlock joint due to damage to the extensor muscles of the distal limb, resulting in the dorsal aspect of the hoof resting on the ground when the animal is standing. Full weight can be borne on the affected limb when the digit is placed in its normal position, but immediately upon walking the digit is dragged. There is a loss of skin sensation on the anterior aspect of the metatarsus and digit.

Damage to the tibial nerve causes mild hyperflexion of the hock and a forward knuckling of the fetlock joint. Tibial nerve damage is very rare, and most cases described as tibial nerve damage are actually sciatic nerve damage.

Metabolic and nutritional

Pantothenic acid deficiency may occur in pigs fed diets based solely on corn (maize). Affected animals develop a goose-stepping gait due to degenerative changes in the primary sensory neurons of the peripheral nerves.

Toxic

Heavy metal poisoning including **lead and mercury poisoning in horses** has been associated with clinical signs of degeneration of peripheral cranial nerves but these are not well documented.

Tumors

A multicentric schwannoma causing chronic ruminal tympany and forelimb paresis has been recorded in an aged cow.[9] Neoplastic masses were present throughout the body and both right and left brachial plexi were involved. The peripheral nerves of each brachial plexus were enlarged. Large tumor masses were present on the serosal surfaces of the esophagus, pericardial sac and epicardium, within the myocardium, endocardium and the ventral branches of the first four thoracic spinal nerves. A large mass was present in the anterior mediastinum near the thoracic inlet.

Autonomic nervous system

Grass sickness in the horse occurs exclusively in the UK and is characterized by a peracute to chronic alimentary tract disease of horses on pasture (hence the name). Gastrointestinal stasis is partial or complete. Peracute cases are in shock and in a state of collapse with gastric refluxing. Acute, subacute and chronic cases also occur. Degenerative changes occur in the autonomic ganglia, especially the celiac–mesenteric, stellate, thoracic sympathetic chain, ciliary, cranial and caudal cervical, the craniospinal sensory ganglia and selected nuclei in the central nervous system.[9] The etiology is unknown.

Congenital defects of the central nervous system

The pathogenesis of congenital defects, including those of the central nervous system, has been dealt with in general terms in Chapter 3. Inheritance, nutrition, virus infection in early pregnancy and some toxins can all play a part in the genesis of these defects and the purpose of this section is to guide the diagnostician through the recognition of the defect to the possible causes. However, many such cases occur sporadically and a specific cause cannot be identified.

Although most developmental defects are present at birth there are a few that appear later in life, especially the abiotrophic diseases. in which an essential metabolic process (essential. that is. for cellular structure and function) is missing and the tissue undergoes degeneration.

The diseases to be identified are listed under the headings of the principal clinical signs and syndromes that they produce. Many affected neonates are weak and die either during birth or soon afterwards so that they tend to be diagnoses for pathologists rather than clinicians. There may be an unintentional bias toward more clinically conspicuous diseases in the following material. The reader is referred to the review literature for details of specific congenital defects.

Defects with obvious structural errors

- Hydrocephalus, sporadic or inherited, with obvious enlargement of the cranium
- Meningocele with protrusion of a fluid-filled sac through the open fontanelle in the cranial vault. The defect is inherited in some pigs
- Hydrocephalus with spina bifida combination – the Arnold–Chiari syndrome – in cattle
- Hydrocephalus with congenital achondroplasia (bulldog calf syndrome)
- Cranium bifidum (may include meningocele) of pigs
- Ventral meningomyelocele in a filly foal[1]
- Microphthalmia – in microcephaly the cranium is usually of normal size
- Some cases of failure of closure of neural tube, e.g. spina bifida in lambs.[2] There is a defect in the skin and dorsal arch of the vertebra in the lumbosacral area in some cases
- Exophthalmos with or without strabismus, an inherited form in Jersey and Shorthorn cattle does not appear until the animal is more than 6 months of age
- Neurofibromas occurring as enlargements on peripheral nerves and seen as subcutaneous swellings. They are passed from cow to calf
- Persistent cloaca and caudal spinal agenesis in calves[3]
- Hydranencephaly, porencephaly and other structural defects due to intrauterine infection with Akabane, Bluetongue, Cache Valley and Wesselsbron viruses.

Diseases characterized by congenital paresis/paralysis

- Enzootic ataxia due to nutritional deficiency of copper. It may also develop later, within the first month of postnatal life
- Inherited congenital posterior paralysis of calves, and of pigs
- Congenital spinal stenosis of calves[4]
- Spina bifida, sometimes accompanied by flexion and contracture and atrophy of hindlegs; most are stillborn. In rare cases the affected calf is ambulatory[5]
- Spinal dysraphism in Charolais and Angus calves, syringomyelia and hydromyelia in calves
- Tetraparesis, tetraplegia, progressive ataxia with head deviation in foals with congenital occipitoatlanto-axial malformations. A familial tendency to the defects occurs in Arab and non-Arabian horses. Additional signs include stiffness of the neck, palpable abnormalities at the site and a clicking sound on passive movement. Foals may be affected at birth or develop signs later. The defect is identifiable radiographically
- A congenital dysplasia of the atlanto-occipital joint with excessive mobility is recorded in Angora goats and causes a compressive myelopathy. Devon calves may be affected by the same deformity[6] and similar ones have been recorded in calves that were recumbent at birth[5] and others in which ataxia developed subsequently[7]
- More widespread malacic changes have been recorded in the spinal cord of calves but without the specific etiology being determined.

Neurogenic arthrogryposis and muscle atrophy

- Akabane virus infection of calves, kids, possibly lambs, in utero
- There are many other causes of arthrogryposis listed under congenital abnormalities of joints but they are not known to be neurogenic.

Spasms of muscle masses

- Inherited spastic paresis (Elso-heel) of calves

- Inherited periodic spasticity (stall-cramp).

Diseases characterized by cerebellar ataxia

- Inherited cerebellar hypoplasia of calves, Arabian foals, lambs
- Cerebellar hypoplasia and hypomyelinogenesis in calves from cows infected with BVD virus and possibly Akabane virus during pregnancy
- Cerebellar hypoplasia in piglets after hog cholera vaccination of dams
- Inherited cerebellar ataxia in pigs and foals
- Familial convulsions and ataxia of Angus cattle
- Mannosidosis of cattle
- Intracranial hemorrhage in newborn foals, discussed in more detail under Neonatal maladjustment syndrome
- Spinal cord hypoplasia in Akabane virus infection in ruminants.

Diseases characterized by tremor

- Congenital paresis and tremor of piglets
- Inherited congenital spasms of cattle
- Inherited neonatal spasticity (Jersey and Hereford cattle) develops at 2–5 days old
- Border disease (hairy shakers) in lambs due to BVD virus
- Inherited neuraxial edema (now inherited congenital myoclonus) of polled Hereford cattle and congenital brain edema of Herefords
- Myoclonia congenita as a result of infection with hog cholera or Aujeszky's disease viruses
- Tremor with rigidity due to hydranencephaly and porencephaly in calves infected in utero with BVD virus
- Shaker calves' in Herefords.

Disease characterized by convulsions

- Brain injury during birth in calves and lambs
- Brain compression due to hypovitaminosis A in calves and pigs
- Neonatal maladjustment syndrome (barkers and wanderers) in Thoroughbred foals
- Congenital toxoplasmosis in calves, bluetongue virus infection in lambs
- Tetanic convulsion in inherited neuraxial edema (now inherited congenital myoclonus) of Hereford calves, but only when lifted to standing position
- Inherited idiopathic epilepsy of Brown Swiss cattle
- Familial convulsions and ataxia of Angus cattle
- Inherited narcolepsy/catalepsy in Shetland ponies and Suffolk horses (not really a convulsion)
- Doddler calves.

Diseases characterized by imbecility

- Microencephaly in calves, probably inherited, with no abnormality of the cranium, but the cerebral hemispheres, cerebellum and brainstem are reduced in size and the corpus callosum and fornix are absent
- Microcephaly recorded in sheep; many are dead at birth, viable ones are unable to stand, blind, incoordinate and have a constant tremor
- Anencephaly in calves with absence of cerebral hemispheres, rostral midbrain, occurs sporadically in calves
- Hydranencephaly associated with Akabane virus infection of calf, kid, and possibly lamb in utero
- Congenital porencephaly in lambs after intrauterine infection with bluetongue virus.

Ocular abnormalities

- Spontaneous microphthalmia and anophthalmia in calves, usually of unknown cause
- Congenital lenticular cataracts in cattle and lambs
- Blindness developing after birth in gangliosidosis of cattle and ceroid lipofuscinosis of sheep
- Constriction of optic nerve by vitamin A deficiency causing blindness in calves and pigs
- Constriction of optic nerve and blindness with BVD virus infection in calves in utero
- Inherited exophthalmos with strabismus of cattle
- Familial undulatory nystagmus (pendular nystagmus).

Defects conditioned by inheritance but not present at birth

- Cerebellar atrophy (abiotrophy) in calves and foals; a probably inherited cerebellar abiotrophy in sheep aged 3.5–6 years
- Inherited idiopathic epilepsy of Jerseys and Shorthorns
- Mannosidosis of cattle
- Gangliosidosis of cattle
- Bovine generalized glycogenosis
- Multifocal symmetrical necrotizing encephalomyelopathy (Leigh's disease) in Angus, Simmental, and Limousin cattle[7]
- Globoid cell leukodystrophy of sheep
- Ceroid lipofuscinosis of sheep
- Inherited myotonia of goats
- Progressive ataxia of Charolais cattle
- Inherited citrullinemia of calves
- Inherited maple syrup urine disease.

Diseases of the musculoskeletal system 13

Diseases of the organs of support, including muscles, bones, and joints, have much in common in that the major clinical manifestations of diseases that affect them are lameness, failure of support, insufficiency of movement and deformity. Insufficiency of movement affects all voluntary muscles, including those responsible for respiratory movement and mastication, but lameness and failure of support are manifestations of involvement of the limbs.

Various classifications of the diseases of the musculoskeletal system, based on clinical, pathological and etiological differences, are in use, but the simplest is that which divides the disease into degenerative and inflammatory types.

- The degenerative diseases of muscles, bones and joints are distinguished as: myopathy, osteodystrophy and arthropathy, respectively
- The inflammatory diseases are myositis, osteomyelitis and arthritis.

Principal manifestations of musculoskeletal disease

LAMENESS

Lameness is an abnormal gait or locomotion characterized by limping (claudication) or not bearing full weight on a leg, usually associated with pain in the musculoskeletal system. Lameness must be distinguished from **ataxia**, which is an abnormal gait characterized by lack of coordination of muscular action, usually because of a lesion of the central or peripheral nervous system.

Weakness is the inability to maintain a normal posture and gait, usually because of a lesion of muscle or generalized weakness due to an abnormal systemic state such as shock, hypocalcemia, or starvation.

Because of the difficulty inherent in the differentiation of diseases causing lameness, and other abnormalities of gait and posture, a summary is presented in Table 13.1. It does not include lameness in racing horses, which is described in textbooks on lameness in horses, or diseases of the nervous system that interfere with normal movement and posture. These are discussed in Chapter 12.

ABNORMAL POSTURE AND MOVEMENT

As a group, diseases of the musculoskeletal system are characterized by reduced activity in standing up and moving, and the adoption of unusual postures. Abnormal movements include limpness, sagging or stiffness and lack of flexion. Abnormal postures include persistent recumbency, including lateral recumbency. There may be signs of pain on standing, moving or palpation. There is an absence of signs specifically referable to the nervous system. For example, there are no signs of brain damage and the spinal cord reflexes are present but may be only partly elicitable (the sensory pathway is intact but the motor response may be diminished). Differentiation from diseases of the nervous system and from each other may be aided by specific biochemical, radiological or hematological findings that indicate the system involved. Specific epidemiological findings may indicate the location of the lesion (which may be secondary) in muscle, bones, or joints, as set out in Table 13.1.

DEFORMITY

Atypical disposition, shape or size of a part of the musculoskeletal system constitutes a deformity. This may occur in a number of ways, and be caused by the following.

Muscle and tendon defects

- Congenital hypermobility of joints, inherited and sporadic
- Congenital flexed or stretched tendons of limbs causing contracture of joints or hyperextension
- Inherited congenital splayleg of pigs
- Muscle hypertrophy (doppelender, culard) of cattle
- Acquired asymmetric hindquarters of pigs.

Joint defects

- Inherited congenital ankylosis of cattle causing fixation of flexion
- Joint enlargement of rickets and chronic arthritis.

Defects of the skeleton

- Dwarfism – inherited miniature calves, achondroplastic dwarves; short legs of inherited congenital osteopetrosis; nutritional deficiency of manganese; acorn calves
- Giant stature – inherited prolonged gestation, not really giantism, only large at birth
- Asymmetry – high withers, low pelvis of hyena disease of cattle
- Limbs – complete or partial absence, inherited or sporadic amputates; curvature of limbs in rickets; bowie or bentleg of sheep poisoned by *Trachymene* sp.
- Head – inherited and sporadic cyclopean deformity; inherited probatocephaly (sheep's head) of

Table 13.1 Differential diagnosis of diseases of the musculoskeletal system

Disease and clinical findings	Epidemiological findings	Clinical pathology	Necropsy findings	Examples
Myasthenia Paresis, paralysis and incoordination	Ischemia or reduced supply of energy or electrolytes	Hypoglycemia, hypocalcemia, hypokalemia, hypomagnesemia	Reversible malfunction	Iliac thrombosis, toxemia, milk fever, lactic acidosis, some poisonous plants
Myopathy *Either* stiff gait, disinclination to move, board-like muscles *or* weakness, pseudoparesis or paralysis, difficult rising, staggery gait, flabby muscles. Always bilateral, mostly hindlimbs	Often precipitated by sudden increase in muscular work. Usually diet-dependent on: (1) High carbohydrate intake (2) Deficiency in selenium/vitamin E intake (3) Ingestion of myopathic agents, e.g. in poison plants, cod liver oil	Marked elevations in serum levels of CPK and AST. Myoglobinemia and possibly myoglobinuria	White, waxy, swollen, 'fish flesh' muscle	*Horses*: Azoturia ('equine paralytic myoglobinuria', 'tying-up', 'equine rhabdomyolysis') Postanesthetic myositis *Pigs*: Porcine stress syndrome, selenium deficiency, inherited splaylegs *Cattle*: Selenium/vitamin E deficiency (enzootic muscular dystrophy), poisoning by *Cassia occidentalis*, *Karwinskia humboldtiana*, ischemic necrosis of recumbency *Sheep*: Approximately the same. Exertional rhabdomyolysis
Myositis Acute inflammation, swelling, pain, may be associated with systemic signs if infectious. Chronic manifested by atrophy, contracture of joint, incomplete extension	Related to trauma or specific infectious disease. Atrophy, pallor in chronic	As for myopathy plus hematological response when infection present	Bruising, edema and hemorrhage in acute	Blackleg, false blackleg (malignant edema). Eosinophilic myositis in beef cattle. Traumatic injury by strain of muscle or forceful impact
Osteodystrophy Stiff gait, moderate lameness often shifting from leg to leg, arched back, crackling sounds in joints while walking. Disinclination to move; horses affected early race very poorly. Severely affected animals disinclined to stand, recumbent much of time. Fractures common. Bones soft, e.g. frontal bones to digital pressure. Deformities of bones, e.g. bowing, pelvic collapse. Ready detachment of tendons and ligaments	Absolute deficiency and/or relative imbalance of dietary calcium, phosphorus and vitamin D. Most apparent in rapidly growing, working and heavy milk-producing animals	Radiographic evidence of osteoporosis, deformed epiphyseal lines, broadness of epiphyses. Subperiosteal unossified osteoid	Osteoporosis, subepiphyseal collapse of bone at pressure points. Fracture of soft bones. Bone ash determinations of Ca, P and Mg content of bones	*Cattle*: Phosphorus deficiency, Marie's disease. Hypovitaminosis D. Calcium deficiency. Poisoning by *Trachymene glaucifolia* (bowie or bentleg) *Horses*: Osteodystrophia fibrosa due to low calcium diet, or to poison plants containing large amounts of oxalate (see under oxalate poisoning) *Pigs*: Osteodystrophia fibrosa due to low Ca high P in diet
Osteomyelitis Pain, swelling (little), toxemia, fever, may be discharge through sinus	Only of specific disease	Radiographic evidence of rarefaction, new bone growth	Osteomyelitis	Actinomycosis, brucellosis in pigs and cattle. Necrotic and atrophic rhinitis disease in pigs
Arthropathy (osteoarthritis) Lameness with pain on walking, standing, palpation. Some enlargement but not gross. Slackness in joints, may be ligament rupture, crepitus	(1) Inherited predisposition in cattle (2) Dietary excess of phosphorus, relative deficiency of calcium (3) Very rapid increase in body weight in young (4) Heavy milk production during many lactations	Excessive sterile brownish fluid with floccules. Radiological evidence of joint erosion, epiphyseal deformity, new bone growth peripherally	Erosion of cartilage and bone, ligament rupture, new bone growth (epiphytes) around edge of joint. Excess brownish sterile clear fluid containing floccules	*Cattle*: Degenerative joint disease (of young beef bulls) inherited osteoarthritis *Horses*: As early part of osteodystrophy syndrome. *Pigs*: Epiphyseolysis of femurs of young breeding boars. Osteochondrosis

Table 13.1 (*Cont'd*) Differential diagnosis of diseases of the musculoskeletal system

Disease and clinical findings	Epidemiological findings	Clinical pathology	Necropsy findings	Examples
Arthritis *Acute*: Sudden onset, severe pain, very lame, sore to touch, swelling, heat in joint *Chronic*: Continuous pain, recumbency, may be toxemia if infectious. Joint may be visibly swollen but may be normal appearance. Pain may be evident only when animal stands on joint	Most commonly in young via navel infection and bacteremia, or residual from septicemia of neonate	Aspiration of fluid under very sterile conditions shows leukocytes and somatic cells in large numbers. Culture may be positive but often negative. Joint fluid may appear normal in chronic case	*Acute*: Inflammation or suppuration, increased fluid content *Chronic*: Thickened synovial membrane Increased amount of clear fluid. Erosion of articular cartilage	*Cattle*: *Mycoplasma* sp., *Erysipelothrix rhusiopathiae Streptococcus* and *Staphylococcus* spp., *Escherichia coli, Salmonella* sp. in newborn. *Brucella abortus, Mycoplasma* sp. and *Chlamydophila* sp. *Pigs*: *E. Erysipelothria rhusiopathiae, Mycoplasma* sp. *Sheep*: *Corynebacterium pseudotuberculosis, E. rhusiopathiae, Histophilus somni, Manheimia haemolytica, Actinobacillus seminis, Chlamydophila* sp., *Mycoplasma* sp. *Horses:* Foal septicemias
Tenosynovitis, cellulitis, lymphangitis, bursitis Inflammation of other supporting tissues. Visible, painful enlargements	Sporadic due to trauma or localization of systemic infection	Culture of aspirate from local lesion	Inflammation of affected part. Acute hemorrhagic or chronic, suppurative	*Horses and cattle:* Bursitis – *B. abortus.* Tenosynovitis – *Histophilus somni,* cattle, *Streptococcus equi* horse, *Histophilus somni,* sheep
Interdigital dermatitis (footrot) Severe foot lameness. Visible local lesion at skin–horn junction, necrotic smell, horn underrun. Allied similar conditions have less severe lesions	Severe epidemics in wet, warm weather in sheep. Infection soil-borne. Some farms have disease persistently	Culture of infectious agent, swab from depth of lesion	Necrosis of soft tissue	*Sheep*: Footrot – *Bacteroides nodosus*; footscald – avirulent *B. nodosus*; foot abscess – *F necrophorus*; *Arcanobacterium pyogenes*; interdigital dermatitis – *F. necrophorum* *Cattle*: Footrot – *F. necrophorum, B. nodosus*
Laminitis Severe foot pain, separation of horn from sensitive laminae, rotation of the pedal bone. Metabolic, traumatic or infectious types	Sporadic except infectious type in sheep related to dipping. Possibly inherited susceptibility to metabolic laminitis in cattle	Very high blood pressure. Radiological demonstration of P_3 rotation	Infection or hemorrhage/edema, sensitive laminae	*Sheep: Erysipelothrix rhusiopathiae* – postdipping laminitis *Horses* – traumatic due to continuous pawing *All species*: Metabolic associated with heavy grain feeding – in mares with retained placenta and metritis
Damage to horn of hoof Severe foot pain if sensitive laminae affected. Horn damage obvious	Related to hard abrasive surfaces – pigs and dairy cattle; soft underfoot – cows indoors on wet bedding	Nil	Foothorn lesion only	*Cattle*: Stable footrot on soft footing; sole wear on rough concrete *Pigs*: Sole wear on rough concrete, predisposed by biotin deficiency in diet. *Horses*: Thrush and canker on soft wet underfoot

Table 13.1 (*Cont'd*) Differential diagnosis of diseases of the musculoskeletal system

Disease and clinical findings	Epidemiological findings	Clinical pathology	Necropsy findings	Examples
Traumatic injuries of feet of newborn piglets Severe lameness in piglets 1–8 days of age. Bruising of sole, congestion and swelling followed by peeling, erosion and cracking of horn of sole; both claws and accessory digits injured more often on medial aspect and incidence in hindfeet twice that of forefeet; abrasions of skin of carpal joints common; accessory digits involved too. Ascending secondary bacterial infection resulting in tenosynovitis and septic arthritis. Most piglets recover following antibacterial therapy	Newborn piglets raised on concrete or slatted floors. Distribution of lesions related to sucking behavior of piglets, the backwards, outwards and downwards thrusting movements of the hindlegs while sucking	Nil	Erosion, necrosis, congestion, fissures and hemorrhage of horn of sole and sensitive laminae of digit. Secondary tenosynovitis and arthritis	*Piglets:* Newborn piglets raised on concrete, expanded metal or plastic slatted floors
Coronitis dermatitis at coronet Lesions vary from granuloma through vesicles, erosions. Lameness in all, but severity varies with type of lesion. Essential to examine oral mucosa	Acute outbreaks of lameness due to coronitis in any species raises specter of food-and-mouth disease	Microbiology of material from local lesion	Local lesions only	*Sheep*: Bluetongue, foot-and-mouth disease, vesicular stomatitis, ecthyma, strawberry footrot, ulcerative dermatosis, heel dermatitis (*B. nodosus*), strongyloidosis *Cattle*: Foot-and-mouth disease, vesicular stomatitis, bovine virus diarrhea, bovine malignant catarrh, epitheliogenesis imperfecta *Pigs*: Foot-and-mouth disease, vesicular exanthema of swine, swine vesicular disease, vesicular stomatitis *Horses*: Vesicular stomatitis, greasy heel, chorioptic mange

calves; inherited moles, bulldog calves; acquired atrophic rhinitis of pigs.

SPONTANEOUS FRACTURES

Spontaneous fractures occur uncommonly in farm animals and pre-existing diseases are usually present, which include the following:

- Nutritional excess of phosphorus causing osteodystrophia in horses
- Nutritional deficiency of calcium causing osteodystrophia in pigs
- Nutritional deficiency of phosphorus or vitamin D in ruminants causing rickets and/or osteomalacia; hypervitaminosis A may contribute to this
- Nutritional deficiency of copper
- Chronic fluorine intoxication.

PAINFUL ASPECTS OF LAMENESS

Musculoskeletal pain can be caused by lacerations and hematomas of muscle, myositis and space-occupying lesions of muscle. Osteomyelitis, fractures, arthritis, joint dislocations, sprains of ligaments and tendons are also obvious causes of severe pain. Among the most painful of injuries are swollen, inflammatory lesions of the limbs caused by deep penetrating injury or in cattle by extension from footrot. Amputation of a claw, laminitis and septic arthritis are in the same category. Ischemia of muscle and generalized muscle tetany, as occurs in electroimmobilization, also appear to cause pain.

Research on the pathophysiology and pharmacology of pain associated with lameness in animals indicates that the thresholds to painful stimuli change in response to pain and this change is seen as an indication of an alteration in nerve function or in nociceptive processing at higher levels. In flocks of sheep with severe lameness due to foot rot, affected sheep had a lower threshold to a mechanical nociceptive stimulus than matched controls and their thresholds remained low when tested 3 months later, after the apparent resolution of the foot lesions.[1] Thus hyperalgesia persisted in severely lame sheep for at least 3 months. It is suggested that *N*-methyl-D-aspartate receptors are involved in the development of this long-term hypersensitivity. Similar findings have been reported in dairy heifers affected with claw lesions during the peripartum period.[2]

Relief of musculoskeletal pain

Several aspects about relieving pain in agricultural animals are important. Cost has always been a deterrent to the use of local anesthetics and analgesics but, with changing attitudes, the need to control pain is more apparent. Treatment of the causative lesion is a major priority but the lesion may be painful for varying lengths of time. Relief and the control of pain should be a major consideration. Details on the use of analgesics are presented in Chapter 2.

ECONOMICS OF LAMENESS IN FOOD-PRODUCING ANIMALS

Diseases of the musculoskeletal system and feet that cause lameness cause major economic losses. A survey of the incidence and prevalence of lameness in cattle on 37 dairy farms in the UK in 1989–91 found a mean annual incidence of 54.6 new cases per 100 cows (farm range 11–170%) and a mean annual prevalence of 21% (farm range 2–54%).[3] Loss of production occurs because animals that are in pain have difficulty moving around and do not eat and milk normally. Reproductive performance may be reduced because of failure to come into heat normally. The culling rate may be higher than is desirable because so many of the lesions of the feet and legs are incurable. The direct monetary costs for the treatment of lame animals are not high, but the actual treatment of either individual animals or groups of animals is time-consuming and laborious. The condemnation of animals to slaughter because of lesions of the musculoskeletal system also contributes to the total economic loss. When lameness is a herd problem not only are the economic losses increased but clinical management becomes very difficult.

The epidemiological factors which contribute to lameness include:

- Injuries due to floor surfaces
- Persistently wet, unhygienic ground conditions
- Overcrowding and trampling during transportation and handling
- Nutritional inadequacies
- Undesirable skeletal conformation
- Failure to provide regular foot-trimming.

Certain breeds may be more susceptible to diseases of the feet and legs than others. Osteoarthritis occurs most commonly in old animals. Diseases of the legs of dairy cattle occur most commonly at the time of parturition and during the first 50 days of lactation. Diseases of the feet of dairy cattle occur most commonly in days 50–150 of the lactation period. Often the etiology is complex and a definitive etiological diagnosis cannot be made. This makes clinical management difficult and often unrewarding.

EXAMINATION OF THE MUSCULOSKELETAL SYSTEM

The clinical examination of the musculoskeletal system and the feet of farm animals would include the following special examinations.

Analysis of gait and conformation

Inspection of the gait of the animal is necessary to localize the site of lameness. Evaluation of its conformation may provide clues about factors that may contribute to lameness. Details on the examination of farm animals for lameness are available in textbooks on lameness in horses and cattle.

Close physical examination

A close detailed physical examination of the affected area is necessary to localize the lesion. This includes passive movements of limbs to identify fractures, dislocations and pain on movement. Muscles can be palpated for evidence of enlargement, pain, or atrophy.

Radiography

Radiography is useful for the diagnosis of diseases of bones, joints and soft tissue swelling of limbs, which cannot be easily defined by physical examination. Detailed radiographic information about the joint capsule, joint cavity or articular cartilage can be obtained using negative (air), positive or double contrast arthrography. Ultrasonographic imaging can be used to differentiate the pathological changes in the soft tissue structures of digital flexor tendon sheaths of cattle.[1]

Ultrasonography

Ultrasonography is used extensively in dogs and horses for the visualization of soft tissue structures of the joint. Most veterinary practices have an ultrasound machine that is used for small-animal imaging or transrectal pregnancy diagnosis in cattle and horses.[2] Ultrasonography is cheaper, faster and provides important information compared to radiography; it is also less invasive and cheaper than joint fluid aspiration and analysis.

The ultrasonographic anatomy of the elbow, carpal, fetlock, and stifle joints of clinically normal sheep using a 7.5 MHz linear transducer with a stand-off pad has been described.[2] The anatomical structures that could be consistently identified in normal ovine joints included bone, articular cartilage, ligaments and tendons. In sheep with chronic arthritis/synovitis, the gross thickening of the joint capsule is visible as a hyperechoic band up to 20 mm thick.

The ultrasonographic examination of the stifle region in cattle has been

described.[3] The homogeneously echogenic patellar and collateral ligaments, the combined tendon of the long digital extensor and peroneus tertius muscles, the popliteal tendon, the anechoic articular cartilage of femoral trochlea, the echogenic menisci and the hyperechoic bone surfaces were imaged successfully. The boundaries of the joint pouches became partially identifiable only when small amounts of anechoic fluid were present in the medial and lateral femorotibial joint pouches. The main indication for ultrasonography of the bovine stifle is evaluation of acute septic and traumatic disorders of the region, when specific radiographic signs are often nonspecific or absent. The cruciate ligaments could not be imaged in live cattle. The cruciate ligaments are identifiable in the horse, in which flexion of the hindlimb is a routine procedure necessary for identification of these structures.

The ultrasonographic examination of the carpal region in cattle has been described.[4] The main indication is the evaluation of septic and traumatic disorders of the carpal joints and tendon sheaths. Each tendon and tendon sheath in carpal region must be scanned separately. The use of a stand-off pad is recommended as it permits adaptation of the rigid transducer to the contours of the carpus. The carpal joint pouches and tendon sheath lumina are not clearly defined in healthy cattle. Thus the ability to image these structures indicates the presence of synovial effusion.

Ultrasonography is a valuable diagnostic aid for septic arthritis. Joint effusion, which is one of the earliest signs of septic arthritis, the accurate location of soft tissue swelling, the extent and character of joint effusion and involvement of concurrent periarticular synovial cavities or other soft tissue structures can be imaged by ultrasonography.[5] The ultrasonogram can image the presence of small, hyperechogenic fragments within the joint, appearing very heterogeneous. Normal synovial fluid is anechoic and appears black on the sonogram. A cloudy appearance is usually associated with the presence of pus.[6]

Muscle biopsy

A muscle biopsy may be useful for microscopic and histochemical evaluations.

Arthrocentesis

Joint fluid is collected by needle puncture of the joint cavity (arthrocentesis) and examined for the presence of cells, biochemical changes in the joint fluid and the presence of infectious agents. The techniques and application of arthrocentesis for some of the joints commonly sampled in the horse have been reviewed.

Arthroscopy

Special endoscopes are available for inspection of the joint cavity and articular surfaces (arthroscopy). Diagnostic and surgical arthroscopy is now commonplace in specialized equine practice. Surgical arthroscopy is rapidly replacing conventional arthrotomy for the correction of several common surgical conditions of the musculoskeletal system of the horse. Accurate quantification of equine carpal lesions is possible when the procedure is performed by an experienced arthroscopist.[7] Convalescent time following surgery is decreased and the cosmetic appearance improved compared to arthrotomy. The arthroscopic anatomy of the intercarpal and radiocarpal joints of the horse have been described. A synovial membrane biopsy can be examined histologically and for infectious agents and may yield useful diagnostic information.

Serum biochemistry and enzymology

When disease of bone or muscle is suspected, the serum levels of calcium, phosphorus, alkaline phosphatase and the muscle enzymes creatinine phosphokinase (CPK) and aspartate aminotransferase (AST), also known as serum glutamic oxaloacetic transaminase (SGOT), may be useful. The muscle enzymes are sensitive indicators of muscle cell damage; the serum levels of calcium, phosphorus and alkaline phosphatase are much less sensitive indicators of osteodystrophy.

Nutritional history

Because the most important osteodystrophies and myopathies are nutritional in origin a complete nutritional history must be obtained. This should include an analysis of the feed and determination of the total amount of intake of each nutrient, including the ratio of one nutrient to another in the diet.

Environment and housing

When outbreaks of lameness occur in housed cattle and pigs the quality of the floor must be examined to evaluate the possibility of floor injuries.

Diseases of muscles

MYASTHENIA (SKELETAL MUSCLE ASTHENIA)

The differential diagnosis of paresis, paralysis and incoordination should include a consideration of skeletal muscle weakness unrelated to primary neurogenic hypotonia or to permanent muscle injury, including myopathy and myositis. Most of the syndromes that fall into this group of myasthenia have been described in detail elsewhere in this book and are referred to briefly here only to complete the list of abnormalities of skeletal muscle that affect gait and posture. Unlike myopathy and myositis, they are reversible states.

The common causes of myasthenia in farm animals are:

- **Ischemia** in iliac thrombosis in the horse and after recumbency in cows with parturient paresis. The end stage is myonecrosis and not reversible
- **Metabolic effect on muscle fibers** – causes include hypokalemia, hypocalcemia and possibly hypophosphatemia (in parturient paresis of dairy cows), hypomagnesemia (in lactation tetany), hypoglycemia of newborn pigs and lactic acidemia after engorgement on grain
- **Toxins** – general toxemia is a cause. Also, many plant toxins exert an effect on skeletal muscle activity. Although in most cases the mode of the action of the toxin is unknown, the toxins have been listed as neurotoxins.

MYOPATHY

The term myopathy describes the noninflammatory degeneration of skeletal muscle that is characterized clinically by muscle weakness and pathologically by hyaline degeneration of the muscle fibers. The serum levels of some muscle enzymes are elevated and myoglobinuria is a common accompaniment.

ETIOLOGY AND EPIDEMIOLOGY

The most important myopathies in farm animals are due to nutritional deficiencies of vitamin E and selenium and the effects of unaccustomed exercise. In humans, in contrast, the muscular dystrophies occur as inherited defects of muscle or degenerative lesions caused by interruption of their nerve supply. The skeletal myopathies can be classified into primary and secondary myopathies.

A retrospective analysis of the case records in a veterinary teaching hospital over a 9-year period revealed that the most common myopathy in horses was exercise-associated muscle disorder (69%). The remainder were postexhaustion syndrome (9%), infectious myopathies (10.5%), immunological myopathy (6.0%), nutritional myopathy (4.5%) and hyperkalemic periodic paralysis (1.5%).[1]

The major causes of myopathy in farm animals and their epidemiological determinants are as follows.

Enzootic nutritional muscular dystrophy

A nutritional deficiency of vitamin E and/or selenium is a common cause in young calves, lambs, foals, and piglets. Factors enhancing or precipitating onset include: rapid growth, highly unsaturated fatty acids in diet and unaccustomed exercise. The disease also occurs in adult horses.

Exertional or postexercise rhabdomyolysis

This is not known to be conditioned by vitamin E (selenium deficiency) and occurs as equine paralytic myoglobinuria (tying-up syndrome, azoturia) in horses after unaccustomed exercise or insufficient training.[1] It also occurs in sheep chased by dogs, in cattle after running wildly for several minutes and as capture myopathy during capture of wildlife. An acute myopathy of undetermined etiology occurred in horses at grass in Scotland.[2] The horses were not in training, creatine kinase levels were elevated and the urine was dark brown; most of them died and the muscles affected were those of posture and respiration rather than movement.[2]

Equine polysaccharide storage myopathy is a metabolic disease being recognized with increasing frequency in many breeds of horse.[3] It occurs in Quarter-Horse-related breeds and more recently has been recognized in draught horse breeds. It is thought to be due to an inherited metabolic defect affecting carbohydrate metabolism (see Ch. 28).

Metabolic

Hyperkalemic periodic paralysis occurs in certain pedigree lines of North American show Quarter Horses.

Degenerative myopathy

This occurs in newborn calves, sheep and goats affected by Akabane virus infected in utero.

Inherited myopathies

The porcine stress syndrome, which is discussed under that heading, now includes **herztod** pale, soft, exudative pork encountered at slaughter and malignant hyperthermia following halothane anesthesia. Certain blood types in pigs have been used as predictors of stress susceptibility and malignant hyperthermia in Pietrain pigs is genetically predetermined. Most of these myopathies of pigs thus have an inherited basis and the stress of transportation, overcrowding and handling at slaughter precipitates the lesion and rapid death.

Congenital myopathy of Braunvieh–Brown Swiss calves is thought to be inherited.[4] Affected calves become progressively weak and recumbent within 2 weeks of birth.[4]

Doubling-muscling in cattle and **splaylegs of newborn pigs** are also considered to be inherited. A **dystrophy-like myopathy** in a foal has been described and is similar to human muscular dystrophy.[5] **Dystrophy of the diaphragmatic muscles** in adult Meuse–Rhine–Yessel cattle is thought to be inherited. **Xanthosis** occurs in the skeletal and cardiac muscles of cattle and is characterized grossly by a green iridescence.

Toxic agents

This is caused by poisonous plants, including *Cassia occidentalis*, *Karwinskia humboldtiana*, *Ixioloena* spp., *Geigeria* spp. and lupins. A special case is enzootic calcinosis of all tissues, especially muscle, and the principal signs are muscular. It is caused by poisoning by *Solanum malacoxylon*, *Tricetum* spp., and *Cestrum* spp.

Ischemia

Ischemic myonecrosis occurs in the thigh muscles of cattle recumbent for about 48 hours or more and is discussed in detail under the heading Downer cow syndrome. Iliac thrombosis in horses is an important cause of ischemic myopathy and has been reported in calves.

Neurogenic

Neurogenic muscular atrophy occurs sporadically due to traumatic injury and subsequent degeneration or complete severance of the nerve supply to skeletal muscle. The myopathy in arthrogryposis associated with the Akabane virus is thought to be due to lesions of the lower motor neurons supplying the affected muscles. It has been suggested that cattle with muscular hypertrophy may be more susceptible to the effects of exercise and the occurrence of acute muscular dystrophy. Suprascapular nerve paralysis in the horse (sweeney) is a traumatic neuropathy resulting from compression of the nerve against the cranial edge of the scapula.

Neoplasms

Neoplasms of striated muscle are uncommon in animals. Rhabdomyosarcomas are reported in the horse, affecting the diaphragm and causing loss of body weight, anorexia and respiratory distress.

PATHOGENESIS

Primary myopathy

The characteristic change in most cases of primary myopathy varies from hyaline degeneration to coagulative necrosis, affecting particularly the heavy thigh muscles and the muscles of the diaphragm. Myocardial lesions are also commonly associated with the degeneration of skeletal muscle and when severe will cause rapid death within a few hours or days. The visible effects of the lesions are varying degrees of muscle weakness, muscle pain, recumbency, stiff gait, inability to move the limbs and the development of respiratory and circulatory insufficiency.

In primary nutritional muscular dystrophy associated with a deficiency of vitamin E and/or selenium there is lipoperoxidation of the cellular membranes of muscle fibers resulting in degeneration and necrosis. The lesion is present only in muscle fibers and the histological and biochemical changes which occur in the muscle are remarkably similar irrespective of the cause. Variations in the histological lesion occur but indicate variation in the severity and rapidity of onset of the change rather than different causes.

Myoglobinuria

Because of the necrosis of muscle, myoglobin is excreted in the urine and **myoglobinuric nephrosis** is an important complication, particularly of acute primary myopathy. The degree of myoglobinuria depends on the severity of the lesion, acute cases resulting in marked myoglobinuria, and on the age and species of animal affected. Adult horses with myopathy may liberate large quantities of myoglobin, resulting in dark brown urine. Yearling cattle with myopathy release moderate amounts and the urine may or may not be colored; calves with severe enzootic nutritional muscular dystrophy may have grossly normal urine. In all species the renal threshold of myoglobin is so low that discoloration of the serum does not occur.

Muscle enzymes

An important biochemical manifestation of myopathy is the increased release of muscle cell enzymes that occurs during muscle cell destruction. CPK and serum glutamic oxaloacetate transaminase are both elevated in myopathy and CPK, particularly, is a more specific and reliable indication of acute muscle damage. Increased amounts of creatinine are also released into the urine following myopathy.

Exertional rhabdomyolysis

In exertional rhabdomyolysis in horses there is enhanced glycolysis with depletion of muscle glycogen, the accumulation of large amounts of lactate in muscle and blood and the development of hyaline degeneration of myofibers. Affected muscle fibers are richer in glycogen in the acute stage of 'tying-up' than in the late stages, suggesting an increased glycogen storage in the early phase of the disease compared with normal healthy horses. During enforced exercise there is local muscle hypoxia and anaerobic oxidation

resulting in the accumulation of lactate and myofibrillar degeneration. The pathogenesis of postanesthetic myositis in horses is uncertain.[6] A significant postischemic hyperemia occurs in horses that develop postanesthetic myopathy.[6] Postanesthetic recumbency can occur in the horse with polysaccharide storage myopathy.[7]

Types of muscle fiber affected

In most animals skeletal muscle is composed of a mixture of fibers with different contractile and metabolic characteristics. Fibers with slow contraction times have been called slow twitch or type I fibers and those with fast contraction time are fast twitch or type II. Histochemically, types I and II fibers can be differentiated by staining for myofibrillar ATPase. Type II fibers can be subgrouped into type IIA and IIB on the basis of acid preincubations.[8] Several different characteristics of these muscle fibers have been studied in the horse. There are variations in the percentage of each type of fiber present and in composition of muscle fibers dependent on genetic background, age, and stage of training.[8] There are also variations in the muscle fibers within one muscle[9] and between different muscles.[10] The histochemical characteristics of equine muscle fibers have been examined:[11,12]

- Type I fibers are characterized by strong aerobic capacity, compared with type IIA
- Type IIA fibers are more glycolytic and have strong aerobic and moderate to strong anaerobic capacities
- Type IIB fibers are characterized by a relatively low aerobic and a relatively high anaerobic capacity and are glycolytic.[11]

The histochemical staining characteristics of normal equine skeletal muscle have been examined and serve as a standard for comparison with data obtained from skeletal muscles with lesions.[12]

Secondary myopathy due to ischemia

In secondary myopathy due to ischemia there may be multiple focal areas of necrosis, which causes muscle weakness and results in an increase of muscle enzymes in the serum. The degree of regeneration with myofibers depends on the severity of the lesion. Some regeneration occurs but there is considerable tissue replacement. In aortic and iliac thrombosis in calves under 6 months of age the thrombosis results in acute-to-chronic segmental necrosis of some skeletal muscles and coagulation necrosis in others.[13]

Neurogenic atrophy of muscle

In neurogenic atrophy there is flaccid paralysis, a marked decrease in total muscle mass and degeneration of myofibers, with failure to regenerate unless the nerve supply is at least partially restored.

CLINICAL FINDINGS

The nutritional myopathies associated with a deficiency of vitamin E and/or selenium occur most commonly in young growing animals and may occur in outbreak form, particularly in calves and lambs. The details are presented under the heading of vitamin E and selenium deficiency.

Primary myopathy

In general terms, in acute primary myopathy there is a sudden onset of weakness and pseudoparalysis of the affected muscles, causing paresis and recumbency and, in many cases, accompanying respiratory and circulatory insufficiency. The affected animals will usually remain bright and alert but may appear to be in pain. The temperature is usually normal but may be slightly elevated in severe cases of primary myopathy. Cardiac irregularity and tachycardia may be evident, and myoglobinuria occurs in adult horses and yearling cattle. The affected skeletal muscles in acute cases may feel swollen, hard and rubbery but in most cases it is difficult to detect significant abnormality by palpation. Acute cases of primary myopathy may die within 24 hours after the onset of signs.

Acute nutritional myopathy

While acute nutritional myopathy in horses occurs most commonly in foals from birth to 7 months of age, acute dystrophic myodegeneration also occurs in adult horses. There is muscle stiffness and pain, myoglobinuria, edema of the head and neck, recumbency and death in a few days. A special occurrence of myopathy has been recorded in suckling Thoroughbred foals up to 5 months of age. The disease occurs in the spring and summer in foals running at pasture with their dams and is unassociated with excessive exercise. In peracute cases there is a sudden onset of dejection, stiffness, disinclination to move, prostration and death 3–7 days later. Lethargy and stiffness of gait are characteristic of less acute cases. There is also a pronounced swelling and firmness of the subcutaneous tissue at the base of the mane and over the gluteal muscles. There may be excessive salivation, desquamation of lingual epithelium and board-like firmness of the masseter muscles. The foals are unable to suck because of inability to bend their necks. Spontaneous recovery occurs in mild cases but most severely affected foals die.

Severe nutritional myopathy of the masseter muscles in a 6-year-old Quarter Horse stallion has been described.[14] The masseter muscles were swollen and painful, and there was exophthalmos and severe chemosis with protrusion of the third eyelids. The mouth could be opened only slightly and masticatory efforts were weak. Serum enzymology supported a diagnosis of nutritional muscular dystrophy, and the concentrations of vitamin E and selenium in the blood and feed were lower than normal.

Tying-up

In tying-up in horses there is a very sudden onset of muscle soreness 10–20 minutes following exercise. There is profuse sweating and the degree of soreness varies from mild, in which the horse moves with a short, shuffling gait, to acute, in which there is a great disinclination to move at all. In severe cases, horses are unable to move their hindlegs, and swelling and rigidity of the croup muscles develops. Myoglobinuria is common.

Postanesthetic myositis

In postanesthetic myositis affected horses experience considerable difficulty during recovery from anesthesia. Recovery is prolonged and when initial attempts are made to stand there is lumbar rigidity, pain and reluctance to bear weight.[7] Some affected horses will be able to stand in within several hours if supported in a sling.[7] The limbs may be rigid and the muscles firm on palpation. In severe cases the temperature begins to rise – reminiscent of malignant hyperthermia. Other clinical findings include anxiety, tachycardia, profuse sweating, myoglobinuria and tachypnea. Death may occur in 6–12 hours. Euthanasia is the only course for some horses. In the milder form of the syndrome, affected horses are able to stand, but are stiff and in severe pain for a few days.

Exertional rhabdomyolysis

In horses, the clinical findings are **variable** and range from poor performance to recumbency and death. Signs may be mild and resolve spontaneously within 24 hours or severe and progressive.

The **usual presentation** is a young (2–5-year-old) female racehorse with recurrent episodes of stiff gait after exercise. The horse does not perform to expectation and displays a **short-stepping gait** that may be mistaken for lower leg lameness. The horse may be reluctant to move when placed in its stall, be apprehensive and anorexic, and frequently shift its weight. More severely affected horses may be unable to continue to exercise, have **hard and painful**

muscles (usually gluteal muscles), sweat excessively, be apprehensive, refuse to walk and be tachycardic and tachypneic. Affected horses may be hyperthermic. Signs consistent with abdominal pain are present in many severely affected horses. Deep red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses may be recumbent and unable to rise.

Many different manifestations of equine polysaccharide storage myopathy occur.[3] All manifestations are related to dysfunction, which results in pain, weakness, segmental fiber necrosis, stiffness, spasm, atrophy or any combination of the above. The muscles most severely affected are the powerful rump, thigh and back muscles, including gluteals, semimembranosus, semitendinosus and longissimus.

In exertional rhabdomyolysis in sheep chased by dogs, affected animals are recumbent, cannot stand, appear exhausted and myoglobinuria is common. Death usually follows. A similar clinical picture occurs in cattle that have run wildly for several minutes.

Hyperkalemic periodic paralysis

Initially there is a brief period of myotonia with prolapse of the third eyelid. In severe cases, the horse becomes recumbent and the myotonia is replaced by flaccidity. Sweating occurs, and generalized muscle fasciculations are apparent, with large groups of muscle fibers contracting simultaneously at random. The animal remains bright and alert and responds to noise and painful stimuli. In milder cases, affected horses remain standing and generalized muscle fasciculations are prominent over the neck, shoulder and flank. There is a tendency to stand base-wide. When the horse is asked to move, the limbs may buckle and the animal appears weak. The horse is unable to lift its head, usually will not eat and may yawn repeatedly early in the course of an episode. The serum potassium levels are elevated above normal during the episodes.

Secondary myopathy due to ischemia

In secondary myopathy due to ischemia, e.g. the downer cow syndrome, the affected animal is unable to rise and the affected hindlegs are commonly directed behind the cow in the frogleg attitude. The appetite and mental attitude are usually normal. No abnormality of the muscles can be palpated. With supportive therapy, good bedding and the prevention of further ischemia by frequent rolling of the animal, most cows will recover in a few days.

In calves with aortic and iliac artery thrombosis there is an acute onset of paresis or flaccid paralysis of one or both pelvic limbs.[13] Affected limbs are hypothermic and have diminished spinal reflexes and arterial pulse pressures. The diagnosis can be defined using angiography. Affected calves die or are euthanized because treatment is not undertaken.

Neurogenic atrophy

With neurogenic atrophy there is marked loss of total mass of muscle, flaccid paralysis, loss of tendon reflexes and failure of regeneration. When large muscle masses are affected, e.g. quadriceps femoris in femoral nerve paralysis in calves at birth, the animal is unable to bear normal weight on the affected leg.

Dystrophy of the diaphragmatic muscles

In dystrophy of the diaphragmatic muscles in adult Meuse–Rhine–Yessel cattle there is loss of appetite, decreased rumination, decreased eructation and recurrent bloat. The respiratory rate is increased with forced abdominal respirations, forced movement of the nostrils and death from asphyxia in a few weeks.

Severe diaphragmatic necrosis in a horse with degenerative myopathy due to polysaccharide storage myopathy has been described.[15] Affected horses may have severe respiratory distress and respiratory acidosis, and do not respond to supportive therapy.

CLINICAL PATHOLOGY

Muscle-derived serum enzymes

The serum levels of the muscle enzymes are characteristically elevated following myopathy due to release of the enzymes from altered muscle cell membranes. Creatine kinase (CK) is a highly specific indication of both myocardial and skeletal muscle degeneration. Plasma CK activity is related to three factors: the amount and rate of CK released from an injured muscle into plasma, its volume of distribution and its rate of elimination.[16] CK has a half-life of about 4–6 hours and, following an initial episode of acute myopathy, serum levels of the enzyme may return to normal within 3–4 days if no further muscle degeneration has occurred. Levels of AST are also increased following myopathy but, because the enzyme is present in other tissues such as liver, it is not a reliable indicator of primary muscle tissue degeneration.

Because AST has a longer half-life than CK, the levels of AST may remain elevated for several days following acute myopathy. The daily monitoring of both CK and AST levels should provide an indication of whether active muscle degeneration is occurring. A marked drop in CK levels and a slow decline in AST levels suggests that no further degeneration is occurring whereas a constant elevation of CK suggests active degeneration.

In acute nutritional muscular dystrophy in calves, lambs, and foals the CK levels will increase from normal values of below 100 IU/L to levels ranging from 1000–5000IU/L and even higher. The levels of CK in calves will increase from a normal of 50IU/L to approximately 5000IU/L within a few days after being placed outdoors followed by unconditioned exercise. There is some preliminary investigation into quantification of the amount of skeletal damage in cattle based on the amount of CK activity.[16]

The measurement of serum levels of glutathione peroxidase is a useful aid in the diagnosis of myopathy due to selenium deficiency.

In downer cows with ischemic necrosis of the thigh muscles, the CK and AST levels will be markedly elevated and will remain elevated if muscle necrosis is progressive in cows that are not well bedded and rolled from side to side several times daily to minimize the degree and extent of ischemic necrosis.

High levels of CK (1000 IU/L and greater) usually indicate acute primary myopathy. Levels from 500–1000 IU/L may be difficult to interpret in animals recumbent for reasons other than primary myopathy. This will necessitate a careful reassessment of the clinical findings, history and epidemiology.

In horses with acute exertional rhabdomyolysis (paralytic myoglobinuria) the CK levels will range from 5000–10 000 IU/L. Following vigorous exercise in unconditioned horses, the CK and AST levels will rise as a result of increased cell membrane permeability associated with the hypoxia of muscles subjected to excessive exercise. Lactate dehydrogenase (LDH) has also been used as a biochemical measurement of the degree of physical work done by horses in training. With progressive training in previously unconditioned horses there is no significant change between rest and exercise in the levels of serum CK, AST, and LDH. In horses with postanesthetic myositis the CK levels may exceed 100 000IU/L, the serum calcium is decreased and the serum inorganic phosphorus is increased. In naturally occurring cases of exertional rhabdomyolysis in horses the most consistent acid–base abnormality may be a hypochloremia rather than metabolic acidosis as has been assumed.

Muscle biopsy

Investigation of the structural and biochemical alterations of muscle tissue in myopathy include biopsy techniques that

have been described.[3,17] Needle biopsies require a specialized Bergstrom muscle biopsy needle, which most practitioners do have on hand. Open biopsy is recommended in order to obtain a strip of muscle. Biopsy of either the semimembranosus or semitendinosus muscles, at a site between the base of the tail and the tuber ischium, provides an adequate sample. Muscle biopsy samples can be processed for either frozen section or routine formalin-fixed, paraffin-embedded sections. The frozen section is considered the gold standard.

Inclusions of periodic-acid–Schiff (PAS)-positive, amylase-resistant complex polysaccharide are abnormal and characteristic findings in muscle of equine polysaccharide storage myopathy.[3]

Histochemical techniques can be used on muscle biopsies of horses with muscular disease and animals with congenital and inherited myopathies [4]

Myoglobinuria

Myoglobinuria is a common finding in adult horses with acute paralytic myoglobinuria but is not a common finding in acute nutritional muscular dystrophy in young farm animals, except perhaps in yearling cattle with acute muscular dystrophy. The myoglobinuria may be clinically detectable as a red or chocolate brown discoloration of the urine. This discoloration can be differentiated from that caused by hemoglobin by spectrographic examination or with the use of orthotoluidine paper strips. Urine becomes dark when myoglobin levels exceed 40 mg/dL of urine. Discoloration of the plasma suggests hemoglobinuria. Both myoglobin and hemoglobin give positive results for the presence of protein in urine. Porphyria causes a similar discoloration although this may not be evident until the urine has been exposed to light for some minutes. The coloration is lighter, pink to red rather than brown, and the urine is negative to the guaiac test and fluoresces with ultraviolet light. Creatinuria accompanies acute myopathy but has not been used routinely as a diagnostic aid.

Electromyography is a special technique for the evaluation of the degree of neurogenic atrophy.

NECROPSY FINDINGS

Affected areas of skeletal muscle have a white, waxy, swollen appearance like fish flesh. Commonly only linear strips of large muscle masses are affected and the distribution of lesions is characteristically bilaterally symmetrical. Histologically the lesion varies from a hyaline degeneration to a severe myonecrosis, with subsequently the disappearance of large groups of muscle fibers and replacement by connective tissue. Calcification of the affected tissue may be present to a mild degree in these cases.

The lesions in exertional rhabdomyolysis in the horse are of a focal distribution and consist of hyaline degeneration with insignificant inflammatory reaction and slight calcification. The degenerative changes affect primarily the fast twitch fibers, which have a low oxidative capacity and are used when the horse trots at very close to its maximum speed.

DIFFERENTIAL DIAGNOSIS

Most myopathies in farm animals occur in rapidly growing, young animals and are characterized clinically by a sudden onset of acute muscular weakness, and pain often precipitated by unaccustomed exercise. There may be evidence of a dietary deficiency of vitamin and selenium in the case of nutritional muscular dystrophy. A sudden onset of recumbency or stiffness in young farm animals that are bright and alert should arouse suspicion of acute muscular dystrophy. Primary myopathies are not common in adult cattle, sheep or pigs but myopathy secondary to recumbency for other reasons does occur.

Secondary myopathy due to aortic and iliac thrombosis in calves must be differentiated from other common causes of hindlimb paresis including traumatic injury to the spinal cord, spinal cord compression due to vertebral body abscess, nutritional muscular dystrophy, myositis and nerve damage due to trauma of intramuscular injections, and clostridial myositis.[14]

The exertional myopathies in the horse in training are usually readily obvious. The CK levels are valuable aids to diagnosis. In special circumstances, such as neurogenic myopathy, muscle biopsy and electromyography may be useful additional diagnostic aids. The histological and histochemical staining characteristics of equine muscle have been described and serve as a standard for comparison with abnormal muscle.

Myositis may present a similar syndrome but is usually present as a secondary lesion in a clinically distinguishable primary disease or is accompanied by obvious trauma or toxemia.

TREATMENT

Vitamin E and selenium are indicated for the treatment of nutritional muscular dystrophy and the details are provided under that heading. The treatment of exertional rhabdomyolysis in horses has not been well defined because of the uncertain etiology, but enforced rest and the relief of pain, if necessary, seems logical. Supportive therapy for any case of myopathy, particularly severe cases in which there is persistent recumbency, consists of:

- Liberal quantities of thick bedding
- Removal from solid floors to softer ground
- Frequent turning from side to side to minimize secondary myopathy
- Provision of fluid therapy to prevent myoglobinuric nephrosis
- A palatable, nutritious diet.

With the exception of the sporadically occurring congenital and inherited myopathies of farm animals, all the nutritional and exertional myopathies are amenable to treatment if it is begun early and if adequate supportive therapy is provided.

In myopathies associated with systemic acidosis the use of a solution of sodium bicarbonate may be indicated. Dietary sodium bicarbonate at the rate of 2% of total dry matter intake has been used for the treatment of exertional rhabdomyolysis in a horse.[18] Horses with postanesthetic myositis must be considered as critical care patients for 18–24 hours. Maintenance of adequate renal perfusion is vital. Large quantities of intravenous polyionic balanced electrolyte fluids (50–100 L) must be given over a 24-hour period. Dantrolene sodium at 4 mg/kg body weight (BW) given orally immediately upon recognition of clinical signs is efficacious.

CONTROL

The nutritional myopathies in farm animals can be satisfactorily prevented by the provision of adequate quantities of dietary vitamin E and selenium in the maternal diet during pregnancy or at the strategic times in postnatal life. The prevention of exertional myopathy in the horse depends on a progressive training program and avoidance of sudden unaccustomed exercise in animals that are in good body condition and have been inactive. Similarly, in general terms, the prevention of the porcine stress syndrome will depend on careful handling and transportation techniques combined with genetic selection of resistant pigs.

MYOSITIS

Myositis may arise from direct or indirect trauma to muscle and occurs as part of a syndrome in a number of specific diseases including blackleg, foot-and-mouth disease, bluetongue, ephemeral fever, swine influenza, sarcosporidiosis and trichinosis, although clinical signs of myositis are not usually evident in the latter. Sporadic cases of a localized infectious myositis of skeletal muscles, associated with *Escherichia coli*, may occur in calves.[1] An asymptomatic eosinophilic myositis is not uncommon in beef cattle and may cause economic loss through carcass condemnation. The cause has not been determined.

Acute myositis of limb muscles

This disease is accompanied by severe lameness, swelling, heat and pain on palpation. There may be accompanying toxemia and fever. In chronic myositis there is much wasting of the affected muscles and this is difficult to differentiate clinically from atrophy due to other causes. Biopsy of the muscles may be necessary to confirm the diagnosis.

Injury to the gracilis muscle can cause acute, severe lameness in performance Quarter Horses.[2] Horses competing in barrel racing may be susceptible to gracilis muscle injury because the muscle functions to adduct the hind limb. The prognosis is good for returning to athletic use after and an adequate period of muscle healing and mild exercise. However, fibrotic myopathy or muscle atrophy can be a complication of the injury resulting in persistent gait deficits.

In horses traumatic myositis of the posterior thigh muscles may be followed by the formation of fibrous adhesions between the muscles (fibrotic myopathy) and by subsequent calcification of the adhesions (ossifying myopathy). External trauma can result in fibrotic myopathy but it may also be associated with excessive exercise or secondary to intramuscular injections.

Occasionally similar lesions may be seen in the foreleg. The lesions cause a characteristic abnormality of the gait in that the stride is short in extension and the foot is suddenly withdrawn as it is about to reach the ground. The affected area is abnormal on palpation.

An inherited disease of pigs, generalized myositis ossificans, is also characterized by deposition of bone in soft tissues. In traumatic injuries caused by penetration of foreign bodies into muscle masses, ultrasonography may be used to detect fistulous tracts and the foreign bodies.

Extensive damage to or loss of muscle occurs in screwworm and sometimes blowfly infestation, although the latter is more of a cutaneous lesion, and by the injection of necrotizing agents. For example, massive cavities can be induced in the cervical muscles of horses by the intramuscular injection of escharotic iron preparations intended only for slow intravenous injection. Similarly, necrotic lesions can result from the intramuscular injection of infected or irritant substances. Horses are particularly sensitive to tissue injury, or are at least most commonly affected. Some common causes are chloral hydrate, antimicrobials suspended in propylene glycol, and even antimicrobials alone in some horses.

Injection site clostridial infections in horses

Clostridial myositis, myonecrosis, cellulitis, and malignant edema are terms used to describe a syndrome of severe necrotizing soft tissue infection associated with *Clostridium* spp. Affected horses typically develop peracute emphysematous soft tissue swelling in the region of an injection or wound within hours of the inciting cause. It can occur following the intramuscular or inadvertent perivascular administration of a wide variety of commonly administered drugs.[3] In a series of 37 cases, the lesion occurred within 6–72 hours of a soft-tissue injection in most cases and most were in the neck musculature. Aggressive treatment can be associated with a survival rate of up to 81% for cases due to *Clostridium perfringens* alone; survival rates for other *Clostridium* spp. are lower. A combination of a high dose of intravenous antibiotic therapy and surgical fenestration and debridement is the recommended approach to treatment.

Injection site lesions in cattle

Muscle lesions associated with injection sites in the cattle industry are a source of major economic loss because of the amount of trim required at slaughter. The presence of injection-site lesions in whole muscle cuts, such as the top sirloin and outside round, limits their use and value. The occurrence of injection-site lesions in muscle is among the top five quality challenges for both beef and dairy market cows and bulls.[4] Because injection-site lesions are concealed in muscles and/or are under subcutaneous fat, they are seldom found during fabrication at the packing plant and appear instead during wholesale/retail fabrication or at the consumer level. In 1998, the National Animal Health Monitoring System found that 47% of producers and 37% of veterinarians administered intramuscular injections in the upper or lower rear leg of cows; the need for further educational effort is apparent.

Monitoring the frequency of injection-site lesions allows educational efforts of state and national beef quality assurance programs to evaluate, more definitively, management practices of producers that can be changed to minimize occurrence of these defects. Audits done at abattoirs between 1998 and 2000 in the USA indicate that the frequency of injection-site lesions has decreased but the need remains for educational programs and continued improvements in beef quality assurance practices among beef and dairy cattle producers.[4] Historically, most intramuscular injections were given in the gluteals and the biceps femoris muscles, which are prime cuts of beef. Surveys of injection sites in beef cattle in North America have found lesions in a significant percentage of prime cuts of beef.[5] Lesions consisting of clear scars and woody calluses are mature and probably originated in calfhood; scars with nodules or cysts are less mature, occurring later in the feeding period. It is now recommended that intramuscular injections be given in the cervical muscles. Reducing the incidence of injection site lesions requires that manufacturers of biological and antibiotic preparations develop less irritating formulations. Products should be formulated for subcutaneous use whenever possible and administered in the neck muscles, which are not prime cuts of beef.

The outcome of an intramuscular injection depends on the nature of the lesion produced. Myodegeneration following intramuscular injections of antibiotics in sheep results in full muscle regeneration within less than 3 weeks.[6] Necrosis following the injection results in scar formation with encapsulated debris, which persists for more than a month and leaves persistent scar tissue.

An outbreak of myositis, lameness and recumbency occurred following the injection of water-in-adjuvanted vaccines into the muscles of the left and right hips of near-term pregnant beef cattle.[7] Within 24 hours, some cattle were recumbent, some had nonweightbearing lameness and, within 10 days, 50% of the herd developed firm swellings up to 24 cm in vaccination sites. Histologically, granulomatous myositis with intralesional oil was present. The swellings resolved over a period of 6 months. The acute transient lameness was attributed to the use of two irritating biological vaccines in the hip muscles of cows near parturition.

Diseases of bones

OSTEODYSTROPHY

Osteodystrophy is a general term used to describe those diseases of bones in which there is a failure of normal bone development, or abnormal metabolism of bone that is already mature. The major clinical manifestations include distortion and enlargement of the bones, susceptibility to fractures and interference with gait and posture.

ETIOLOGY

The common causes of osteodystrophy in farm animals include the following.

Nutritional causes

Calcium, phosphorus and vitamin D

Absolute deficiencies or imbalances in calcium–phosphorus ratios in diets cause:

- Rickets in young animals, e.g., growing lambs fed a diet rich in wheat bran
- Absolute deficiencies of calcium
- Beef calves on intensive rations with inadequate supplementation[1]
- Osteomalacia in adult ruminants.

Osteodystrophia fibrosa in the horse occurs most commonly in animals receiving a diet low in calcium and high in phosphorus.

Osteodystrophia fibrosa in pigs occurs as a sequel to rickets and osteomalacia, which may occur together in young growing pigs that are placed on rations deficient in calcium, phosphorus and vitamin D following weaning.

Copper deficiency

- Osteoporosis in lambs
- Epiphysitis in young cattle.

Other nutritional causes

- Inadequate dietary protein and general undernutrition of cattle and sheep can result in severe osteoporosis and a great increase in ease of fracture
- Chronic parasitism can lead to osteodystrophy in young growing ruminants
- Hypovitaminosis A and hypervitaminosis A can cause osteodystrophic changes in cattle and pigs
- Prolonged feeding of a diet high in calcium to bulls can cause nutritional hypercalcitoninism combined with replacement of trabecular bone in the vertebrae and long bones with compact bone, and neoplasms of the ultimobranchial gland
- Multiple vitamin and mineral deficiencies are recorded as causing osteodystrophy in cattle. The mineral demands of lactation in cattle can result in a decrease in bone mineral content during lactation with a subsequent increase during the dry period.

Chemical agents

- Chronic lead poisoning is reputed to cause osteoporosis in lambs and foals
- Chronic fluorine poisoning causes the characteristic lesions of osteofluorosis, including osteoporosis and exostoses
- Grazing the poisonous plants *Setaria sphaceleta*, *Cenchrus ciliaris*, and *Panicum maximum* var. *trichoglume* causes osteodystrophia in horses
- Enzootic calcinosis of muscles and other tissues is caused by the ingestion of *Solanum malacoxylon*, *Solanum torvum*, *Trisetum flavescens* (yellow oatgrass), and *Cestrum diurnum*, which exert a vitamin-D-like activity
- Bowie or bentleg, a disease caused by poisoning with *Trachymene glaucifolia*, is characterized by extreme outward bowing of the bones of the front limbs.

Inherited and congenital causes

There are many inherited and congenital defects of bones of newborn farm animals, which are described, and discussed in detail in Chapter 34. In summary, these include:

Achondroplasia and chondrodystrophy in dwarf calves and some cases of prolonged gestation
Osteogenesis imperfecta in lambs and Charolais cattle. There is marked bone fragility and characteristic changes on radiological examination
Osteopetrosis in Hereford and Angus calves
Chondrodystrophy in 'acorn' calves
Inherited exostoses in horses; inherited thicklegs and inherited rickets of pigs, which are well-established entities.

Angular deformities of joints of long bones due to asymmetric growth plate activity are common in foals and are commonly repaired surgically.[2] The distal radius and distal metacarpus are most often affected, the distal tibia and metatarsal less commonly. Physiologically immature foals subjected to exercise may develop compression-type fractures of the central or third tarsal bones. Some of these foals are born prematurely or are from a twin pregnancy. Retained cartilage in the distal radial physis of foals 3–70 days of age presents without apparent clinical signs.

Physitis is dysplasia of the growth plate, characterized by an irregular border between the cartilage and the metaphyseal zone of ossification, an increase in the lateromedial diameter of the physis, and distoproximally oriented fissures at the medial aspect of the metaphysis, which originate at the physis. In some cases, these may result in bilateral tibial metaphyseal stress fractures in foals.[3]

Abnormal modeling of trabecular bone has been recognized in prenatal and neonatal calves.[4] Abnormalities included growth retardation lines and lattices, focal retention of primary spongiosa and the persistence of secondary spongiosa. Intrauterine infection with viruses such as bovine virus diarrhea (BVD) may be a causative factor.[4]

Physical and environmental causes

Moderate osteodystrophy and arthropathy may occur in rapidly growing pigs and cattle raised indoors and fed diets that contain adequate amounts of calcium, phosphorus and vitamin D. Those animals raised on slatted floors or concrete floors are most commonly affected and it is thought that traumatic injury of the epiphyses and condyles of long bones may be predisposing factors in osteochondrosis and arthrosis in the pig (leg weakness) and epiphysitis in cattle. Experimentally raising young calves on metal slatted floors may result in more severe and more numerous lesions of the epiphysis than occurs in calves raised on clay floors. Total confinement rearing of lambs can result in the development of epiphysiolysis and limb deformities. However, the importance of weight-bearing injury as a cause of osteodystrophy in farm animals is still uncertain. In most reports of such osteodystrophy, all other known causes have not been eliminated.

Chronic osteodystrophy and arthropathy have been associated with undesirable conformation in the horse.

Vertebral exostoses are not uncommon in old bulls and usually affect the thoracic vertebrae (T2 and T12) and the lumbar vertebrae (L2–L3), which are subjected to increased pressure during the bending of the vertebral columns while copulating. The exostoses occur mainly on the ventral aspects of the vertebrae, fusing them to cause immobility of the region. Fracture of the ossification may occur, resulting in partial displacement of the vertebral column and spinal cord compression. The disease is commonly referred to as spondylitis or vertebral osteochondrosis

and also occurs less commonly in adult cows and in pigs. It is suggested that the anulus fibrosus degenerates and that the resulting malfunctioning of the disk allows excessive mobility of the vertebral bodies, resulting in stimulation of new bone formation. A similar lesion occurs commonly in horses and may affect performance, particularly in hurdle races and cross-country events. The initial lesion may be a degeneration of the intervertebral disk.

Some types of growth plate defect occur in young growing foals and these are considered to be traumatic in origin. Failure of chondrogenesis of the growth plate may be the result of crush injuries in heavy, rapidly growing foals with interruption of the vascular supply to the germinal cells of the growth plate. Asymmetric pressures due to abnormal muscle pull or joint laxity may slow growth on the affected side and result in limb angulation.

Femoral fractures occur in newborn calves during the process of assisted traction during birth.[5] Laboratory compression of isolated femurs from calves revealed that the fracture configurations and locations are similar to those found in clinical cases associated with forced extraction. The breaking strength of all femurs fell within the magnitude of forces calculated to be created when mechanical devices are used to assist delivery during dystocia. It is suggested that the wedging of the femur in the maternal pelvis and resulting compression during forced extraction accounts for the occurrence of supracondylar fractures of the femur of calves delivered in anterior presentation using mechanical devices in a manner commonly used by veterinarians and farmers.

Tumors

Osteosarcomas are highly malignant tumors of skeletoblastic mesenchyme in which the tumor cells produce osteoid or bone. Osteosarcomas are the most common type of primary bone tumor in animals such as dogs and cats but are rare in horses and cattle. Most tumors of bone in large animals occur in the skull. A periosteal sarcoma on the scapula has been recorded in the horse[6] and an osteosarcoma of the mandible in a cow.[7]

PATHOGENESIS

Osteodystrophy is a general term used to describe those diseases of bones in which there is a failure of normal bone development, or abnormal metabolism of bone that is already mature. There are some species differences in the osteodystrophies that occur with dietary deficiencies of calcium, phosphorus, and vitamin D. **Rickets and osteomalacia** occur primarily in ruminants, osteodystrophia fibrosa in horses, and all three may occur in pigs.

Rickets

Rickets is a disease of young growing animals in which there is a failure of provisional calcification of the osteoid plus a failure of mineralization of the cartilaginous matrix of developing bone. There is also failure of degeneration of growing cartilage, formation of osteoid on persistent cartilage with irregularity of osteochondral junctions and overgrowth of fibrous tissue in the osteochondral zone. Failure of provisional calcification of cartilage results in an increased depth and width of the epiphyseal plates, particularly of the long bones (humerus, radius and ulna and tibia) and the costal cartilages of the ribs. The uncalcified, and therefore soft, tissues of the metaphyses and epiphyses become distorted under the pressure of weightbearing, which also causes medial or lateral deviation of the shafts of long bones. There is a decreased rate of longitudinal growth of long bones and enlargement of the ends of long bones due to the effects of weight causing flaring of the diaphysis adjacent to the epiphyseal plate. Within the thickened and widened epiphyseal plate there may be hemorrhages and minute fractures of adjacent trabecular bone of the metaphyses. and in chronic cases the hemorrhagic zone may be largely replaced by fibrous tissue. These changes can be seen radiographically as 'epiphysitis' and clinically as enlargements of the ends of long bones and costochondral junctions of the ribs. These changes at the epiphyses may result in separation of the epiphysis, which commonly affects the femoral head. The articular cartilages may remain normal or there may be subarticular collapse resulting in grooving and folding of the articular cartilage and ultimately degenerative arthropathy and osteochondrosis. Eruption of the teeth in rickets is irregular and dental attrition is rapid. Growth of the mandibles is retarded and is combined with abnormal dentition. There may be marked malocclusion of the teeth.

Osteomalacia

Osteomalacia is a softening of mature bone due to extensive resorption of mineral deposits in bone and failure of mineralization of newly formed matrix. There is no enlargement of the ends of long bones or distortions of long bones but spontaneous fractures of any bone subjected to weightbearing is common.

Osteodystrophia fibrosa

Osteodystrophia fibrosa may be superimposed on rickets or osteomalacia and occurs in secondary hyperparathyroidism. Diets low in calcium or that contain a relative excess of phosphorus cause secondary hyperparathyroidism. There is extensive resorption of bone and replacement by connective tissue. The disease is best known in the horse and results in swelling of the mandibles, maxillae and frontal bones (the 'bighead' syndrome). Spontaneous fracture of long bones and ribs occurs commonly. Radiographically there is extreme porosity of the entire skeleton.

Osteoporosis

Osteoporosis is due to failure or inadequacy of the formation of the organic matrix of bone; the bone becomes porous, light and fragile, and fractures easily. Osteoporosis is uncommon in farm animals and is usually associated with general undernutrition rather than specifically a deficiency of calcium, phosphorus, or vitamin D. Copper deficiency in lambs may result in osteoporosis due to impaired osteoblastic activity. Chronic lead poisoning in lambs also results in osteoporosis due to deficient production of osteoid. In a series of 19 lactating or recently weaned sows with a history of lameness, weakness or paralysis, 10 had osteoporosis and pathological fractures while six had lumbar vertebral osteomyelitis. Bone ash, specific gravity of bone and the cortical to total ratio were significantly reduced in sows with osteoporosis and pathological fractures.

Ovariectomized sheep that are fed a calcium-wasting diet develop osteoporosis, which is being used as a model to study the disease in humans.[8]

Osteodystrophy of chronic fluorosis

Osteodystrophy of chronic fluorosis is characterized by the development of exostoses on the shafts of long bones due to periosteal hyperostosis. The articular surfaces remain essentially normal but there is severe lameness because of the involvement of the periosteum and encroachment of the osteophytes on the tendons and ligaments.

Congenital defects of bone

These include complete (**achondroplasia**) and partial (**chondrodystrophy**) failure of normal development of cartilage. Growth of the cartilage is restricted and disorganized and mineralization is reduced. The affected bones fail to grow, leading to gross deformity, particularly of the bones of the head.

CLINICAL FINDINGS

In general terms there is weakening of the bones due to defective mineralization and osteoporosis, which results in the **bending of bones**, which probably causes pain and shifting lameness – one of the earliest clinical signs of acquired osteodystrophy.

The normal weight and tension stresses cause distortion of the normal axial relationships of the bones, which results in the bowing of long bones. The distortions occur most commonly in young, growing animals. The distal ends of the long bones are commonly enlarged at the level of the epiphyseal plate and circumscribed swellings of the soft tissue around the epiphyses may be prominent, and painful on palpation.

The effects of osteodystrophy on appetite and body weight will depend on the severity of the lesions and their distribution. In the early stages of rickets in calves and pigs the appetite and growth rate may not be grossly affected until the disease is advanced and causes considerable pain. Persistent recumbency due to pain will indirectly affect feed intake unless animals are hand-fed.

Spontaneous fractures occur commonly and usually in mature animals. Common sites for fractures include the long bones of the limbs, pelvic girdle, femoral head, vertebrae, ribs, and transverse processes of the vertebrae. Ordinary hand pressure or moderate restraint of animals with osteomalacia and osteodystrophia fibrosa is often sufficient to cause a fracture. The rib cage tends to become flattened and in the late stages affected animals have a slab-sided appearance of the thorax and abdomen. Separations of tendons from their bony insertions also occur more frequently and cause severe lameness. The osteoporotic state of the bone makes such separations easy. Any muscle group may be affected but, in young cattle in feedlots, separations of the gastrocnemius are the most common. Thickening of the bones may be detectable clinically if the deposition of osteoid or fibrous tissue is excessive, or if exostoses develop as in fluorosis. Compression of the spinal cord or spinal nerves may lead to paresthesia, paresis or paralysis, which may be localized in distribution. Details of the clinical findings in the osteodystrophies caused by nutritional deficiencies are provided in Chapter 30.

Calcinosis of cattle is characterized clinically by chronic wasting, lameness, ectopic calcifications of the cardiovascular system, lungs and kidneys, ulceration of joint cartilage and extensive calcification of bones.

CLINICAL PATHOLOGY

The **laboratory analyses** that are indicated include the following:

- **Serum calcium and phosphorus**
- **Serum alkaline phosphatase**
- **Feed analysis for calcium, phosphorus, vitamin D and other minerals when indicated** (such as copper, molybdenum, and fluorine)
- **Bone ash chemical analysis**
- **Histopathology of bone biopsy**
- **Radiographic examination of the skeleton**
- Single photon absorptiometry, a safe and noninvasive method for the measurement of bone mineral content, is now available.

Radiographic examination of the affected bones and comparative radiographs of normal bones is indicated when osteodystrophy is suspected. Radiographic examination of slab sections of bone is a sensitive method for detecting abnormalities of trabecular bone in aborted and young calves.[4]

Serum calcium and **phosphorus** concentrations in nutritional osteodystrophies may remain within the normal range for long periods and not until the lesions are well advanced will abnormal levels be found. Several successive samplings may be necessary to identify an abnormal trend.

Alkaline phosphatase levels may be increased in the presence of increased bone resorption but this is not a reliable indicator of osteodystrophy. Increased serum levels of alkaline phosphatase may originate from osseous tissues, intestine or liver, but osseous tissue appears to be the major source of activity.

Nutritional history and **feed analysis** results will often provide the best circumstantial evidence of osteodystrophy.

The definitive diagnosis is best made by a combination of chemical analysis of bone, histopathological examination of bone and radiography. The details for each of the common osteodystrophies are discussed under the appropriate headings.

DIFFERENTIAL DIAGNOSIS

In both congenital and acquired osteodystrophy the clinical findings are usually suggestive. There are varying degrees of lameness, stiff gait, long periods of recumbency and failure to perform physical work normally, progressive loss of body weight in some cases and there may be obvious contortions of long bones, ribs, head and vertebral column. The most common cause of osteodystrophy in young growing animals is a dietary deficiency or imbalance of calcium, phosphorus and vitamin D. If the details of the nutritional history are available and if a representative sample of the feed given is analyzed, a clinical diagnosis can be made on the basis of clinical findings, nutritional history and response to treatment. In some cases, osteodystrophy may be due to overfeeding, such as might occur in rapidly growing, large foals.

However, often the nutritional history may indicate that the animals have been receiving adequate quantities of calcium, phosphorus and vitamin D, which necessitates that other less common causes of osteodystrophy be considered. Often the first clue is an unfavorable response to treatment with calcium, phosphorus and vitamin D. Examples include copper deficiency in cattle, leg weakness in swine of uncertain etiology – but perhaps there is weight-bearing trauma and a relative lack of exercise due to confinement – or chemical poisoning such as enzootic calcinosis or fluorosis. These will require laboratory evaluation of serum biochemistry, radiography of affected bones and pathological examination. The presence of bony deformities at birth suggests congenital chondrodystrophy, some cases of which appear to be inherited while some are due to environmental influences.

NECROPSY FINDINGS

The pathological findings vary with the cause, and the details are described under each of the osteodystrophies elsewhere in the book. In general terms, the nutritional osteodystrophies are characterized by bone deformities, bones that may be cut easily with a knife and that bend or break easily with hand pressure and the presence in prolonged cases of degenerative joint disease. In young, growing animals the ends of long bones may be enlarged and the epiphyses may be prominent and circumscribed by periosteal and fibrous tissue thickening. On longitudinal cut sections the cortices may appear thinner than normal and the trabecular bone may have been resorbed, leaving an enlarged marrow cavity. The epiphyseal plate may be increased in depth and width and appear grossly irregular, and small fractures involving the epiphyseal plate and adjacent metaphysis may be present. Separation of epiphyses is common, particularly of the femoral head. The calluses of healed fractures of long bones, ribs, vertebrae and pelvic girdle are common in pigs with osteodystrophy. On histological examination there are varying degrees of severity of rickets in young growing animals and osteomalacia in adult animals, and osteodystrophia fibrosa is possible in both young and adult animals.

TREATMENT

The common nutritional osteodystrophies due to a dietary deficiency or imbalance of calcium, phosphorus and vitamin D will usually respond favorably following the oral administration of a suitable source of calcium and phosphorus combined with parenteral injections of vitamin D. The oral administration of dicalcium phosphate, at the rate of three to four times the daily requirement, daily for 6 days followed by a reduction to the daily requirement by the 10th day, combined with one injection of vitamin D at the rate of 10 000 IU/kg BW is recommended.

Affected animals are placed on a diet that contains the required levels and ratios of calcium, phosphorus, and vitamin D. The oral administration of the calcium and phosphorus will result in increased absorption of the minerals, which will restore depleted skeletal reserves. Calcium absorption is increased in adult animals following a period of calcium deficiency; young animals with high growth requirements absorb and retain calcium in direct relation to intake. General supportive measures include adequate bedding for animals that are recumbent.

The treatment of the osteodystrophies due to causes other than calcium and phosphorus deficiencies depends on the cause. Copper deficiency will respond gradually to copper supplementation. There is no specific treatment for the osteodystrophy associated with leg weakness in pigs and slaughter for salvage is often necessary. Overnutrition in young, rapidly growing foals may require a marked reduction in the total amount of feed made available daily.

Oxytetracycline has been used for the treatment of flexural deformities of the distal interphalangeal joints of young foals.[9] It is postulated that oxytetracycline chelates calcium, rendering it unavailable for use for striated muscle contraction. It is considered effective for obtaining a short-term moderate decrease in metacarpophalangeal joint angle in newborn foals. Hemicircumferential periosteal transection and elevation has gained wide acceptance for correction of angular limb deformities in young foals.[1]

HYPERTROPHIC PULMONARY OSTEOARTHROPATHY (MARIE'S DISEASE, ACHROPACHIA OSSEA)

Although hypertrophic pulmonary osteoarthropathy is more common in dogs than in the other domestic animals it has been observed in horses,[1] cattle and sheep. The disease is characterized by proliferation of the periosteum leading to the formation of periosteal bone, and bilateral symmetrical enlargement of bones, usually the long bones of limbs. The enlargement is quite obvious, and in the early stages is usually painful and often accompanied by local edema. On radiographic examination there is a shaggy periostitis and evidence of periosteal exostosis. The pathogenesis is obscure but the lesion appears to be neurogenic in origin, unilateral vagotomy causing regression of the bony changes. Stiffness of gait and reluctance to move are usually present, and there may be clinical evidence of the pulmonary lesion with which the disease is almost always associated. Such lesions are usually chronic, neoplastic or suppurative processes such as tuberculosis.

The disease is considered to be incurable, unless the thoracic lesion can be removed, and affected animals are usually euthanized. At necropsy the periostitis, exostosis and pulmonary disease are evident. There is no involvement of the joints.

OSTEOMYELITIS

ETIOLOGY AND PATHOGENESIS

Inflammation of bone is uncommon in farm animals except when infection is introduced by traumatic injury or by the hematogenous route. **Bacteria can reach bone by any of three routes:**

- **Hematogenously**
- **By extension from an adjacent focus of infection**
- **By direct inoculation through trauma or surgery.**

Focal metaphyseal osteomyelitis can occur following open fractures in the horse. Specific diseases that may be accompanied by osteomyelitis include actinomycosis of cattle and brucellosis, atrophic rhinitis and necrotic rhinitis of pigs. Nonspecific, hematogenous infection with other bacteria occurs sporadically and is often associated with omphalitis, abscesses from tail-biting in pigs or infection of castration or docking wounds in lambs. A series of 28 cases of osteomyelitis of the calcaneus of adult horses has been described.[1]

Foals and calves under 1 month of age and growing cattle 6–12 months of age may be affected by osteomyelitis in one or more bones. The majority of foals with suppurative polyarthritis have a polyosteomyelitis of the bones adjacent to the affected joints. In a series of cases of tarsal osteomyelitis in foals there was usually evidence of infectious arthritis.[2] Osteomyelitis of the pubic symphysis associated with *Rhodococcus equi* in a 2-year-old horse has been described.[3] The lameness was localized to the pelvis and was associated with a fever and an inflammatory leukogram.

The infections occur commonly in the metaphysis, physis, and epiphysis, which are sites of bony growth and thus susceptible to blood-borne infections. The metaphyseal blood vessels loop toward the physis and ramify into sinusoids that spread throughout the metaphyseal region. Blood flow through the sinusoids is sluggish and presents an ideal environment for propagation of bacteria. Lesions occur on both sides of the physis in both the metaphysis and the epiphysis. Multiple lesions are common and support the explanation that septic emboli are released from a central focus.

In a series of 445 cattle with bone infection of the appendicular skeleton a distinction was made between hematogenous and post-traumatic orgin (wound/fracture).[4] Bone infection was classified into four types according to the site of infection: Type 1 is metaphyseal and/or epiphyseal osteomyelitis close to the growth plate; type 2 is primary subchondral osteomyelitis, mostly accompanied by septic arthritis; type 3 is infectious osteoarthritis with subchondral osteomyelitis, implying that infection in the subchondral bone originates from the infection. Type 4 includes bone infections that cannot be categorized in the other groups. Hematogenous osteomyelitis was 3.2 times more frequent than post-traumatic osteomyelitis. *Arcanobacterium (Corynebacterium) pyogenes* was the most common etiological agent. About 55% of the affected animals with osseous sequestration had physical evidence of lacerations, contusions, abrasions or puncture wounds from a previous traumatic event.

Hematogenous osteomyelitis in cattle can be of:

- Physeal type, in which an infection generally of metaphyseal bone originates at or near the growth plate, usually affecting the distal metacarpus, metatarsus, radius or tibia[5]
- Epiphyseal type, in which an infection originates near the junction of the subchondral bone and the immature epiphyseal joint cartilage, most often affecting the distal femoral condyle epiphysis, the patellar and the distal radius.

The epiphyseal osteomyelitises are usually due to infection with *Salmonella* spp. and are most common in calves under 12 weeks of age. The physeal infections are usually due to *A. pyogenes* and occur most commonly in cattle over 6 months of age.

Osseous sequestration in cattle

Osseous sequestration is a common orthopedic abnormality in cattle and

horses.[6] In most cases, the lesions develop in the bones of the distal portion of the limbs. Sequestration is associated with trauma that results in localized cortical ischemia and bacterial invasion secondary to loss of adjacent periosteal and soft-tissue integrity and viability. The soft tissues covering the bones that comprise the distal portions of the limbs fail to provide adequate protection and collateral blood supply to the bone.

Osteomyelitis secondary to trauma

In horses, osteomyelitis is a frequent sequela to wounds of the metacarpal and metatarsal bones and the calcaneus. These bones have limited soft tissue covering, which may predispose them to osteomyelitis following traumatic injury. Similarly, a portion of the lateral aspect of the proximal end of the radius has limited soft-tissue covering. Penetrating and nonpenetrating wounds in this region, therefore, may result in serious consequences even though they may initially appear to be minor. Because lesions may be an extension of septic arthritis, a thorough examination of the wound area is necessary.

Osteomyelitis of the sustentaculum tali in horses has been described.[7]

Inflammation of bone marrow

Inflammation of bone marrow in animals has been described.[8,9] Acute inflammation commonly accompanies bacterial sepsis, resulting in either multifocal microabscesses or perivascular infiltrates of neutrophils, fibrin, edema, and hemorrhage. The most common abnormality associated with fibrinous inflammation is disseminated intravascular coagulopathy. Discrete granulomas may occur in the marrow of animals with systemic mycotic disease, idiopathic granulomatous disease and serous atrophy of fat.

CLINICAL FINDINGS

The common clinical findings of osteomyelitis include:

- **Lameness**
- **Generalized soft tissue swelling** and **inflammation**
- **Pain on palpation of the affected area**
- **Chronic persistent drainage**
- **Secondary muscle atrophy of the affected limb** [1]

Erosion of bone occurs and pus discharges into surrounding tissues, causing a cellulitis or phlegmon, and to the exterior through sinuses, which persist for long periods. The affected bone is often swollen and may fracture easily because of weakening of its structure. When the bones of the jaw are involved, the teeth are often shed and this, together with pain and the distortion of the jaw, interferes with prehension and mastication. Involvement of vertebral bodies may lead to the secondary involvement of the meninges and the development of paralysis. Lameness and local swelling are the major manifestations of involvement of the limb bones.

Most osseous sequestra in cattle are associated with the bones of the extremities, most commonly the third metacarpal or metatarsal bone. Cattle 6 months to 2 years of age are most likely to have a sequestrum compared with animals less than 6 months of age.[6]

The lesions are typically destructive of bone and cause severe pain and lameness. Those associated with *Salmonella* spp. are characteristic radiographically in foals and calves. *A. pyogenes*, *Corynebacterium* spp., and *E. coli* may also be causative agents. Affected animals are very lame and the origin of the lameness may not be obvious. A painful, discrete soft-tissue swelling over the ends of the long bones is often the first indication. The lameness characteristically persists in spite of medical therapy and the animal may become lame in two or more limbs and spend long periods recumbent.

Osteomyelitis affecting the cervical vertebrae, usually the fourth to sixth vertebra, causing a typical syndrome of abnormal posture and difficulty with ambulation. Initially there is a stumbling gait, which then becomes stiff and restricted and with a reluctance to bend the neck. Soon the animal has difficulty eating off the ground and must kneel to graze pasture. At this stage there is obvious atrophy of the cervical muscles and pain can be elicited by deep, forceful compression of the vertebrae with the fists. There is no response to treatment and at necropsy there is irreparable osteomyelitis of the vertebral body and compression of the cervical spinal cord. Radiological examination is usually confirmatory.

Cervicothoracic vertebral osteomyelitis in calves between 2 and 9 weeks of age is characterized by difficulty in rising with a tendency to knuckle or kneel on the forelimbs, which are hypotonic and hyporeflexic. Pain can be elicited on manipulation of the neck. The lesion usually involves one or more of the vertebrae from C6–T1.[8] *Salmonella dublin* is commonly isolated from the vertebral lesion.

CLINICAL PATHOLOGY

Radiographic changes include:

- **Necrotic sequestrum initially**
- **New bone formation**
- **Loss of bone density.**

The lesions are characteristically centered at the growth and extend into both metaphysis and epiphysis. Culture of the inflammatory exudate and necrotic sequestra removed surgically is necessary to determine the species of bacteria and their antimicrobial sensitivity.[6] Samples of bone obtained at surgery provide the most accurate culture results compared to specimens obtained from the draining sinuses, which may yield a mixed flora. Specimens should consist of sequestra and soft tissues immediately adjacent to bone thought to be infected. Special transport media are desirable for optimum culture results. Anaerobic bacteria are frequently associated with osteomyelitis and should be considered when submitting samples for culture.

NECROPSY FINDINGS

At necropsy the osteomyelitis may not be obvious unless the bones are opened longitudinally and the cut surfaces of the metaphysis and epiphysis are examined.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis for a destructive lesion in the end of a long bone of a foal or calf would include: a healing fracture, traumatic periostitis or osteitis, bone tumor, nutritional osteodystrophy and infection of the bone due to external trauma, fracture, extension from adjacent infection or hematogenous spread. The absence of equal pathological involvement in the comparable parts of long bones and the young age of the animal will usually suggest infection of bone. The pathological features of multiple bone infection in foals are described.

TREATMENT

Despite advances in antimicrobial therapy and refined diagnostic techniques, the clinical management of osteomyelitis is difficult. Medical therapy alone is rarely completely successful because of the poor vascularity of the affected solid bone and the inaccessibility of the infection. In cases of long-term infection or those with extensive bone necrosis, surgery is generally recommended to remove sequestra, devitalized tissue and sinus tracts that are harboring large numbers of bacteria.[1,6] Good results are obtained when the affected bone is removed and the affected area is irrigated daily through a temporary drainage tube.

In septic physitis, the implantation of homologous cancellous bone grafts following debridement of necrotic bone, and the application of a walking cast for 4–5 weeks and antimicrobial therapy for 2 weeks was highly successful.[10] Absolute asepsis is required for successful application of a bone graft and, after

debridement of the necrotic bone, the cavity is flushed with saline and ampicillin.

Antimicrobials are an integral part of the treatment and selection of the most appropriate drug should be based on identification of the organism. Parenteral antimicrobial therapy should be continued for 4–6 weeks following surgical curettage. However, in a series of osteomyelitis of the calcaneus of adult horses, there was no difference in the survival rate of animals between those treated surgically and those treated conservatively.[1] Prolonged antibiotic therapy can be successful for the treatment of osteomyelitis of the proximal end of the radius in the horse.[11]

Most anaerobic bacteria associated with osteomyelitis are sensitive to penicillin and the cephalosporins, but some species of *Bacteroides fragilis* and *Bacteroides asaccharolyticus* and other species of *Bacteroides* are known to produce beta-lactamases, which can inactivate penicillin and cephalosporin. Metronidazole and clindamycin will penetrate bone and can be considered.

Diseases of joints

ARTHROPATHY (OSTEOARTHROPATHY, DEGENERATIVE JOINT DISEASE)

The terms osteoarthropathy and degenerative joint disease are used here to describe noninflammatory lesions of the articular surfaces of joints characterized by:

- Degeneration and erosion of articular cartilage
- Eburnation of subchondral bones
- Hypertrophy of bone surrounding the articular cartilage resulting in lipping and spur formation at the joint margins.

Osteochondrosis is a degeneration of both the deep layers of the articular cartilage and the epiphyseal plate – a defect in endochondral ossification – which occurs in pigs and horses and is similar to the well-recognized disease in dogs.

ETIOLOGY AND EPIDEMIOLOGY

The etiology is not clear but in most of the commonly occurring cases the lesions are considered to be multifactorial and perhaps secondary to conformational defects resulting in excessive joint laxity, acute traumatic injury of a joint, the normal aging process and nutritional deficiencies. The etiological information is primarily circumstantial and some of the epidemiological observations that have been associated with osteoarthritis of farm animals are outlined here.

Nutritional causes

- Secondary to, or associated with, rickets, osteomalacia, bowie and osteodystrophia fibrosa
- Coxofemoral arthropathy in dairy cattle associated with aphosphorosis
- Copper deficiency thought to be related to enlargement of limb joints in foals on pasture and pigs fed experimental copper-deficient diets
- Experimental diets deficient in manganese or magnesium causing arthropathy and joint deformity in some calves
- Experimental riboflavin deficiency in pigs.

Poisonings

- Chronic zinc poisoning in pigs and foals
- Fluorosis in cattle
- As part of the enzootic calcinosis syndrome caused by poisoning with *Solanum malacoxylon* and others.

Steroid-induced

The intra-articular injection or prolonged parenteral administration of corticosteroids in horses may lead to degenerative joint disease.

Biomechanical trauma

- **Acute traumatic injury**, e.g. injury to joint surfaces, menisci and ligaments, especially the cruciate ligaments of the stifle joints of breeding bulls, may lead to chronic progressive osteoarthritis. Injuries to the femorotibial ligaments of horses can predispose to osteoarthropathy of the stifle joint
- **Repeated subacute trauma** to joint surfaces can lead to degenerative arthropathy. This is common in young racehorses in training, which may have their joint surfaces and surrounding tissues made susceptible to injury because of conformational defects and subtle deficiencies of calcium and phosphorus. Hard running surfaces may also contribute to the onset
- **Trauma caused by movement** is suspected of contributing to the erosive lesions on the articular surfaces of some horses affected by enzootic incoordination, the intervertebral joints of caudal thoracic and cranial lumbar vertebrae of old bulls with spondylitis, and the condition of bulls with inherited spasticity. Coxofemoral osteoarthritis may occur in aged horses with joint instability and in calves with hip dysplasia.

Growth rate, body size, and genetic predisposition

Degenerative coxofemoral arthropathy occurs in **young beef bulls** as early as 9 months of age. A congenital shallow acetabulum may predispose. It may be secondary to hip dysplasia, but in some cases there is no evidence of this. The large, weightbearing joints subjected to the greatest movement and concussion appear to be most susceptible. Rapidly growing bull calves appear to be most susceptible and some of them have an inherited susceptibility.

Osteochondrosis

Osteochondrosis is an important cause of lameness in horses. It is usually seen in young rapidly growing animals, and affects males more commonly than females. The predilection sites of osteochondrosis in the horse and their general order of incidence are hock, stifle, shoulder, fetlock, and cervical spine. The stifle, hock, and shoulder joints are more commonly affected, but many other joints may also be affected, including the metatarsal and metacarpal bones and rarely the acetabula of young foals.

The epidemiology, heritability and body measurements and clinical findings of osteochondrosis of hock and fetlock joints in Standardbred trotters have been examined.[1] The incidence of the disease is high in the Swedish Standardbred population and well developed by the age of 1.5 years. The incidence of osteochondrosis is higher in horses born later in the foaling season than earlier and the incidence was related to body size: affected horses were taller at the withers and had a greater circumference of the carpus.[1] This suggests that differences in body size at birth and the first few months of the foal's life are of major importance in the development of osteochondrosis. The heritability estimates of osteochondrosis in the hock and fetlock joints of 753 Standardbred trotters 6–21 months of age was 0.52 and 0.21, respectively.[2]

Aging process

Degenerative arthropathy in aged dairy cows and bulls may be a manifestation of the normal aging process. Osteochondrosis, degenerative joint disease and vertebral osteophysis occur in middle-aged bulls.

Osteoarthrosis of the antebranchial joint of riding horses has been described.[3] Affected animals were aged mares that developed osteoarthrosis and ankylosis. The cause was unknown.

Conformation and intensive animal production

Osteoarthropathy occurs in rapidly growing cattle and pigs raised in confinement on hard, usually concrete, floors and with minimal exercise. Osteochondrosis in feedlot cattle may be associated with a high-caloric diet and rapid growth rate. It is thought that weight-bearing trauma in these rapidly growing animals is sufficient to cause degenerative lesions of certain joints, especially in animals with a skeletal conformation that results in abnormal stress on certain weightbearing condyles of long bones.

In a series of 42 cases of stifle lameness in cattle, 18 had evidence of subchondral bone cyst and ranged in age from 6–18 months. It is suggested that the subchondral bone cyst is an indicator of osteochondrosis. In a series of osteochondrosis in cattle, male, purebred cattle of a mean age of 21 months were affected.[4]

Osteochondrosis may occur in rapidly growing bull beef calves fed a diet lacking adequate calcium, sodium, copper and vitamins A, D, and E,[5,6] grazing beef cattle on improved native pasture in which a common ancestral sire and gender (all males) may have been contributing factors.[7] Severe osteochondrosis of multiple joints but with remarkable changes in the humeral head and glenoid of both shoulder joints in 10-month-old beef calves has been described.[8]

Osteochondrosis similar to that seen in pigs has been recorded in purebred Suffolk lambs raised in a system designed to produce rapidly growing, high-value rams.[9] The disease has been recorded in a single pedigree Suffolk ram.[10]

Osteochondrosis and arthrosis are considered to be major causes of 'leg weakness' in rapidly growing pigs.[11] Restricting the energy intake appears to decrease the prevalence and severity of osteochondrosis when gilts are examined at 100 kg. The prevalence and severity of osteochondrosis in growing pigs is probably not related to floor type.[11] Recent work has shown a significant relationship between body conformation and the presence of joint lesions. Pigs with a narrow lumbar region, broad hams and a large relative width between the stifle joints were highly susceptible to poor locomotor ability due to lesions in the elbow and stifle joints, the lumbar intervertebral joints and the hip joint.

This excellent work represents real progress in understanding the relationship between skeletal conformation and bone and joint lesions. It is postulated that inherited weakness of muscle, ligaments, cartilage and exterior joint conformation results in local overloading in the joint and the development of osteochondrosis and arthrosis. Some breeds, such as the Duroc, have more problems of structure and movement in the front legs than in the rear legs, but osteochondrosis is not responsible for the leg weakness. Osteochondrosis has been recorded in wild boar–Swedish Yorkshire crossbred pigs in which the growth rate was low.[12]

Osteoarthrosis of the distal tarsal joints of the horse (bone spavin)

Osteoarthrosis of the distal tarsal joints (hock), commonly known as bone spavin, is common in Icelandic horses and strongly related to age.[13,14] In Icelandic horses aged 6–12 years and used for riding, the prevalence of radiographic signs of osteoarthrosis in the distal tarsus increased from 18% in horses 6 years of age up to 54% in 12-year-old horses. The age onset of radiographic signs reflect a predisposition to bone spavin indicating a trait with medium–high heritability.[13] There is a high prevalence of chondronecrosis in young Icelandic horses, indicating an early onset and slow progression of disease.[14] The disease is the most common cause of culling due to disease in riding horses in the age group 7–17 years.[15]

PATHOGENESIS

The details of the pathogenesis of degenerative joint disease have been reviewed.[16] A brief review of the structure and biochemistry of the normal articular joint will serve as background for understanding the pathogenesis of osteoarthropathy.[17]

Articular cartilage is a tissue consisting of chondrocytes scattered in a matrix of collagen fibers and an amorphous intercellular substance containing proteoglycans. Articular cartilage contains no nerves, is avascular and has a high matrix-to-cell ratio. The chondrocytes are the only living matter in cartilage, produce the fine strands of collagen and are engaged in protein and proteoglycan synthesis. The matrix of the cartilage consists of water-soluble proteoglycans interspersed with collagen fibers, which are arranged in parallel rows superficially and crisscross rows closer to the calcified layer. This enables the cartilage to withstand shearing stresses superficially and compression more deeply.

The proteoglycans are glycosaminoglycan–protein complexes, bound by a link glycoprotein to a linear hyaluronic acid molecule. The glycosaminoglycans in articular cartilage are chondroitin 4-sulfate, chondroitin 6-sulfate and keratan sulfate. About 75% of the proteoglycans exist on aggregates that protect them from degradation and, because of their high water content, form large polyanionic complexes that have considerable elastic resistance to compression.

Nutrition of the articular cartilage is provided via the synovial fluid and is dependent on the capillary flow to the synovial membrane. Nutrients flow through the synovial fluid and diffuse through the cartilage to the chondrocytes. Proteoglycans are synthesized by the chondrocytes and secreted to the cell exterior. Proteoglycans are also degraded intracellularly by lysosomes. The normal equilibrium between anabolism and catabolism is maintained by several different low-molecular-weight proteins. When the equilibrium is disturbed and shifts toward catabolism, degeneration occurs.

Primary osteoarthropathy

This is due to normal aging processes and ordinary joint usage. The initial lesions occur in the superficial layers of the articular cartilages where, with increasing age, there is loss of the normal resilience of the cartilage, a lowering of the chondroitin sulfate content and reduction in the permeability of the cartilaginous matrix, which results in progressive degeneration of the articular cartilage. There is grooving of the articular cartilage, eburnation of subchondral bone and secondary hypertrophy of marginal cartilage and bone, with the formation of pearl-like osteophytes. In experimentally induced arthritis in the horse the major changes include synovitis, increased synovial effusion and superficial fibrillation with chondrocyte necrosis in the articular cartilage. These are comparable to the early changes in naturally occurring degenerative joint disease.

Secondary osteoarthropathy

This appears to be initiated by injuries or congenital conformational defects that create greater shearing stresses on particular points, in contrast to the intermittent compressive stresses typical of ordinary weightbearing. These irregular stresses result in cartilaginous erosion, increased density of subchondral bone at points of physical stress and proliferation of bone and cartilage at the articular margins.

Following acute trauma, the initial changes are often characterized by acute synovitis and capsulitis. As a result of the inflammatory response, leukocytes, prostaglandins, lysosomal enzymes and hyaluronidase enter the synovial fluid, which becomes less viscous and affects the nutrition of the cartilage. There is

some evidence of immune complexes associated with collagen-type-specific antibodies in horses with secondary osteoarthritis. Cytokines can be detected in the synovial fluid after racing in horses with degenerative joint disease.[18] The cartilage matrix undergoes a variety of changes, possibly because of chondrocyte damage with lysosomal enzyme release, or to collagen fiber injury. There is an increase in water content and loss of orientation of the collagen fibers. Proteoglycans are lost and, while increased chondrocyte activity synthesizes proteoglycans, they are of lower molecular weight and altered glycosaminoglycan composition. This leads to loss of elasticity and surface integrity of the cartilage, resulting in increased friction, blistering and ulceration. There is additional lysosomal enzyme release from the chondrocytes, resulting in matrix destruction and further proteoglycan destruction. The degrading enzymes enter the altered matrix and cause further degradation.

The first stage of matrix degradation involves discoloration, softening and blistering of the tangential layer of the cartilage surface, a process known as early fibrillation. As the fissuring extends to the radial layer, microfractures occur, with loss of cartilage fragments (detritus) into the synovial fluid. As the cartilage is destroyed the underlying bone is exposed and becomes sclerotic. Bony proliferation occurs in the floor of the cartilage lesions, while at the joint margins osteophyte formation occurs. The pathogenesis of degenerative joint disease indicates that the ideal treatment would be the use of a substance that would promote synthesis of matrix components and retard catabolic processes.

The major proteoglycan in cartilage is a high-molecular-weight aggrecan that contains chondroitin sulfate and keratin sulfate chains located on specific regions of the core protein. These macromolecules are continuously released into the synovial fluid during normal cartilage matrix metabolism. Cartilage proteoglycans are degraded early in the course of joint disease and released from the cartilage into the synovial fluid, where they can be identified.[19]

In horses with degenerative joint disease, proteoglycan fragments – glycosaminoglycans – have been determined in equine synovial fluid as indicators of cartilage metabolism in various types of arthritides.[19] The presence of high-molecular-weight proteoglycans and high concentrations of hyaluronate in horses with various arthritides – acute or chronic traumatic arthritis, intra-articular fracture and infectious arthritis, with and without abnormal radiographic and/or arthroscopic findings – compared with control joints has been investigated.[19]

The intra-articular injection of corticosteroids depresses chondrocyte metabolism, alters the biochemical composition and causes morphological changes in the articular cartilage, which remains biochemically and metabolically impaired for several or more weeks.

In femoral–tibial osteoarthrosis of bulls the secondary degenerative joint lesions are due to rupture of the attachments of the lateral meniscus resulting in mechanical instability in the joint with unusual mechanical stresses on the articular cartilage leading to degeneration. The cranial cruciate ligament becomes progressively worn and eventually ruptures, resulting in loss of all joint stability and the development of gross arthrosis. In cattle with severe degenerative joint disease of the coxofemoral joints, an acetabular osseous bulla may develop at the cranial margin of the obturator foramen.

Osteochondrosis

Osteochondrosis (dyschondroplasia) is characterized by disturbance of the normal differentiation of the cells in the growing cartilage. Both the metaphyseal growth plate (the growth zone of the diaphysis) and immature joint cartilage (the growth zone of the epiphysis) are affected. The loss of normal differentiation of the cartilage cells results in failure of provisional calcification of the matrix and endochondral ossification ceases. Degeneration and necrosis of blood vessels in cartilage canals results in ischemia of an area of growing cartilage followed by chondrocyte degeneration and death. The initial lesion occurs in growing cartilage and dyschondroplasia is a more appropriate term. The primary lesion of osteochondrosis directly affects the differentiation and maturation of the cartilage cells and the surrounding matrix that are destined to become replaced by bone. This can occur at the two sites of endochondral ossification in long bones – the articular/epiphyseal cartilage complex and the metaphyseal growth plate. In osteochondrosis, the capillary buds fail to penetrate the distal region of the hypertrophic zone, which leads to a failure of the final stages of cartilage maturation and modification of the surrounding matrix. These changes lead to retention and thickening of cartilage with subsequent weakening of the articular/epiphyseal cartilage complex.

Typical lesions in the horse involve extensive cartilaginous and subchondral bone degeneration with flap formation and, ultimately, loose pieces in the joint. This is usually referred to as osteochondritis dissecans and is associated with synovial effusion and varying degrees of synovitis. Osteochondral fracture associated with severe pathological changes to the subchondral bone occurs most commonly on the trochlear ridges and the lateral or medial malleoli of the hock. In some instances, cartilage damage weakens underlying bone and causes a bone cyst to form, usually at a site of biomechanical stress or weightbearing.[11]

It is suggested that osteochondrosis lesions in horses develop prior to 7 months of age and that ischemic necrosis of cartilage secondary to a defect in vascular supply is an important factor in the pathogenesis of the disease in horses.[20] An osteochondrotic lesion in the metaphyseal growth plate may disturb growth to such a degree that the whole shape of the bone is altered. Epiphyseolysis may also occur. Osteochondrosis of joint cartilage may lead to osteochondritis dissecans and secondary osteoarthrosis. The lesion may heal and only the sequelae are present once the period of growth is over.

In rapidly growing pigs raised in confinement with minimal exercise, **osteochondrosis and arthrosis** are seen as degeneration of the deep layer of the articular cartilage and adjacent subchondral bone with degenerative lesions of the epiphyseal plate. Lesions in the epiphyseal plate may result in epiphysiolysis, which occurs most commonly in the femoral head. The typical lesions are usually symmetrical and commonly involve the elbow, stifle and hip joints and the distal epiphyseal plate of the ulna. Lesions also occur in the intervertebral articulations. The lesions are common in pigs when they are examined at slaughter (90–100 kg BW) and there may have been no evidence of clinical abnormality or a proportion of the pigs with severe lesions may have been affected with the leg-weakness syndrome. Osteochondrosis and *Erysipelothrix rhusiopathiae* are the most common causes of nonsuppurative joint disease of pigs examined at the abattoir. Thus not all lesions are clinical.

CLINICAL FINDINGS

The major clinical characteristic is a chronic lameness that becomes progressively worse over a long period of time and does not usually respond to treatment. The disease is insidious and generally not clinically apparent in the early stages. A common clinical history is that the affected animal becomes progressively more lame over a period of weeks and months and prefers long periods of recumbency. The lesion may develop slowly over a period of weeks and months during the convalescent

stages of an acute traumatic injury to the joint when recovery is expected but the animal continues to be lame. Young breeding bulls in the early stages of coxofemoral arthropathy may be reluctant to perform the breeding act and yet appear to have sufficient libido. One of the first clinical abnormalities of osteochondrosis and epiphyseolysis in young breeding boars may be inability to mount the sow – impotentia coeundi.

There is usually difficulty in flexing affected joints normally, which results in a stiff and stilted gait. In cattle confined to stanchions one of the earliest and persistent signs is shifting of weight from limb to limb. In dairy cattle, as the lesions become more painful, there is a decline in appetite and milk production, prolonged recumbency and considerable difficulty in rising from the recumbent state. In the early stages there may be an apparent remission of the lameness, but relapses are common. The bony prominences of the joint eventually appear more prominent than normal, which is due to disuse muscle atrophy of the affected limbs. Distension of the joint capsule is not a characteristic, as it is in an infectious or suppurative arthritis. The joint capsule of palpable joints is usually not painful on palpation. Passive flexion of affected joints may be painful and it may be possible to elicit crepitus due to detached pieces of cartilage and bone and osteophytes surrounding the articular cartilage. However, crepitus is most common in the large movable joints, such as the stifle, and commonly in osteoarthropathy secondary to acute traumatic injury of the meniscus and cranial cruciate ligament of the joint.

Epiphysiolysis of the head of the femur occurs in young pigs from 5 months to 1 year of age. There is usually a history of slight to moderate lameness, sudden in onset and affecting one or both hindlimbs. The onset of lameness may coincide with some physical activity such as breeding, farrowing or transportation. The lameness is progressive and in about 7–10 days the animal is unable to use its hindlegs. Crepitus may be audible on circumduction of the affected limb and radiography may reveal the separation.

In **leg weakness associated with osteochondrosis and arthrosis of pigs** the common clinical findings are hyperflexion of the carpus, limb bowing, adduction of both forelegs at the level of the carpus, hyperextension of the fore and hind phalanges and anterior curvature of the tarsus. Locomotory dysfunction involves primarily the hindlegs. There is pronounced swaying of the hindquarters, and crossing the hindlegs with each step, which makes the pig appear incoordinated.

Osteochondrosis in cattle is characterized by chronic long-standing lameness, either with or without joint effusion.[4] Joint fluid analysis is usually normal or indicates nonseptic inflammation. The stifle joint is most commonly affected followed by the hock joint. In osteochondrosis in young growing bulls there is reluctance to move, stiffness, enlargement of the ends of long bones and a straightened joint. While there may be clinical evidence of lameness in less than 40% of affected cattle, radiographically, 88% of the lesions are bilateral.[4]

Osteochondrosis in the horse is characterized by a wide range of clinical signs and in some cases lesions are not accompanied by clinical signs. The most common sign of osteochondrosis is a nonpainful distension of an affected joint. In foals under 6 months of age, a tendency to spend more time lying down is common. This is accompanied by joint swelling, stiffness and difficulty keeping up with the other animals in the group. An upright conformation of the limbs may also be present. In yearlings or older animals the common clinical signs are stiffness of joints, flexion responses and varying degrees of lameness.

In the horse with osteochondrosis of the shoulder joint there is intermittent lameness, characterized by a swinging leg, shoulder lameness with pain elicited by extension, flexion or abduction of the limb. Secondary joint disease is also a common finding. In a retrospective study of osteochondrosis dissecans in 21 horses, affected animals were 8 months to 5 years of age. The usual age of onset of clinical abnormalities was 18–24 months. The common presenting complaints included joint effusion and lameness of either gradual or sudden onset. The prevalence was higher in males than in females.

CLINICAL PATHOLOGY

Joint fluid

The changes in the synovial fluid of joints affected with degenerative arthropathy are usually unremarkable and can be distinguished from the changes in infectious arthritis. A summary of the laboratory evaluation of synovial fluid in diseases of the joints is set out in Table 13.2. The isolation of an infectious agent from the synovial fluid of a diseased joint suggests the presence of an infectious arthritis but failure to isolate an organism must not be interpreted as the presence of a noninfectious arthritis. In well advanced cases of infectious arthritis the number of organisms may be small or they have been phagocytosed by neutrophils in the joint fluid.

Total protein concentration and viscosity of synovial fluid of horses can be determined. Normal values are available[21] and the concentration and molecular weight distribution of hyaluronate in synovial fluid from clinically normal horses and horses with diseased joints have been compared.[19,22] Synovial fluid viscosity is reduced in horses with infectious and chronic arthritides and with radiographic evidence of cartilage degeneration. The synovial fluid hyaluronate concentration can be used as a diagnostic marker for chronic traumatic arthritis. However, high-molecular-weight proteoglycans or other markers in the synovial fluid cannot be used for diagnosing or monitoring degenerative joint disease.[19]

Hematology and serum biochemistry should be combined with appropriate hematology and serum biochemistry where indicated. The concentration of hyaluronic acid in synovial fluid can be determined using an assay technique. The determination of serum calcium and phosphorus may reveal the existence of a dietary deficiency or imbalance of minerals.

Radiography

Radiography of the hock joints in a craniomedial–caudolateral oblique view and of the fetlock joints in lateromedial view are standard techniques for the diagnosis of osteochondrosis in the horse. Those joints with abnormal radiographs may be radiographed from additional perspectives. Horses with bony fragments or defects at the cranial edge of the intermediate ridge of the distal aspect of the tibia or defects at the lateral trochlea of the talus can be classified as having osteochondrosis.[2] The radiographic progression of femoropatellar osteochondrosis in horses under 1 year of age at the onset of clinical signs has been examined.[22] The full extent of the radiographic lesions may take several weeks to develop.

Arthroscopy

Arthroscopic examination and surgery of affected joints of horses with osteochondrosis can provide considerably more information than is possible from clinical and radiographic examination alone.[23]

NECROPSY FINDINGS

In degenerative joint disease the joint cartilage is thin or patchily absent and polished subchondral bone is evident. The articular surfaces are irregular and sometimes folded. Exposed bone may be extensively eroded and osteophytes (small bony excrescences, like pearls) may be present on the nonarticular parts of the joint on the circumference of the articular cartilage. The synovial fluid is usually only slightly increased in volume and appears

Table 13.2 Laboratory evaluation of synovial fluid in diseases of the joints

Synovial fluid analysis	Normal joint	Degenerative arthropathy	Infectious arthritis
Gross appearance	Colorless, clear	Pale yellow, may contain flocculent debris	Turbid, yellow
Total volume	–	Normal or slight increase	Usually marked increase
Clot formation	No clot	No clot	May clot within minutes after collection
Erythrocytes (μL)	< 4000	6000–12 000	4000–8000
Leukocytes (μL)	< 250	250–1000	50 000–150 000
Neutrophils (%)	7	10–15	80–90
Lymphocytes (%)	35–40	45–50	4–8
Monocytes (%)	45–50	35–40	1–3
Microbiology	–	–	May be able to culture bacteria, mycoplasma or virus, but not always
Total protein (g/dL)	1.2–1.8	1.6–1.8	3.20–4.5
Relative viscosity	–	Slightly reduced	Decreased
pH	–	–	Decreased

Other laboratory analyses of synovial fluid include: sugar content, alkaline phosphatase activity, lactic dehydrogenase activity, aldolase activity, glumatic oxaloacetic transaminase activity, glutamic pyruvic transaminase activity, mucinous precipitate quality.

amber-colored. Menisci, intra-articular, cartilages and ligaments may be entirely absent and there may be areas of calcification in the joint capsule and cartilages free in the synovium. When the stifle is affected, fractures of the head of the tibia occur commonly, usually a chip of the lateral condyle having become separated. In such cases, fractures of the lateral condyle of the distal end of the femur may follow. With either of these fractures, lameness is extreme and the animal may often refuse to rise.

The radiographic and pathological findings of femoral–tibial osteoarthrosis in bulls is described. When the hip joint of bulls is affected, the head of the femur becomes smaller and more flattened than normal, the acetabulum is shallower and the round ligament is usually ruptured. The pathology of coxofemoral arthropathy is young bulls is described.

The pathological changes in experimentally induced osteoarthritis in the horse are similar to the early changes of naturally occurring degenerative joint disease.

In osteochondrosis there is splitting and invagination of articular cartilage, loss of articular cartilage, chip fractures of condyles, exposed and collapsed subchondral bone, osteophyte formation around the circumference of the articular cartilage and loose pieces of cartilage in the joint. In the epiphyseal plates (e.g., the distal ulna in pigs with leg weakness) the cartilage is uneven and thickened with hemorrhage, fibrous tissue, collapse of bone tissue in the metaphysis and epiphyseal separation. Complete separation of the epiphysis occurs most commonly at the head of the femur. The ultrastructural appearance of normal epiphyseal cartilage of the articular–epiphyseal cartilage complex in growing swine has been examined and serves as a standard for comparison with the lesions in affected pigs. The lesions may be present in pigs at an early age as part of the usual growth pattern of cartilages.

In equine osteochondrosis (dyschondroplasia), the histological lesions can be divided into two groups.[24] In one group there are accumulations of small rounded chondrocytes, areas of necrosis and chondrocyte clusters. In the second group, there are alterations in the appearance of the mineralized matrix, areas of necrosis, chondrocyte clusters and an alteration in type VI collagen immunoreactivity within the chondrocyte clusters.

TREATMENT

The treatment of arthropathy depends largely upon correction of the cause, but in most cases the lesions are progressive and irreparable and food-producing animals should be slaughtered for salvage. Tarsal degenerative joint disease in cattle has been treated with intra-articular injections of corticosteroids and has provided temporary relief from pain and discomfort. However, the corticosteroids do not promote healing of the joint and their use in arthropathy may actually accelerate erosion of articular cartilage, loss of joint sensation and the development of 'steroid arthropathy'. Large doses of acetylsalicylic acid may be given to reduce pain in animals that are kept for breeding purposes.

DIFFERENTIAL DIAGNOSIS

Osteoarthropathy is characterized clinically by a chronic lameness that becomes progressively worse and usually does not respond to treatment. The gait is stiff, there is disuse muscle atrophy, the bony prominences of the joint are more apparent but usually there is no marked distension and pain of the joint capsule, as in infectious arthritis. Examination of synovial fluid may aid in differentiation from infectious arthritis.

Radiographically there is erosion of articular cartilage, sclerosis of subchondral bone and periarticular accumulations of osteophytes. In the early stages of the disease in large animals, radiographic changes may not be visible and repeated examinations may be necessary. The radiographic changes of osteochondrosis in the shoulder joint of the horse consist of:

- Alteration in the contour of the humeral head and glenoid cavity
- Periarticular osteophyte formation
- Sclerosis of the subchondral bone
- Bone cyst formation.

The literature on the medical management of **osteoarthritis** in the **horse** has been reviewed.[25] There are many choices available for controlling inflammation in osteoarthritis. Treatment is symptomatic and largely nonspecific.

Nonsteroidal anti-inflammatory agents

Several nonsteroidal anti-inflammatory drugs (NSAIDs), such as **phenylbutazone**, **flunixin meglumine**, **ketoprofen**, **naproxen**, and **carprofen**, are available treatment options. Each has associated toxicities. They are now the most commonly used drugs because of their analgesic, antipyretic and anti-inflammatory properties.[25] They inhibit some component of the enzyme system that converts arachidonic acid into prostaglandins and thromboxanes. All cells, including chondrocytes and synoviocytes, possess arachidonic acid as a fatty acid constituent of phospholipids. Once released, arachidonic acid is oxidized by either cyclooxygenase (COX) or 5-lipooxygenase. COX oxidation leads to prostaglandin production, while lipoxygenase oxidation leads to leukotriene formation. The effect of NSAIDs is primarily from inhibiting COX, which blocks arachidonic acid conversion to prostaglandin.

Intra-articular steroids

Various steroidal formulations for intra-articular administration are available and correct dosage, frequency of administration, indications and toxicity are factors to consider for each drug. They include methylprednisolone acetate, betametasone, and triamcinolone acetonide.[25]

Chondroprotective agents

Various **chondroprotective** drugs such as **hyaluronic acid, polysulfated glycosaminoglycan**, and oral **glucosamine-chondroitin sulphate** are also used to control inflammation and provide viscosupplementation.[25]

There is a notable lack of treatment information based on randomized, blinded placebo-controlled clinical trials in the horse to identify the efficacy of therapeutic agents for both symptomatic and disease-modifying activity in degenerative joint disease.[25] Until there are validated outcome measures that can be used practically in clinical trials, there will always be uncertainty about whether these therapeutic agents have any real disease-modifying action.[26]

Hyaluronic acid

The changes in the synovia following the intra-articular injection of **sodium hyaluronate** into normal equine joints and after arthrotomy and experimental cartilage damage have been examined, but in general the results are inconclusive.

Polysulfated glycosaminoglycans

Polysulfated glycosaminoglycans have been reported to induce articular cartilage matrix synthesis and to decrease matrix degradation.[27] Experimentally, intra-articular injections of **polysulfated glycosaminoglycan** provides some protection against chemically induced articular cartilage damage but not against physical defects of articular cartilage in the horse. The polysulfated glycosaminoglycans inhibit lysosomal enzymes and neutral proteases. The allo-transplantation of synovial fluid into the joints of horses with arthropathies has been examined. A survey of the use of polysulfated glycosaminoglycans by equine practitioners for the treatment of lameness in horses found that the drug is moderately effective overall and is considered most beneficial in the treatment of subacute degenerative joint disease.[28] Its efficacy for incipient and chronic forms of degenerative joint disease is considered comparable to that of sodium hyaluronate.

The prevention of further trauma should be assured and possible nutritional causes corrected. The treatment of active disease, particularly in soft tissues, that is contributing to articular degeneration includes rest, immobilization, physical therapy, intra-articular injections of corticosteroids, NSAIDs, joint lavage and intra-articular injection of sodium hyaluronate, all of which have been used with variable success.[29]

Other treatments

Surgical therapy includes curettage of articular cartilage, removal of osteophytes and surgical arthrodesis.[29] In a retrospective study of stifle lameness in 42 cattle admitted to two veterinary teaching hospitals over a period of 6 years, 18 had radiographic evidence of subchondral bone cyst without radiographic evidence of degenerative joint disease. The prognosis in those with a subchondral bone cyst was favorable, 75% returning to their intended function, while in septic arthritis only 22% returned to normal.

Chemical arthrodesis using the intra-articular injections of monoiodoacetate (MIA) has been described as an alternative to surgical arthrodesis for the treatment of degenerative joint disease of the distal tarsal joints.[30] MIA causes an increase in intracellular concentration of adenosine triphosphate resulting in inhibition of glycolysis and cell deaths. It causes dose-dependent cartilage degeneration characterized by cartilage fibrillations, chondrocyte death and glycosaminoglycan and proteoglycan depletion. MIA produces reliable radiographic and histological ankylosis of the distal tarsal joints. Resolution of the lameness required 12 months and occasionally longer. Soundness was achieved in 82% and 85% of horses at 12 and 24 months, respectively. Complications of the injections were uncommon and were probably related to peri-articular injection or leakage of MIA, or to use of higher concentrations or volumes. Postinjection pain was marked in a small number of horses but was transient and managed effectively with analgesic drugs. The procedure is controversial.[31] Some clinicians argue that arthrodesis should only be used where lameness is localized to the tarsometatarsal and centrodistal joints with objective means such as local analgesic techniques, and when other more conservative treatments have failed.

CONTROL AND PREVENTION

Prevention of osteoarthropathy will depend upon recognition and elimination of the predisposing causes: provision of an adequate diet and the avoidance of overnutrition; regular exercise for confined animals; the provision of suitable flooring to minimize persistent concussion and the use of breeding stock that have a body conformation that does not predispose to joint lesions.

ARTHRITIS AND SYNOVITIS

Inflammation of the synovial membrane and articular surfaces as a result of infection occurs commonly in farm animals. It is characterized by varying degrees of lameness and a warm and swollen painful joint. The synovial fluid is usually abnormal, containing an increased leukocyte count and the pathogens causing the arthritis. The arthritis may be severe enough to cause systemic illness, and in some cases a draining sinus tract may occur.

ETIOLOGY AND EPIDEMIOLOGY

Specific bacterial infections of the joints are most common in newborn farm animals, in which localization of infection occurs in joints following bacteremia or septicemia. Surveys of Thoroughbred studs have shown that the incidence of infectious arthritis is higher in foals with other perinatal abnormalities and in which the ingestion of colostrum was delayed for more than 4 hours after birth. Calves with hypogammaglobulinemia are particularly susceptible to bacteremia and meningitis, ophthalmitis and arthritis. Some of the important infectious causes of arthritis are as follows.

Calves

- Nonspecific joint-ill from omphalophlebitis associated with

A. pyogenes, Fusobacterium necrophorum, Staphylococcus sp.
- *Erysipelothrix rhusiopathiae* sporadically in older calves
- *Salmonella dublin, Salmonella typhimurium* and *Mycoplasma bovis.*

Lambs
- *E. rhusiopathiae* in newborn and recently tail-docked lambs
- Sporadic cases associated with *F. necrophorum, Staphylococcus* sp., *Corynebacterium pseudotuberculosis, Histophilus somni, Mannheimia haemolytica*
- *Chlamydophila* spp. cause polyarthritis extensively in feedlot lambs
- In tick pyemia associated with *Staphylococcus aureus.*

Foals
- *Actinobacillus equuli, Rhodococcus equi, Salmonella abortivoequina* in the newborn
- *Chlamydophila* sp. has caused polyarthritis in foals.

Piglets
- Streptococci, Lancefield groups C, E, and L
- *Streptococcus suis*
- *E. rhusiopathiae* in pigs of any age. Up to 65% of joints of pigs at slaughter are affected and up to 80% of the farms from which the pigs come do not vaccinate for erysipelas. Mortality in preweaning groups of pigs may affect 18% of litters, 3.3% of the piglets with a herd mortality of 1.5%
- In a 4-year period in a swine research station, 9411 piglets were born alive and 9.8% were treated for lameness.[1] About 75% of the cases were observed in piglets under 3 weeks of age. The incidence of lameness was much higher in piglets born from sows of parity 3 (11.4%) compared to piglets born to sows of parity 4–7 (8%).

Cattle
- *Histophilus somni* is a cause of synovitis
- *Mycoplasma agalactia* var. *bovis* is a common cause of synovitis, arthritis and pneumonia in young feedlot cattle
- *Mycoplasma bovigenitalium* may cause mastitis in cows, with some animals developing arthritis
- *Mycoplasma mycoides* may cause arthritis in calves vaccinated with the organism against contagious bovine pleuropneumonia. Calves already sensitive to the organism develop an immediate-type allergic reaction of the synovial membrane
- *Brucella abortus*: occasional cows with brucellosis develop an arthrodial synovitis
- Some cases of ephemeral fever have a sterile arthritis
- BVD virus in young bulls, rarely
- Idiopathic septic arthritis in dairy heifers. The etiology is unknown
- Septic arthritis of the proximal interphalangeal (pastern) joint in cattle due to perforating wounds.[2] *A. pyogenes* is the most common cause in cattle.

Sheep and goats
- As part of melioidosis
- *Mycoplasma* sp. of serositis – arthritis
- *Streptococcus dysgalactiae* in dairy goats.

Pigs
- Glasser's disease
- *Mycoplasma* sp. in synovitis and arthritis of growing pigs especially in housed pigs
- *Brucella suis* commonly infects bones, especially vertebrae, and joints.

Horses
- Septic arthritis after penetrating wounds, intra-articular injection of corticosteroids, and surgery; young foals under 6 months of age usually associated with a septicemia; adult horses without a known etiology
- In a series of 34 cases of monoarticular infectious arthritis in adult horses admitted to a veterinary teaching hospital over a period of 10 years, 16 had a penetrating wound over the joint, four had a puncture wound of the sole and in five the infection was iatrogenic (three had received intra-articular corticosteroids, one had received intra-articular anesthesia and one had sepsis after a purulent thrombophlebitis).[3] In nine cases, no cause could be determined
- Spread to the joints from generalized strangles
- Rare cases of non-erosive polysynovitis in a horse, possibly immunological and immune-mediated polysynovitis in foals[4]
- *Acedosporium prolificans*, a newly recognized opportunistic fungus, has been associated with an incurable arthritis and osteomyelitis in a mature horse.[5]

All species
Sporadic cases are due to:
- Traumatic perforation of the joint capsule
- Spread from surrounding tissues, e.g. footrot to interphalangeal joints in cattle and pigs, interdigital abscess in sheep
- Hematogenous spread from suppurative lesions commonly in udder, uterus, diaphragmatic abscess, infected navel or tail, castration wound.

PATHOGENESIS

In infectious arthritis that is hematogenous in origin there is usually a synovitis initially, followed by changes in the articular cartilages and sometimes bone. With almost any systemic infection there may be localization of the infectious agent in the synovial membrane and joint cavity. The synovial membrane is inflamed and edematous, and there are varying degrees of villous hypertrophy and deposition of fibrin. Bacteria colonize in synovial membranes, which makes treatment difficult. The synovitis causes distension of the joint capsule with fluid and the joint is painful and warm. Successful treatment and elimination of infection at this early stage of synovitis will minimize changes in articular cartilage and bone and healing will result. A progressive infectious synovitis commonly results in pannus formation between articular surfaces with erosion of articular cartilage, infection of subchondral bone and osteomyelitis. In the chronic stages there is extensive granulation tissue formation, chronic synovitis and degenerative joint disease with osteophyte formation, and ankylosis is possible. Depending on the organism, the arthritis may be suppurative or serofibrinous. Suppurative arthritis is particularly destructive of cartilage and bone and commonly there is rupture of the joint capsule. In foals with septic arthritis there may be a concurrent polyosteomyelitis, usually in either the epiphysis and/or the metaphysis of the long bones.

Experimental infectious arthritis in calves

Septic arthritis induced by *E. coli* is a reliable and reproducible model of infectious arthritis in laboratory animals, horses and calves.[6] The inoculation of *E. coli* into the tarsal joint of newborn colostrum-fed calves resulted in septic arthritis in all calves. Clinical signs of septic arthritis appeared on day 2 after infection and persisted until day for all calves. *E. coli* was cultured from synovial fluid on day 2 for one calf and until day 4 for five other calves. Polymerase chain reaction (PCR) for *E. coli* was positive in the synovial fluid of all calves. Synovial fluid neutrophil and white blood cell counts were increased on days 2–4. All bacterial cultures were negative on day 8, although clinicopathological signs of inflammation persisted until day 20. Rapid recovery occurred within 1 week when an appropriate treatment was begun early in the course of the disease.

Foals with septicemia

Septicemic foals may develop infectious arthritis and a concurrent polyosteomyelitis because of the patency of transphyseal vessels in the newborn foal; this allows spread of infection across the physes with the development of lesions in the metaphysis, epiphysis and adjacent to the articular cartilage. The syndrome is classified according to the location of the lesions:

- A foal with S-type septic arthritis–osteomyelitis has synovitis without macroscopic evidence of osteomyelitis
- Foals with E-type osteomyelitis have osteomyelitis of the epiphysis at the subchondral bone -cartilage junction
- Those with P-type have osteomyelitis directly adjacent to the physis
- The same joint may have a single type or any combination of types but most foals with the S-type have concurrent bone lesions.

Horses

Septic arthritis has been reproduced experimentally in horses and the sequential synovial fluid changes monitored. Following intra-articular inoculation of *S. aureus*, clinical signs are evident as early as 8 hours after infection. A high and persistent neutrophilia is one of the earliest and most accurate diagnostic abnormalities. The total white blood cell count rises within 12–24 hours to a mean value of 100×10^9/L. Total protein also increases. Synovial fluid acidosis also occurs in infectious arthritis, which may interfere with the antibacterial activity of some antimicrobials. In experimental arthritis, the synovial pH declined from a mean value of 7.43 to 7.12. Bacteria could be detected in 40% of the smears of infected synovial fluid samples and primary cultures of the fluid were positive in 70%. The intra-articular inoculation of *E. coli* into horses induces a reliable, reproducible and controlled model of infectious arthritis consistent with the naturally occurring disease and has been used to evaluate the efficacy of gentamicin for treatment. The injection of *E. coli* lipopolysaccharide into various joints of horses can cause clinical signs of endotoxemia, and the synovial fluid total nucleated cell count and total protein are linearly responsive in increases in endotoxin.[7]

Endothelin (ET)-1, a 21-amino-acid polypeptide, is locally synthesized in the joints of horses with various forms types of joint disease.[8] It induces a potent and sustained vasoconstriction. Synovial fluid concentrations of ET-1 varies among horses with joint disease, with higher concentrations in animals with joint sepsis suggesting a pathogenetic role in septic arthritis.

Synovial fluid in infectious arthritis in the horse may contain the proteolytic enzymes collagenase and caseinase which may derive from both synovial cells and neutrophils.[9] These enzymes are involved in the degradation of connective tissue and loss of cartilage matrix. Lavage of affective joints is intended to remove these enzymes.

Infectious arthritis may occur following traumatic injury to a joint but the pathogenesis is obscure. Traumatic injury of the joint capsule resulting in edema and inflammation may allow latent organisms to localize, proliferate and initiate an arthritis.

CLINICAL FINDINGS

Inflammation of the synovial membrane causes pain and lameness in the affected limb, sometimes to the point that the animal will not put it to the ground. Pain and heat are usually detectable on palpation and passive movement of the joint is resented. The joint may be swollen but the degree will depend on the type of infection. Pyogenic bacteria cause the greatest degree of swelling and may result in rupture of the joint capsule. Some enlargement of the epiphysis is usual and this may be the only enlargement in nonpyogenic infections, particularly that associated with *E. insidiosa*.

Fever, inappetence to anorexia, endotoxemia, loss of body weight and discomfort may occur in animals with only one severely affected joint or when several joints are less severely affected.

In many of the neonatal infections there will also be an accompanying omphalophlebitis and evidence of lesions in other organs, particularly the liver, endocardium and meninges. Arthritis in older animals may also be accompanied by signs of inflammation of the serous membranes and endocardium when the infection is the result of hematogenous localization.

The joints most commonly involved are the hock, stifle and knee but infection of the fetlock, interphalangeal and intervertebral joints is not uncommon. In chronic cases there may by physical impairment of joint movement because of fibrous thickening of the joint capsule, periarticular ossification and rarely ankylosis of the joints. Crepitus may be detectable in joints where much erosion has occurred.

In newborn and young animals, involvement of several joints is common. The joints may become inflamed simultaneously or serially. Lameness is often so severe that affected foals lie down in lateral recumbency most of the time and may have to be assisted to rise. Decubitus ulcerations due to prolonged recumbency are common. The gait may be so impaired as to suggest ataxia of central origin.

The prognosis in cases of advanced septic arthritis is poor. Neglected animals may die or have to be destroyed because of open joints or pressure sores. The subsequent development of chronic arthritis and ankylosis may greatly impede locomotion and interfere with the usefulness of the animal.

CLINICAL PATHOLOGY

Arthrocentesis

Aspiration of joint fluid for culture and analysis is necessary for a definitive diagnosis. Careful disinfection of the skin and the use of sterile equipment is essential to avoid the introduction of further infection.

Analysis of joint fluid

Total and differential cell count, total protein concentration and specific gravity are determined.

In infectious arthritis the volume of joint fluid is increased and the total leukocyte count is increased, with a high percentage (80–90%) of neutrophils. The severity of infectious arthritis may be manifested systemically by a leukocytosis with a marked regenerative left shift. In degenerative joint disease, the volume may be normal or only slightly increased and the total and differential leukocyte count may be manifested within the normal range. In traumatic arthritis there may be a marked increase in the number of erythrocytes. Special biochemical examinations of joint fluid are available that measure for viscosity, strength of the mucin clot and concentrations of certain enzymes. The laboratory findings in examination of the joint fluid are summarized in Table 13.2. The synovial fluid analysis of 130 cases in cattle compared the characteristics of animals with infectious and noninfectious arthritis.[10]

Culture of joint fluid

Joint fluid must be cultured for aerobic and anaerobic bacteria and on specific media when *Mycoplasma* sp. is suspected. It is often difficult to isolate bacteria from purulent synovial fluid. The rates of recovery of organisms vary from 40–75%. In one study of suspected infectious arthritis in 64 horses admitted to a veterinary teaching hospital over a period of 8.5 years, positive cultures were obtained from 55% of the joints sampled.[11] The most common organisms were *S. aureus*, *E. coli* and *Pseudomonas aeruginosa*, accounting for more than half the isolates obtained.

There is no single test that is reliable for the diagnosis of septic arthritis. Failure to isolate organisms on culture does not exclude the a bacterial cause, and

organisms are often not observed in synovial fluid smears. Poor collection, storage and laboratory techniques, prior administration of antibiotics or partial success of the immune system in containing the infection may explain the failure to detect organisms. Arthrocentesis should be done before antibiotics are given and a blood culture bottle should be inoculated immediately, a Gram stain made and culture for anaerobes included.[12] Positive cultures from synovial fluid can be expected in only about 65% of cases.

A biopsy sample of synovial membrane may be more reliable than synovial fluid for culture but there is little evidence based on comparative evaluations to support such a claim. PCR has been examined in in-vitro studies to detect selected bacterial species in joint fluid compared with microbial culture.[13] The benefits would include rapid and accurate diagnosis infectious arthritis, ability to detect bacteria in synovial fluid in the presence of antimicrobial drugs and diagnosis of infectious arthritis when culture results are inconclusive. However, initial studies found no difference between microbial culture and PCR analyses.

Serology of joint fluid

Serological tests may be of value in determining the presence of specific infections with *Mycobacterium mycoides*, *Salmonella* spp., *Brucella* spp., and *E. insidiosa*. Radiographic examination may aid in the detection of joint lesions and can be used to differentiate between inflammatory and degenerative changes. In foals with arthritis and suspected osteomyelitis there may be radiographic evidence of osteolysis of the metaphysis or epiphysis.

Radiography

Radiography of the affected joint will often reveal the nature and severity of the lesions. Typical radiographic findings of septic arthritis include osteolytic lesions of the articular cartilage, increased width of intra-articular joint space, and soft tissue swelling. Osteomyelitic changes are seen in some cases. Because radiographic changes usually appear after 2–3 weeks when destruction of subchondral bone has become extensive, it may be necessary to take a series of radiographs several days apart before lesions are detectable.

Ultrasonography

Arthrosonography is an effective, fast and noninvasive complement to traditional diagnostic techniques for comprehensive evaluation of the pathology of joints of cattle.[14] Distension of the joint cavities can be imaged; assessing echogenicity, acoustic enhancement and ultrasonographic character of the exudate correlates well with findings by arthrocentesis, arthrotomy or at necropsy. Joint effusion, which is the earliest indication of septic arthritis, can usually be detected with ultrasound by an experienced operator in the early stages. The synovial membrane, synovial fluid, ligaments, tendons and periarticular soft tissue, only inadequately imaged by radiography, can be imaged with ultrasonography. In advanced septic arthritis, ultrasonography provides accurate information on the location of the soft-tissue swelling, the extent and character of the joint effusion and involvement of concurrent periarticular synovial cavities.

Arthroscopy

Endoscopy is now used widely to define joint abnormalities more clearly and to gain access to the joint cavity as an aid in the treatment of septic arthritis.[15]

NECROPSY FINDINGS

The nature of the lesions varies with the causative organism. The synovial membrane is thickened and roughened and there is inflammation and erosion of the articular cartilage. There is usually an increase in the amount of synovial fluid present, varying from a thin, clear, serous, brownish fluid through a thicker, serofibrinous fluid to pus. There may be some inflammation of the periarticular tissues in acute cases and proliferation of the synovial membrane in chronic cases. In the latter, plaques of inspissated necrotic material and fibrin may be floating free in the synovial fluid. Infectious arthritis due to *A. pyogenes* is characterized by extensive erosion and destruction of articular cartilage and extensive suppuration. There may be a primary omphalophlebitis in newborn animals and metastatic abscesses may be present in other organs.

DIFFERENTIAL DIAGNOSIS

Infectious arthritis is characterized clinically by swollen joints which are painful and warm to touch, and lameness of varying degrees of severity. The volume of joint fluid is usually markedly increased and the leukocyte count is increased with a high percentage of neutrophils. In the early stages of synovitis and in chronic nonsuppurative arthritis, the joint may not be visibly enlarged and careful examination by palpation may be necessary to reveal abnormalities of the joint capsule. Lameness is common, however, even though only slight in some cases, and should arouse suspicion of the possibility of arthritis.

- The diseases of the musculoskeletal system that cause lameness and stiffness of gait include:
  - Degenerative joint disease
  - Osteodystrophy and epiphysitis
  - Osteomyelitis
  - Degenerative myopathy
  - Myositis
  - Traumatic injuries of tendons and ligaments
- Diseases of the nervous system, especially the peripheral nerves and spinal cord, may be confused with arthritis unless the joints are examined carefully
- Some severe cases of polyarthritis may cause recumbency that may be erroneously attributed to the nervous system.

Degenerative joint disease is characterized by an insidious onset of moderate lameness and stiffness of gait that becomes progressively worse over several weeks. The joint capsule is usually not grossly enlarged and not painful, and there is usually no systemic reaction. The total leukocyte count in the joint fluid is only slightly increased and the differential count may be normal. Chronic arthritis is often difficult to differentiate clinically from degenerative joint disease. Chronic arthritis is more common in young animals than in older animals such as rapidly growing yearling bulls, adult bulls, aged dairy cows and horses, in which degenerative arthropathy is most common. A sudden onset of acute lameness and marked swelling of a joint with severe pain suggests an infectious arthritis or traumatic injury to the joint. Marked swelling of several joints suggests infectious polyarthritis.

Osteodystrophy is characterized by:

- Lameness and stiffness of gait
- Usually an absence of joint capsule abnormalities
- Enlargements and deformities of the long bones in growing animals
- A number of animals may be affected at about the same time.

Radiography may reveal the abnormal bones and the nutritional history may explain the cause.

Degenerative myopathy causes acute lameness, a stiff and trembling gait, often leading to recumbency and absence of joint or bone involvement.

Traumatic sprains of tendons or ligaments and fractures of the epiphyses may cause lameness and local pain and, when they involve periarticular tissues, may be difficult to differentiate from arthritis.

Arthritis is never present at birth and apparent fixation of the joints should arouse suspicion of a congenital anomaly. The differentiation between arthritis and diseases of the peripheral nerves or spinal cord, both of which can cause lameness and/or recumbency, may be difficult if the arthritis is not clinically obvious. Diseases of the peripheral nerves cause lameness due to flaccid paralysis and neurogenic atrophy. Lesions of the spinal cord usually result in weakness of the hindlimbs, weak or absent withdrawal reflexes and loss of skin sensation.

TREATMENT

Parenteral antimicrobials

Acute septic arthritis should be treated as an emergency to avoid irreversible changes in the joint. The conservative approach is the use of antimicrobials given parenterally daily for several days and up to a few weeks in some cases. The selection of the drug of choice will depend on the suspected cause of the arthritis. The antimicrobial sensitivities of bacterial isolates from horses with septic arthritis/synovitis or osteomyelitis after fracture repair vary widely. A combination of cephalosporin and amikacin is recommended before culture and sensitivity results are available.

The antimicrobials that perfuse into the joint in therapeutic concentrations include the natural and synthetic penicillins, tetracycline, trimethoprim-potentiated sulfonamides, neomycin, gentamicin, and kanamycin.

Cloxacillin, methicillin, or penicillin have been used successfully for the treatment of staphylococcal septic arthritis in the horse.

Amphotericin B given intravenously daily for up to 30 days combined with joint drainage has been used for the treatment of *Candida* sp. arthritis in the horse.[16]

The relative efficacies of antimicrobials administered parenterally versus by intra-articular injections has been uncertain. Trimethoprim–sulfadiazine, given to calves parenterally, results in therapeutic concentrations of the drug in the synovial fluid of calves and penetrability was not enhanced nor restricted by experimental joint inflammation. Oxytetracycline and penicillin given parenterally readily penetrate the synovial membrane of both normal neonatal calves and those with experimental arthritis. Since peak synovial joint fluid levels of oxytetracycline and penicillin exceeded the minimum inhibitory concentrations for organisms such as *A. pyogenes*, the use of parenteral antimicrobials for the treatment of infectious arthritis in calves is appropriate. Ceftiofur at 1 mg/kg BW intravenously every 12 hours for 20 days, along with joint lavage, was successful in treating experimental septic arthritis associated with *E. coli*.[6] The duration of antibiotic therapy is empirical; 3 weeks is recommended. Cephapirin administered parenterally to normal calves or those with arthritis resulted in synovial fluid levels approximately 30% of serum levels. The use of ampicillin trihydrate in calves with suppurative arthritis, at a dose of 10 mg/kg BW intramuscularly, resulted in a peak serum concentration of 2.5 µg/mL, 2 hours after injection; the highest concentration in normal synovial fluid was 3.5 µg/mL at 4 hours and the highest concentration in suppurative synovial fluid was 2.7 µg/mL at 2 hours.

Marbofloxacin at 4 mg/kg BW intramuscularly daily for 10 days was effective for the treatment of infectious arthritis in calves.[17] Amoxicillin at 40 mg/kg BW intravenously is effective for the treatment of infectious joint disease in horses.[18]

The administration of trimethoprim–sulfadiazine at 30 mg/kg BW orally once daily to horses with experimentally induced *S. aureus* arthritis was ineffective in maintaining adequate levels of both drugs in infected synovial fluid. The use of the same drug at 30 mg/kg BW orally given every 12 hours was effective in maintaining therapeutic concentrations of both drugs in the serum and in the joint fluid.

In piglets at 2 weeks of age, streptococcal arthritis is most likely and it will respond quickly to penicillin given parenterally. Likewise, acute arthritis associated with erysipelas in pigs will respond beneficially if treated early before there is pannus formation.

Synovitis due to *Histophilus somni* infection responds quickly to systemic treatment. However, in other specific types of infectious arthritis the response is poor and recovery, if it does occur, requires several days or a week. Mycoplasmal arthritis in cattle is relatively non-responsive to treatment and affected cattle may be lame for up to several weeks before improvement occurs and complete recovery may not occur. Chronic arthritis due to infection of pigs with *E. insidiosa* will commonly develop into a rheumatoid- like arthritis and be refractory to treatment.

Failure to respond to conservative therapy has been attributed to:

- Inadequate concentrations of antimicrobials achieved in the joint cavity
- Presence of excessive amounts of exudate and fibrin in the joint making the infectious agent inaccessible to the antimicrobial
- Drug-resistant infections
- The development of rheumatoid-like arthritis, which is chronic and progressive.

It is often not possible to determine which situation is responsible.

If conservative treatment is not providing sufficient improvement and the value of the animal warrants extended therapy, a joint sample should be obtained for culture and sensitivity. The most suitable antimicrobial may then be given parenterally and/or by intra-articular injection. Strict asepsis is necessary to avoid introduction of further infection.

Intra-articular antimicrobials

The combined intra-articular and intravenous administration of gentamicin to normal horses can result in concentrations 10–100 times greater than after intravenous administration alone. In addition, gentamicin concentration in synovial fluid remained above the minimum inhibitory concentration for many common equine bacterial pathogens for at least 24 hours after treatment. The intra-articular administration of gentamicin is advantageous for the treatment of infectious arthritis in animals in which the systemic administration of the drug may be contraindicated, especially in the presence of impaired renal function or endotoxemia. Continuous infusion of gentamicin into the tarsocrural joint of horses for 5 days is an acceptable method of treating septic arthritis.[19]

Antimicrobial-impregnated polymethylmethacrylate beads have been used for the treatment of orthopedic infections involving bone, synovial structures and other soft tissues.[20–22] The antimicrobials diffuse from the beads in a bimodal fashion. There is a rapid release of 5–45% of the total amount of antimicrobial within the first 24 hours after implantation and then a sustained elution that persists for weeks to months, depending on the antimicrobial used. For effective diffusion, the antimicrobials must be water-soluble, heat-stable and available in powder form. Aminoglycosides and the cephalosporins have been incorporated most commonly into the beads.

Regional limb perfusion with antimicrobials has been used for the treatment of experimentally induced septic arthritis. The antimicrobial is infused under pressure to a selected region of the limbs through the venous system. The concentration of the antimicrobial in the septic synovial fluid will usually exceed those obtained by intravenous administration. However, there are insufficient data available to evaluate the procedure in naturally occurring cases. Therapeutic concentrations of cefazolin are achieved in the synovial fluid of clinically normal cows when injected intravenously distal to a tourniquet and the technique could be used as an alternative to systemic administration of antimicrobials to provide adequate concentrations in a joint cavity.

Lavage of joint

Drainage of the affected joint and through-and-through lavage of the joint is also desirable along with the systemic administration of antimicrobials. Aspiration and distension–irrigation of the joint cavity using polyionic electrolyte solutions buffered to 7.4 is recommended.[6] The

irrigation removes exudates and lysozymes that destroy articular cartilage. A through-and-through lavage system may also be used with drainage tubes. General or local anesthesia should be provided. The distended joint is identified by palpation, the hair is clipped short and the skin is prepared with appropriate surgical disinfection. A 2 cm 16-gauge needle is inserted into the joint cavity, avoiding direct contact with the bones of the joint. A second needle is inserted into the joint as far as possible from the first needle to cause any fluid perfused into the joint to pass through as much of the joint cavity as possible. 0.5–1 L of Ringer's solution warmed to 37°C is flushed through the joint using a hand-pumped pressure bag to keep a steady fluid flow into the joint.[6]

Arthroscopy

Arthroscopy provides excellent visualization of most parts of an affected joint and can be used to access the joint for the treatment of septic arthritis.[15] The endoscope can be used to explore and debride the affected joint during the same intervention. Purulent exudate can be removed and necrotic areas within the synovial membrane can be debrided.

Surgical drainage and arthrotomy

Failure to respond to parenteral and intra-articular medication may require surgical opening of the joint capsule, careful debridement and excision of synovium and infected cartilage and bone. This may be followed by daily irrigation of the joint cavity with antimicrobials and saline. A lavage system can be established and the joint cavity infused with an antimicrobial and saline daily for several days.[23] Arthrotomy with lavage was more effective in eliminating joint infections by providing better drainage than arthroscopy, synovectomy and lavage. However, with arthrotomy the risk of ascending bacterial contamination is greater and the major difficulty is to eliminate the infection from the joint and incision site.[24] Infected sequestra and osteomyelitis of subchondral bone will prevent proper healing. Curettage of septic physeal lesions in foals may be necessary.

Open drainage and intra-articular and parenteral antimicrobials has been used to treat persistent or severe septic arthritis/tenosynovitis. While joint lavage through needles is still effective in many horses with acute infectious arthritis or tenosynovitis, in those with chronic or recurring septic arthritis, open drainage is indicated to remove the inflammatory exudate from the synovial space. Infected synovial structures are drained through a small (3 cm) arthrotomy incision left open and protected by a sterile bandage. Joint lavage using antimicrobials is done daily and parenteral antimicrobials are given intensively.

Septic pedal arthritis in cattle may be treated successfully by the creation of a drainage tract to promote adequate drainage. In cattle with septic arthritis of the digit, placement of a wooden block under the unaffected digit decreases weight-bearing on the affected digit and provides for earlier, less painful ambulation.[25]

Arthrodesis or artificial ankylosis

Surgical arthrodesis can be used for the treatment of chronic septic arthritis in horses and calves.[26,27]

Septic arthritis of the distal interphalangeal joint is a common complication of diseases of the feet of cattle. Facilitated ankylosis of the joint is a satisfactory alternative to amputation of the affected digit in valuable breeding animals.[28] In a series of 12 cases of septic arthritis of the distal interphalangeal joint treated by use of facilitated ankylosis, the success rate was 100%.

Physical therapy

The local application of heat, by hot fomentations or other physical means, is laborious but, if practiced frequently and vigorously, will reduce the pain and local swelling. Analgesics are recommended if there is prolonged recumbency. Persistent recumbency is one of the problems in the treatment of arthritis, particularly in foals. The animal spends little time feeding or sucking and loses much condition. Compression necrosis over bony prominences is a common complication and requires vigorous preventive measures.

Anti-inflammatory agents

NSAIDs are used parenterally to decrease the inflammatory response and to provide analgesia. In experimental synovitis in the horse, similar to septic arthritis, phenylbutazone was more effective than ketoprofen in reducing lameness, joint temperature, synovial fluid volume and synovial fluid prostaglandin.[29]

Prognosis for survival and athletic use in horses with septic arthritis

The factors affecting the prognosis for survival and athletic use in 93 foals treated for septic arthritis have been examined.[12] The femoropatellar and tarsocrural joints were most commonly affected. Osteomyelitis or degenerative joint disease were detected in 59% of the foals. Failure of transfer of passive immunity, pneumonia and enteritis were common. Treatment consisted of lavage, lavage and arthroscopic debridement with or without partial synovectomy, or lavage and arthrotomy to debride infected bone and parenteral antibiotics. Seventy-five foals survived and were discharged from hospital, and approximately one-third raced. Isolation of *Salmonella* from synovial fluid was associated with an unfavorable prognosis for survival, and multisystemic disease was associated with an unfavorable prognosis for survival and ability to race. The key to successful outcome for septic arthritis is rapid diagnosis and initiation of treatment.

In a series of 507 horses treated for joint disease at one equine hospital during a period of 7 years, the risk factors affecting discharge from the hospital, of ever being sound, or of being alive after a 3-month followup were examined;[30] 58% of foals, 78% of yearlings and 94% of racing adults were discharged. Foals with a less severe lameness, duration of less than 1 day and infectious arthritis had increased odds of discharge.

CONTROL

The control of infectious arthritis is of major importance in newborn farm animals. The early ingestion of adequate quantities of good-quality colostrum and a clean environment for the neonate are necessary. The prophylactic use of antimicrobials may be considered to reduce incidence. Some of the infectious arthritides associated with specific diseases can be controlled through immunization programs. For example, vaccination of piglets at 6–8 weeks of age will provide protection against both the septicemic and arthritic forms of erysipelas.

Congenital defects of muscles, bones, and joints

Defects of the musculoskeletal system are among the most common congenital abnormalities in farm animals. In cattle 476 such defects are listed. Many of them are lethal, and most of the remainder are life-threatening because of interference with grazing or the prehension of food. Many of them occur in combinations so that single defects are uncommon. For example, most axial skeletal defects and cleft palates occur in calves that already have arthrogryposis.

Because of the very large volume of literature involved it is not possible to deal with all the recorded defects here, and the text is limited to those defects that are thought to be of general importance. Whether or not they are inherited or have an environmental cause is often not known so that an etiological classification is not very effective. Nor is an anatomical or pathological classification, so we are reduced to a classification based on abnormal function.

FIXATION OF JOINTS

Because arthrogryposis, which has been used to convey the description of joint fixation, strictly means fixation in flexion, the term congenital articular rigidity has been introduced. The immobilization of the joint may be due to lack of extensibility of muscles, tendons, ligaments or other tissues around the joint, or to deformity of articular surfaces, or theoretically to fusion between the bones at the articular surface. Muscle contracture, which is the principal cause of joint fixation, has been produced experimentally, and occurs naturally, as a result of primary muscle atrophy or of atrophy resulting from denervation. Articular surface deformity is usually associated with gross deformity of the limb bones and is usually identifiable but the principal problem in the diagnosis of congenital articular rigidity is to determine what the pathogenesis might have been and, beyond that, what was the specific cause.

Congenital fixation of joints can be caused by some well known entities, as follows.

Cattle
- Hereditary congenital articular rigidity (HCAR) with cleft palate in Charolais
- HCAR with normal palates in Friesians, Danish Reds, Swedish, Shorthorns
- Inherited arthrogryposis
- Inherited multiple tendon contracture
- Inherited multiple ankylosis of Holstein–Friesian cattle.

Environmentally induced congenital articular rigidity caused by:

- Intrauterine infection with Akabane virus
- Ingestion of lupins
- Ingestion of *Astragalus* and *Oxytropis* spp. (locoweeds)
- Sorghum, Johnson grass, Sudan grass
- Dietary deficiency of manganese.

Sheep and goats
- Inherited congenital articular rigidity in Merino sheep
- Infection with Akabane virus
- Poisonous plants as for cattle
- Poisoning with parbendazole and cambendazole.

Piglets
- Inherited congenital articular rigidity
- Nutritional deficiency of vitamin A
- Poisonous plants, hemlock (*Conium maculatum*), *Prunus serotina*, Jimson weed (*Datura stramonium*), tobacco wastes.

Foals
- **'Contracted' foals** having congenital axial and appendicular contractures of joints in the us, cause unknown, not thought to be inherited. Deformities include torticollis, scoliosis, thinning of ventral abdominal wall, sometimes accompanied by eventration, asymmetry of the skull, flexion contracture in distal limb joints
- **Congenital articular rigidity** also occurs in foals from mares fed on hybrid Sudan grass pastures
- **Sporadic cases of congenital joint deformity** occur in foals and calves. They are manifested usually by excessive flexion of the metacarpophalangeal joints causing affected animals to 'knuckle' at the fetlocks and sometimes walk on the anterior aspect of the pastern. A similar defect occurs in the hindlegs. Many mild cases recover spontaneously but surgical treatment may be required in badly affected animals. The cause in these sporadic cases in unknown and necropsy examination fails to reveal lesions other than excessive flexion of the joints caused by shortening of the flexor tendons. Rarely such fixations are associated with spina bifida or absence of ventral horn cells of the spinal cord.

HYPERMOBILITY OF JOINTS

This is recorded as an inherited defect in Jersey cattle. Affected animals are unable to rise or stand because of the lack of fixation of limb joints. The joints and limbs are usually all affected simultaneously and are so flexible that the limbs can be tied in knots. Causes include:

- Inherited joint hypermobility in Jersey cattle
- Heredity in Holstein–Friesian cattle, which also have pink teeth due to absence of enamel
- In inherited congenital defects of collagen formation including dermatosparaxis, hyperelastosis cutis and Ehlers–Danlos syndrome in cattle
- Sporadically in newborn animals.

WEAKNESS OF SKELETAL MUSCLES

A number of sporadic myopathies are recorded in cattle and sheep. Causes have not been determined in most of them. Splayleg in pigs has been well described and occurs in most countries.

CONGENITAL HYPERPLASIA OF MYOFIBER

There is only one identified state; it is the inherited form of doppelender, double muscling or culard of cattle, described in Chapter 35. The principal cause of the bulging muscles is an increase in the number of myofibers in the muscle.

OBVIOUS ABSENCE OR DEFORMITY OF SPECIFIC PARTS OF THE MUSCULOSKELETAL SYSTEM

A number of these defects are known to be inherited and are dealt with in Chapter 34. They include:

- Achondroplastic dwarfism, inherited miniature calves, bulldog calves
- Umbilical, scrotal hernia, cryptorchidism
- Tail deformity (kinking), taillessness
- Reduced phalanges, including hemimelia (individual bones missing), amputates (entire limbs missing), vestigial limbs (all parts present but limbs miniaturized). Amputates in outbreak form are recorded in cattle and produced experimentally by irradiation injury of sows, cows and ewes during early pregnancy.

Inherited arachnomyelia (spidery limbs) of calves
- Congenital thickleg of pigs, osteopetrosis of calves, muscular hypertrophy of calves
- Cyclopian deformity. Inherited form associated with prolonged gestation. Toxic form associated with ingestion of *Veratrum californicum*
- Displaced molar teeth, mandibular prognathism. Agnathia in lambs takes a variety of forms, including complete absence of lower jaw and tongue.

Diseases of the skin, conjunctiva, and external ear

14

Introduction

The major functions of the skin are:

- To maintain a normal body temperature
- To maintain a normal fluid and electrolyte balance within the animal
- To act as a sensory organ perceiving those features of the environment which are important to the subject's survival.

In general these functions are not greatly impeded by most diseases of the skin of large animals, with the exceptions of failure of the sweating mechanism, which does seriously interfere with body temperature regulation, and severe burns or other skin trauma, which may cause fatal fluid and electrolyte loss.

The major effects of skin diseases in large animals are esthetic and economic. The unsightly appearance of the animal distresses the owner. Discomfort and scratching interfere with normal rest and feeding and when the lips are affected there may be interference with prehension. There is loss of the economic coat and the sales value and acceptability of animals for transport and appearance in exhibitions, especially in other sovereign states, is greatly reduced.

Primary/secondary lesions

Diseases of the skin may be primary or secondary in origin. In primary skin disease the lesions are restricted initially to the skin although they may subsequently spread from the skin to involve other organs. On the other hand, cutaneous lesions may be secondary to disease originating in other organs. Differentiation between primary and secondary skin diseases should be attempted by seeking evidence that organs other than the skin are affected. If there is no such evidence produced during a complete clinical examination of the patient, it is reasonable to assume that the disease is primary. Even if involvement of other organs is diagnosed it is still necessary to determine whether the involvement constitutes the primary state or whether it has developed secondarily to the skin disease. This decision can be based on the chronology of the signs, elicited by careful history-taking, and a detailed knowledge of the individual diseases likely to be encountered.

When a careful clinical examination has been made and an accurate history taken it is then necessary to make a careful examination of the skin itself, using the proper technique of examination, especially (and essentially) histopathological examination of a biopsy specimen. It is then possible to determine the basic defect, whether it be inflammatory, degenerative or dysfunctional, and thus to define the type of lesion present.

The purpose of this chapter is to describe the basic skin lesions so that the differential diagnosis, up to the point of defining the type and nature of the lesion, the pathoanatomical diagnosis, can be accomplished. A definitive etiological diagnosis requires further examination and is included in the discussion of the specific diseases in Part Two of this book.

Clinical signs and special examination

A general clinical examination is followed by a special examination of the skin and must include inspection and, in most cases, palpation. Additional information can be obtained by taking swabs for bacteriological examinations, scrapings for examination for dermatophytes and metazoan parasites, and biopsy for histopathological examination.

Biopsy material should include abnormal, marginal, and normal skin. Artifacts are common in biopsy specimens, including nonrepresentative sampling, crushing the specimen by forceps or hemostat, and inadequate fixation.

Wood's lamp finds a special use in the examination of the skin for dermatophytes.

Descriptions of lesions should include size, depth to which they penetrate, geographical distribution on the body and size of the area covered. Abnormalities of sebaceous and sweat secretion, changes in the hair or wool coat and alterations in color of the skin should be noted, as should the presence or absence of pain or

pruritus and the manifestations of skin disease and the common lesions defined below.

Lesions

An accurate definition of the lesions, summarized in Table 14.1, is an essential part of a skin patient's clinical record. The table makes a primary differentiation into discrete and diffuse lesions and these categories need to be further categorized in terms of size, e.g. they may be limited diffuse lesions or extensive localized ones.

Abnormal coloration

This parameter includes jaundice, pallor and erythema, and these are best seen in the oral or vaginal mucosa or in the conjunctiva. In animals they are rarely visible in light-colored skins. Red–purple discoloration of the skin of septicemic, white pigs may be dramatic but no diagnostic significance can be attached to its degree. Early erythema is a common finding where more definite skin lesions are to develop, as in early photosensitization. The blue coloration of early gangrene (e.g. of the udder and teat skin in the early stages of peracute bovine mastitis associated with *Staphylococcus aureus*) is characterized by coldness and loss of elasticity.

Hypopigmentation of the skin may be general, as in albino, pseudoalbino and lethal white animals. Local patches of hypopigmentation are characteristic of vitiligo and leukoderma.

Pruritus

- **Pruritus or itching** is the sensation that gives rise to scratching
- **Hyperesthesia** is increased sensitivity to normal stimuli
- **Paresthesia** is perverted sensation, a subjective sensation, and not diagnosed in animals.

All sensations that give rise to rubbing or scratching are therefore included with pruritus, more properly defined as scratching. Pruritus can arise from peripheral or central stimulation. When it is peripheral in origin it is a primary cutaneous sensation like heat, cold, pain and touch; it differs from pain because it is purely epidermal, whereas pain can still be felt in areas of skin denuded of epidermis. Thus itching does not occur in the center of deep ulcerations nor in very superficial lesions, such as those of ringworm, where only the hair fibers

Table 14.1 Terms used to identify skin lesions

Name of lesion	Nature of lesion	Relation to skin surface	Skin surface
Scales	Dry, flaky exfoliations	On surface only, no penetration of skin	Unbroken
Excoriations	Traumatic abrasions and scratches	Penetration below surface	Variable skin surface damage – depends on severity
Fissures	Deep cracks	Penetrate into subcutis	Disrupted
Dry gangrene	Dry, horny, black, avascular, shield-like	Above skin, usually all layers affected	Removed
Early, moist gangrene	Blue-black, cold, oozing serum	In plane of skin or below	Complete depth of subcutis
Keratosis	Overgrowth of dry, horny, keratinized epithelium	Above skin	Undamaged stratum corneum is retained
Acanthosis	Like keratosis but moist, soft	Above skin	Prickle cell layer swollen; is really part of skin
Hyperkeratosis	Excessive overgrowth of keratinized, epithelium-like scab	Above skin	Skin surface unbroken
Parakeratosis	Adherent to skin	Above skin	Cells of stratum corneum nucleated and retained; really part of skin
Eczema	Erythematous, itching dermatitis	Superficial layer of epidermis affected	Weeping, scabby disruption of surface
Hypermelanosis	Increased deposits of melanin, e.g. melanosis, meloderma	In epidermis or dermis	Unbroken
Hypomelanosis	Decreased deposits of melanin	In epidermis or dermis	Unbroken
Discrete lesions			
Vesicle, bleb, bulla, blister	Fluid (serum or lymph)-filled blister 1–2 cm diameter	Above skin surface, superficial	Unbroken but will slough
Pustule	Pus-filled blister, 1–5 mm	Above, superficial	Will rupture
Wheal	Edematous, erythematous, swellings, transitory	Above, all layers affected	Undamaged
Papules (pimples)	Elevated, inflamed, necrotic center, up to 1 cm diameter	Above surface, all layers affected	Points and ruptures
Nodules, nodes	Elevated, solid, up to 1 cm diameter. Acute or chronic inflammation. No necrotic center	Above surface, all layers	Surface unbroken
Plaque	A larger nodule, up to 3–4 cm diameter	All layers affected; raised above surface	Surface unbroken
Acne	Used synonymously with pimple but strict meaning is infection of sebaceous gland	Above surface of skin; all layers affected	May point and rupture
Comedo	Plugged (sebum, keratin) hair follicle	Raised above skin	May rupture
Impetigo	Flaccid vesicle, then pustule, then scab, up to 1 cm diameter	Raised above skin; very superficial	Upper layers destroyed
Scab (or crust)	Crust of coagulated, blood, pus and skin debris	Raised above skin	Disrupted, depth varying with original lesion
Macule (patch)	Small area of color change; patch is larger	Within superficial layers	Unbroken

[1] *Above skin, usually all*
[2] *Pyoderma is any infection of skin; includes impetigo, acne, pustule, pimple*

and keratinized epithelium are involved. Itching can be elicited over the entire skin surface but is most severe at the mucocutaneous junctions. Common causes include the following.

Cattle
- Sarcoptic and chorioptic mange
- Aujeszky's disease
- Nervous acetonemia
- Lice infestation.

Sheep
- Lice, mange, ked, blowfly and itch-mite infestations
- Scrapie.

Pigs
- Sarcoptic and chorioptic mange
- Lice infestation.

Horses
- Chorioptic mange on the legs
- Queensland (sweet) itch along the dorsum of the body
- Lice infestation
- Perianal pruritus due to *Oxyuris equi* infestation.

All species
- The early stages of photosensitive dermatitis
- Urticarial wheals in an allergic reaction
- **'Licking syndromes'** such as occur in cattle on copper-deficient diets are accompanied by pica and the licking of others as well as themselves. They are examples of depraved appetites developed in response to nutritional deficiency and are not a response to pruritus
- **Itching of central origin** derives in the main from the scratch center below the acoustic nucleus in the medulla. It may have a structural basis, as in scrapie and pseudorabies, or it may be functional in origin, as in the nervous form of acetonemia. The only lesions observed are those of a traumatic dermatitis with removal of the superficial layers to a variable depth, breakage or removal of the hairs and a distribution of lesions in places where the animal can bite or rub easily.

Secretion abnormalities of skin glands

The activity of the **sweat glands** is controlled by the sympathetic nervous system and is for the most part a reflection of body temperature. Excitement and pain may cause sweating due to cerebral cortical activity. A generalized form of hyperhidrosis, apparently inherited, has been recorded in Shorthorn calves. Local areas of increased or decreased sweating may arise from peripheral nerve lesions or obstruction of sweat gland ducts. A generalized anhidrosis is recorded in horses and occasionally in cattle.

Excess secretion of sebum by **sebaceous glands** causes oiliness of the skin or seborrhea but its pathogenesis is poorly understood.

Abnormalities of wool and hair fibers

Deficiency of hair or wool in comparison to the normal pilosity of the skin area **is alopecia** or **hypotrichosis**.

Hirsutism, abnormal hairiness, manifested by a long, shaggy, usually curly, coat is most common in aged ponies with adenomas of the pars intermedia of the pituitary gland.

The character of the fiber may also vary with variations in the internal environment. For example, in copper deficiency the crimp of fine wool fibers is lost and the wool becomes straight and 'steely'. Alternation in coat color, achromotrichia, may be generalized or segmental along the fiber.

Principles of treatment of diseases of the skin

PRIMARY TREATMENT

Primary treatment commences with removal of hair coat and debris to enable topical applications to come into contact with the causative agent. Accurate diagnosis of the cause must precede the selection of any topical or systemic treatment. In bacterial diseases sensitivity tests on cultures of the organism are advisable. Specific skin diseases due to bacteria, fungi and metazoan parasites are reasonably amenable to treatment with the appropriate specific remedy.

Bacterial resistance to antimicrobials used in veterinary dermatological practice is a concern.[1] The broad application of antimicrobials for various therapeutic and nontherapeutic purposes has accelerated the spread of pre-existing resistance genes and led to the apparent development of mechanisms by which resistance genes are spread, not only within a bacterial species, but also between bacterial species. Every veterinarian must strive to practice prudent use of antimicrobials in order to minimize the resistance problem.

Removal of the causative agent in allergic diseases and photosensitization may be impossible and symptomatic treatment may be the only practicable solution. In many cases, too, the primary disease may be confounded by the presence of a secondary agent, which can lead to confusion in diagnosis. Treatment may be unsuccessful if both agents are not treated.

SUPPORTIVE TREATMENT

Supportive treatment includes prevention of secondary infection by the use of bacteriostatic ointments or dressings and the prevention of further damage from scratching.

- Effective treatment of pruritus depends upon the reduction of central perception of itch sensations by the use of ataractic, sedative or narcotic drugs administered systemically or on successful restraint of the mediator between the lesion and the sensory end organ. In the absence of accurate knowledge of the pathogenesis of pain it is usual to resort to local anesthetic agents, which are shortlived in their activity, and corticosteroids, which are longer-acting and effective, provided that vascular engorgement is part of the pruritus-stimulating mechanism
- When large areas of skin are involved it is important to prevent the absorption of toxic products by continuous irrigation or the application of absorptive dressings. Losses of fluid and electrolytes should be made good by the parenteral administration of isotonic fluids containing the necessary electrolytes
- Ensure an adequate dietary intake of protein, particularly sulfur-containing amino acids to facilitate the repair of skin tissues
- Boredom contributes significantly to an animal's response to itch stimuli, and close confinement of affected animals is best avoided.

Diseases of the epidermis and dermis

PITYRIASIS

Primary pityriasis, excessive bran-like scales on the skin, characterized by overproduction of keratinized epithelial cells, can be caused by:

- Hypovitaminosis A
- Nutritional deficiency of B vitamins, especially of riboflavin and nicotinic acid, in pigs, or linolenic acid, and probably other essential unsaturated fatty acids
- Poisoning by iodine
- Pityriasis rosea occurs in humans and pigs and the etiology is unknown. The literature for and against an infectious etiology has been reviewed.[1]

Secondary pityriasis, characterized by excessive desquamation of epithelial cells is usually associated with:

- Scratching in flea, louse and mange infestations
- Keratolytic infection, e.g. with ringworm fungus.

Pityriasis scales are accumulations of keratinized epithelial cells, sometimes softened and made greasy by the exudation of serum or sebum. Overproduction, when it occurs, begins around the orifices of the hair follicles and spreads to the surrounding stratum corneum.

Primary pityriasis scales are superficial, accumulate where the coat is long, and are usually associated with a dry, lusterless coat. Itching or other skin lesions are not features. Secondary pityriasis is usually accompanied by the lesions of the primary disease.

Pityriasis is identified by the absence of parasites and fungi from skin scrapings.

DIFFERENTIAL DIAGNOSIS

- Hyperkeratosis (see below)
- Parakeratosis (see below)

TREATMENT

Primary treatment requires correction of the primary cause.

Supportive treatment commences with a thorough washing, followed by alternating applications of a bland, emollient ointment and an alcoholic lotion. Salicylic acid is frequently incorporated into a lotion or ointment with a lanolin base.

HYPERKERATOSIS

Epithelial cells accumulate on the skin as a result of excessive keratinization of epithelial cells and intercellular bridges, interference with normal cell division in the granular layer of the epidermis and hypertrophy of the stratum corneum.

Lesions may be **local** at pressure points, e.g. elbows, when animals lie habitually on hard surfaces. **Generalized hyperkeratosis** may be caused by:

- Poisoning with highly chlorinated naphthalene compounds
- Chronic arsenic poisoning
- Inherited congenital ichthyosis
- Inherited dyserythropoiesis–dyskeratosis.

The skin is dry, scaly, thicker than normal, usually corrugated, hairless and fissured in a gridlike pattern. Secondary infection of deep fissures may occur if the area is continually wet. However, the lesion is usually dry and the plugs of hyperkeratotic material can be removed, leaving the underlying skin intact.

Confirmation of the diagnosis is by the demonstration of the characteristically thickened stratum corneum in a biopsy section, which also serves to differentiate the condition from parakeratosis (see below) and inherited ichthyosis.

Primary treatment depends on correction of the cause. Supportive treatment is by the application of a keratolytic agent (e.g. salicylic acid ointment).

PARAKERATOSIS

Parakeratosis, a skin condition characterized by incomplete keratinization of epithelial cells, can be:

- Caused by nonspecific chronic inflammation of cellular epidermis
- Associated with dietary deficiency of zinc
- Part of an inherited disease listed below.

The initial lesion comprises edema of the prickle cell layer, dilatation of the intercellular lymphatics, and leukocyte infiltration. Imperfect keratinization of epithelial cells at the granular layer of the epidermis follows, and the horn cells produced are sticky and soft, retain their nuclei and stick together to form large masses, which stay fixed to the underlying tissues or are shed as thick scales.

The lesions may be extensive and diffuse but are often confined to the flexor aspects of joints (referred to historically in horses as mallenders and sallenders). Initially the skin is reddened, followed by thickening and gray discoloration. Large, soft scales accumulate, are often held in place by hairs and usually crack and fissure, and their removal leaves a raw, red surface. Hyperkeratosis scales are thin, dry and accompany an intact, normal skin.

Confirmation of a diagnosis of parakeratosis is by the identification of imperfect keratinization in a histopathological examination of a biopsy or a skin section at necropsy.

DIFFERENTIAL DIAGNOSIS

- Hyperkeratosis (see above)
- Pachyderma (see below)
- Ringworm
- Inherited ichthyosis
- Inherited Adema disease in cattle
- Inherited dermatosis vegetans in pigs
- Inherited epidermal dysplasia

TREATMENT

Primary treatment requires correction of any nutritional deficiency.

Supportive treatment includes removal of the crusts by the use of keratolytic agent (e.g. salicylic acid ointment) or by vigorous scrubbing with soapy water, followed by application of an astringent (e.g. white lotion paste), which must be applied frequently and for some time after the lesions have disappeared.

PACHYDERMA

Pachyderma, including scleroderma, is thickening of the skin affecting all layers, often including subcutaneous tissue, and usually localized but often extensive as in lymphangitis and greasy heel in horses. There are no specific causes, most cases being due to nonspecific chronic or recurrent inflammation.

In affected areas the hair coat is thin or absent and the skin is thicker and tougher than usual. It appears tight and, because of its thickness and reduced volume of subcutaneous tissue, cannot be picked into folds or moved easily over underlying tissue. The skin surface is unbroken and there are no lesions and no crusts or scabs as in parakeratosis and hyperkeratosis (see above).

Confirmation of the diagnosis depends on histopathological examination of a biopsy. The cells in all layers are usually normal but the individual layers are increased in thickness. There is hypertrophy of the prickle cell layer of the epidermis and enlargement of the interpapillary processes.

DIFFERENTIAL DIAGNOSIS

- Parakeratosis (see above)
- Cutaneous neoplasia
- Papillomatosis

TREATMENT

Primary treatment requires removal of the causal irritation but in well-established

cases little improvement can be anticipated, and surgical removal may be a practical solution when the area is small. In early cases local or systemic corticosteroids may effect a recovery.

IMPETIGO

A superficial eruption of thin-walled, small vesicles, surrounded by a zone of erythema, that develop into pustules, then rupture to form scabs.

In humans, impetigo is specifically a streptococcal infection but lesions are often invaded secondarily by staphylococci. In animals the main organism found is usually a staphylococcus. The causative organism appears to gain entry through minor abrasions, with spread resulting from rupture of lesions causing contamination of surrounding skin and the development of secondary lesions. Spread from animal to animal occurs readily.

The only specific examples of impetigo in large animals are:

- Udder impetigo of cows
- Infectious dermatitis or 'contagious pyoderma' of baby pigs associated with unspecified streptococci and staphylococci.

Small (3–6 mm) vesicles appear chiefly on the relatively hairless parts of the body and do not become confluent. In the early stages each vesicle is surrounded by a narrow zone of erythema. No irritation is evident. Vesicle rupture occurs readily but some persist as yellow scabs. Involvement of hair follicles is common and leads to the development of acne and deeper, more extensive lesions. Individual lesions heal rapidly in about a week but successive crops of vesicles may prolong the duration of the disease.

Confirmation of the diagnosis is by culture of vesicular fluid and identification of the causative bacterium and its sensitivity.

DIFFERENTIAL DIAGNOSIS

- Cowpox, in which the lesions occur almost exclusively on the teats and pass through the characteristic stages of pox
- Pseudocowpox, in which lesions are characteristic and also restricted in occurrence to the teats.

TREATMENT

Primary treatment with antibiotic topically is usually all that is required because individual lesions heal so rapidly.

Supportive treatment is aimed at preventing the occurrence of secondary lesions and spread of the disease to other animals. Twice daily bathing with an efficient germicidal skin wash is usually adequate.

URTICARIA

An allergic condition characterized by cutaneous wheals. It is most common in horses.[2]

ETIOLOGY

Primary urticaria results directly from the effect of the pathogen, e.g.:

- Insect stings
- Contact with stinging plants
- Ingestion of unusual food, with the allergen, usually a protein
- Occasionally an unusual feed item, e.g. garlic to a horse[3]
- After a recent change of diet
- Administration of a particular drug, e.g. penicillin; possibly guaifenesin or other anesthetic agent[4]
- Allergic reaction in cattle 8 days following vaccination for foot-and-mouth disease[5]
- Death of warble fly larvae in tissue
- Milk allergy when Jersey cows are dried off
- Transfusion reaction.

Secondary urticaria occurs as part of a syndrome, e.g.:

- Respiratory tract infections in horses, including strangles and the upper respiratory tract viral infections
- Erysipelas in pigs.

PATHOGENESIS

The lesions are characteristic of an allergic reaction. There is degranulation of mast cells followed by liberation of chemical mediators inflammation, resulting in the subsequent development of dermal edema. A primary dilatation of capillaries causes cutaneous erythema. Exudation from the damaged capillary walls causes local edema in the dermis and a wheal develops. Only the dermis, and sometimes the epidermis, is involved. In extreme cases the wheals may expand to become seromas, when they may ulcerate and discharge. The lesions of urticaria usually resolve in 12–24 hours but in recurrent urticaria an affected horse may have persistent and chronic eruption of lesions over a period of days or months.[6]

CLINICAL FINDINGS

Wheals, mostly circular, well delineated, steep-sided, easily visible elevations in the skin, appear very rapidly and often in large numbers, commencing usually on the neck but being most numerous on the body. They vary from 0.5–5 cm in diameter, with a flat top, and are tense to the touch. There is often no itching, except with plant or insect stings, nor discontinuity of the epithelial surface, exudation or weeping. Pallor of the skin in wheals can be observed only in unpigmented skin. Other allergic phenomena, including diarrhea and slight fever, may accompany the eruption. The onset of the lesions is acute to peracute with the wheals developing within minutes to hours after exposure to the triggering agent. When associated with severe adverse systemic responses, including apnea, respiratory arrest, atrial fibrillation, cardiac arrest or sudden death, the case qualifies as one of anaphylaxis.

Subsidence of the wheals within 24–48 hours is usual but they may persist for 3–4 days because of the appearance of fresh lesions. In some very sensitive horses, dermatographism, the production of a continuous wheal following the pattern of a blunt-pointed instrument drawn across the skin, can be demonstrated about 30 minutes later.[7]

Urticaria lasting 8 weeks or longer is classified as chronic or recurrent urticaria, which may require testing for atopic disease using intradermal skin testing and serum testing for antigen-specific IgE.

Adverse reactions in dairy cattle following annual vaccination for foot-and-mouth disease are characterized by wheals (3–20 mm in diameter) covering most of the body, followed by exudative and necrotic dermatitis.[5] The affected areas become hairless and the wheals exude serum and become scabbed over. Edema of the legs is common and vesicles occur on the teats. The lesions appear 8–12 weeks postvaccination and may persist for 3–5 weeks. Loss of body weight and lymphadenopathy also occur. Pruritus, depression and a drop in milk yield are common.

CLINICAL PATHOLOGY

Intradermal skin tests to detect the presence of hypersensitivity are of little value because many normal horses, as well as those with urticaria, will respond positively to injected or topically applied allergens. Also, reactions usually occur within the first 24 hours after the injection, but the interval is very erratic. The duration of the reaction also varies a great deal.[8] Intradermal tests in horses without atopy and horses with atopic dermatitis or recurrent urticaria using environmental allergens indicate a greater number of positive reactions for intradermal tests in horses with atopic dermatitis or recurrent urticaria, compared with horses without atopy. This provides evidence of type-1 IgE-mediated hypersensitivity for these diseases.[6]

Biopsies show that tissue histamine levels are increased and there is a local accumulation of eosinophils. Blood histamine levels and eosinophil counts may also show transient elevation.

DIFFERENTIAL DIAGNOSIS

Urticaria is manifested by a sudden appearance of a crop of cutaneous wheals, sometimes accompanied by restlessness, mostly in horses, occasionally in cattle. Identification of the etiology is also helpful in diagnosis but is often difficult, depending on a carefully taken history and examination of the environment.

The differential diagnosis list is limited to angioedema, but in urticaria the lesions can be palpated in the skin itself. Angioedema involves the subcutaneous tissue rather than the skin and the lesions are much larger and more diffuse. The two conditions may appear in the one animal at the one time.

TREATMENT

Primary treatment

A change of diet and environment, especially exposure to the causal insects or plants, is standard practice. Spontaneous recovery is common.

Supportive treatment

Corticosteroids, antihistamines, or epinephrine by parenteral injection provide the best and most rational treatment, especially in the relief of the pruritus, which can be annoying in some cases. One treatment is usually sufficient but lesions may recur. The local application of cooling astringent lotions such as calamine or white lotion or a dilute solution of sodium bicarbonate is favored. In large animal practice parenteral injections of calcium salts are used with apparently good results.

Long-term medical management of persistent urticaria involves the administration of corticosteroids and or antihistamines. Oral administration or prednisone or prednisolone at the lowest possible dose on alternate days is the method of choice.[2] The antihistamine of choice is oral hydroxyzine hydrochloride initially at 600 mg three times daily, followed by gradual reduction to a minimum maintenance dose required to keep the horse free of lesions.

DERMATITIS AND DERMATOSIS

Synopsis

Etiology Any disease of skin, including those characterized by inflammation. All pathogens, infectious, chemical, physical, allergic, autoimmune

Epidemiology Sporadic or outbreak, acute or chronic course, cosmetic to lethal, but of most importance as constraints on movement, sale or exhibition

Clinical signs Primarily localized to skin, including lesions varying from parakeratosis and pachyderma to weeping, through necrosis, vesicles and edema. Secondarily signs of shock, toxemia, anaphylaxis

Clinical pathology Positive findings in the area of skin swabs or scrapings

Necropsy lesions Inflammatory, degenerative or vascular lesions in skin biopsy

Diagnostic confirmation Positive finding in skin biopsy

Treatment primary is removal of the pathogen; supportive includes treatment for shock, toxemia or fluid and electrolyte loss

ETIOLOGY

Some of the identifiable occurrences of dermatitis in food animals and horses are as follows.

All species

- Mycotic dermatitis due to *Dermatophilus congolensis*, in horses, cattle, sheep
- *Staphylococcus aureus* is a common finding in cases in all species, either as a sole pathogen or combined with other agents
- Ringworm
- Photosensitive dermatitis
- Chemical irritation (contact dermatitis) topically
- Arsenic – systemic poisoning
- Mange mite infestation – sarcoptic, psoroptic, chorioptic, demodectic mange
- Trombidiiform mite infestation (tyroglyphosis)
- Biting flies especially *Culicoides* spp. Observed most commonly in horses, but also in other species[1]
- *Stephanofilaria* sp. dermatitis
- *Strongyloides (Pelodera)* sp. dermatitis
- Infection with the protozoon *Besnoitia* spp.

Cattle

- Udder impetigo – *S. aureus*
- Cutaneous botryomycosis of the udder caused by a combination of trauma and infection by *Pseudomonas aeruginosa*
- Cowpox
- Ulcerative mammillitis – udder and teats only
- Lumpy skin disease – Allerton and Neethling 'strains'
- Foot-and-mouth disease – vesicles around natural orifices; vesicular stomatitis with lesions on teats and coronet
- Rinderpest, bovine virus diarrhea, bovine malignant catarrh, bluetongue – erosive lesions around natural orifices, eyes, coronets
- Sweating sickness
- Perianal vesicular and necrotic dermatitis associated with mushroom poisoning
- Dermatitis on legs – potato poisoning, topical application of irritants or defatting agents, e.g. diesoline
- Dermatitis due to the ingestion of *Vicia villosa* and *Vicia dasycarpa*
- Plaque-like and cracked skin lesions on the udder, hindquarters, lips and muzzle of cattle bedded on straw heavily contaminated with *Fusarium sporotrichioides*[2]
- Flexural seborrhea
- Bovine exfoliative dermatitis (see below)
- Slurry heel (see below).

Sheep and goats

- Strawberry footrot – *Dermatophilus pedis*
- Sheep pox
- Contagious ecthyma
- Ulcerative dermatosis
- Rinderpest, peste de petits ruminants, bluetongue – as for cattle
- Foot-and-mouth disease and vesicular stomatitis
- Fleece rot – constant wetting and associated with *P. aeruginosa*[3]
- Lumpy wool – *D. congolensis*
- Itch-mite (*Psorergates ovis*) infestation
- Blowfly infestation (cutaneous myiasis)
- 'Cockle' (probably related to louse infestation)[4]
- Elaeophoriasis (*Elaeophora* sp. infestation)
- Ovine atopic dermatitis
- Caprine idiopathic dermatitis
- Postdipping necrotic dermatitis (see below).

Pigs

- Ulcerative granuloma – *Borrelia suilla*
- Exudative epidermitis – *Staphylococcus hyicus* (greasy pig disease)
- Pig pox
- Swine vesicular disease, vesicular exanthema of swine, foot-and-mouth disease – vesicles around natural orifices
- Contact with fresh parsnip tops, celery
- Sunburn
- Porcine necrotic ear syndrome
- Nonspecific nutritional dermatitis – experimental nutritional deficiency of

nicotinic acid, riboflavin, pantothenic acid, biotin
- Pityriasis rosea – cause unknown
- Idiopathic chronic recurrent dermatoses.

Horses
- *Staphylococcus hyicus* in a syndrome reminiscent of greasy heel
- *Actinomyces viscosum*
- Horsepox
- Canadian horsepox
- Viral papular dermatitis
- Vesicular stomatitis – vesicles around natural orifices
- Vesicular dermatitis around nasal area, eyes, ears in horses stabled on shavings of a tree of the *Quassia* spp.[5]
- Spongiotic vesicular dermatitis of unknown etiology[6]
- Sporotrichosis
- Dermatophytes, including ringworm, follicular dermatitis, hyphomycosis (pythiosis), tinea versicolor dermatitis
- Scald – constant wetting
- Queensland (sweet) itch – sensitivity to *Culicoides* spp. sandflies[7]
- Atopic dermatitis (IgE-mediated hypersensitivity)[8]
- Chronic eosinophilic dermatitis (see below)
- Pemphigus, lupus erythematosus, erythema multiforme, eosinophilic dermatitis and stomatitis, described separately below
- Molluscum contagiosum (see below)
- Linear hyperkeratosis (see below)
- Nodular necrobiosis (see below)
- Ear plaque (see below)
- Uasin gishu disease
- Cutaneous habronemiasis
- Tropical lichen (see below)
- Midline, ventral dermatitis due to infestation with *Hydrotaea irritans* (horn fly and buffalo fly)
- Trombidiiform mites, e.g. *Pyemotes tritici* and *Acarus (Tyroglyphus) farinae*
- Ulcerative dermatitis, thrombocytopenia and neutropenia in neonatal foals (see Alloimmune hemolytic anemia of the newborn (Neonatal isoerythrolysis, isoimmune hemolytic anemia of the newborn), Ch. 33).

Special local dermatitides
These include dermatitis of the teats and udder, the bovine muzzle and coronet, and flexural seborrhea, and are dealt with under their respective headings.

PATHOGENESIS
Dermatitis is basically an inflammation of the deeper layers of the skin involving the blood vessels and lymphatics. The purely cellular layers of the epidermis are involved only secondarily. The noxious agent causes cellular damage, often to the point of necrosis, and, depending on the type of agent responsible, the resulting dermatitis varies in its manifestations. It may be acute or chronic, suppurative, weeping, seborrheic, ulcerative or gangrenous. In all cases there is increased thickness and increased temperature of the part. Pain or itching is present and erythema is evident in unpigmented skin. Histologically there is vasodilatation and infiltration with leukocytes and cellular necrosis. These changes are much less marked in chronic dermatitis.

CLINICAL FINDINGS
Affected skin areas first show erythema and increased warmth. The subsequent stages vary according to the type and severity of the causative agent. There may be development of discrete vesicular lesions or diffuse weeping. Edema of the skin and subcutaneous tissues may occur in severe cases. The next stage may be the healing stage of scab formation or, if the injury is more severe, there may be necrosis or even gangrene of the affected skin area. Spread of infection to subcutaneous tissues may result in a diffuse cellulitis or phlegmonous lesion. A distinctive suppurative lesion is usually classified as pyoderma. Deep lesions which cause damage to dermal collagen may cause focal scarring and idiopathic fibrosing dermatitis (see below).

A systemic reaction is likely to occur when the affected skin area is extensive. Shock, with peripheral circulatory failure, may be present in the early stages. Toxemia, due to absorption of tissue breakdown products, or septicemia due to invasion via unprotected tissues, may occur in the later stages.

Individual dermatitides are as follows:

- **Bovine exfoliative dermatitis** in calves associated with the excretion of an unidentified agent in the dam's milk. The calves show a widespread dermatitis, including vesicles on the muzzle, scaling and hair loss, at a few days of age but recover spontaneously before 3 months of age. The dam has the same disease in a mild but chronic form[9]
- **Slurry heel**[10] is erosion and deep fissuring of the epithelium and horn of the heel of cattle housed indoors and standing continuously in slurry. The affected claws are destabilized by the disappearance of support so that the pedal bone projects downwards and through the dorsal surface of the sole; the heel sinks and the toe overgrows. Sole ulceration is a common sequel. The condition can be confused with interdigital dermatitis
- **Ovine postdipping necrotic dermatitis** is associated with *P. aeruginosa* and related to dipping in solutions containing no bacteriostatic agent.[11] Necrotic lesions (1–3 cm in diameter), with cellulitis down to the underlying muscle, occur only along the backline and may be related to trauma during dipping. It may be accompanied by an outbreak of fatal otitis media with *P. aeruginosa* present in the lesion
- **Ovine atopic dermatitis**: Only the wool-less parts of the skin are affected by symmetrical erythema, alopecia, lichenification and excoriation. Only occasional sheep in the flock are affected and these are affected each summer, with remission during the winter months[12]
- **Caprine idiopathic dermatitis**: Alopecic, exudative dermatitis of all ages and both sexes of pygmy goats[13] is characterized by hair loss, scaling and crusting around eyes, lips and chin, ears, poll, perineum and ventral abdomen. Histologically the lesions have a psoriasis-like form
- **Porcine dermatitis–nephropathy syndrome**, an idiopathic low morbidity but highly fatal disease of feeder pigs,[14–16] is characterized by papular, vascular dermatopathy, systemic necrotizing vasculitis and exudative, proliferative glomerulonephritis. Skin lesions are full-depth necrosis appearing as multiple, flat, red-blue papules up to 2 cm in diameter (which may coalesce to form large plaques) on any part of the body. Some pigs die of glomerulonephritis without skin lesions having been apparent. Many cases that show only skin lesions recover spontaneously in several weeks. The disease may disappear if the commercial grain ration used is ground more coarsely
- **Porcine necrotic ear syndrome** is an extensive necrosis of the edges of the ears. The cause is unknown but the possibility that a combination of *S. hyicus* infection and trauma by biting by pen mates is the cause seems high
- **Porcine idiopathic chronic, recurrent dermatitis** is recorded in sows in specific farrowing houses.[17] Boars and piglets were not affected and lesions disappeared as soon as the sows left the houses. Annular macules 11 cm diameter and patches of erythema 11 cm diameter occur only on white skin. There are no systemic signs
- **Equine staphylococcal dermatitis** is a serious disease because the lesions are intractable to treatment and are so painful to touch that the horse is hard

to handle, and the presence of the lesions under harness, where they commonly are, prevents the horse from working kindly. Harness horses are at a particular disadvantage. Individual lesions are raised nodules, 3–5 mm diameter, covered by a small, easily removed scab. When these lift they take a tuft of hair with them and a small crater is left. A little pus exudes and only a red serous fluid can be expressed. Individual lesions last a long time, at least several weeks, and fresh crops occur, causing the disease to spread slowly on the animal

- **Chronic equine eosinophilic dermatitis** is characterized by marked acanthosis and hyperkeratosis, and eosinophilic granulomas in pancreas, salivary glands and other epithelial organs. The systemic involvement is accompanied by severe weight loss. The disease is chronic, and the cause unknown
- **Spongiotic vesicular dermatitis** has been described in horses.[6] Lesions are characterized by a multifocal, exudative, oozing dermatitis characterized histologically by epidermal spongiotic vesicles and perivascular eosinophilic, neutrophilic and mixed mononuclear inflammation. Some horses are pruritic
- **Equine nodular necrobiosis**: Firm, small (up to 1 cm diameter) nodules, usually a number of them, occur on the sides of the trunk and neck. The cause is unknown. The lesions consist largely of an accumulation of eosinophils
- **Molluscum contagiosum** is a chronic, progressive dermatitis[18] characterized by raised, hairless lesions 0.5–2 cm in diameter, covered by soft keratin, that bleed profusely when the horse is groomed. The lesions are on the face, shoulders, trunk, lateral aspects of limbs, fetlocks and pasterns. Histological examination identifies the disease because of the presence of characteristic inclusions in cells. These are thought to be pox virus virions, but the virus cannot be cultivated from the lesions. There is no specific treatment
- **Systemic lupus erythematosus** (SLE) is an extensive dermatitis, manifested as a scaly, crusty dermatitis of the face, neck and trunk, with loss of hair over the lesions, edema of the limbs and a mild to moderate lymph node enlargement.[7,19] Multiple ulcers 11 cm in diameter are present on the oral mucosa, especially the mucocutaneous junctions of the lips and nares, and on the tongue. There is a severe systemic reaction, including a marked loss of body weight, a temperature up to 39.5°C, heart rate 80/min, respiratory rate up to 60/min, painful swollen joints containing sterile serous fluid, stiff gait, reluctance to move, and persistent lateral recumbency. SLE is an immune-mediated disease with a characteristic histopathology including a necrotizing, lymphocytic dermatitis and focal accumulations of lymphocytes in the liver, membranous glomerulonephritis and synoviocyte hyperplasia. An antinuclear antibody test is diagnostic. No treatment is effective and the disease runs a chronic progressive course marked by remissions and exacerbations
- **Discoid lupus erythematosus** is an uncommon, benign variant of the systemic disease, with cutaneous lesions similar to those in the major disease but with no involvement of other tissues
- **Erythema multiforme** is a self-limiting skin disease of horses and cattle characterized by macular, papular, urticarial or bullous skin lesions but without any abnormality of the epidermis or loss of hair, and with no apparent itching or pain. The lesions occur symmetrically on most parts of the body, persist for long periods and increase in size up to 4–5 cm to form annular or crescent-shaped wheals. Spontaneous disappearance of the lesions after about 3 months is usual. Symptomatic treatment may be effective but is not usually necessary
- **Equine ear plaque**: Multiple white plaques, resembling papilloma and about 1 cm in diameter, develop on the inner surface of the ear pinna of horses
- **Equine tropical lichen** is an intensely irritating, papular eruption in the skin on the side of the neck, under the mane, the shoulders and at the tail head, occurring in summer and recurring annually. The disease closely resembles the cutaneous sensitivity to *Culicoides* spp. but responds dramatically to treatment with ivermectin. Microfilariae, thought to be *Onchocerca* spp., can be found in histological sections
- **Linear keratosis** is most common in horses, especially Quarter horses. One case has been recorded in cattle.[20] Lesions appear spontaneously in horses 1–5 years old and persist, usually for life. They appear first as isolated scaly lumps, which then coalesce to form a ridge, usually vertical, 3–4 cm wide and up to 70 cm long, of hyperkeratotic, hairless skin. There may be one or more lesions, commonly on the sides of the neck and chest. Symptomatic treatment appears to have no effect on the lesions
- **Idiopathic fibrosing dermatitis**: The end stage of several severe dermatoses, this causes damage to dermal collagen.[21] Manifested by multiple fibrous plaques in the skin caused by sclerosis of the skin or subcutis, it resembles human morphea and the skin granulomas of animals.

Pemphigus

This is an autoimmune disease of the skin, sometimes affecting mucosae and characterized by the presence of vesicles or bullae, which are usually very difficult to find, and subsequent erosions and ulcerations. There are a number of manifestations, including pemphigus vulgaris, bullous pemphigoid and pemphigus foliaceus.[7] It is a chronic autoimmune disease often accompanied by severe weight loss.

Pemphigus foliaceus is the most common autoimmune disease of the horse.[7] The majority of cases occur in mature horses, usually 5 years of age or older; a small number occur in horses 1 year of age or younger. The classic, but rarely seen, primary lesion is a vesicle or pustule. Usually, the earliest lesions visible are crusted papules best seen in lightly or nonhaired skin adjacent to mucocutaneous junctions – the nostrils, eyelids or lips. Lesions rapidly coalesce to form multifocal or diffuse areas of crusting. It occurs as a generalized scabby, weeping dermatitis[22] but it may be localized as circumscribed, circular lesions in the mouth and vulva and on the skin at mucocutaneous junctions. The lesions are subepidermal bullae from which the top layer can be pulled away, and are sore to the touch. In some cases the lesions are around the coronary bands on all limbs. Edema of the extremities, especially the hindlimbs, and the ventral abdominal region are commonly present.

The differential diagnoses include all skin diseases caused by scaling and crusting. These include dermatophytosis, dermatophilosis, systemic granulomatous disease and primary or idiopathic abnormalities of keratinization.

A direct immunofluorescence examination, consisting of a fluorescein–antihorse IgG applied to the lesion, can confirm the diagnosis. Corticosteroid or gold (aurothioglucose) therapy has been reported to effect improvement but an

inexorable deterioration is usual. Pemphigus foliaceus is recorded in goats as a widespread disease characterized by the presence of scales, sometimes in heavy crusts, and involvement of the coronets.

CLINICAL PATHOLOGY

Examination of skin scrapings or swabs for parasitic, bacterial or other agents is essential. Culture and sensitivity tests for bacteria are advisable to enable the best treatment to be selected. Skin biopsy may be of value in determining the causal agent. In allergic or parasitic states there is usually an accumulation of eosinophils in the inflamed area. In mycotic dermatitis organisms are usually detectable in the deep skin layers although they may not be cultivable from superficial specimens.

DIAGNOSIS

The clinical features of dermatitis are apparent. The characteristic features of the etiological types of dermatitis are described under each specific disease. **Diagnostic confirmation** is by histopathological demonstration in a biopsy specimen.

DIFFERENTIAL DIAGNOSIS

- **Hyperhidrosis** and **anhidrosis** are dysfunctions of sweating and have no cutaneous lesion
- **Cutaneous neoplasm** is differentiable on histopathological examination
- **Epitheliogenesis imperfecta** is a congenital absence of all layers of skin
- **Vascular nevus** is a congenital lesion commonly referred to as 'birth mark'

TREATMENT

Primary treatment must be to remove the noxious physical or chemical agent from the environment or to supplement the diet to repair a nutritional deficiency. The choice of a suitable treatment for infectious skin disease will depend upon the accurate identification of the etiological agent.

Supportive treatment includes both local and systemic therapy. Local applications may need to be astringent either as powders or lotions in the weeping stage or as greasy salves in the scabby stage. The inclusion of corticosteroids or antihistamine preparation is recommended in allergic states and it is desirable to prescribe sedative or anesthetic agents when pain or itching is severe.

If shock is present, parenteral fluids should be administered. If the lesions are extensive or secondary bacterial invasion is likely to occur, parenterally administered antibiotics or antifungal agents may be preferred to topical applications. To facilitate skin repair, a high protein diet or the administration of protein hydrolysates or amino acid combinations may find a place in the treatment of valuable animals. Non-specific remedies such as gold-containing remedies (e.g. aurothioglucose) are commonly used in autoimmune diseases such as pemphigus.

The use of vaccines as prophylaxis in viral and bacterial dermatitides must not be neglected. Autogenous vaccines may be most satisfactory in bacterial infections. An autogenous vaccine is particularly recommended in the treatment of staphylococcal dermatitis in horses and bovine udder impetigo in which long and repeated courses of treatment with penicillin produce only temporary remission. An autogenous vaccine produces a cure in many cases.

PHOTOSENSITIZATION

Synopsis

Etiology Caused by the sensitization of dorsally situated, lightly pigmented skin, mucosa and cornea to light. Dermatitis develops when the sensitized skin is exposed to sunlight

- Intake of primary photodynamic agents (PDAs)
- Faulty excretion of phylloerythrin (metabolic product of chlorophyll and a PDA) due to liver damage
- Inherited defects of porphyrin metabolism, producing PDAs
- Many unexplained cases and outbreaks in pastured or housed animals

Epidemiology Exposure to photosensitizing substances and sunlight. Similar incidence of sporadic cases and outbreaks. Always life-threatening unless exposure to sunlight can be avoided

Clinical signs Primary cases have cutaneous signs only (erythema, edema, necrosis, gangrene of light colored skin or mucosae exposed to sunlight). Secondary cases have also signs of hepatic dysfunction (jaundice, prostration, short course, death), or porphyrin metabolism

Clinical pathology Nil for evidence of photosensitivity. In secondary cases there is evidence of the primary disease

Necropsy lesions Only skin lesions in primary cases. Secondary cases show liver lesions or evidence of porphyrin accumulation

Differential diagnosis Clinical evidence of restriction of damage to white, wool-less skin on body dorsum and lateral aspects of limbs, teats, corneas and tongue and lips

Treatment Primary: remove from exposure to sunlight and PDA. Supportive: treat for infection, shock, toxemia

ETIOLOGY AND EPIDEMIOLOGY

If photosensitizing substances (photodynamic agents) are present in sufficient concentration in the skin, dermatitis occurs when the skin is exposed to light. Photodynamic agents are substances that are activated by light and may be ingested preformed (and cause primary photosensitization) or be products of abnormal metabolism (and cause photosensitization due to aberrant synthesis of pigment) or be normal metabolic products that accumulate in tissues because of faulty excretion through the liver (and cause hepatogenous photosensitization). Faulty excretion through the liver may be due to hepatitis, caused in most instances by poisonous plants, or to biliary obstruction caused by crystal-associated cholangiohepatopathy, or rarely by cholangiohepatitis or biliary calculus.

Primary photosensitization

Photosensitization due to the ingestion of exogenous photodynamic agents usually occurs when the plant is in the lush green stage and is growing rapidly. Livestock are affected within 4–5 days of going on to pasture and new cases cease soon after the animals are removed. In most cases the plant responsible must be eaten in large amounts and will therefore usually be found to be a dominant inhabitant of the pasture. All species of animals are affected by photodynamic agents, although susceptibility may vary between species and between animals of the same species. Photosensitizing substances that occur naturally in plants include:

- Dianthrone derivatives – hypericin in *Hypericum perforatum* (St John's wort) and other *Hypericum* spp. and fagopyrin in seeds and dried plants of *Fagopyrum esculentum* (buckwheat)

- Furocoumarins in *Cymopterus* spp. (wild carrot), *Ammi majus* and *Thamnosma texana*
- Perloline from perennial ryegrass (*Lolium perenne*)
- Cocoa shells in feedlot rations causing photosensitization in feedlot calves[1]
- Gluten metabolites in dairy cattle concentrates being fed to horses[2]
- *Erodium moschatum*, an exotic weed in South Africa, causing photosensitization in sheep[3]
- Unidentified photodynamic agents in *Medicago denticulata* (burr trefoil) and the aphids that infest it, and in *Brassica* spp., *Erodium* spp., and *Trifolium* spp.
- Miscellaneous chemicals including phenothiazine (its metabolic end-product phenothiazine sulfoxide is photosensitizing to calves), rose Bengal and acridine dyes
- Cows treated with corticosteroids to induce calving may develop a photosensitive dermatitis of the teats, escutcheon and udder. Its occurrence is sporadic and does not appear to be related to a particular drug.

Photosensitization due to aberrant pigment synthesis

The only known example in domestic animals is inherited congenital porphyria, in which there is an excessive production in the body of porphyrins, which are photodynamic.

Hepatogenous photosensitization

The photosensitizing substance is in all instances phylloerythrin, a normal end-product of chlorophyll metabolism excreted in the bile. When biliary secretion is obstructed by hepatitis or biliary duct obstruction, phylloerythrin accumulates in the body and may reach levels in the skin that make it sensitive to light. Although hepatogenous photosensitization is more common in animals grazing green pasture, it can occur in animals fed entirely on hay or other stored feeds and in animals exposed to hepatotoxic chemicals e.g. carbon tetrachloride. There appears to be sufficient chlorophyll, or breakdown products of it, in stored feed to produce critical tissue levels of phylloerythrin in affected animals. The following list includes those substances or plants that are common causes of hepatogenous photosensitization. The individual plants are discussed in more detail in the section on poisonous plants.

Plants containing hepatotoxins

- *Pithomyces chartarum* fungus on perennial ryegrass – causing facial eczema
- *Periconia* sp. fungus on Bermuda grass
- Cyanobacteria associated with blue-green algae (water bloom) on drinking water in ponds, dams and dugouts – *Microcystis flosaquae*
- Lupins – *Lupinus angustifolius* plus the accompanying fungus, *Phomopsis leptostromiformis*
- Signal grass (*Brachiaria decumbens* and *Brachiaria brizantha*), a common component of established pastures in Brazil[4]
- Alligator weed (*Alternanthera philoxeroides*), a South American aquatic plant causing photosensitization in dairy cattle in Australia and New Zealand[5]
- Weeds including lantana (*Lantana camara*), *Lippia rehmanni*, sacahuiste (*Nolina texana*), coal oil bush (*Tetradymia* spp.), alecrim (*Holocalyx glaziovii*), ngaio (*Myoporum laetum*), *Crotalaria retusa*, ragwort (*Senecio jacobea*), *Sphenosciadium* spp.

Plants containing steroidal saponins

These cause crystal-related cholangio-hepatopathy.

- *Agave lecheguilla*, *Narthecium ossifragum*, *Panicum* spp. (panic and millet grasses), *Tribulus terrestris* (caltrop, geeldikkop), plants being grazed particularly by sheep
- Alveld, a hepatogenous photosensitivity disease of sheep (lambs) grazing on pastures containing *Narthecium ossifragum* (bog asphodel) on the west coast of Norway and in Scotland, northern England, Ireland, and the Faroe Islands.[6] The disease is known as alveld (literally 'elf fire') in Norway, plochteach, saut or yellowses in the British Isles and ormajuka ('worm disease') in the Faroe Islands. *Narthecium ossifragum*-containing pastures in these countries are commonly used for grazing sheep. Photosensitization of sheep grazing this plant usually occurs in 2–6-month-old lambs and is rarely seen in adult sheep. It produces similar clinical signs to those due to facial eczema, a disease most commonly seen in New Zealand and associated with the fungal toxin sporidesmin.

Congenitally defective hepatic function

Inherited congenital photosensitivity in Corriedale and Southdown lambs is an inherited defect in the excretion of bile pigment.

Photosensitization of uncertain etiology

In the following diseases it has not been possible to ascertain whether the photosensitization is primary or due to hepatic insufficiency:

- Feeding on rape or canola (*Brassica rapa*), kale, lucerne or alfalfa (*Medicago sativa*), burr medic or burr trefoil (*Medicago denticulata*), *Medicago minima*, *Trifolium hybridum* (alsike or Swedish clover), *Erodium cicutarium* and *Erodium moschatum* (lamb's tongue, plantain)
- Cattle feeding on water-damaged or moldy alfalfa hay or alfalfa silage; extensive outbreaks usually with no signs suggestive of hepatic disease
- Cattle, sheep and horses grazing lush pasture; many clinical cases occur sporadically
- Corticosteroids used systemically to terminate parturition in cows
- Phenanthridium used in the treatment of trypanosomiases.

PATHOGENESIS

Penetration of light rays to sensitized tissues causes local cell death and tissue edema. Irritation is intense because of the edema of the lower skin level, and loss of skin by necrosis or gangrene and sloughing is common in the terminal stages. Nervous signs may occur and are caused either by the photodynamic agent, as in buckwheat poisoning, or by liver dysfunction.

Hepatogenous photosensitization involves production of a toxin, by a higher plant, fungus or cyanobacterium (algae), that causes liver damage or dysfunction, resulting in the retention of the photosensitizing agent phylloerythrin.

CLINICAL FINDINGS

General signs

These commence with intense irritation and the animal rubs the affected parts, often lacerating the face by rubbing it in bushes. When the teats are affected the cow may kick at them and walk into ponds to immerse the teats in water, sometimes rocking backwards and forwards as if to cool the affected parts. In nursing ewes there may be resentment towards the lambs sucking, and heavy lamb mortalities due to starvation may result.

Local edema is often severe and may cause drooping of the ears, closure of the eyelids and nostrils, causing dyspnea, and dysphagia due to swelling of the lips. An early sign is increased lacrimation, with the initially watery discharge developing into a thicker, serous discharge accompanied by blepharospasm and swelling of the eyelids. Initial erythema of the muzzle is followed by fissuring, then sloughing of the thick skin.

Skin lesions

Skin lesions are initially erythema, followed by edema and subsequently weeping with matting then shedding of clumps of

hair, and finally gangrene. They have a characteristic distribution, restricted to the unpigmented areas of the skin and to those parts which are exposed to solar rays. They are most pronounced on the dorsum of the body, diminishing in degree down the sides and are absent from the ventral surface. The demarcation between lesions and normal skin is very clear-cut, particularly in animals with broken-colored coats.

Predilection sites for lesions are the ears, conjunctiva, causing opacity of the lateral aspect of the cornea, eyelids, muzzle, face, the lateral aspects of the teats and, to a lesser extent, the vulva and perineum. In solid black cattle dermatitis will be seen at the lips of the vulva and on the edges of the eyelids, and on the cornea. Linear erosions often occur on the tip and sides of the tongue in animals with unpigmented oral mucosa. In severe cases the exudation and matting of the hair and local edema causes closure of the eyelids and nostrils. In the late stages necrosis or dry gangrene of affected areas leads to sloughing of large areas of skin.

Systemic signs

These include shock in the early stages, due to extensive tissue damage. There is an increase in the pulse rate with ataxia and weakness. Subsequently a considerable elevation of temperature (41–42°C, 106–107°F) may occur.

Nervous signs

These including ataxia, posterior paralysis and blindness; depression or excitement are often observed. A peculiar sensitivity to water is sometimes seen in sheep with facial eczema: when driven through water they may lie down in it and have a convulsion.

Liver insufficiency

Signs are described elsewhere and may accompany photosensitive dermatitis when it is secondary to liver damage.

CLINICAL PATHOLOGY

There are no suitable field tests to determine whether or not photosensitivity is present.

Hepatogenous photosensitization can be diagnosed by analysis of plasma phylloerythrin concentration using a spectroscopic method. Plasma or serum fluorescence can be used to measure the elevation of phylloerythrin above normal levels prior to hepatogenous photosensitization.[7–9] The levels of phylloerythrin in plasma of lambs grazing *Narthecium ossifragum* are increased from a normal of less than 0.05 µg/mL to more than 0.3 µg/mL when clinical signs of photosensitization are observed.[9] Levels in skin are also increased.

In lambs in which facial eczema was experimentally induced by dosing with the mycotoxin sporidesmin, the plasma concentrations of phylloerythrin were increased from a normal of less than 0.1 µmol/L to 0.3 µmol/L when clinical signs were evident.[8] The concentration of phylloerythrin in the skin began increasing 2–3 days later than that in the blood.

NECROPSY FINDINGS

In primary photosensitization, lesions are restricted to white-haired or pale-skinned areas of skin or mucosa that have been exposed to sunlight, and vary from necrosis to gangrene. Lesions characteristic of hepatic injury or metabolic defects of porphyrin metabolism are described elsewhere.

Diffuse hepatocellular hydropic degeneration and hyperplasia of the smooth endoplasmic reticulum associated with marked multifocal cholangitis in the portal triads with bile duct proliferation are characteristic of the hepatic lesions of sheep grazing *Brachiaria decumbens*.[4] Foam cells are present in the liver and mesenteric and hepatic lymph nodes of cattle grazing *Brachiaria* spp.[10] Hepatocellular degeneration is the primary event in alveld photosensitization in sheep.[6] High concentrations of conjugated episapogenins are present in both liver and bile in alveld-affected lambs.

DIFFERENTIAL DIAGNOSIS

The diagnosis of photosensitivity depends almost entirely on the distribution of the lesions. It can be readily confused with other dermatitides if this restriction to unpigmented and hairless parts is not kept in mind.

- Mycotic dermatitis is often mistaken for photosensitization because of its tendency to commence along the back line and over the rump, but it occurs on colored and white parts alike
- Frequent wetting, as in periods of heavy rainfall, along the back in horses or cattle with a dense hair coat
- Bighead of rams associated with *Clostridium novyi* infection may also be confused with photosensitization but the local swelling is an acute inflammatory edema and many clostridia are present in the lesion
- The eye lesions in photosensitization have been confused with those of pink-eye but that disease is not accompanied by extensive dermatitis.

Treatment

Primary treatment includes immediate removal from direct sunlight, prevention of ingestion of further toxic material and the administration of laxatives to eliminate toxic materials already eaten. In areas where the disease is enzootic the use of dark-skinned breeds may make it possible to utilize pastures that would otherwise be too dangerous.

Local treatment will be governed by the stage of the lesions. Nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids or antihistamines can be administered parenterally and adequate doses maintained. To avoid septicemia the prophylactic administration of antibiotics may be worthwhile in some instances.

Diseases of the hair, wool, follicles, skin glands, horns, and hooves

ALOPECIA AND HYPOTRICHOSIS

ETIOLOGY

Alopecia is complete absence of the hair or wool coat; hypotrichosis is less than the normal amount of hair or wool. Both may be caused by the following conditions.

Failure of follicles to develop

- Congenital hypotrichosis.

Loss of follicles

- Cicatricial alopecia due to scarring after deep skin wounds that destroy follicles. Cicatricial alopecia occurs following permanent destruction of the hair follicles, and regrowth of hair will not occur. Examples include physical, chemical or thermal injury, severe furunculosis, neoplasia and certain infections such as cutaneous onchocerciasis.[1]

Failure of the follicle to produce a fiber

- Inherited symmetrical alopecia
- Congenital hypotrichosis
- Hair-coat-color-linked follicle dysplasia
- Inherited dyserythropoiesis and dyskeratosis
- In baldy calves and adenohypophyseal hypoplasia

- Congenital hypothyroidism (goiter) due to iodine deficiency in the dam
- After viral infection of the dam, alopecia congenitally in the newborn, e.g. after bovine virus diarrhea in cattle and infection by a similar virus in sheep (Border disease)
- Neurogenic alopecia due to peripheral nerve damage
- Infection in the follicle
- Alopecia areata of horses and, less commonly, cows[2] characterized by one or more round lesions of spontaneously disappearing, nonscarring alopecia over the face, neck, shoulders and brisket. At histopathological examination normal skin contains accumulations of lymphocytes around the hair follicles.

Loss of preformed fibers

- Dermatomycoses – ringworm
- Mycotic dermatitis in all species due to *D. congolensis*
- Metabolic alopecia subsequent to a period of malnutrition or severe illness –'a break in the wool', e.g. excessive whale, palm or soya oil in milk replacers to calves; the fibers grown during the period of nutritional or metabolic stress have a zone of weakness and are easily broken
- Traumatic alopecia due to excessive scratching or rubbing associated with louse, tick or itch-mite infestations; rubbing against narrow doors, feed troughs or tethers in confined housing, against harness in working animals
- Poisoning by thallium, selenium, arsenic, mercury or the tree *Leucaena leucocephala*
- Idiopathic hair loss from the tail-switch of well-fed beef bulls
- In sterile eosinophilic folliculitis of cattle
- Wool slip
- In many primary skin diseases, e.g. parakeratosis, hyperkeratosis, dermatitis, cutaneous neoplasia, sarcoid; pythiosis hair is lost at the site of local lesions.

PATHOGENESIS

Normal shedding of hair fibers is a constant but largely unexplained process, especially during significant changes in environmental temperature. The long winter coat is shed in response to warmer spring temperatures and increased hours of sunlight, and rapidly regrows as environmental temperatures fall in the autumn. In inherited hair defects there may be a reduction in follicle numbers or a reduced capacity of each follicle to produce fibers. Chemical depilation produced by cytotoxic agents, such as cyclophosphamide, occurs as a result of induced cytoplasmic degeneration in some of the germinative cells of the bulb of the wool follicle. The alteration in cell function is temporary, so that regrowth of the fiber should follow.

CLINICAL FINDINGS

When alopecia is due to breakage of the fiber, the stumps of old fibers or developing new ones may be seen. When fibers fail to grow the skin is shiny and in most cases is thinner than normal. In cases of congenital follicular aplasia, the ordinary covering hairs are absent but the coarser tactile hairs about the eyes, lips and extremities are often present. Absence of the hair coat makes the animal more susceptible to sudden changes of environmental temperature. There may be manifestations of a primary disease and evidence of scratching or rubbing.

Congenital hypotrichosis results in alopecia which is apparent at birth or develops within the neonatal period.

CLINICAL PATHOLOGY

If the cause of the alopecia is not apparent after the examination of skin scrapings or swabs, a skin biopsy will reveal the status of the follicular epithelium.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation of alopecia is by visual recognition, the diagnostic problem being to determine the primary cause of the hair or fiber loss.

Hypotrichosis is a reduction in numbers of fibers instead of a complete absence. Inherited diseases of the skin are presented in Chapter 34.

TREATMENT

Primary treatment consists of removing the causes of trauma or other damage to fibers. In cases of faulty follicle or fiber development treatment is not usually attempted.

REVIEW LITERATURE

Pascoe RR. Alopecia, diagnosis and treatment. Equine Pract 1993; 15:8–16.

REFERENCES

1. Stannard AA. Vet Dermatol 2000; 11:191.
2. Scott DW, Guard CL. Agri-practice 1988; 9(4):16.

ACHROMOTRICHIA

Deficient pigmentation in hair or wool fiber as follows:

- Bands of depigmentation in an otherwise black wool fleece are the result of a transitory deficiency of copper in the diet
- Cattle on diets containing excess molybdenum and deficient copper show a peculiar speckling of the coat caused by an absence of pigment in a proportion of hair fibers. The speckling is often most marked around the eyes, giving the animal the appearance of wearing spectacles
- General loss of density of pigmentation in all coat colors, e.g. Hereford cattle shade off from their normal deep red to a washed-out orange.

LEUKODERMA AND LEUKOTRICHIA

Several skin diseases of the horse are characterized by an acquired loss of melanin pigment in the epidermis of hair.[1] Melanocytes in the epidermis and those in the hair bulbs are frequently affected independently. Leukotrichia occurs when the melanocytes in the hair bulbs lose their normal amount of melanin pigment. When the melanocytes in the epidermis are affected and the skin loses normal pigmentation, the abnormality is leukoderma. The etiology and pathogenesis of leukoderma are unknown. Reticulated leukotrichia, spotted leukotrichia and juvenile Arabian leukoderma have been described.[1]

VITILIGO

Patchy depigmentation of the skin with premature graying of the local hair is not uncommon in cattle and horses. The usual manifestation is the appearance of patches of gray or white hair –'snowflakes'– in an otherwise pigmented coat. The defect is esthetic only. Histopathological examination reveals a complete absence of melanocytes from affected areas but the cause is unknown in most cases. A genetic etiology is suspected in Arabian horses and Holstein–Friesian cattle. It can also be caused by:

- Application of 'supercooled' instruments that selectively destroy melanocytes, the basis for freeze branding
- Prolonged pressure, e.g. by poorly fitting harness
- X-irradiation
- An idiopathic state in horses, usually during a debilitating disease, with patchy depigmentation of skin appearing on the prepuce, perineum, underneath the tail, and on the face. There is no discontinuity of the skin.

SEBORRHEA

ETIOLOGY

Seborrhea is an excessive secretion of sebum on to the skin surface. In large animals it is always secondary to dermatitis or other skin irritation, e.g.:

- Exudative epidermitis of pigs associated with *S. hyicus*

- Greasy heel of horses, including infection with *S. hyicus*
- Greasy heel of cattle
- Flexural seborrhea of cattle.

PATHOGENESIS
Increased blood supply to the skin and increased hair growth appear to stimulate the production of sebum, but why seborrhea is provoked in some individuals and not in others is unknown.

CLINICAL FINDINGS
In primary seborrhea there are no lesions, only excessive greasiness of the skin. The sebum may be spread over the body surface like a film of oil or be dried into crusts, which can be removed easily. Sebaceous glands may be hypertrophied.

Flexural seborrhea
Flexural seborrhea is most common in young, periparturient dairy cows. Severe inflammation and a profuse outpouring of sebum appear in the groin between the udder and the medial surface of the thigh, or in the median fissure between the two halves of the udder. Extensive skin necrosis follows, causing a pronounced odor of decay, which may be the first sign observed by the owner. Irritation may cause lameness and the cow may attempt to lick the part. Shedding of the oily, malodorous skin leaves a raw surface beneath; healing follows in 3–4 weeks.

Greasy heel of cows
Cows grazing constantly irrigated, wet pastures, or in very muddy conditions in tropical areas may develop local swelling, with deep fissuring of the skin and an outpouring of evil-smelling exudate, on the back of the pastern of all four feet but most severely in the hind limbs. Affected animals are badly lame and their milk yield declines sharply. Removing the cows to dry land and treating systemically with a broad-spectrum antibiotic effects a rapid recovery.

Greasy heel of horses (scratches)
Greasy heel occurs mostly on the hind pasterns of horses that stand continuously in wet, insanitary stables.[2] Some cases do occur in well managed stables. It has been suggested that secondary infections associated with either *S. aureus* and *D. congolensis* may be causative factors.[2] Dermatophytosis, chorioptic mange and photosensitization are also possible causative factors.

Lameness and soreness to touch are due to excoriations called 'scratches' on the back of the pastern that extend down to the coronary band. The skin is thick and greasy and, if neglected, the condition spreads around to the front and up the back of the leg; this involvement can be severe enough to interfere with normal movement of the limb.

CLINICAL PATHOLOGY
The primary cause of the seborrhea may be diagnosed by a suitable examination for the presence of parasitic or bacterial pathogens.

DIFFERENTIAL DIAGNOSIS
The lesion is characteristic and diagnostic confirmation is by histopathological examination of a biopsy specimen; the principal difficulty is to determine the primary cause. All the types listed may be mistaken for:

- Injury, commonly wire cuts or rope burn
- Flexural seborrhea for injury, usually due to straddling a gate or wire fence
- Greasy heel of horses for chorioptic mange.

TREATMENT
The skin must be kept clean and dry. Affected areas should be defatted with hot soap and water washes, then properly dried, and an astringent lotion, e.g. white lotion, should be applied daily. In acute cases of greasy heel the application at 5-day intervals of an ointment made up of five parts salicylic acid, three parts boric acid, two parts phenol, two parts mineral oil and two parts petroleum jelly is recommended. Long-standing cases profit from the twice-daily washing of the part and covering with an ointment containing an antibiotic, a fungistat and a corticosteroid, e.g. gentamicin, clotrimazole, betametasone.

FOLLICULITIS

ETIOLOGY
Infection and inflammation of hair follicles associated with suppurative organisms, including staphylococci. Identifiable forms of folliculitis as individual diseases include:

- Staphylococcal dermatitis of horses
- Contagious acne of horses
- Benign facial folliculitis of sucking lambs
- Demodectic mange
- **Bovine sterile eosinophilic folliculitis.**

PATHOGENESIS
Sebaceous gland ducts blocked by inspissated secretion and epithelial debris or by pressure become infected. Folliculitis is also a sequel to seborrhea, with hypertrophy of sebaceous glands and dilatation of their ducts.

CLINICAL FINDINGS
The sequence of lesion development is: nodules around the base of the hair, then pustules, then crusts, finally hair fiber loss. Itching may occur, but pain and rupture of pustules under pressure are more common. Pustule rupture leads to contamination of the surrounding skin and development of further lesions.

In bovine sterile, eosinophilic folliculitis, the multiple lesions are crusted, alopecic, 3–5 cm diameter nodules on all parts of the body except the limbs. They are composed largely of eosinophils and are negative on culture.

CLINICAL PATHOLOGY
Swabs should be taken for bacteriological and parasitological examination.

DIFFERENTIAL DIAGNOSIS
Diagnostic confirmation is by demonstration of infection of hair follicles in a biopsy specimen.

- **Udder impetigo of cattle**; lesions are superficial and confined to the udder
- **Infectious dermatitis (contagious pyoderma) of baby pigs** associated with streptococci and staphylococci; lesions are limited to face and caused by bites from needle teeth
- **Exudative epidermitis of pigs** due to *S. hyicus*, with extensive seborrheic dermatitis
- **Ulcerative dermatitis of face in adult sheep**
- **Leg dermatitis down to coronet of sheep**
- **Chronic pectoral and ventral midline abscesses in horses** due to *Corynebacterium pseudotuberculosis*; not a skin lesion but it resembles furunculosis.

TREATMENT
Primary treatment commences with cleaning the skin by washing followed by a disinfectant rinse. Affected areas should be treated with antibacterial ointments or lotions. If the lesions are extensive the parenteral administration of antibiotics is recommended. The course of treatment should last 1 week; in chronic cases this may need to be at least 1 month; a broad-spectrum preparation such as trimethoprim–sulfadiazine is recommended. In stubborn cases an autogenous vaccine may be helpful.

Supportive treatment – infected animals should be isolated and grooming tools and blankets disinfected.

DISEASES OF HOOVES AND HORNS

Diseases of the hooves are presented in textbooks on large animal surgery and lameness in horses and cattle.

Horn cancer is covered in the section on squamous-cell carcinoma of the skin,

and hoof diseases that cause lameness are listed in Table 13.1.

Skin diseases of the bovine digit associated with lameness

Diseases of the skin of bovine digit include digital dermatitis (hairy heel warts), interdigital necrobacillosis (foot rot), dermatitis verrucosa and interdigital hyperplasia.[1] These are presented in Chapters 16–20.

Sloughing of the hooves and dewclaws (chestnuts)

Separation of the hooves from the sensitive laminae and, in severe cases, sloughing of the horn occur in:

- Severe edema of the legs, due to limb lymphangitis or from severe trauma, causing capillary dilatation and fluid effusion into the laminar tissues
- Burns in grass fires where only the undersurface of the body is burned
- Coronitis occurring as part of pemphigus in horses
- Horses poisoned by eating mushrooms
- Terminally in laminitis.

There is no treatment once the hooves have sloughed and all attempts should be made to avoid it if separation is already evident at the coronet. Reduction of the swelling in the limb is critical, requiring enhancement of lymphatic and vascular drainage from the area.

Diseases of the subcutis

SUBCUTANEOUS EDEMA (ANASARCA)

ETIOLOGY

Extensive accumulation of edema fluid in the subcutaneous tissue is part of general edema and caused by the same diseases, as follows.

Increased hydrostatic pressure

- Congestive heart failure
- Vascular compression by tumor, e.g. anterior mediastinal lymphosarcoma, udder engorgement in heifer about to calve.

Hypoproteinemic edema

- In liver damage with reduced albumin production due to liver insufficiency, especially fascioliasis
- Renal damage with protein loss into urine occurs rarely in animals.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is by clinical detection of serous fluid in a subcutaneous site.

- In cattle, **extravasation of urine** as a result of urethral obstruction and perforation
- **Subcutaneous hemorrhage, hematoma or seroma**, which is not necessarily dependent, nor bilaterally symmetrical
- **Ventral hernia**, usually unilateral and does not pit on pressure
- **Cellulitis**, usually asymmetric, hot, often painful, does not pit on pressure and can be sampled by needle puncture

Renal amyloidosis

- Protein-losing enteropathy, e.g. in intestinal lymphosarcoma
- Intestinal nematodiasis
- Protein starvation

Vascular damage

- In purpura hemorrhagica
- Anasarca in hypovitaminosis A
- Subcutaneous plaques of equine infectious anemia and dourine
- Subcutaneous plaques in dourine
- Horses standing in black walnut shavings as bedding.

Inflammatory edema

Many bacteria cause local edema due to infection:

- *Clostridium* spp. are the most noted
- Anthrax in swine and horses
- Sporadic lymphangitis of horses
- Insect, especially bee, stings.

Fetal anasarca

- Some pigs with congenital goiter also have **myxedema**, especially of the neck
- Sporadic cases due to unknown causes are sometimes associated with deformities, e.g. in Awassi sheep[1]
- Congenital absence of lymph nodes and some lymph channels causes edema to be present at birth.

PATHOGENESIS

Alteration to the balance between the hydrostatic pressure of intravascular fluids, the blood and lymph, to the osmotic pressure of those fluids or to the integrity of the filtering mechanism of the capillary endothelium leads to a positive advantage by the hydrostatic pressure of the system and causes a flow of fluid out of the vessels into the tissues. This results in anasarca and, coincidentally, in fluid accumulations in the body cavities.

CLINICAL FINDINGS

There is visible swelling, either local or diffuse. The skin is puffy and pits on pressure; there is no pain unless inflammation is also present. In large animals the edema is usually confined to the ventral aspects of the head, neck and trunk and is seldom seen on the limbs.

CLINICAL PATHOLOGY

Anasarca is a clinical diagnosis but many estimates, for example of arterial blood pressure, serum and urine protein levels, provide contributory evidence. Differentiation between obstructive and inflammatory edema can be made by cytological and bacteriological examination of the fluid.

TREATMENT

Primary treatment requires correction of the causal abnormality. Supportive treatment includes removal of the fluid by drainage methods such as intubation or multiple incision, both likely to result in damaging infection in animals in the average farmyard situation, or by the use of a diuretic.

ANGIOEDEMA (ANGIONEUROTIC EDEMA)

ETIOLOGY

Transient, localized subcutaneous edema due to an allergic reaction and caused by endogenous and exogenous allergens provokes either local or diffuse lesions. Angioedema occurs most frequently in cattle and horses on pasture, especially during the period when the pasture is in flower. This suggests that the allergen is a plant protein. Fish meal may also provoke an attack. Recurrence in individual animals is common.

PATHOGENESIS

After an initial erythema, local vascular dilatation is followed by leakage of plasma through damaged vessels.

CLINICAL FINDINGS

Local lesions most commonly affect the head with diffuse edema of the muzzle, eyelids, conjunctiva and cheeks. Occasionally only the conjunctiva is affected, so that the eyelids are puffy, the nictitating membrane swollen and protruding, and lacrimation is profuse. Affected parts are not painful to touch but shaking the head and rubbing against objects suggest irritation. Salivation and nasal discharge may be accompanying signs.

Perineal involvement includes vulvar swelling, often asymmetrical, and the perianal skin, and sometimes the skin of the udder, is swollen and edematous. When the **udder** is affected, the teats and base of the udder are edematous and cows may paddle with the hind limbs, suggesting irritation in the teats. Edema

of the lower limbs, usually from the knees or hocks down to the coronets, is a rare sign.

Systemic signs are absent, except in those rare cases where angioedema is part of a wider allergic response, when bloat, diarrhea and dyspnea may occur, often with sufficient severity to require urgent treatment.

CLINICAL PATHOLOGY

The blood eosinophil count is often within the normal range, but may be elevated from a normal level of 4–5% up to 12–15%.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is found with sudden onset and disappearance of edema at the typical sites.

- **Subcutaneous edema (above) due to vascular pressure** occurs mostly in dependent parts and is not irritating
- In horses, and rarely in cattle, angioedema may be simulated by **purpura hemorrhagica**, but hemorrhages are usually visible in the mucosae in purpura.

TREATMENT

Primary treatment to remove the specific cause is usually impossible but affected animals should be removed from the suspected source of allergens. Cattle running at pasture should be confined and fed on dry feed for at least a week.

Supportive treatment to relieve the vascular lesion is always administered even though spontaneous recovery is the rule. In acute cases with severe dyspnea epinephrine can be administered parenterally, but cautious intravenous injection is recommended. For subacute cases corticosteroids or other anti-inflammatories are preferred over antihistamines or epinephrine; usually only one injection is required.

SUBCUTANEOUS EMPHYSEMA

ETIOLOGY

Emphysema, free gas in the subcutaneous tissue, occurs when air or gas accumulates in the subcutaneous tissue as a result of:

- Air entering through a cutaneous wound made surgically or accidentally
- Air entering tissues through a discontinuity in the respiratory tract lining, e.g. in fracture of nasal bones; trauma to pharyngeal, laryngeal, tracheal mucosa caused by external or internal trauma as in lung puncture by a fractured rib; a foreign body, as in traumatic reticulitis
- Rumen gases migrating from a rumenotomy or ruminal trocharization
- Extension from a pulmonary emphysema
- Gas gangrene infection.

PATHOGENESIS

Air moves very quickly through fascial planes, especially when there is local muscular movement. For example when a lung is punctured, or in cases of severe interstitial pulmonary edema, air escapes under the visceral pleura and passes to the hilus of the lung, hence to beneath the parietal pleura, between the muscles and into the subcutis.

CLINICAL FINDINGS

Visible subcutaneous swellings are soft, painless, fluctuating and grossly crepitant to the touch, but there is no external skin lesion. In gas gangrene, discoloration, coldness and oozing of serum may be evident. Emphysema may be sufficiently severe and widespread to cause stiffness of the gait and interference with feeding and respiration.

CLINICAL PATHOLOGY

None is necessary except in cases of gas gangrene, when a bacteriological examination of fluid from the swelling should be carried out to identify the organism present.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is based on the observation of crepitus and the extreme mobility of the swelling; these distinguish emphysema from other superficial swellings.

- **Anasarca**, dependent and pits on pressure (see above)
- **Hematoma, seroma at injury sites**, confirmed by needle puncture (see below)
- **Cellulitis** is accompanied by toxemia, confirmed by needle puncture.

TREATMENT

Primary treatment is to close the entry point for the gas but this is usually impossible to locate or to close. **Supportive treatment** is only necessary when the emphysema is extensive and incapacitating, when multiple skin incisions may be necessary. Gas gangrene requires immediate and drastic treatment with antibiotics.

LYMPHANGITIS

This is characterized by inflammation and enlargement of the lymph vessels and is usually associated with lymphadenitis.

ETIOLOGY

Lymphangitis is due in most cases to local skin infection with subsequent spread to the lymphatic system. Common causes are as follows.

Horse

- Glanders, epizootic lymphangitis, sporadic lymphangitis, ulcerative lymphangitis due to *C. pseudotuberculosis*
- Strangles in cases where bizarre location sites occur
- In foals ulcerative lymphangitis associated with *Streptococcus zooepidemicus.*

Cattle

- Skin farcy associated with *Nocardia farcinica, Rhodococcus equi*
- Cutaneous tuberculosis associated with atypical mycobacteria, rarely *Mycobacterium bovis.*

PATHOGENESIS

Spread of infection along the lymphatic vessels causes chronic inflammation and thickening of the vessel walls. Abscesses often develop, with discharge to the skin surface through sinuses.

CLINICAL FINDINGS

An indolent ulcer usually exists at the original site of infection. The lymph vessels leaving this ulcer are enlarged, thickened and tortuous and often have secondary ulcers or sinuses along their course. Local edema may result from lymphatic obstruction. In chronic cases much fibrous tissue may be laid down in the subcutis and chronic thickening of the skin may follow. The medial surface of the hindlimb is the most frequent site, particularly in horses.

CLINICAL PATHOLOGY

Bacteriological examination of discharges for the presence of the specific bacteria or fungi is common practice.

TREATMENT

Primary treatment requires vigorous, early surgical excision or specific antibiotic therapy.

Supportive treatment is directed toward removal of fluid and inflammatory exudate and relief of pain.

PANNICULITIS

Panniculitis is diffuse, sterile inflammation of subcutaneous fat. Deep-seated, firm and painful nodules up to 5 cm in diameter develop, often in large numbers, anywhere over the body but especially on the neck and sides, most commonly in young horses and rarely in cattle.[1] The lesions may fluctuate greatly in size and number, or even disappear spontaneously. In a few cases there is transient fever, reduced feed intake and weight loss. Lameness may be evident in horses with extensive lesions.[2]

Diagnosis is by histological examination of a biopsy specimen. At necropsy examination there are no other lesions. The

lesions reduce in size and number after the administration of dexametasone, but recur when treatment stops.[3]

HEMORRHAGE

This is extravasation of whole blood into the subcutaneous tissues.

ETIOLOGY

Accumulation of blood in the subcutaneous tissues beyond the limit of that normally caused by trauma may be due to defects in the coagulation mechanism or to increased permeability of the vessel wall.

Common causes include:

- Dicoumarol poisoning from moldy sweet clover hay
- Purpura hemorrhagica in horses
- Bracken poisoning in cattle, and other granulocytopenic disease. These diseases are manifested principally by petechiation and the lesions are observed only in mucosae
- Hemangiosarcoma in subcutaneous sites
- Inherited hemophilia.

PATHOGENESIS

Leakage of blood from the vascular system can cause local swellings, which interfere with normal bodily functions but are rarely sufficiently extensive to cause signs of anemia.

CLINICAL FINDINGS

Subcutaneous swellings resulting from hemorrhage are diffuse and soft with no visible effect on the skin surface. There may be no evidence of trauma. Specific locations of subcutaneous hemorrhages include the frontal aspect of the chest – due to fracture of the first rib in collisions at full gallop and often fatal through internal hemorrhage – and perivaginal at foaling, causing massive swelling of the perineum and medial aspect of the thigh.

CLINICAL PATHOLOGY

Visual examination of a needle aspirate confirms the existence of subcutaneous hemorrhage. Diagnosis of the primary cause is greatly assisted by platelet counts and prothrombin, clotting and bleeding times.

TREATMENT

Primary treatment targets removal or correction of the cause.

Supportive treatment: The hemorrhages should not be opened until clotting is completed, except in the case of a massive hemorrhage that is interfering with respiration, defecation or urination. If blood loss is severe, blood transfusions may be required. Parenteral injection of coagulants can be justified if the hemorrhages are recent and severe.

DIFFERENTIAL DIAGNOSIS

Subcutaneous hemorrhages are usually associated with hemorrhages into other tissues, both manifestations being due to defects in clotting or capillary wall continuity.

Diagnostic confirmation is by opening the swelling, preferably by needle puncture to avoid massive blood loss and difficulty in locating the bleeding point.

NECROSIS AND GANGRENE

Necrosis is tissue death; gangrene is sloughing of dead tissue. When either change occurs in the skin it involves the dermis, epidermis and subcutaneous tissue.

ETIOLOGY

Severe **damage to the skin** in the following categories causes gangrene:

- Severe or continued trauma, e.g. pressure sores, saddle and harness galls, carpal or tarsal necrosis in recumbent animals
  Strong caustic chemicals, e.g. creosote
  Severe cold or heat, bushfires and stable fires being the worst offenders. Frostbite is an unusual occurrence in animals unless the patient has a circulatory deficit, e.g. in the neonate, in severe shock or toxemia
  Beta-irradiation.

Infections, especially:

Erysipelas and salmonellosis in pigs
Clostridial infections in cattle affecting subcutis and muscle
Staphylococcal mastitis in cattle, pasteurella mastitis in sheep
Bovine ulcerative mammillitis of the udder and teats.

Local vascular obstruction – obstruction by thrombi or arterial spasm causes skin gangrene, but includes deeper structures also from poisoning by:

Claviceps purpurea
Festuca arundinacea (probably due to an accompanying fungus)
Aspergillus terreus
Mushrooms.

Similar cutaneous and deeper structure involvement occurs in systemic infections in which bacterial emboli block local vessels, e.g. in salmonellosis in calves, and after tail vaccination of calves with *Mycoplasma mycoides.*

Other causes

Final stages of photosensitive dermatitis and flexural seborrhea
Screw-worm infestation.

PATHOGENESIS

The basic cause of gangrene is interference with local blood supply by external pressure, by severe swelling of the skin, as in photosensitization, or by arteriolar spasm or damage to vessels by bacterial toxins.

CLINICAL FINDINGS

If the arterial and venous systems are closed the initial lesions will be moist and the area is swollen, raised, discolored and cold. Separation occurs at the margin and the affected skin may slough before it dries; the underlying surface is raw and weeping.

If the veins and lymphatics remain patent, the lesion is dry from the beginning and the area is cold, discolored and sunken. Sloughing may take a long time and the underlying surface usually consists of granulation tissue.

DIFFERENTIAL DIAGNOSIS

Confirmation of the diagnosis is by visual recognition.

- **Gangrenous mastitis** in cows or ewes
- **Photosensitive dermatitis**
- ***Claviceps purpurea* poisoning.**

TREATMENT

Primary treatment requires removal of the etiological insult.

Supportive treatment comprises the application of astringent and antibacterial ointments to facilitate separation of the gangrenous tissue and to prevent bacterial infection.

SUBCUTANEOUS ABSCESS

Most subcutaneous abscesses are matters of purely local and esthetic concern but if sufficiently extensive and active **localized infections**, they may cause mild toxemia. Their origins include the following.

Trauma

Most subcutaneous abscesses are the result of traumatic skin penetration with resulting infection. For example **facial subcutaneous abscesses** are common in cattle eating roughage containing foxtail grass (*Hordeum jubatum*). Several animals in a herd may be affected at one time. The awns of these plants migrate into the

cheek mucosa, causing subcutaneous abscesses containing *Arcanobacterium* (formerly *Actinomyces*) *pyogenes* and *Actinobacillus* spp. The abscesses contain purulent material, are well encapsulated and must be surgically drained and treated as an open wound. Medical therapy with parenteral antimicrobials and iodine is ineffective.

Hematogenous

Rarely the infection reaches the site via the bloodstream, e.g. chronic pectoral abscesses of horses, infections in foals with *R. equi*, infections in all species with *Pasteurella pseudotuberculosis*, infections in lambs with *Histophilus somni* (formerly *Histophilus ovis*) or *Pseudomonas pseudomallei*.

Extension

Abscesses may originate by **extension** from lesions of furunculosis, pyoderma or impetigo. or by **contiguous spread** by contact from an internal organ, e.g. from traumatic reticuloperitonitis.

CUTANEOUS CYSTS

Cysts contained by an epithelial wall enclosing amorphous contents or living tissue may be congenital, inherited defects or acquired as a result of inappropriate healing of accidental wounds. They are smooth, painless, about 1.5–2.5 cm in diameter, round and usually fluctuating, although inspissated contents may make them feel quite hard. The skin and hair coat over them is usually normal, although some may leak mucoid contents on to the skin. Epidermoid cysts are lined with skin; dermoid cysts usually contain differentiated tissue such as sebaceous glands and hair follicles; dentigerous cysts contain teeth or parts of them. Acquired cysts include apocrine, sebaceous and keratin varieties.

Developmental cysts, which are present from birth, are usually located at specific anatomical sites, and include:

- **Branchial cysts** in the neck, formed from an incompletely closed branchial cleft
- **False nostril cysts** in horses
- **Wattle cysts** in goats.

Cysts may occur anywhere on the body, but most commonly they are found near the dorsal midline.[1] In horses a common site is the base of the ear.

Other diseases that cause cutaneous nodules in horses include collagenolytic granuloma, mastocytosis, amyloidosis, lymphoma, sarcoid and infestation with *Hypoderma* spp.

Surgical excision for cosmetic reasons is common practice.[2]

Granulomatous lesions of the skin

Granulomatous lesions are chronic inflammatory nodules, plaques and ulcers; they are cold, hard, progress slowly and are often accompanied by lymphangitis and lymphadenitis. In many cases there is no cutaneous discontinuity, nor alopecia. Some of the common causes in animals are as follows.

Cattle

- *Mycobacterium* spp. especially *Mycobacterium farcinogenes*
- *Nocardia farcinica*
- *A. lignieresi*
- Infestation with *Onchocerca* sp.
- *Hypoderma* sp. larvae
- *Mucor* sp. fungi in thick-walled nodules in the skin on the posteroventral aspect of the udder
- Lechiguana, a disease of cattle in Brazil in which very large granulomata consisting of fibrous tissue and containing *Pasteurella granulomatis* develop in subcutaneous sites in any part of the body.[1]

Sheep

- Strawberry footrot – *D. congolensis*
- Ecthyma
- Ulcerative lesions of lower jaw and dewlap associated with *A. lignieresi*.

Pigs

- *Actinomyces* spp. and *B. suilla* cause lesions on the udder.

Horses

- Tumorous calcinosis causes hard, painless, spherical granulomata, up to 12 cm in diameter, near joints and tendon sheaths, especially the stifle joint. Surgical removal is recommended
- Cutaneous amyloidosis
- Collagenolytic granuloma (nodular necrobiosis) – the most common nodular skin disease of the horse.[2] The etiology is unknown. There are multiple firm nodules located in the dermis ranging in size from 0.5–5 cm in diameter. The overlying skin surface and hair are usually normal. Biopsy reveals collagenolysis. Treatment consists of surgical removal and consideration of corticosteroids
- Botryomycosis, or bacterial pseudomycosis, results from bacterial infection at many sites, often accompanied by a foreign body. Lesions on the limbs, brisket, ventral abdomen and scrotum vary in size from nodules to enormous fungating growths composed of firm inflammatory tissue riddled by necrotic tracts, leading to discharging sinuses, often containing small, yellow-white granules or 'grains'. Surgical excision is the only practicable solution
- Equine eosinophilic granuloma – non-alopecic, painless, nonpruritic, firm nodules, 2–10 cm in diameter and covered by normal skin develop on the neck, withers and back of horses, especially in the summer. The cause is unknown and palliative treatment, surgical excision or corticosteroid administration is usually provided
- Systemic granulomatous disease (equine sarcoidosis)[3] – a rare disease of horses characterized by skin lesions and widespread involvement of the lungs, lymph nodes, liver, gastrointestinal tract, spleen, kidney, bones, and central nervous system
- *Actinobacillus mallei* – cutaneous farcy or glanders
- *Actinomadura* spp. and *Nocardia brasiliensis* – painless mycetomas
- *Histoplasma farciminosum* – epizootic lymphangitis
- *C. pseudotuberculosis* – ulcerative lymphangitis
- *Habronema megastoma*, *Hyphomyces destruens* as causes of swamp cancer, bursattee, Florida horse leech and blackgrain mycetoma
- Infestation with *Onchocerca* sp.
- Chronic urticaria.[4]

Cutaneous neoplasms

Many cutaneous neoplasms have been recorded in large animals but at a very low incidence. A brief description of only the more common types is given here.

PAPILLOMA AND SARCOID

Sarcoid of horses and cutaneous papillomatosis of horses, goats, and cattle are specific diseases. The lesions are characteristically nodular growths of viable tissue and, if there is no traumatic injury, with no discontinuity of the covering epidermis.

Aural flat warts (aural plaques) occur commonly in the horse and are

caused by the papilloma virus.[1] Blackflies may serve as a vector. Lesions consist of one to several gray or white plaques involving the inner surface of the pinna. Similar lesions may occur around the anus, vulva and inguinal regions. The lesions are usually asymptomatic, may persist indefinitely, may regress spontaneously and are refractory to treatment.

SQUAMOUS-CELL CARCINOMA

This neoplasm can occur anywhere on the skin, and also in the mouth and maxillary sinus.

- **Cancer-eye** is the commonest lesion, on the eyelids and the eyeball in horses and cattle
- **Genital squamous-cell carcinomas** affecting the glans penis and prepuce of aged horses can cause fatal metastases unless amputation is performed in the early stages. Grossly similar lesions are caused by epithelial hyperplasia, habronemiasis, and squamous papillomata. Squamous-cell carcinomas also occur on the vulva of cattle and a greater incidence has been observed on unpigmented than on pigmented vulvas
- **Vulvar squamous-cell carcinoma** appears frequently in Merino ewes as a result of excessive exposure of vulvar skin to sunlight after radical perineal surgery to help control blowfly strike[2]
- **Cancer of the horn core** in cattle and rarely in sheep[3] is a squamous-cell carcinoma arising from the mucosa of the frontal sinus and invading the horn core; it is most prevalent in aged, white, Indian breeds of cattle. In the early stages affected animals may rub the horns against a fixed object, or shake the head frequently. A bloody discharge begins from the nostril on the affected side, or from the base of the horn, and the animal holds its head down and toward one side. The horn becomes loosened and falls off, leaving the tumor exposed to infection and fly infestation. Secondary metastases are not uncommon. The high prevalence of metastases in regional lymph nodes and internal organs discourage treatment but a phenol extract of horn core tissue is immunogenic and immunotherapy may be a successful treatment technique.[4] Other forms of therapy are also practiced for squamous-cell carcinoma generally, including surgical excision, preferably by cryotherapy, and radiofrequency hyperthermia
- **Ear cancer** in sheep is in most cases a squamous-cell carcinoma. The lesion commences around the free edge of the ear and then invades the entire ear, which becomes a large, cauliflower-shaped mass. A high incidence may occur in some flocks but the cause is not known; the presence of papilloma virus in many aural precancerous lesions suggests that the virus may participate in the etiology
- **Ovine skin cancer**: a high incidence of epitheliomas has been recorded in some families of merino sheep in Australia. The lesions occurred on the woolled skin and were accompanied by many cutaneous cysts. It has been suggested that predisposition to the neoplasm is inherited. Metastasis is common with both epitheliomas and squamous-cell carcinomas
- **'Brand cancer'**, which occurs as a granulomatous mass at the site of a skin fire or freeze brand, is usually considered to be of chronic inflammatory rather than neoplastic origin, but squamous cell carcinomas are recorded at branding sites in sheep and cattle[5]
- **In goats**, the perineum is a common site for squamous-cell carcinoma. The udder, ears, and base of the horns may also be affected. Ulceration, fly strike and matting of hair are unattractive sequels. A bilaterally symmetrical vulvar swelling due to ectopic mammary tissue that enlarges at parturition is likely to be confused with squamous-cell carcinoma. Milk can be aspirated from the swellings.

MELANOMA

Superficially situated melanomas occur most commonly at the tail root in aged, gray horses and rarely in dark-skinned cattle, sheep and goats. Equine lesions are not usually malignant and rarely metastasize widely. The skin is intact but ulcerates in rapidly growing tumors. Bovine melanomas are usually benign. A high rate of occurrence of malignant melanomas has been observed in neonatal pigs of the Duroc–Jersey breed. Inherited melanomas and kindred neoplasms occur commonly in Sinclair miniature and NIH miniature swine but they frequently regress spontaneously.

CUTANEOUS ANGIOMATOSIS

This condition is manifested clinically by recurrent profuse hemorrhage from small (1–1.5 cm diameter), single, inconspicuous, cutaneous lesions situated most commonly along the dorsum of the back in adult dairy cows. The lesions consist of what appears to be protruding granulation tissue and are benign. Surgical excision is effective.

A juvenile version of angiomatosis in calves[6] is characterized by similar lesions, but in many organs, sometimes including the skin.

LYMPHOMATOSIS

In cattle and horses skin lesions occur as nodules in the subcutaneous tissue, most commonly in the paralumbar fossae and the perineum. In cattle the lesions are associated with the virus of epizootic bovine leukosis, and are only one manifestation of the disease, usually being accompanied by lesions in other organs. In horses there are no leukemic lesions in lymph nodes or visceral organs.

MAST CELL TUMORS

Cattle

Cutaneous mastocytoma appears as a rapidly growing intradermal nodule, which may become widely disseminated if excised or, less commonly, there may be multiple tumors in the first instance. The nodules show no tendency to metastasize internally and are compatible with life provided they do not ulcerate and become repulsive.

Horses

Cutaneous mastocytomas (mastocytosis) is a neoplasm recorded in horses of all ages. The neonatal form is manifested by multiple cutaneous nodules up to 3 cm in diameter; in adults there are usually only single lesions. The skin surface is intact except for larger lesions, which are sometimes ulcerated. Lesions occur all over the body, but especially on the flanks. Each nodule appears, enlarges and then regresses during a period of about 30 days. Fresh lesions may appear for up to about a year. Histologically the lesions contain aggregations of mast cells. Surgical excision is recommended, few cases showing any recurrence at the surgery site.

NEUROFIBROMATOSIS

This common lesion of nerves in cattle usually attracts attention only in abattoir specimens but can occur in a cutaneous form resembling a similar disease of humans;[7] a particularly high prevalence of this benign disease is recorded in breeds of European pied cattle. Clinical cases are usually recorded in calves, in which there are cutaneous lesions that appear as tumor-like lumps between the eyes and on the cheeks. They are flat, round tumors up to 8 cm in diameter and of a lumpy, elastic consistency.

HISTIOCYTOMA

This is a very rare benign neoplasm in farm animals but is recorded as cutaneous nodules or plaques, which bleed easily, in

goats and cattle. The lesions regress spontaneously.

HEMANGIOMA AND HEMANGIOSARCOMA

Benign cutaneous hemangiomas occur rarely in most species, including a rare occurrence in cattle[8] and relatively commonly on distal parts of limbs in young horses, sometimes in neonates.[9] The lesions are small (1–3 cm diameter), round, blue to black lumps that bleed easily and are morphologically the same as bovine cutaneous angiomatosis lesions. Vascular nevi in newborn foals have a very similar appearance.

Hemangiosarcomas (hemangioepithelioma) are malignant tumors recorded relatively frequently in older horses. They are large, highly vascular, subcutaneous masses, usually associated with one or more internal lesions. The primary lesion may be internal, commonly in the spleen, or cutaneous. Recurrence after excision, extensive local infiltration and death due to anemia are common sequelae.[10]

LIPOMA

External lipomas are not cutaneous neoplasms but they do occur as large subcutaneous masses and invade fascia and muscle.[11] They are generally susceptible to surgical removal.

Congenital defects of the skin

The common diseases are inherited. Examples are:

- Inherited parakeratosis (lethal trait A46, Adema disease, inherited nutritional zinc deficiency) of cattle
- Dermatosis vegetans of pigs
- Inherited congenital ichthyosis (fish-scale disease) of calves
- Inherited hypotrichoses and alopecias in cattle
- Congenital absence of skin (epitheliogenesis imperfecta) in all species
- Epitheliogenesis imperfecta, a rare congenital defect in foals inherited as a single autosomal recessive trait.[1] There are sharply demarcated areas in which there is absence of epidermis. The lesions bleed easily and secondary bacterial infection is common; death usually due to septicemia
- Epidermolysis bullosa of foals, which occurs especially the Belgian breed and may occur in American Saddlebred, is inherited as autosomal recessive.[1] The defect is present at birth but it may be several months before the disease is clinically apparent.[2] Lesions involve the skin, mucocutaneous junctions and oral mucosa and are characterized by separation of the dermal–epidermal junction beneath the basal epithelium
- Hyperelastosis cutis of newborn foals[1] is a group of inherited connective tissue diseases, also known as cutaneous asthenia, Ehlers–Danlos syndrome and dermatopraxis, that is seen only in Quarter horses. The condition is characterized by sharply demarcated areas of loose skin, which is hyperfragile, tears easily and exhibits impaired healing
- Epitheliogenesis imperfecta in piglets due to ingestion of *Fusarium* spp. toxin
- Dyserythropoiesis and dyskeratosis of cattle
- Hair-coat-color-linked follicular dysplasia
- Familial acantholysis and dermatosparaxis – in familial bovine acantholysis the skin is normal at birth, but is shed later at the carpus and the coronet
- Hereditary junctional mechanobullous disease of foals, calves, lambs
- Inherited epidermolysis bullosa and inherited redfoot, both of sheep
- Dermatosparaxis, hyperelastosis cutis and the Ehlers–Danlos syndrome, all in cattle. A mild form of dermatosparaxis is recorded in sheep
- Vascular nevus: irregularly shaped, cutaneous masses, present at birth and originally covered with hair, but subsequently hairless. Individual lesions in foals are 3–4 cm in diameter, bright pink, ulcerated and inflamed. The lesions consist of densely packed convoluted blood vessels, which bleed easily. Most lesions are on the lower limbs, especially at the coronet. Surgical excision is usually attempted
- Dermoid cysts.

Congenital skin neoplasms

Congenital tumors are defined as those existing at birth. A broader definition is that congenital tumours can be detected in fetuses, and newborns until 2 months of age.[1] Embryonic tumours are those that arise during embryonic, fetal or early postnatal development from a particular organ rudiment or tissue while it is still immature. Hamartomas are benign, tumor-like nodules composed of overgrowth of mature cells, which normally occur in the affected part but often with one element predominating. Hamartomas include hemangiomas, ameloblastomas and rhabdomyomas. Teratomas are true neoplasms consisting of different types of tissue not native to the area in which they occur.

Cattle

Congenital skin neoplasms of cattle described include mast cell tumors, lymphosarcoma, myxoma and vascular hamartoma.[2] Benign melanomas, mastocytomas[1,3] hemangiomas and lymphangiomas, fibrosarcomas, neurofibromatosis, subcutaneous lipomas, multiple lipomas and retroperitoneal lipomas have also been recorded in calves.[1] The comparative aspects of tumors in calves have been described.[4]

Pigs

The literature on congenital and hereditary tumors in piglets has been reviewed.[5] Spindle cell sarcoma, malignant melanoma and papillomatosis are common congenital tumors of the skin of piglets. Congenital cutaneous papillomatosis of the head and neck of a newborn piglet has been described from a pig-breeding farm where sporadic cutaneous papillomatosis of the prepuce and scrotum had previously occurred in several boars.[4]

Foals

Congenital tumors in foals are rare. Congenital skin tumors are of the papillomatous, vascular and melanocytic types.[6] The vascular tumors are capillary hemangiomas, cavernous hemangiomas, and hemangiosarcomas.

Diseases of the conjunctiva

Some of the common diseases of the conjunctiva are listed here because they are often treated medically as they are often secondary to the presence of some other disease, and also because an examination of the conjunctiva often provides additional information on which to base a diagnosis. General practitioners need to know something of the common diseases of the eye for these reasons.

The following notes are intended only to provide guidelines to the relevant sections of Part Two, where specific forms of conjunctivitis have been described in detail.

CONJUNCTIVITIS AND KERATOCONJUNCTIVITIS

This is inflammation of the covering membrane of the eye, including the orbit and the inner surface of the eyelids. The inflammation commonly extends to layers below the conjunctiva, hence keratoconjunctivitis.

ETIOLOGY

Specific conjunctivitis

Cattle

Infectious bovine keratoconjunctivitis is associated with:

- *Moraxella bovis*, the only significant cause
- *M. bovis* with infectious bovine rhinotracheitis virus
- *Neisseria catarrhalis*
- *Mycoplasma* spp.
- *Chlamydophila* spp.

Sheep

- *Rickettsia conjunctivae* is the important infection
- *N. catarrhalis*
- *Mycoplasma conjunctivae*
- *Acholeplasma oculi* is also listed
- *Chlamydophila* spp.

Goats

- *R. conjunctivae.*

Pigs

- *Rickettsia* spp.

Horses

There is no well-identified specific conjunctivitis in this species but *Moraxella equi* has been recorded as a cause on several occasions.[1] There is also infestation with *Thelazia* spp. and *Habronema* spp.

Specific keratitis lesions

- *Thelazia* spp. in cattle and horses
- *Onchocerca* spp. in cattle
- *Elaeophora schneideri* in sheep and goats
- *Habronema* spp. in horses
- Fungal keratomycosis in foals[1] and adult horses; *Aspergillus flavus* has been identified in some cases.

Aspergillus fumigatus is listed amongst the causes of mycotic keratitis in animals.[2] Most cases begin as traumatic injuries with secondary infections or begin in eyes treated for long periods with broad-spectrum antibiotics.

Secondary diseases in which conjunctivitis is a significant but secondary part of the syndrome

Cattle

- Bovine viral diarrhea
- Bovine malignant catarrh
- Rinderpest
- Infectious bovine rhinotracheitis
- Viral pneumonia due to various viruses.

Sheep

- Bluetongue.

Pigs

- Swine influenza
- Inclusion body rhinitis.

Horses

- Equine viral arteritis
- Equine viral rhinopneumonitis.

Nonspecific conjunctivitis

- Inflammation caused by foreign bodies or chemicals, or secondarily as exposure keratitis, and conjunctivitis/keratitis in paralysis of eyelids as in listeriosis. Ant-bite conjunctivitis occurs in similar circumstances.

CLINICAL FINDINGS

Blepharospasm and weeping from the affected eye are the initial signs. Watery tears are followed by mucopurulent, then purulent ocular discharge if the lesion extends below the conjunctiva. Varying degrees of opacity of the conjunctiva may develop, depending on the severity of the inflammation. In the severest lesions there is underrunning of the conjunctiva with pus accompanied by vascularization of the cornea. During the recovery stage there is often long-lasting, diffuse opacity of the eye and terminally a chronic white scar in some cases.

CLINICAL PATHOLOGY

In herd or flock outbreaks conjunctival swabs and/or scrapings should be taken for culture and examination of cells using special stains and histological techniques.

Congenital defects of the eyelids and cornea

DERMOID CYSTS

Ocular dermoid cysts are solid, skin-like masses of tissue, adherent usually to the anterior surface of the eye, causing irritation and interfering with vision. The eyelid, the third eyelid and the canthus may also be involved, and the lesions may be unilateral or bilateral. When they occur at a high frequency in a population, it is likely they are inherited, as they can be in Hereford cattle. It is also recorded in foals. The defect is sometimes associated with microphthalmos. Surgical ablation is recommended.

Diseases of the external ear

Ear cancer is discussed in the section on squamous cell carcinoma.

OTITIS EXTERNA

Otitis externa, inflammation of the skin and external auditory canal, can affect cattle of all ages, in isolated cases, an entire herd or in entire regions.[1] The literature on the causes of otitis in cattle has been reviewed.[1]

Arthropod parasites, foreign bodies and sporadic miscellaneous infections may cause irritation in the ear, accompanied by rubbing of the head against objects and frequent head-shaking.

In tropical and subtropical regions, parasitic otitis is more important than in other more temperate regions.[1,2] The mites *Raillietia auris* and *Dermanyssus avium*, the tick *Otobius magnini*, larvae (*Stephanofilaria zahaeeri*), free-living nematodes (*Rhabditis bovis*) and the blue fly (*Chrysomia bezziano*) are of importance in Europe, Africa, India and America. *Malassezia* spp., *Candida* spp., *Rhodotorula mucilaginosa*, *Aspergillus* spp. and *Micelia sterilia* are common causes of otitis externa in cattle in Brazil.[3,4]

When the syndrome occurs in a large number of a herd, as it does in tropical countries, it is necessary to look for a specific causative agent. *Rhabditis bovis* is the common cause. Affected animals are depressed, eat little and appear to experience pain when they swallow, and they shake their heads frequently. Both ears are affected in most cases and there is a stinking, blood-stained discharge that creates a patch of alopecia below the ear. The area is painful when touched, the external meatus of the aural canal is

obviously inflamed and the parotid lymph nodes are enlarged. Extension to the middle ear is an unusual sequel. Topical treatment with ivermectin and a broad-spectrum antibiotic is effective.

OTITIS MEDIA

Otitis media (middle ear infection) occurs in milk-fed calves from a few days of age up to 10 weeks and in weaned calves from 4–8 months and from 12–18 months of age.[1] The major bacteria that cause otitis media in calves include *Actinomyces* spp., *C. pseudotuberculosis, Escherichia coli, Histophilus somni* (formerly *Haemophilus somnus*), *Pasteurella multocida, Mannheimia* (formerly *Pasteurella*) *haemolytica, Pseudomonas* spp., *Streptococcus* spp. and *M. bovis.*

Diseases of the mammary gland

15

Introduction

Mastitis is inflammation of the parenchyma of the mammary gland regardless of the cause. Mastitis is therefore characterized by a range of physical and chemical changes in the milk and pathological changes in the glandular tissue. The most important changes in the milk include discoloration, the presence of clots and the presence of large numbers of leukocytes. There is swelling, heat, pain and edema in the mammary gland in many clinical cases. However, a large proportion of mastitic glands are not readily detectable by manual palpation nor by visual examination of the milk using a strip cup; these quarters represent subclinical infections. Because of the large numbers of subclinical cases, the diagnosis of mastitis depends largely on indirect tests, which depend, in turn, on the somatic cell concentration (SCC) or electrolyte (sodium or chloride) concentration of milk. It seems practicable and reasonable to define mastitis as a disease characterized by the presence of a significantly increased SCC in milk from affected glands. The increased SCC is, in almost all cases, due to an increased neutrophil concentration, represents a reaction of glandular tissue to injury and is preceded by changes in the milk that are the direct result of damage to glandular tissue. However, the exact clinical and laboratory changes that occur in the udder as a result of infection can also be caused by other factors in the absence of infection.[1] Until such time as it becomes common usage to define mastitis in terms of the sodium or chloride concentration of the milk (as measured by electrical conductivity) or increased permeability of the blood–milk barrier (as measured by albumin concentration) there appears to be no point in changing the current definition of mastitis based on an abnormal looking secretion or an increased SCC. Characterization of mastitis depends on the identification of the causative agent whether it be infectious or physical.

Most of the information presented here deals almost entirely with bovine mastitis because of its economic importance, but small sections on ovine, caprine, porcine and equine mastitis are included at the end of the chapter.

Synopsis

Etiology
- **Contagious pathogens**: *Staphylococcus aureus*, *Streptococcus agalactiae*, *Mycoplasma bovis* and *Corynebacterium bovis*
- **Teat skin opportunistic pathogens**: coagulase-negative staphylococci
- **Environmental pathogens**: environmental *Streptococcus* spp. including *Streptococcus uberis* and *Streptococcus dysgalactiae*, which are the most prevalent; less prevalent is *Streptococcus equinus* (formerly referred to as *Streptococcus bovis*). Environmental coliforms include the Gram-negative bacteria *Escherichia coli*, *Klebsiella* spp. and *Enterobacter* spp., and *Arcanobacterium* (formerly *Actinomyces*) *pyogenes*
- **Uncommon pathogens**: many, including *Nocardia* spp., *Pasteurella* spp., *Mycobacterium bovis*, *Bacillus cereus*, *Pseudomonas* spp., *Serratia marcescens*, *Citrobacter* spp., anaerobic bacterial species, fungi and yeasts

Epidemiology
- Incidence of clinical mastitis ranges from 10–12% per 100 cows at risk per year. Prevalence of intramammary infection is about 50% of cows and 10–25% of quarters. Case fatality rate depends on cause of mastitis

Bovine mastitis

GENERAL FEATURES

A total of about 140 microbial species, subspecies and serovars have been

- Contagious pathogens are transmitted at time of milking; teat skin opportunistic pathogens take any opportunity to induce mastitis; environmental pathogens are from the environment and induce mastitis between milkings
- Environmental pathogens are the most common cause of clinical mastitis in herds that have controlled contagious pathogens
- Prevalence of infection with contagious pathogens ranges from 7–40% of cows and 6–35% of quarters
- Prevalence of infection with environmental pathogens: coliforms 1–2% of quarters; streptococci less than 5%

Risk factors

- **Animal risk factors**: prevalence of infection increases with age. Most new infections occur in dry period and in early lactation. Highest rate of clinical disease occurs in herds with low somatic cell counts (SCCs). Morphology and physical condition of teat are risk factors. Selenium and vitamin E status influence incidence of clinical mastitis. High-producing cows are more susceptible
- **Environmental risk factors**: poor quality management of housing and bedding increases infection rate and incidence of clinical mastitis due to environmental pathogens
- **Pathogen risk factors**: ability to survive in environment, virulence factors (colonizing ability, toxin production), susceptibility to antimicrobial agents
- **Economics**: subclinical mastitis is a major cause of economic loss due to loss of milk production, costs of treatment and early culling

Clinical signs

- **Gross abnormalities in milk** (discoloration, clots, flakes, pus)
- **Physical abnormalities of udder**: acute – diffuse swelling, warmth, pain, gangrene in severe cases; chronic – local fibrosis and atrophy
- **Systemic response**: may be normal or mild, moderate, acute, peracute with varying degrees of anorexia, toxemia, dehydration, fever, tachycardia, ruminal stasis, and recumbency and death

Clinical pathology

- **Detection at the herd level**: bulk tank milk SCCs. Culture of bulk tank milk
- **Detection at the individual cow level**: abnormal looking milk, culture of composite or quarter milk samples. Indirect tests include SCCs of composite or quarter milk samples, California Mastitis Test (CMT) of quarter milk samples, inline milk conductivity tests of quarter milk samples
- **Use of selective media to differentiate Gram-positive and Gram-negative pathogens** in cases of clinical mastitis
- **Differential diagnosis list**: other mammary abnormalities: Periparturient udder edema, rupture of suspensory ligament, and hematomas. Blood in the milk of recently calved cows

Treatment

- **Clinical mastitis in lactating cow**: mild cases of clinical mastitis (abnormal secretion only) may not require treatment; however, all clinical mastitis episodes accompanied by an abnormal gland or systemic signs of illness should be treated with antimicrobial agents given by intramammary infusion (all cases) and parenterally (selected cases). Acute and peracute mastitis cases require also require supportive therapy (fluid and electrolytes) and nonsteroidal anti-inflammatory agents (NSAIDs). Culture milk of representative clinical cases but antimicrobial susceptibility testing has not been validated
- **Dry cow therapy**: intramammary infusion of long-acting antimicrobial agents at drying off provides the best treatment for subclinical mastitis due to contagious pathogens. Must adhere to milk withholding times after treatment with antimicrobial agents to prevent milk drug residues, which is major public health issue. Currently available cowside antimicrobial residue tests are not reliable

Control

- Principles of control:
  A. Eliminate existing infections
  B. Prevent new infections
  C. Monitor udder health status
- Components of Mastitis Control Program:
  1. Use proper milking management methods
  2. Proper installation, function, and maintenance of milking equipment
  3. Dry cow management
  4. Appropriate therapy of mastitis during lactation
  5. Culling chronically infected cows
  6. Maintenance of an appropriate environment
  7. Good record keeping
  8. Monitoring udder health status
  9. Periodic review of the udder health management program
  10. Setting goals for udder health status

isolated from the bovine mammary gland. Microbiological techniques have enabled precise determination of the identity of many of the mastitis pathogens. Based on their epidemiology and pathophysiology, these pathogens have been further classified as causes of **contagious**, **teat skin opportunistic** or **environmental** mastitis.

Contagious mastitis pathogens

There are many contagious mastitis pathogens. The most common are *Staphylococcus aureus* and *Streptococcus agalactiae*. The usual source of contagious pathogens is the infected glands of other cows in the herd; however, the hands of milkers can act as a source of *S. aureus*. The predominant method of transmission is from cow to cow by contaminated common udder wash cloths, residual milk in teat cups and inadequate milking equipment. Programs for the control of contagious mastitis involve improvements in hygiene and disinfection aimed at disrupting the cow-to-cow mode of transmission. In addition, methods to eliminate infected cows involve antimicrobial therapy and the culling of chronically infected cows.

In general, a conscientious mastitis control program will eradicate *S. agalactiae* from most dairy herds. It is much more difficult to deal with a herd that has a high prevalence of *S. aureus*, but *S. aureus* can be eradicated from low-prevalence herds.

Mycoplasma bovis is a less common cause of contagious mastitis; it causes outbreaks of clinical mastitis that do not respond to therapy and are difficult to control. Most outbreaks of *M. bovis* are associated with recent introductions of new animals into the herd. Characteristically, clinical mastitis occurs in more than one quarter, there is a marked drop in milk production and there is little evidence of systemic disease. The laboratory diagnosis of mycoplasmal mastitis requires specialized media and culture conditions. Antimicrobial therapy is relatively ineffective and culling is the predominant strategy.

Teat skin opportunistic mastitis pathogens

The incidence of mild clinical mastitis associated with bacterial pathogens that normally reside on the teat skin is increasing, particularly in herds that have controlled major contagious mastitis pathogens. Teat skin opportunistic pathogens have the ability to create an intramammary infection via ascending infection through the streak canal. Accordingly, their epidemiology of infections differs from those of contagious and environmental pathogens, and it is useful to consider them in a separate category. Coagulase-negative staphylococci are the most common teat skin opportunistic mastitis pathogens.

Environmental mastitis pathogens

Environmental mastitis is associated with three main groups of pathogens, the coliforms (particularly *E. coli* and *Klebsiella* spp.), environmental *Streptococcus* spp. and *Arcanobacterium pyogenes*. The source of these pathogens is the environment of the cow. The major method of transmission is from the environment to the cow by inadequate management of the environment. Examples include wet bedding, dirty lots, milking wet udders, inadequate premilking udder and teat preparation, housing systems that allow teat injuries, and poor fly control. Control strategies for environmental mastitis

include improved sanitation in the barn and yard areas, good premilking udder preparation so that teats are clean and dry at milking time, and fly control. Special attention is necessary during the late dry period and in early lactation.

Coliform organisms are a common cause of clinical mastitis, occasionally in a severe peracute form. Clinical cases of coliform infection are generally found in low levels in most herds and do not routinely result in chronic infections. There is increasing evidence that, as the contagious pathogens are progressively controlled in a herd, the incidence of clinical cases associated with coliform organisms increases. The pathogenesis, epidemiology, predisposing risk factors, diagnostic problems, therapy and control methods have been the subject of extensive, worldwide research efforts.

Environmental streptococci have become a major cause of mastitis in dairy cattle. Streptococcal infections are associated with many different species, however the most prevalent species are *Streptococcus uberis* and *Streptococcus dysgalactiae*. Infections with these organisms can cause clinical mastitis that is commonly mild to moderate in nature. More frequently, these organisms cause a chronic subclinical infection with an increased milk SCC. Many herds that have implemented the five-point program for mastitis control have found that environmental streptococci represent their most common mastitis problem.

A. pyogenes is an important seasonal cause of mastitis in dry cows and late pregnant heifers in some parts of the world. Intramammary infections with *A. pyogenes* are severe and the gland is almost always lost to milk production.

Several other pathogens are included in the environmental class of infections. These pathogens invade the mammary gland when defense mechanisms are compromised or when they are inadvertently delivered into the gland at the time of intramammary therapy. This group of opportunistic organisms includes *Pseudomonas* spp., yeast agents, *Prototheca* spp., *Serratia marcescens* and *Nocardia* spp. Each of these agents has unique microbiological culture characteristics, mechanisms of pathogenesis and clinical outcomes. These infections usually occur sporadically. However, outbreaks can occur in herds or in an entire region and are usually the result of problems with specific management of hygiene or therapy. For example, mastitis associated with *Pseudomonas aeruginosa* has occurred in outbreaks associated with contaminated wash hoses in milking parlors. Iodide germicides used in wash lines are often at too low a concentration to eliminate *Pseudomonas* spp. Outbreaks of clinical mastitis associated with *Nocardia* spp. have been associated with the use of blanket dry cow therapy and the use of a specific neomycin-containing dry cow preparation.

The mastitis pathogens, and their relative importance, continue to evolve as new management methods and control practices are developed. Thus, there is an ongoing need for epidemiological studies to characterize the pathogens and describe their association with the animals and their environment. Improved control methods can develop only from investigations into the distribution and pathogenic nature of the microorganisms isolated.

ETIOLOGY

Bovine mastitis is associated with many different infectious agents, commonly divided into those causing **contagious mastitis**, which are spread from infected quarters to other quarters and cows, those that are normal teat skin inhabitants and cause **opportunistic mastitis**, and those causing **environmental mastitis**, which are usually present in the cow's environment and reach the teat from that source. Pathogens causing mastitis in cattle are further divided into **major pathogens** (those that cause clinical mastitis) and **minor pathogens** (those that normally cause subclinical mastitis and less frequently cause clinical mastitis).

Major pathogens

Contagious pathogens

- *S. agalactiae*
- *S. aureus*
- *M. bovis.*

Environmental pathogens

Environmental *Streptococcus* species include *S. uberis* and *S. dysgalactiae*, which are the most prevalent; less prevalent is *S. equinus* (formerly referred to as *S. bovis*). The environmental coliforms include the Gram-negative bacteria *E. coli*, *Klebsiella* spp. and *Enterobacter* spp. *A. pyogenes* mastitis can be an important problem in some herds.

Minor pathogens

Several other species of bacteria are often found colonizing the teat streak canal and mammary gland. They rarely cause clinical mastitis and are known as **minor pathogens.** They include the **coagulase-negative *Staphylococcus* spp.** such as *Staphylococcus hyicus and Staphylococcus chromogenes*, which are commonly isolated from milk samples and the teat canal. *Staphylococcus xylosus* and *Staphylococcus sciuri* are found free-living in the environment; *Staphylococcus warneri*, *Staphylococcus simulans* and *Staphylococcus epidermidis* are part of the normal flora of the teat skin (and therefore are teat skin opportunistic pathogens). The prevalence of coagulase-negative *Staphylococcus* spp. is higher in first-lactation heifers than cows, and higher immediately after calving than in the remainder of lactation. In recent studies, they have been found as teat canal and intramammary infections in nulliparous heifers.

C. bovis is also a minor pathogen; it is mildly pathogenic and the main reservoir is the infected gland or teat duct. However, in some herds, *C. bovis* appears to be a common cause of mild clinical mastitis. *C. bovis* spreads rapidly from cow to cow in the absence of adequate teat dipping. The prevalence of *C. bovis* is low in herds using an effective germicidal teat dip, good milking hygiene and dry cow therapy. The presence of *C. bovis* in a gland will reduce the likelihood of subsequent infection with *S. aureus.*

Uncommon mastitis pathogens

Many other bacteria can cause severe mastitis, which is usually sporadic and usually affects only one cow or a few cows in the herd. These include *Nocardia asteroides, Nocardia brasiliensis* and *Nocardia farcinica*, *Histophilus somni*, *Pasteurella multocida, Mannheimia* (formerly *Pasteurella*) *haemolytica, Campylobacter jejuni*, *B. cereus* and other Gram-negative bacteria including *Citrobacter* spp., *Enterococcus faecalis*, *Enterococcus faecium*, *Proteus* spp., *P. aeruginosa*, and *Serratia* spp. Anaerobic bacteria have been isolated from cases of mastitis, usually in association with other facultative bacteria, e.g. *Peptostreptococcus indolicus, Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*), *Eubacterium combesii*, *Clostridium sporogenes* and *Fusobacterium necrophorum.*

Fungal infections include *Trichosporon* spp., *Aspergillus fumigatus*, *Aspergillus nidulans* and *Pichia* spp.; yeast infections include *Candida* spp., *Cryptococcus neoformans*, *Saccharomyces* spp. and *Torulopsis* spp. Algal infections include *Prototheca trispora* and *Prototheca zopfii.*

Leptospiras, including *Leptospira interrogans* serovar. *pomona*, and especially *Leptospira interrogans hardjo*, cause damage to blood vessels in the mammary gland and gross abnormality of the milk. They are more correctly classified as systemic diseases with mammary gland manifestations, and are described under those headings in the book.

Some viruses may also cause mastitis in cattle, but they are of little importance.

EPIDEMIOLOGY

This section deals with the general aspects of epidemiology of bovine mastitis. For information about the epidemiology of mastitis in the other animal species see the appropriate sections at the end of this chapter.

Occurrence and prevalence of infection

Occurrence refers to the location of the disease and the kinds of animals affected. **Prevalence** is the percentage of the population affected with a specific disease in a given population at a certain point in time. The **incidence** is a rate, such as the total number of new cases of clinical mastitis as a percentage of the animals at risk that occur during a certain period of time. Prevalence is a function of the incidence and the duration of infection.

Prevalence

In most countries, surveys in dairy herds indicate that the **prevalence of infection** of mastitis pathogens is approximately 50% of cows and 10–25% of quarters. The prevalence of infection in dairy heifers of breeding age and in pregnant dairy heifers varies widely[1] from 30–50% of heifers and 18% of quarters[2] to as high as 97% of heifers and 75% of quarters.[3]

Incidence

The **average annual incidence of clinical mastitis**, calculated as the number of clinical quarter cases per 100 cows at risk per year, including the dry period, in individual herds ranges from 10–12% in most herds[4] but higher incidences, ranging from 16–65%, occur in some herds.[5,6] The greatest risk of first acquiring mastitis occurs early in lactation, usually in the first 50 days.[7] The risk of clinical mastitis also increases with increasing parity.[7] In beef herds, 32–37% of cows and 18% of quarters may have intramammary infection, which has a significant negative effect on calf weaning weights.[8]

Case fatality rates vary widely depending largely on the identity of the causative organism. For example, *S. agalactiae* mastitis is not a fatal disease but peracute staphylococcal mastitis in a recently calved cow often may be fatal. Details of the occurrence of the different types of mastitis are presented in their individual sections in this chapter.

Relative prevalence of infection with intramammary pathogens

The prevalence of infection with intramammary pathogens in cattle is remarkably similar in different countries. The bacteriological identification of mastitis pathogens is important because control and eradication procedures depend on the kind of infection prevalent in the herd. In addition, the validity of epidemiological investigations aiming at determining transmission patterns or the impact of environmental and managemental factors to a large extent depends on exact bacteriological diagnosis.

Contagious pathogens

The prevalence of infection with *S. aureus* in cows ranges widely, usually from 7–40%, but higher in some herds.[9] A survey of Danish dairy herds found that 21–70% of all cows and 6–35% of all quarters were infected.[10] *S. aureus* was isolated from 10% of quarter samples and was the most common species isolated.[10] The prevalence of streptococci, including *S. agalactiae*, ranges from 1–8% of cows. A relative incidence of *S. agalactiae*, other streptococci and *S. aureus* of 1:1:2 is a common finding. *S. aureus* may still assume some importance as a cause of subclinical mastitis but its prevalence has been reduced by modern mastitis control programs, leading to a higher proportion of culture-negative mastitic quarters and a corresponding, and perhaps consequent, increase in infections by *E. coli* and *Klebsiella* spp. The prevalence of infection due to *Mycoplasma* spp. varies widely.

The prevalence of infection due to an individual pathogen, and therefore the ratio between its incidence and that of other pathogens, depends on several risk factors such as size of herd and quality of management, especially milking parlor hygiene and cleanliness of accommodation, and parity of animal (heifer or cow). For example, large, zero-grazed herds kept in drylot conditions are likely to encounter more hygiene problems than conventionally housed herds mainly because of constant soiling of the udder by inadequate or improper bedding in larger units. In those circumstances there is likely to be a much higher prevalence than usual of mastitis associated with *E. coli* and *S. uberis*.

Teat skin opportunistic pathogens

Coagulase-negative staphylococcal species were found in 4.1% of samples; the most frequently isolated were *S. epidermidis* (1.3%), *S. chromogenes* (1.0%) and *S. simulans* (0.7%).

Environmental pathogens

The prevalence of intramammary coliform infections in a dairy herd seldom exceeds 1–2%; the prevalence of intramammary environmental streptococci is less than 5% in well managed herds but may exceed 10% in some problem herds.[11] A characteristic of intramammary coliform infections is the short duration: 40–50% persist less than 7 days. The majority of environmental streptococci infections last less than 30 days. In a survey of Danish dairy herds, *S. dysgalactiae* (1.6%) and *S. uberis* (1.4%) were the second and third most common species isolated.

Heifers

Surveys of intramammary infection of heifers in regions such as Louisiana indicate variability in prevalence and duration of intramammary infection according to species of bacteria present around the time of parturition. About 20% of heifers were infected with *S. aureus* and 70% with coagulase-negative staphylococci, the minor pathogens that are part of the normal teat skin flora of heifers.[12] *S. chromogenes* was isolated from 15% of all quarters of heifers before parturition but decreased shortly after parturition to 1%.[13] Up to 97% of breeding age and pregnant dairy heifers and 75% of their quarters may be infected with *S. aureus*, *S. hyicus* and *S. chromogenes*.[3] Infections with *S. simulans* and *S. epidermidis* occurred in 1–3% of quarters both before and after parturition. *S. dysgalactiae* was isolated from 4–6% of quarters before and immediately after parturition. Intramammary infections with *S. aureus* rarely occurred before parturition but increased during the first week after parturition. There was no association between the prevalence of *S. aureus* in heifers before parturition and the prevalence in lactating cows.

Distribution of pathogens in clinical mastitis

The distribution of pathogens isolated from cases of clinical mastitis has changed with the adoption of control programs from a high frequency of isolation of *S. aureus* and *S. agalactiae* to a higher isolation rate of other pathogens, particularly environmental pathogens. For example, in 171 randomly selected dairy herds, the average annual incidence of clinical mastitis was 12.7 quarter cases per 100 cows per year. The most frequent isolates from clinical cases were *E. coli* (16%), *S. aureus* (14%), *S. uberis* (11%), and *S. dysgalactiae* (8%).[4] In another survey, the most common isolates from clinical cases were coagulase-negative staphylococci and *E. coli*, each at 15% of samples taken. In a 2-year observational study of 65 dairy herds in Canada, there was considerable variation in the incidence of clinical mastitis among farms.[7] Overall, 20% of cows experienced one or more cases of clinical mastitis during lactation. The pathogens isolated were coliforms (17%), other *Streptococcus* spp. (14%), *S. aureus* (7%), Gram-positive bacilli (6%), *C. bovis* (2%), *S. agalactiae* (1%), and other *Staphylococcus* spp. (29%). There was no growth in 18% of samples and 8% were contaminated. Clearly the main difference is that the rate of *S. aureus* in clinical cases is higher in continental Europe[4] and lower in England and North America.

Source of infection

Contagious pathogens

S. agalactiae and *S. aureus* reside primarily in the udder of infected cows; the source of infection is other infected cows and exposure to uninfected quarters is limited to the milking process.

Teat skin opportunistic pathogens
A number of species of coagulase-negative staphylococcus reside primarily on the teat skin of cattle.

Environmental pathogens
S. uberis, *S. dysgalactiae*, and coliforms are common inhabitants of the cow's environment such as bedding. The exposure of uninfected quarters to environmental pathogens can occur at any time during the life of the cow, including milking time, between milkings, during the dry period and prior to first calving in heifers.

Methods of transmission

Infection of each mammary gland occurs via the teat canal, the infection originating from either an infected udder or the environment; in dairy cattle the infection originating from infected udders is transmitted to the teat skin of other cows by milking machine liners, milkers' hands, wash cloths and any other material that can act as an inert carrier.

Risk factors

Risk factors that influence the prevalence of infection and the incidence of clinical mastitis are outlined here. Individual factors that are of particular importance in the individual types of mastitis are described under those headings.

Animal risk factors

Age and parity

The prevalence of infected quarters increases with age, peaking at 7 years. Surveys of the prevalence of intramammary infection in dairy heifers a few days before their first parturition reveals that 45% are infected, and the quarter infection rate may be 18%.[2] Some studies found intramammary infections in 97% of heifers and 74% of quarters.[3]

Stage of lactation

Most **new infections** occur during the **early part of the dry period** and in the **first 2 months of lactation**, especially with the environmental pathogens. In heifers, the prevalence of infection is often high in the last trimester of pregnancy and several days before parturition, followed by a marked decline after parturition.[13] In dairy heifers, most of these prepartum infections are associated with the minor pathogens but some surveys have found evidence of infection by the major pathogens.[2,3] The mean prevalence of *S. aureus* intramammary infection in primiparous cows at first parturition in high prevalence herds can be as high as 30%, ranging from 13–65%, and in low prevalence herds it may as low as 2%, ranging from 0–5%.[14] The overall prevalence of infection of *S. aureus* intramammary infection in primiparous cows at parturition was 8%, ranging from 0–27%. Of those cows with *S. aureus* intramammary infection at parturition, 43% had *S. aureus* intramammary infection at least 2 months after parturition. Primiparous cows with these infections may represent significant reservoirs of infection to uninfected animals in the herd.

Some of these differences may be related to changes in the milk as a medium for bacterial growth. For example, bacteria such as *C. bovis* grow best in milk secreted in the middle of lactation, whereas dry period secretion inhibits its growth.[15] During the dry period the quarter's capacity to provide phagocytic and bactericidal activities diminishes.[16]

Somatic cell count

The highest average incidence of clinical mastitis due to environmental bacteria may occur in herds with the lowest bulk tank milk SCC (< 150 000 cells/mL) and a low prevalence of subclinical infection.[17]

Breed

Generally the incidence of mastitis is greater in Holstein–Friesians than in Jerseys, but this may reflect differences in management rather than a true genetic difference. Valid comparisons between breeds have not been reported.

Milking characteristics and morphology of udder and teat

High milking rate and large teat canal diameter have been associated with increased SCC or risk of intramammary infection.[18] Milk leaking in cows in herds with a low bulk tank milk SCC has also been associated with an increased rate of clinical mastitis. Decreasing teat-end-to-floor distance is also a risk factor for clinical mastitis and may be associated with an increased incidence of teat lesions. Heritability estimates of teat-end-to-floor distance or udder height range from 0.2–0.7, which may be a consideration in the selection indices of bulls. Periparturient udder edema may also be a risk factor for clinical mastitis.

Physical condition of teat

The teat end is the first barrier against invading pathogens, and the efficiency of teat defense mechanisms depends on the integrity of teat tissue; its impairment leads to an increase in the risk of intramammary infection. Teat thickness is an aid to evaluating teat tissue status. Milking machine characteristics can induce a decrease or increase in teat thickness after milking compared with premilking values. Increases in teat thickness of more than 5% are significantly associated with infection and new infection, but the association was not significant when teat thickness decreased by more than 5%.[19] Coagulase-negative staphylococcal infections are significantly associated with both increases and decreases in teat thickness numerically greater than 5%, but there is no association between teat thickness and *S. aureus* infections.

Hyperkeratosis of the teat orifice is a commonly observed condition in the dairy cow because of machine milking; the degree of hyperkeratosis may be increased by a poor milking system.[20] There is wide variation in the degree of hyperkeratosis between herds; the score increases with lactational age and peaks, for any lactation, at 3–4 months after parturition, declining as the cows dry off. There is no significant relationship between mean SCC and the degree of hyperkeratosis at the herd level.

Udder hygiene

Dirty udders are associated with increased SCC and an increased prevalence of intramammary infection due to contagious pathogens, but surprisingly are not associated with intramammary infections due to environmental pathogens.[21] This suggests that udder hygiene is a proxy for general mastitis management skills, in that good mastitis control programs result in low prevalence of infection with contagious pathogens.

Nutritional status

Vitamins E and A and selenium may be involved in resistance to certain types of mastitis.[22] Early reports found that supplementation with antioxidants such as selenium and vitamin E had a beneficial effect on udder health in dairy cattle by decreasing the incidence and duration of clinical mastitis. An increase in selenium concentration in whole blood was associated with a decrease in all infections, including *S. aureus*, *A. pyogenes*, and *C. bovis*.[23] There was no association between different infections or SCC and concentrations of vitamin E, vitamin A, or beta-carotene, but an association existed between vitamin A concentration and SCC. The lower selenium concentration in whole blood did not increase the incidence of clinical mastitis.

Genetic resistance to mastitis

A variety of morphological, physiological and immunological factors contribute to a cow's resistance or susceptibility to mastitis, and each of these factors is influenced to some extent by heredity. Differences in udder depth, teat length, teat shape, and teat orifice morphology are thought to be associated with differences in mastitis. The production of keratin in the streak canal and the physical and biochemical characteristics of keratin are important contributors to mastitis resistance. Many of the defense mechanisms of the udder, including

lysozyme, lactoferrin, immunoglobulins and leukocytes, are direct products of genes and have a genetic basis. For dairy cattle, heritability estimates for clinical mastitis average about 0.05. These low heritability estimates indicate that there is very little genetic influence on clinical mastitis but a very strong environmental influence.[24]

Somatic cell count Differences in heritability between herds with high and low SCCs are not significant. However, differences among bulls' daughter groups for both clinical mastitis and SCC are reasonably large, suggesting that selection of sires can be important in mastitis control.[25] An analysis of the disease and breeding records of a large number of Swedish bulls siring daughters whose milk had a low SCC count found genetic correlations from 0.71–0.79 between SCC and clinical mastitis. It was concluded that it is possible to improve resistance to clinical mastitis by selecting for a low SCC.

The strong phenotypic and genetic association between SCC and mastitis indicates that breeding programs based on SCC may be effective as an indirect means of improving mastitis resistance. However, greater emphasis on SCC may decrease genetic gain in yield traits, which are economically more important.[26]

Milk yield

The genetic correlation between milk yield and mastitis is about 0.2–0.3, which suggests that animals genetically above average for milk yield are more susceptible to mastitis and that low-yielding cows tend to be more resistant. However, the low correlation value suggests that this relationship is not a strong tendency. The positive correlation implies that genetic improvement for milk yield is accompanied by a slow decline in genetic resistance to mastitis. Examination of the association between milk yield and disease in a large number of dairy cows found that higher milk yield was not a factor for any disease except mastitis.[27] However, the association between milk yield and mastitis does not imply causation. At least two biological explanations are plausible: increased injury and leaking of milk between milkings. Improved mastitis control efforts have offset the genetic trend for increased susceptibility to mastitis. The low heritability for mastitis indicates the great importance of environmental factors in causing differences in the prevalence of infection and the incidence of clinical mastitis.

In summary, selection for milk yield alone results in increased incidence of mastitis. The positive genetic correlation between milk yield and mastitis suggests that genes that increase milk yield tend to increase susceptibility to mastitis. Selection indices that maximize genetic improvement for net economic benefit will not decrease the incidence of mastitis, but indices that include SCC, udder depth or clinical mastitis will diminish the rate of increase in mastitis by 20–25%. Using **predicted transmitting ability** (PTA), an estimate of genetic merit, it has been found on average that daughters of bulls with high PTAs for SCC have a higher incidence of mastitis; sires with low PTA for somatic cell scores should therefore be selected. All of the economically important traits are weighted into a selection index for the selection of bulls which will improve net income over cost of production.

Other concurrent diseases

These may be important risk factors for mastitis. Retained placentas, teat injuries and teat sores may be associated with a higher incidence of mastitis. Sole ulceration of any severity occurring in more than one digit has been associated with an approximately threefold higher risk of *S. aureus* infections in the first lactation.[28] It is suggested that sore feet could increase the risk of teat lesions, presumably as a result of difficulty in standing.

Immunological function of mammary gland

The immune function of the mammary gland is impaired during the periparturient period; it is susceptible to mastitis during transition periods, such as drying off and colostrogenesis. As a result, the **incidence of new intramammary infections is highest during the early nonlactating period and the periparturient period.**

The most important components of the defense against common bacterial pathogens are blood-derived **neutrophils** and **opsonizing antibodies**. An inadequate rate of neutrophil recruitment to combat a new intramammary infection has a profound effect on the outcome of infection, in that cows with a rapid and massive recruitment of neutrophils to an infected gland clear an intramammary infection within 12–18 hours postinfection.

It is also important that an early inflammatory response in the infected mammary gland enables leakage of IgG_2 (opsonizing antibodies) as this facilitates neutrophil phagocytosis of bacteria. The **staggered one–two punch** of **peak IgG_2 concentrations** within 4 hours of infection and **peak neutrophil response** within 6–12 hours of infection greatly facilitates clearance of new intramammary infections.

Blood-derived neutrophils must undergo **margination**, **adherence** and **migration** in order to arrive in the mammary gland, where they perform **phagocytosis**, **respiratory burst** and **degranulation**. Margination is via expression of three adhesion molecules from the selectin family, specifically L-selectin (also called CD62L) on neutrophils, E-selectin (also called CD62E), and P-selectin (also called CD62P) on vascular endothelial cells. Neutrophil L-selectin makes the initial contact between 'streaming' neutrophils in the blood stream and the vascular wall; this contact slows neutrophil movement and allows them to 'roll' along the endothelium while surveying for the presence of proinflammatory mediators at the sites of tissue infection. When the rolling neutrophils detect the presence of one or more proinflammatory mediators they immediately shed surface L-selectin (CD62L) adhesion molecules and upregulate and activate Mac-1 (CD11b/CD18) adhesion molecules, thereby stopping neutrophil rolling and permitting tight adherence of the neutrophil to the endothelium. Once adhered, neutrophils commence diapedesis by migrating between endothelial cells to the site of infection. Neutrophil migration therefore has three components; hyperadherence (cessation of rolling), diapedesis and chemotaxis. Any delay or inhibition in this process can lead to peracute mastitis and severe clinical disease. This is best illustrated by bovine leukocyte adhesion deficiency (BLAD) in Holstein–Friesian cattle; affected calves cannot produce Mac-1 molecules and have a prominent neutrophilia because streaming neutrophils cannot migrate to the site of infection. Migration of neutrophils is slow during the first few weeks of lactation and this delay in neutrophil migration is believed to be responsible for the increased incidence and severity of intramammary infections during early lactation.

Previous mastitis

Cows with a history of mastitis in the preceding lactation may be almost twice as susceptible to clinical mastitis in the current lactation as those without mastitis in the preceding lactation.[29]

Pre-existing intramammary infections

Natural infection with minor pathogens has a **protective effect** against infections with major pathogens.[30] The lowest rate of infection with major pathogens has been observed in quarters infected with *C. bovis*. Elimination of these minor pathogens with postmilking teat disinfection may result in an increase in the incidence of clinical mastitis. Discontinuation of the teat dipping may be associated with an increase in the prevalence of minor pathogens, increase in the incidence of *S. aureus* infections, and decrease in the incidence of *E. coli* infections. Thus quarters already infected with

a minor or major infection are less likely to acquire a new infection than uninfected quarters.

Use of recombinant bovine somatotropin

Because the risk of clinical mastitis increases as milk production increases there has been considerable scientific and public controversy over the potential effects that the use of recombinant bovine somatotropin (bST) might have on the incidence of clinical mastitis and the subsequent use of antimicrobials from therapy. In some field trials, the use of bST did not result in an increase in the incidence of clinical mastitis compared to controls. In other trials, a significant increase in the incidence of clinical mastitis occurred in treated cows compared to controls. However, the incidence of clinical mastitis was greater in treated cows compared to controls before bST was used. In trials done on well managed farms which had controlled contagious mastitis and had low rates of clinical mastitis due to environmental pathogens, the use of bST was not associated with an increase in clinical mastitis, discarded milk because of therapy or culling for mastitis.[31] Interpretation of a direct effect of bST on mastitis incidence is confounded by the higher incidence of mastitis in cows of higher milk production.

Environmental and management risk factors

Quality and management of housing

Factors such as climate, housing system, type of bedding and rainfall interact to influence the degree of exposure of teat ends to mastitis pathogens. Because dairy cattle spend 40–65% of their time lying down, **the quality and management of housing for dairy cattle has a major influence on the types of mastitis pathogen that infect the mammary gland, as well as the degree of infection pressure.**

The major sources of environmental pathogens are the cow's environment, including bedding, soil, feedstuffs and water supplies. Environmental pathogens multiply in bedding materials, with which the cow's teats are in close and prolonged contact. Bacterial growth in bedding depends on temperature, amount of moisture and nutrients available, and the pH. Fresh bedding can be a source of contamination even before it is used: *Klebsiella pneumoniae* can be present in green, hardwood sawdust in higher numbers than in other types of bedding and major outbreaks of environmental mastitis due to *K. pneumoniae* have occurred following the use of contaminated wood products bedding, described in detail in that section. Dry, unused bedding contains few pathogens but after being used it becomes contaminated and provides a source in which pathogens multiply to high numbers in 24 hours. Organic bedding materials such as straw, sawdust, wood shavings and paper support the growth of pathogens. Inorganic materials such as sand retain less moisture and do not provide a supply of nutrients for the pathogens; bacterial counts in these materials are usually lower than in organic materials. Housing lactating cattle on sawdust leads to six times more *Klebsiella* bacteria and twice as much coliform bacteria on the teat ends compared to housing cattle on sand. In contrast, there were 10 times more environmental streptococci bacteria on teat ends when cows were housed on sand, compared to housing on sawdust.[32] Surveys indicate that herds using wood chips or sawdust as bedding material have higher rates of clinical mastitis compared to those using straw bedding.[33]

High humidity and high ambient temperatures favor growth of pathogens. Cows in confinement housing with organic bedding materials have the highest incidence of environmental mastitis in the warm, humid months of the year. Pasturing herds during the summer months usually reduces the incidence of coliform mastitis, although rates of environmental streptococci may remain high. In drylot systems the incidence of coliform mastitis may be associated with periods of high rainfall. Herds with more months on pasture may have a higher incidence of clinical mastitis,[33] which may be associated with factors such as sanitation and the stress of transition between pasture and confinement housing.

The **management and design of housing systems** influence the prevalence of intramammary infection and the incidence of clinical mastitis. Any housing factor or management system that allows cows to become dirty or damage teats or that causes overcrowding will result in an increase in clinical mastitis. This includes the size and comfort of free stalls, the size of the alleyways, ease of movement of cattle and the cleaning system. Failure to keep alleyways, cow stalls and bedding clean and dry will increase the level of contamination of the teats. Overcrowding, poor ventilation, access to dirty ponds of water and muddy areas where cows congregate are major risk factors.

The **size of the milking cow herd** may be positively associated with an increased incidence of clinical mastitis because it can be more difficult to control contagious mastitis in a herd with a greater prevalence of infection and a larger number of cow-to-cow contacts. As herd size increases, manure disposal and sanitation problems may increase exposure to environmental pathogens. However, regional and management differences may confound the association of size with infection status. Some recent data suggest lower SCC in large herds. The use of designated maternity areas providing an isolated and clean environment for parturition[33] may be associated with a lower incidence of clinical mastitis.

If hygiene and bedding maintenance are neglected in the housing accommodation the prevalence of environmental forms of mastitis may increase markedly. Periodic inspection of dry cows is an essential part of mastitis control.

Milking practices

The failure to employ established and reliable methods of mastitis control is an important risk factor. This is a major subject, which includes efficiency of milking personnel, milking machines, high milking speed and especially hygiene in the milking parlor. Wet teats and udders are a risk factor for increased SCC, especially in the presence of teat impacts from liner slippage.[33] The use of a separate drying cloth for each cow is associated with a lower SCC. Effective use of a postmilking germicidal teat dip is critical for the control of contagious mastitis. Increasing person-hours spent milking per cow may be associated with a higher rate of clinical mastitis.[33] Contaminated milking equipment – including milk hoses, udder wash towels and teat dip products – has been associated with outbreaks of environmental mastitis from *S. marcescens* and *P. aeruginosa*. Drying off procedures at the end of lactation and an active policy on drying off treatment are equally important.

The **absence of milk quality regulations that place emphasis on SCC is also a risk factor.** Conversely, the presence of strict regulations with penalties for high SCC is an important incentive to institute mastitis control programs that improve the quality of milk. The absence of a health management program consisting of regular farm visits by the veterinarian may also be a risk factor for mastitis, which may be associated with a relative lack of awareness by the producer of the importance of the principles of mastitis control.

Season of year

The relationship between the incidence of mastitis and season of the year is variable, depending on geographical and climatic conditions. In subtropical and tropical areas the incidence may be higher during winter or spring calvings from the increase in infection pressure associated with increased humidity. In temperate climates, the incidence of mastitis is higher in autumn and winter, when calving occurs along with an extended period of housing.[34]

Under conditions of housing for long winter periods, infectious agents are most likely to be found in higher numbers in the bedding. In the UK there is an increased frequency of mastitis when cows are housed for the winter.

Pathogen risk factors

Viability of pathogens

The ability of the pathogen to survive in the cow's immediate environment (resistance to environmental influences including cleaning and disinfection procedures) is a characteristic of each pathogen. The causes of contagious mastitis are more susceptible to disinfection than the causes of environmental mastitis.

Virulence factors

There is a wide variety of virulence factors among the mastitis pathogens. These are described under specific mastitides. The influence of many bacterial virulence factors depends on the stage of lactation and severity of the intramammary infection and the effects elicited by the virulence factors on bovine mammary tissue. A few examples of the common virulence factors are noted here.

Colonizing ability

The ability of the pathogens to colonize the teat duct, then to adhere to mammary epithelium and to initiate mastitis is a major characteristic of the major bacterial causes of mastitis. *S. aureus* strains that cause mastitis can bind to ductular udder epithelial cells and to explant cultures of bovine mammary glands. There are differences in the adhesion characteristics among strains of the organism, which may explain the different epidemiological characteristics of the organisms in some herds. Comparison of strains isolated from different *S. aureus* mastitis cases between herds reveals that only a limited number of genotypes of *S. aureus* are most prevalent.[34]

Toxins

E. coli isolates that cause mastitis produce lipopolysaccharide endotoxin, which is responsible for many of the inflammatory and systemic changes observed during acute coliform mastitis. *S. aureus* isolated from intramammary infections produces many potential virulence factors, including enterotoxins, coagulase and alpha, beta, delta toxins, hemolysin, hyaluronidase and leukocidins, which are considered to be involved in the varying degrees of inflammation characteristic of staphylococcal mastitis from subclinical to peracute gangrenous mastitis. Virulence factors of *S. uberis* include hyaluronidase and the hyaluronic capsule.

Production and economic losses

Although mastitis occurs sporadically in all species, it assumes major economic importance in dairy cattle and may be one of the most costly diseases in dairy herds. Mastitis results in economic loss for producers by increasing the costs of production and by decreasing productivity. The premature culling of potentially profitable cows because of chronic mastitis is also a significant loss. Because of the large economic losses, there is a potential for high returns on investment in an effective control program. The component economic losses can be divided into:

- Loss of milk production
- Discarded milk from cows with clinical mastitis and treated cows
- Replacement cost of culled cows
- Extra labor required for treatment and monitoring
- Veterinary service for treatment and control
- Cost of first trimester abortions due to clinical mastitis[36]
- Cost of control measures.

There are additional costs such as antimicrobial residues in milk from treated cows, milk quality control, dairy food manufacturing, nutritional quality of milk, degrading of milk supplies due to high bacteria or SCC, and interference with the genetic potential of some cows from early involuntary culling because of chronic mastitis. The total annual cost of mastitis in the dairy cattle population is estimated to be 10% of the total value of farm milk sales, and about two-thirds of this loss is due to reduced milk production in subclinically affected cows.

The production and economic losses are commonly divided into those associated with subclinical and clinical mastitis.

Subclinical mastitis

Total milk losses from quarters affected with subclinical mastitis have been estimated to range from 10–26%.[37] Lower SCCs are associated with higher milk production, and rolling herd average milk production has been estimated to decrease by 190 kg per unit increase of linear somatic cell score. Most estimates indicate that on average an affected quarter results in a 30% reduction in productivity, and an affected cow is estimated to lose 15% of its production for the lactation. This loss is sometimes expressed as a loss of about 340 kg of saleable milk, due to loss of production and the value of milk that has to be withheld from sale. The loss in production by an infected quarter may be largely compensated by increased production in the other quarters so that the net loss from the cow may be less than expected. In addition to these losses, there is an added loss of about 1% of total solids by changes in composition (fat, casein, and lactose are reduced and glycogen, whey proteins, pH, and chlorides are increased), which interferes with manufacturing processes, and other losses include increased culling rates and costs of treatment. Comparisons between low- and high-prevalence herds always show a financial advantage of about 20% to the low-prevalence herds, the gain varying with the local price of milk or butter fat. In beef herds the losses are in the form of rare deaths of cows and failure of the calves to gain weight.

Approximately 75% of the economic loss from subclinical mastitis is attributable to loss of milk production. Other costs include discarding milk from treated cows, drug costs, veterinary costs, labor and loss of genetic potential of culled cows.

Clinical mastitis

Clinical mastitis results in marked decreases in milk production, which are much larger in early than late lactation. Milk production losses are also greater in cows with multiple lactations than first-lactation cows, and clinical mastitis also decreases the duration of lactation and increases the likelihood of culling. Clinical cases of brief duration that occur after the peak of lactation affect milk production very little but can induce abortion during the first 45 days of gestation.[36] Clinically affected quarters may not completely recover milk production in subsequent lactations but these carry-over losses are not as large as the losses from acute mastitis. In the National Animal Health Monitoring System of dairy herds in the US, clinical mastitis alone was the most costly disease identified, at a loss to the producer of $27–50 per cow per year.[37]

The **costs of clinical mastitis** and mastitis prevention in dairy herds have been estimated, based on monitoring 50 dairy herds over 1 year.[38] Mean incidence of clinical mastitis was 39 cases/100 cow-years; each clinical case cost $38/cow-year, with a mean cost per clinical episode of US$107. Prevention of mastitis cost $14.50/cow-year.[39] Lost milk production was estimated at $14.85/cow-year, which does include the losses associated with subclinical mastitis.

The component causes of economic loss associated with mastitis outlined above vary according to the causative pathogen and are described under specific mastitides. In general terms *S. aureus* and *E. coli* may cause death from peracute mastitis; *A. pyogenes* causes complete loss of quarters; staphylococci and streptococci cause acute clinical mastitis, but their principal role is in causing subclinical mastitis, resulting in a reduction of milk produced and a downgrading of its

quality. Of these, *S. agalactiae* causes the greatest production loss, whereas *S. aureus* has the higher infection rate, greater resistance to treatment and longer duration of infection. At one time *S. aureus* represented the impassable barrier to mastitis control programs.

Other factors that affect the magnitude of the loss associated with mastitis include age (the loss is greatest in mature cows), and when the attack occurs in the first 150 days of lactation.

Zoonotic potential

With mastitis there is the danger that the bacterial contamination of milk from affected cows may render it unsuitable for human consumption by causing food poisoning, or interfere with manufacturing processes or, in rare cases, provide a mechanism of spread of disease to humans. Tuberculosis, streptococcal sore throat and brucellosis may be spread in this way. Raw (unpasteurized) milk can be a source of food-borne pathogens, and consumption of raw milk can result in sporadic disease outbreaks. For instance, sampling bulk tank raw milk in Ontario revealed the presence of *Listeria monocytogenes*, *Salmonella* spp., *Campylobacter* spp. or verocytoxigenic *E. coli* in 2.7%, 0.2%, 0.5% and 0.9% of milk samples, respectively.[40] These findings emphasize the importance of continued diligence in the application of hygiene programs within dairies and the separation of raw from pasteurized milk and milk products.

PATHOGENESIS

Infection of the mammary gland always occurs via the teat canal and on first impression the development of inflammation after infection seems a natural sequence. However, the development of mastitis is more complex than this and can be most satisfactorily explained in terms of three stages: **invasion, infection, inflammation.** Of the three phases, prevention of the invasion phase offers the greatest potential for reducing the incidence of mastitis by good management, notably in the use of good hygienic procedures.

Invasion is the stage at which pathogens move from the teat end to the milk inside the teat canal.

Infection is the stage in which the pathogens multiply rapidly and invade the mammary tissue. After invasion the pathogen population may be established in the teat canal and, with this as a base, a series of multiplications and extensions into mammary tissue may occur, with infection of mammary tissue occurring frequently or occasionally depending on its susceptibility. Multiplication of certain organisms may result in the release of endotoxins, as in coliform mastitis, which causes profound systemic effects with minimal inflammatory effects.

Inflammation follows infection and represents the stage at which clinical mastitis occurs with varying degrees of clinical abnormalities of the udder and variable systemic effects from mild to peracute; gross and subclinical abnormalities of the milk appear. Abnormalities of the udder include marked swelling, increased warmth and, in acute and peracute stages, gangrene in some cases and abscess formation and atrophy of glands in chronic stages. The systemic effects are due to the mediators of inflammation. Gross abnormalities of the milk include a decrease in milk yield, the presence of the products of inflammation and marked changes in the composition of the milk.

The most significant subclinical abnormality of the milk is the increase in the **somatic cell count**, the most common measurement of milk quality and udder health. Milk somatic cells in a healthy gland consist of several cell types, including neutrophils (< 11%), macrophages (66–88%), lymphocytes (10–27%), and a smaller percentage of epithelial cells (0–7%).[41] Neutrophils are the predominant cell type found in mammary tissues and secretions during inflammation, in mastitis they constitute more than 90% of total mammary gland leukocytes. Once at the site of infection, neutrophils phagocytose and kill pathogens. Neutrophils exert their bactericidal effect through a respiratory burst that produces hydroxyl and oxygen radicals, important components of the oxygen-dependent killing mechanism.

In the healthy lactating mammary gland, the SCC is less than 100 000 cells/mL of milk. During intramammary infection, the glandular SCC can increase to more than 1 000 000 cells/mL of milk within a few hours because of the combined effect of an increased number of neutrophils (numerator) and a decreased glandular secretion volume (denominator). **The severity and duration of mastitis are critically related to the promptness of the neutrophil migratory response and their bactericidal activity at the site of infection.** As they colonize and multiply in the mammary gland, some bacteria release metabolic byproducts or cell-wall components (endotoxin if a Gram-negative bacteria) that serve as chemoattractants for leukocytes. If neutrophils move rapidly from the blood stream and are able to eliminate the inflammatory stimuli (bacteria), then recruitment of neutrophils ceases and the SCC returns to normal levels. If bacteria are able to survive this immediate host response, then the inflammation continues, resulting in neutrophil migration between adjacent mammary secretory cells toward the alveolar lumen. Prolonged diapedesis of neutrophils damages mammary tissue, resulting in decreased milk production. The duration and severity of the inflammatory response therefore has a major impact on the quantity and quality of milk produced.

The major factor affecting the SCC at the herd and individual cow level is the prevalence of intramammary infection at a glandular level. Because marked increases in SCC are a result of cells being attracted to the mammary tissue because of the mediators produced during a local infection, events that do not affect udder health are unlikely to have a direct or dramatic effect on SCC. Little evidence exists that any factor other than normal diurnal variation has a major influence on SCC in the absence of intramammary infections.

The effects of mastitis on milk yield are highly variable and depend on the severity of the inflammation, the causative agents and the lesions produced, the efficiency of treatment, the production level and the stage of lactation.[42] Mastitis in early lactation causes a larger decrease in milk yield with long-term effects than mastitis in late lactation. Mastitis due to *S. aureus* generally evolves into persistent but moderate infections, unlike those associated with coliforms. Mastitis associated with *A. pyogenes* results in suppurative lesions, poor response to treatment and culling. *M. bovis* causes chronic induration and almost complete loss of milk production without recovery.

CLINICAL FINDINGS

Details of the clinical findings are provided under each specific type of mastitis. The clinical findings should be used only as a guide because different pathogens can cause chronic, subclinical, subacute, acute and peracute forms of the disease, and clinical differentiation of the different causes of mastitis is difficult. The greatest clinical accuracy achievable, even in a specialist hospital environment and after adaptation to suit local conditions, is about 70%,[43] which is not sufficiently accurate to be clinically useful. In other words, bacteriological culture of milk from an affected gland is required before specific pathogen-directed treatment can be implemented.

Clinical mastitis is detected using only the results of the physical examination, and a useful definition of clinical mastitis is a negative answer to the question 'would you drink this?' In other words, 'undrinkable' is a simple and generalizable concept for defining clinical mastitis, in that milk from cows with clinical mastitis is not suitable for drinking. New cases of

clinical mastitis are defined as being separated by at least 14 days.

The clinical findings in mastitis include abnormalities of secretion, abnormalities of the size, consistency and temperature of the mammary glands and, frequently, a systemic reaction. In other words, there are **three categories of clinical mastitis**: **abnormal milk**, **abnormal gland** and an **abnormal cow** (systemic disease). Abnormal milk is visibly abnormal (i.e. is not 'drinkable'). An abnormal gland is larger and firmer than other quarters. An abnormal cow is pyrexic, depressed or has decreased appetite or milk production. This three-part categorization scheme has excellent clinical utility, is readily understood by everyone and provides a sound pathophysiological basis for treatment. In particular, it is likely that optimal treatment protocols can be developed for the three levels of clinical mastitis. Other categorization systems have been developed, but they lack the simplicity and generalizability of the secretion, gland and cow system.

Clinical mastitis episodes are also categorized according to their severity and duration.

Severity is characterized as:

- **Peracute**: severe inflammation, with swelling, heat and pain of the quarter, with a marked systemic reaction, which may be fatal
- **Acute:** severe inflammation without a marked systemic reaction
- **Subacute:** mild inflammation with persistent abnormality of the milk.

Duration is characterized as:

- **Short-term** (as in *E. coli* and *Klebsiella* spp.)
- **Recurrent** (as in *S. aureus* and *S. dysgalactiae*)
- **Persistent** (as in *S. agalactiae* and *M. bovis*).

Abnormal milk

Proper examination of the milk requires the use of a **strip cup**, preferably one that has a **shiny, black plate,** permitting the detection of discoloration as well as clots, flakes and purulent material. Milk is drawn on to the black plate in pools and comparisons are made between the milk of different quarters. Because the herdsman frequently has little time to examine milk for evidence of mastitis it is customary to milk the first few streams on to the floor; in some parlors black plates are set in the floor. The practice does not appear to be harmful if the floor is kept washed down.

Discoloration may be in the form of blood-staining or wateriness, the latter usually indicating chronic mastitis when the quarter is lactating. Little significance is attached to barely discernible wateriness in the first few streams but, if this persists for 2–3 streams or more, it is an abnormality. One of the major unresolved issues in bovine mastitis is how to treat a cow with abnormal secretion on the first 1–2 streams that subsequently has normal-looking milk. Clots or flakes are usually accompanied by discoloration and they are always significant, indicating a severe degree of inflammation, even when small and present only in the first few streams. Blood clots are of little significance in a mastitis case, neither are the small plugs of wax that are often present in the milk during the first few days after calving, especially in heifers. Flakes at the end of milking may be indicative of mammary tuberculosis in cattle.

During the **dry period** in normal cows, the secretion changes from normal milk to a clear watery fluid, then to a secretion the color and consistency of honey, and finally to colostrum in the last few days before parturition. Some variation may occur between individual quarters in the one cow; if this is marked, it should arouse suspicion of infection.

The **strip cup** provides a valuable tool to detect clinical mastitis and constitutes part of the routine physical examination of the lactating cow. The most sensitive use of the strip cup is to observe the ability of milk from one quarter to mix with milk from another quarter; incomplete mixing (evidence of 'streaming') indicates that secretions from the two quarters differ and suggests the presence of an intramammary infection in one of the quarters. However, it should be remembered that the strip cup can only detect clinical mastitis, and detection of subclinical mastitis requires use of indirect tests such as SCC of composite milk samples from individual cows, or application of the California Mastitis Test to quarter samples or measuring the electrical conductivity of quarter samples.

Abnormal gland

Abnormalities of size and consistency of the quarters may be seen and felt. Palpation is of greatest value when the udder has been recently milked, whereas visual examination of both the full and empty udder may be useful. The udder should be viewed from behind and the two hind quarters should be examined for symmetry. By lifting up the hind quarters, the fore quarters can be viewed. A decision on which quarter of a pair is abnormal may depend on palpation, which should be carried out simultaneously on the opposite quarter of the pair. Although in most forms of mastitis the observed abnormalities are mainly in the region of the milk cistern, the whole of the quarter must be palpated, particularly if tuberculosis is suspected. The teats should be inspected and palpated for skin lesions, especially around the teat end. The supramammary lymph nodes should also be palpated for evidence of enlargement.

Palpation and inspection of the udder are directed at the detection of fibrosis, inflammatory swelling and atrophy of mammary tissue. Fibrosis occurs in various forms. There may be a diffuse increase in connective tissue, giving the quarter a firmer feel than its opposite number and usually a more nodular surface on light palpation. Local areas of fibrosis may also occur in a quarter; these may vary in size from pealike lesions to masses as large as a fist. Acute inflammatory swelling is always diffuse and is accompanied by heat and pain and marked abnormality of the secretion. In severe cases there may be areas of gangrene, or abscesses may develop in the glandular tissue. The terminal stage of chronic mastitis is atrophy of the gland. On casual examination an atrophied quarter may be classed as normal because of its small size, while the normal quarter is judged to be hypertrophic. Careful palpation may reveal that, in the atrophic quarter, little functioning mammary tissue remains.

Abnormal cow (systemic response)

A systemic response including toxemia, fever, tachycardia, ruminal stasis, depression, recumbency and anorexia may or may not be present, depending on the type and severity of the infection. A systemic response is usually associated with severe mastitis associated with *E. coli*, *Klebsiella* spp. or *A. pyogenes* and occasionally with *Streptococcus* spp. or *Staphylococcus* spp. Clinical mastitis episodes due to *A. pyogenes* produces the greatest decrease in milk production. In contrast, clinical mastitis due to environmental streptococci and coagulase-negative staphylococci is associated with the smallest decrease in milk production.[44] Clinical mastitis episodes due to *S. aureus* are associated with the highest risk of culling.[45]

DIAGNOSIS

Detection of clinical mastitis

The initial diagnosis of clinical mastitis is made during the routine physical examination. Laboratory culturing of milk samples for bacteria and *Mycoplasma* spp., and for determining the antimicrobial susceptibility of *S. aureus* (specifically whether it produces beta-lactamase), is very useful for instituting optimal treatment protocols for cows with clinical mastitis and for instituting appropriate control measures.

However, because subclinical mastitis has the greatest influence on the cost of mastitis to the producer, it is advantageous to also diagnose subclinical mastitis, on a cow and quarter level.

Detection of subclinical mastitis

Culturing large numbers of milk samples, although the gold standard for intramammary infection and subclinical mastitis, is expensive and impractical for routine use. Much attention has therefore been given to the development of indirect tests to predict the presence of an intramammary infection. Currently available indirect tests detect only the presence of inflammation but are of value as screening tests; milk from quarters or cows with a positive screening test are then submitted to bacteriological culture. **Subclinical mastitis can only be detected by laboratory examination** and cannot, by definition, be detected during the routine physical examination. In other words, the secretion from a quarter with subclinical mastitis appears drinkable.

Detection at the herd level

The prevalence of subclinical mastitis or intramammary infection is monitored by determining the **bulk tank milk SCC** and the most likely mastitis pathogens are identified by **culturing bulk tank milk**. These two methods are recommended to diagnose the presence and prevalence of mastitis pathogens on a herd basis.

Bulk tank milk somatic cell counts

The SCC of bulk tank milk is an indirect measure of the prevalence of mastitis within a dairy herd. The SCC is increased primarily, but not exclusively, because of subclinical mastitis associated with Gram-positive bacterial intramammary infections. There is a good correlation between the number of streptococci (*S. agalactiae*, *S. dysgalactiae*, and *S. uberis*) colony-forming units found in bulk tank milk and its SCC. The number of colony forming units (cfu) of *S. aureus* is moderately correlated to the bulk tank milk SCC.[46] As contagious mastitis has become more effectively controlled, environmental mastitis pathogens have become a relatively more important cause of high SCC in bulk tank milk, especially in herds with moderate (< 400 000 cells/mL) to low (< 150 000 cells/mL) bulk tank milk SCC.

The association between management practices, dairy herd characteristics and SCC of bulk tank milk has been examined in about 60 000 cows in 843 herds over a 2-year period.[47] Results indicated that the prevalence of *S. agalactiae* and *S. aureus* intramammary infections was associated with bulk tank SCC.[47] In herds free of *S. agalactiae* mastitis, the prevalence of *S. aureus* and *C. bovis* intramammary infections were correlated with bulk tank SCC. For herds without *S. agalactiae*, use of sawdust bedding was associated with a decrease in SCC in bulk tank milk, while a dirty loose housing area was associated with an increase in SCC in bulk tank milk. Increased milk production, repeated mastitis control visits and use of particular predip compounds were significantly associated with decreased SCC in bulk tank milk in all herds, regardless of whether any cows in the herd had *S. agalactiae* mastitis. In herds with *S. agalactiae* mastitis, use of iodine, chlorhexidine, peroxide or sodium chlorite–lactic acid as a predip was associated with a decrease in SCC of bulk tank milk.[47]

The **SCC of bulk tank milk** has become a widely used test because it provides a sensitive and specific indicator of udder health and milk quality. The sample for analysis is obtained by agitating the milk for 5–10 minutes and collecting a sample from the top of the bulk tank milk using a clean dipper. The sample should not be collected near the outlet valve because this varies from that in the rest of the tank. The SCC of bulk tank milk is widely used to regulate whether milk may be legally sold and to determine the price paid for raw milk. Premium and penalty payments are calculated on the basis of 3-month geometric mean of weekly bulk milk tank SCC measurements. Milk processing plants in most developed countries use automatic electronic somatic cell counters routinely in order to provide a monthly report of the bulk tank milk SCC. The test requires only that the sample for examination be taken randomly and not frozen, that it be prepared with the correct reagent, that the laboratory counter be set at the right calibration and that the sample be examined quickly or preserved with formalin to prevent cell losses during storage. The bulk tank milk SCC is extremely useful in creating awareness of the existence of a mastitis problem, so that when the SCC of bulk tank milk exceeds permissible limits further investigation of the herd is indicated. In a seasonal herd in which all cows are at the same stage of lactation the bulk milk cell count will normally be high in early lactation and just before drying off. To overcome these and other factors that are likely to transiently influence bulk tank milk SCC, it is recommended that correction factors be introduced into the estimation or that a rolling SCC, in which monthly data are averaged for the preceding 3 months, be used. Consideration of this figure will avoid too hasty conclusions on one high count caused by an extraneous factor.

Table 15.1 Estimated prevalence of infection and losses in milk production associated with bulk tank milk somatic cell count

Bulk tank milk somatic cell count (cells/mL)	Infected quarters in herd (%)	Production loss (%)
200 000	6	0
500 000	16	6
1 000 000	32	18
1 500 000	48	29

It is not possible to use the bulk tank milk SCC to determine the number of cows in a herd affected by mastitis but it is possible to estimate fairly accurately the number of infected quarters. In general, as the bulk tank milk SCC increases, the prevalence of infection increases and losses in production increase. Production losses calculated as a percentage of production expected with a count of 200 000 cells/mL are shown in Table 15.1. A bulk tank milk SCC of more than 300 000 cells/mL is considered to indicate a level of mastitis in the herd that warrants examination of individual cows. Herds with a high bulk tank milk SCC have significantly lower production levels and are less likely to use a postmilking teat dip or to have a regular program of milking machine maintenance or automatic cluster removal.[46]

Culture of bulk tank milk

Bacteria present in bulk tank milk may originate from infected udders, from teat and udder surfaces or from a variety of other environmental sources; however, despite the large number of potential sources for bacteria, culture of bulk tank milk is a useful technique for screening for major mastitis pathogens.[48] The culture of *S. aureus* and *S. agalactiae* from bulk tank milk is a reliable indicator of infection by those pathogens in the herd. The number of those pathogens found on culture is determined by the number of bacteria shed, the number of infected cows, the milk production level of infected cows relative to herd mates, and the severity of infection. A single culture of bulk tank milk has low sensitivity but high specificity for determining the presence of *S. agalactiae* or *S. aureus* in the herd. Thus many infected herds will be called negative but few uninfected herds will be called positive. Pathogens such as *Nocardia* spp. and *Mycoplasma* spp. have also been identified by culture of bulk tank milk. In general, the sensitivity of a single bulk tank milk culture to detect the presence of intramammary infections due to *S. agalactiae* ranges from 21–77%, for *S. aureus* it ranges from 9–58% and for *M. bovis* it is 33%.

Environmental bacteria such as *S. uberis*, *S. dysgalactiae*, and coliforms may enter milk from intramammary infections, but also from nonspecific contamination. The presence of these organisms in bulk tank milk may relate to the general level of environmental contamination and milking hygiene in the herd. Udder infections with these environmental pathogens are predominantly of short duration and characterized by clinical disease, which makes their inadvertent introduction to the bulk tank less likely.

String sampling or milk line sampling from the positive pressure side of the milking system is the collection of milk samples from a group of cattle instead of the entire herd, as in bulk tank milk sampling. String sampling may have some merit in identifying subgroups of cattle with the highest prevalence of infection. String sampling is thought to be more sensitive in monitoring herds for contagious pathogens than bulk tank milk sampling. If a production group tests positive on a string culture, then individual composite milk cultures can be performed to identify individual animals. Information of the culture results from string sampling should assist development of control programs; however, milk samples left in the pipeline from one string can confound the culture results of subsequent strings.

Numerous bacteriological techniques have been used to isolate and identify pathogens in bulk tank milk but none has been established as the gold standard method for the culture of milk from bulk tanks. The most suitable laboratory medium for growth and classification of the pathogens from bulk tank milk needs to be assessed. Sampling strategies have included weekly and monthly samples, but it remains to be determined which strategy is optimal relative to herd size and management, disease characteristics and practicality.

Culture of bulk tank milk has been compared to bulk tank SCC, herd summaries of SCC of individual cows and herd summaries of cultures of individual cows.[48] A significant correlation was found between bulk tank SCC and the frequency of isolating *S. agalactiae* from monthly samples of bulk tank milk. The correlations between *S. aureus* from bulk tank milk and SCC are lower.

Detection at the individual cow level

Abnormalities of the udder and **gross abnormalities of milk** in cattle with clinical mastitis have been described above under clinical findings. In individual cows with clinical mastitis, culture of the secretion from an infected quarter can be done. In animals without clinical mastitis, culture of the secretion represents a direct test for subclinical mastitis. The objective is to identify cows with contagious mastitis so that they can be treated or culled, or to identify the nature and source of environmental mastitis pathogens. Fulfillment of these requirements requires bacteriological culture of milk samples so that the pathogens can be named; **identification of mastitis pathogens is central to the development of effective treatment and control programs**. Detection of infected cows requires an individual cow examination and application of an indirect (screening) test for infection, such as the SCC of a composite milk sample, followed by culture of a representative subset of cows in order to determine the most prevalent pathogen. **Indirect tests estimate the prevalence of infection** and **microbiological examination identifies the mastitis pathogens;** from this information an appropriate control plan can be formulated.

Culture of individual cow milk

Individual cow milk can be cultured as part of a herd examination for mastitis, or on individual quarter samples, or on composite samples including milk from all four quarters. An intramammary infection is defined as the presence of the same pathogen in duplicate samples collected immediately after each other, or the presence of the same pathogen in two of three consecutive cultures obtained on different sampling dates. **Individual quarter samples are preferred** because the costs of treatment dictate that the least possible number of quarters be treated. With this technique only affected quarters are treated; if the quarter infection rate is low the saving in treatment costs is relatively large.

Milk sampling for culture must be carried out with due attention to cleanliness since samples contaminated during collection are worthless. The technique of cleaning the teat is of considerable importance. If the teats are dirty, they must be washed and then properly dried or water will run down the teat to the teat end and infect the milk sample. The end of the teat is cleaned with a swab dipped in 70% alcohol, extruding the external sphincter by pressure to insure that dirt and wax are removed from the orifice. Brisk rubbing is advisable, especially of teats with inverted ends. The first two or three streams are rejected because their cell and bacterial counts are likely to be a reflection of the disease situation within the teat rather than within the udder as a whole. The next few streams, the premilking sample, is the approved one because of its greater accuracy. For complete accuracy a premilking and a postmilking sample are taken. If tuberculosis is suspected, the last few streams are the critical ones. Indirect and chemical tests for mastitis can be carried out as accurately on foremilk as on later milk.

If individual quarter samples are collected, screw-cap vials are most satisfactory. During collection the vial is held at an angle to the ground in order to avoid as far as possible the entrance of dust, skin scales and hair. If there is delay between the collection of samples and laboratory examinations, the specimens should be refrigerated or frozen. Freezing of milk samples appears to have variable effects on bacterial counts, depending on the bacteria. *A. pyogenes* and *E. coli* counts are decreased by freezing, coagulase-negative *Staphylococcus* spp. counts are increased, and *Streptococcus* and *S. aureus* counts are either unaffected or increased by about 200%.[49]

The laboratory techniques used vary widely and depend to a large extent on the facilities available. Incubation on blood agar is most satisfactory, selective media for *S. agalactiae* having the disadvantage that other pathogens may go undetected. Smears of incubated milk are generally unsatisfactory as not all bacteria grow equally well in milk. An augmented system of culturing milk samples, which has given superior results in terms of the number of infected quarters detected, includes preculture incubation, then freezing of the milk sample, then inoculation of the medium with a larger than normal inoculum of milk.[50] The concern with augmented culture systems is that they may amplify contaminants obtained during sampling and therefore decrease the specificity of milk culture. Laboratory culturing techniques can be very time-consuming and expensive unless modern, prepackaged identification systems are used. They also provide the speed needed to make the examination a worthwhile one.

A milk sample is considered contaminated when more than three species of bacteria are isolated. A quarter is considered to be infected when the same bacteria is isolated in at least two out of three milk samples. A quarter is considered to be cured when bacteria, isolated at drying off, are not present in any samples 28 days after calving. An uninfected quarter at drying off that is infected at calving is considered to indicate a new intramammary infection. A quarter that is infected at drying off but infected with another bacteria at calving also indicates a new intramammary infection.

Selective culture plates, such as **biplates** (MacConkey agar and blood agar with 1% esculin), **triplates** (MacConkey agar, blood agar and TKT agar (thallium, crystal violet and staphylococcal toxin in 5%

blood agar with 1% esculin)), **Petrifilm®** plates, which are selective culture media products,[51] the **MASTiK®** diagnostic kit or the **ColiMast®** test can be used to differentiate between Gram-positive and Gram-negative pathogens and no growth,[52] and may aid in the rational and targeted use of antimicrobial agents for clinical cases of mastitis. A commercially available cowside test for endotoxin (**Limast-test®**) is available in Scandinavia. The test takes 15 minutes to run on milk samples and is able to detect the presence of endotoxin using the Limulus amebocyte lysate assay. The test therefore can detect the presence or absence of Gram-negative bacteria but does not differentiate between *E. coli* and *K. pneumoniae*.[53] At least 10^4–10^5 cfu of Gram-negative bacteria are necessary for a positive test result; this does not decrease the clinical utility of the test, because low bacterial counts in the milk from infected quarters usually indicates that antimicrobial agents are not required in order to clear the infection.

There is interest in developing other cowside tests to determine whether the causative pathogen is Gram-negative or Gram-positive. One such approach uses dilution of the milk sample, filtration through a membrane with a pore size that retains bacteria, and staining of the bacteria with specific stains.[54] The filtration procedure reportedly takes 5 minutes, but the need for microscopic examination decreases the utility of this as a cowside test.

A common diagnostic problem is a bacteriologically negative culture in cows with clinical mastitis. Even when milk samples are collected appropriately and bacteriological culture is done using routine laboratory methods, 15--40% of samples from clinical mastitis episodes are bacteriologically negative (yield no growth). Failure of these samples to yield a mastitis pathogen may be the result of spontaneous elimination of infection, a low concentration of pathogens in the milk, intermittent shedding of the pathogen, intracellular location of the pathogens or the presence of inhibitory substances in the milk. Augmented culture techniques may reduce, but do not eliminate negative culture results and may facilitate growth of contaminant organisms. Dairy producers and veterinarians therefore face a dilemma when no bacteria or bacteria commonly regarded to be of minor pathogenicity, such as *C. bovis* or coagulase-negative *Staphylococcus* spp., are cultured from the milk of cows with clinical mastitis, particularly if clinical signs persist.[55] Most bacteriologically negative cases of clinical mastitis appear to be caused by low-grade infections with Gram-negative bacteria.[55] When no bacterial pathogen can be isolated from cases of clinical mastitis using standard culture techniques, enzyme-linked immunosorbent assays (ELISAs) may be used to detect antigens against *S. aureus*, *E. coli*, *S. dysgalactiae*, and *S. agalactiae*.[56] Antigens to these pathogens may be detectable using an ELISA in up to 50% of quarter samples from cows with clinical mastitis in which no pathogens were isolated but in which the SCC was more than 500 000 cells/mL. Despite these promising findings, ELISAs are not widely used in the identification of mastitis pathogens.

Indirect tests for subclinical mastitis

Indirect tests include **SCC**s using automated electronic counters, the **California Mastitis Test**, increases in **electrical conductivity** of milk, and increases in the activity of cell associated enzymes (such as **NAGase**) in milk. ELISA tests to detect neutrophil components have been developed but are not commercially available.[57] Of these indirect tests, **only the CMT and electrical conductivity can be used cowside**, with CMT providing a more accurate screening test than electrical conductivity.

The somatic cell count of composite or quarter samples

There is a strong relationship between the SCC of quarter samples of milk and the milk yield, with SCC increasing slightly as milk production decreases but increasing markedly with intramammary infection of the quarter. The distribution of SCC in a herd therefore reflects the distribution of intramammary infections. The most important factor affecting SCC in an individual cow is the number of quarters infected with a major or minor pathogen. In most herds, the prevalence of infection will increase through a lactation and will also increase with the age of the cow. Cell counts in the first few days of the lactation are often exceptionally high and unreliable as indicators of intramammary infection, and in uninfected cows the counts will drop to a low level within 2 weeks of calving and remain low throughout the lactation unless an intramammary infection occurs. The SCC of a cow that remains free of infection throughout her life will remain very low. However, older cows may have higher counts because the prevalence of infection is higher with age and older cows are more likely to have had previous infections with residual lesions and leaking of somatic cells into the milk. There are also consistent and significant differences in actual SCC between cows, individual cows tending to maintain the same class of count throughout their lives. Cows that have consistently low SCC do not seem to be more susceptible to mastitis than others. Attempts to base a breeding program to reduce the prevalence of mastitis on the selection of cows with an innately low composite SCC have been discarded because of fluctuations in numbers within cows.

Healthy quarters have a SCC below 100 000 cells/mL, and **this cutpoint should be used to indicate the absence or presence of intramammary infection on a gland basis**. This cutpoint looks very solid for a gland, because many milk components differ from normal values whenever the SCC exceeds 100 000 cells/mL. Moreover, mean SCC counts for bacteriologically negative quarters, quarters infected with minor pathogens and quarters infected with major pathogens were 68 000, 130 000, and more than 350 000 cells/mL, respectively.[58]

Because of the time and labor saved it is now customary to do automated electronic cell counts on **composite milk samples** that have already been collected for butterfat testing. Regular reports of individual cow SCCs are therefore widely available in herds that routinely test production parameters of their cattle. An exciting new development in mastitis control is the **portable somatic cell counter**, which was designed for on farm use, thereby providing targeted and immediate SCC information for quarter or composite milk samples. Using the composite sample technique does distort the SCC; for example, the dilution of high-SCC milk from a bad quarter by low-SCC milk from three normal quarters could mean that a cow with one infected quarter might not be detected. Composite SCCs of less than 200 000 cells/mL are considered to be below the limit indicative of inflammation, even though uninfected quarters have a SCC of less than 100 000 cells/mL. Factors that affect the composite milk SCC include the number of infected quarters infected, the kind of infection (*S. agalactiae* is a more potent stimulator of cellular reaction than *S. aureus*), the strictness with which milk from cows with clinical mastitis is kept out of the bulk tank, the age of the cows (older cows have higher counts), the stage of lactation (counts are highest in the first days after calving and toward the end of lactation) and the herd's average production, the cell count reducing as milk yield increases.[59]

A SCC scoring system that divides the SCC of composite milk into 10 categories from 0–9, known as **linear score**, is becoming more widely used. The linear score is a base 2 logarithm of the SCC (in cells/mL), whereby linear score = $\log_2(\text{SCC}/100\,000) + 3$. Likewise, to calculate SCC (in cells/mL) from the linear score (LS), the following formula is used: $\text{SCC} = 100\,000 \times 2^{(\text{LS}-3)}$. A SCC of

100 000 cells/mL therefore converts to a score of 3. Each 1-unit increase (or decrease) in linear score is associated with a doubling (or halving) of the SCC. For example, score 2 is equivalent to a SCC of 50 000 cells/mL, and scores of 4 and 5 correspond to 200 000 and 400 000 cells/mL. Conversion of SCC to **linear score** values is performed as shown in Tables 15.3 and 15.4. The principal reason for using the linear score is to achieve properties that are required in order to use conventional statistical methods: mean equal to median, normal distribution and uniform variance amongst samples within lactation, amongst cows within herd or among daughters within sire.

The proportion of neutrophils in the SCC is very low (< 11%) in healthy quarters but is markedly increased in quarters with intramammary infection (to > 90%). Accordingly, the percentage of neutrophils in the SCC may provide a useful indication of intramammary infection, but is not currently performed.[58]

Somatic cell counts can also be determined for colostrum, where they are useful in indicating the presence of intramammary infection (Table 15.2).[60]

Table 15.3 Linear score calculation from the somatic cell count

Example: SCC = 200 000 cells/mL
a. Divide the SCC by 100 000 cells/mL (200 000/100 000 = 2)
b. Determine the natural log (ln) of the results of step 1 (ln 2 = 0.693)
c. Divide this value by 0.693 (i.e. 0.693/0.693 = 1)
d. Add 3 to the result of step c = 1 + 3 = 4 linear score

The California Mastitis Test of quarter samples

The CMT **is the most reliable and inexpensive cowside test for detecting subclinical mastitis.** The CMT is also known as the Rapid Mastitis test, Schalm test or Mastitis-N-K test, was developed in 1957 and constituted a modification of the Whiteside test. The CMT reagent contains a detergent that reacts with DNA of cell nuclei, and a pH indicator (bromcresol purple) that changes color when the milk pH is increased above its normal value of approximately 6.6 (mastitis increases pH to 6.8 or above). The CMT is mixed with quarter milk samples that have been previously collected into a white container and the sample is gently swirled; the result is read within 15 seconds as a negative, trace, 1, 2, or 3 reaction depending on the amount of gel formation in the sample. Maximum gel formation actually occurs from 1–2.5 minutes, depending on the quarter SCC and continued swirling of the mixture after the time of peak viscosity produces an irreversible decrease in viscosity.[61] Cows in the first week after calving or in the last stages of lactation may give a strong positive reaction.

The close relationship between the CMT reaction and the SCC of milk and the reduced productivity of affected cows is shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).

CMT scores can also be determined for colostrum, where the score is useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are different for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are similar for colostrum and milk.[62]

The NAGase test of composite or quarter samples

The NAGase test is based on the measurement of a cell-associated enzyme (*N*-acetyl-β-D-glucosaminidase) in the milk, a high enzyme activity indicating a high cell count. NAGase is an intracellular lysosomal enzyme derived primarily from neutrophils but also from damaged epithelial cells. The test is suited to the rapid handling of large numbers of samples because of the ease of its automation, and the test can be done on fresh milk and read on the same day.[63] However, because most of the NAGase activity is intracellular, samples should be frozen and thawed before analysis to induce maximal

Table 15.4 [illegible]

Test result	Reaction observed	Equivalent milk SCC	Equivalent linear score	Colostrum geometric mean SCC
Negative	The mixture remains fluid without thickening or gel formation	0–200 000 cells/mL	0–4	500 000 cells/mL
Trace	A slight slime formation is observed. This reaction is most noticeable when the paddle is rocked from side to side	150 000–500 000 cells/mL	5	670 000 cells/mL
1+	Distinct slime formation occurs immediately after mixing solutions. This slime may dissipate over time. When the paddle is swirled, fluid neither forms a peripheral mass nor does the surface of solution become convex or 'domed up'	400 000–1 500 000 cells/mL	6	890 000 cells/mL
2+	Distinct slime formation occurs immediately after mixing solutions. When the paddle is swirled the fluid forms a peripheral mass and the bottom of the cup is exposed	800 000–5 000 000 cells/mL	7–8	3 400 000 cells/mL
3+	Distinct slime formation occurs immediately after mixing solutions. This slime may dissipate over time. When the paddle is swirled the surface of the solution becomes convex or 'domed up'	> 5 000 000 cells/mL	9	6 260 000 cells/mL

Table 19.4 Conversion of linear scores to somatic cells counts (cells/mL) and predicted loss of milk[99]

Linear score	Somatic cell count midpoint (cells/mL)	Pounds of milk lost per lactation First	Second
0	12 500	0	0
1	25 000	0	0
2	50 000	0	0
3	100 000	200	400
4	200 000	400	800
5	400 000	600	1200
6	800 000	800	1600
7	1 600 000	1000	2000
8	3 200 000	1200	2400
9	6 400 000	1400	2800

NAGase activity.[58] The NAGase test is reputed to be the most accurate of the indirect tests and as good as SCC in predicting the infected status of a quarter. The NAGase test uses a less sophisticated reading instrument than the average automatic cell counter. If all tests are available it is best to consider the NAGase test and SCC as complementary tests and carry out both of them. Milk NAGase levels are high at the beginning and the end of lactation, as with cell counts. The test has also been validated for use with goat milk.

Electrical conductivity tests of quarter samples

A test that has received a lot of attention because it can be used in robotic milking systems is based on the increase in concentration of sodium and chloride ions, and the consequent increase in electrical conductivity, in mastitic milk.[64] The electrolyte changes in milk are the first to occur in mastitis and the test has attractions for this reason. A number of factors affect these characteristics, however, and to derive much benefit from the test it is necessary to examine all quarters and use differences between the quarters to indicate affected quarters. For greater accuracy all quarters need to be monitored each day. An experimental unit that takes all these factors into consideration has been fitted to a milking machine and, by a computer-prepared analysis, monitors variations in electrical conductivity in each quarter every day.[65] Electrical conductivity is attractive as a test because it measures actual injury to the udder rather than the cow's response to the damage, as SCC and NAGase activity do.[66] However, a meta-analysis indicated that using an absolute threshold for conductance did not provide a suitable screening test, as both sensitivity and specificity were unacceptably low.[67] The use of differential conductivity (within cow quarter comparison) results in improvement in test sensitivity and specificity, and is currently the only recommended application of this indirect test.[58,68]

The most commonly promoted method for measuring electrical conductivity is a hand-held device with a built-in cup into which milk is squirted (foremilk is preferred). Experimentally induced clinical mastitis due to *S. aureus* and *S. uberis* was detectable by changes in electrical conductivity of foremilk: 90% of cases were detectable when clots first appeared and 55% of cases were detectable up to two milkings prior to the appearance of clots.[64] This suggests that clinical mastitis associated with these two major pathogens may be able to be detected earlier by electrical conductivity than by waiting for milkers to detect visible changes in the milk.

Comparison of indirect methods

The effects of subclinical intramammary infection on several parameters in foremilk from individual quarter milk samples have been compared.[62] Somatic cell count, electrical conductivity, pH, NAGase activity and the concentrations of sodium, potassium, lactose and alpha-1-antitrypsin were measured from individual quarters. Somatic cell count, NAGase activity, electrical conductivity and concentrations of sodium, alpha-1-antitrypsin and lactose were all useful indirect indicators of infection. The SCC was better able to discriminate between infected and uninfected quarters and cows than were the electrical conductivity, pH and NAGase activity.

Hematology and serum biochemistry

In severe clinical mastitis there may be marked changes in the leukocyte count, packed cell volume and serum creatinine and urea nitrogen concentration because of the effects of severe infection and toxemia.[69] In particular, clinical mastitis episodes associated with Gram-negative bacteria frequently cause a profound leukopenia, neutropenia, lymphopenia and monocytopenia as a result of the endotoxemia. as well an increased packed cell volume.[70] In contrast, the leukogram in cattle with clinical mastitis associated with Gram-positive bacteria is normal or mildly increased.

Ultrasonography of the mammary gland

Two-dimensional ultrasonographic images of the gland cistern, parenchymal tissue and teat are easily obtained using a 5, 7.5, or 8.5 MHz linear array transducer, and ultrasonography is becoming more widely used to guide treatment of teat and gland cistern abnormalities. However, there are few reports of the use of ultrasonography to diagnose or prognose clinical mastitis episodes, although this is likely to be a fruitful area for investigation.

The best two-dimensional images of the udder parenchyma are obtained by clipping the hair on the udder and applying a coupling gel. This minimizes air between the transducer face and skin. Imaging the normal adjacent quarter is very helpful in identifying abnormalities. Imaging should be performed in two planes, sagittal to the teat (and therefore perpendicular to the ground), and transverse to the teat (and therefore horizontal to the ground). The injection of sterile 0.9% NaCl through a teat cannula into the gland provides a practical contrast agent that can help further define the extent of any abnormalities. The superficial supermammary lymph nodes can be ultrasounded using a 7.5 MHz linear transducer, with the lymph node being well demarcated from the surrounding tissues. Mean lymph node length was 7.4 cm (range 3.5–15.0 cm) and mean depth was 2.5 cm (range, 1.2–5.7 cm). Lymph node size increased with age but was not correlated with SCC.[71]

Mastitis produces an increased heterogeneous echogenicity to the milk in the gland cistern, compared to an uninfected quarter. It is important to make this visual comparison without altering the contrast and brightness setting on the ultrasonographic unit.[72]

Three-dimensional ultrasonography of the bovine mammary gland and teat has recently been evaluated[73] and has many promising applications.

Biopsy of mammary tissue

A biopsy of mammary tissue can be used for histological and biochemical evaluation in research studies. The use of a rotating stainless steel cannula with a retractable blade at the cutting edge has been described for obtaining biopsy material from cows.[74] Despite some postoperative bleeding, milk yield and composition in the biopsied gland were affected only transiently.

NECROPSY FINDINGS

Necropsy findings are not of major interest in the diagnosis of mastitis and are

omitted here but included in the description of specific infections.

DIFFERENTIAL DIAGNOSIS

The diagnosis of clinical mastitis is not difficult if a careful clinical examination of the udder is carried out as part of the complete examination of a cow with systemic clinical findings. Examination of the udder is sometimes omitted in a recumbent animal only for severe mastitis to be discovered later. The diagnosis of mastitis depends largely upon the detection of clinical abnormalities of the udder and gross abnormalities of the milk or the use of an indirect test like the CMT to detect subclinical mastitis.

Other mammary abnormalities that must be differentiated from clinical mastitis include **periparturient edema**, **rupture of the suspensory ligament**, and **hematoma**. These are not accompanied by abnormalities of the milk unless there is hemorrhage into the udder. The presence of stray voltage in the milking plant should not be overlooked in herds where the sudden lowering of production arouses an unfounded suspicion of mastitis. Differentiation of the different causes of mastitis is difficult on the basis of clinical findings alone but must be attempted, especially in peracute cases where specific treatment must be given before results of laboratory examinations are available. A pretreatment sample of milk from the affected glands for culture and antimicrobial sensitivity may provide useful information about the health record of the cow and the need to consider alternative therapies, and could provide information on new infections in the herd.

TREATMENT

The treatment of the different causes of clinical and subclinical mastitis may require specific protocols, which are described under specific mastitis pathogens later in the chapter. The general principles of mastitis treatment are outlined here.

Historical aspects of antimicrobial therapy for clinical and subclinical mastitis

Between about 1950 and 1990, on a worldwide basis, all forms of both clinical and subclinical bovine mastitis were treated with a wide variety of antimicrobial agents either by intramammary infusions or parenterally, and commonly by both routes in acute and peracute cases. Most veterinarians treated clinical mastitis and evaluated the response on the basis of clinical outcome. In general, it was believed that antimicrobial agents were effective for the treatment of clinical and subclinical mastitis in lactating cows. However, there are very few scientific publications based on randomized clinical trials in which the efficacy of intramammary antimicrobial agents for treatment of clinical mastitis was compared to untreated controls. If antimicrobial agents were used and the animal recovered, it was assumed that treatment was efficacious. If the cow did not respond favorably, several reasons were usually enumerated for the treatment failure. However, most of these reasons, while biologically attractive, are hypothetical and have not been substantiated scientifically. Gradually, over the years, veterinarians began to doubt the efficacy of antimicrobial agents for the treatment of all cases of clinical mastitis. In addition, and of major importance, milk from treated cows had to be discarded for up to several days after the last day of treatment because of antimicrobial residues; this was a major expense. Currently, optimized treatment strategies focus on efficacy, economics, animal welfare aspects and the milk withhold time of antimicrobial treatment.

Efficacy is assessed on the basis of **clinical cure** or **bacteriological cure**. Most producers are interested in the return to normal milk (clinical cure) and are much less interested in the return to a sterile quarter (bacteriological cure). Because clinical mastitis is defined as abnormal milk, the return to normal ('drinkable') milk represents a clinical cure. Bacteriological cure represents the inability to isolate the initial pathogen 14–28 days after the start of treatment. Other important indicators of efficacy are milk production, dry matter intake, the amount of saleable milk and mortality or culling rates after treatment.

Some examples of the efficacy or inefficacy of antimicrobial agents illustrate the controversy. It is well accepted that the cure rate following intramammary treatment of clinical or subclinical mastitis due to *S. agalactiae* in the lactating cow is high (80–90%). In contrast, the cure rate of clinical and subclinical mastitis due to *S. aureus* in the lactating cow is considerably lower (40–50%), but certainly not 0%. In herds with a low prevalence of contagious mastitis, most cases of mild clinical mastitis (abnormal secretion only) in lactating cows are due to environmental streptococci and coliforms and may recover without antimicrobial therapy, although antimicrobial administration increases the clinical and bacteriological cure rate. Antimicrobial agents may be ineffective for the treatment of clinical mastitis associated with *M. bovis*, *A. pyogenes*, *Nocardia* spp., and *P. aeruginosa*.

In the 1970s dairy processing plants, veterinarians, consumer advocates, public health authorities and milk-quality regulating agencies began to express concern about antimicrobial residues in milk from cows treated for mastitis. The public health and milk industry concerns about residues combined with the controversy about the efficacy of antimicrobial agents for clinical mastitis has also provided a stimulus to evaluate the efficacy and consequences of using antimicrobial agents. Since the early 1990s much emphasis has been placed on alternative methods of treating clinical mastitis, leading to a reduction in the use of antimicrobial agents during the lactating period.[75] Such strategies have been defended based on a lack of information concerning the efficacy and economics of antimicrobial therapy associated with pathogens other than *S. agalactiae*, and by the need to reduce the risk of residue violation. However, a recent study concluded that not administering antibiotics to cows with clinical mastitis was imprudent and unethical.[76]

There is a need for randomized controlled field trials to evaluate the use of antimicrobial agents for the treatment of clinical mastitis; the design for such trials and the statistical analysis required have been reviewed.[77] Well conducted clinical mastitis treatment trials represent an invaluable, although difficult and expensive, effort to evaluate efficacy of antimicrobial agents under field conditions. The use of intramammary antimicrobial agents for the treatment of clinical mastitis in lactating cows in 40 dairy herds over 4 years found an economic benefit compared to nonmedicated controls.[78] In the antimicrobial-treated group, the number of pathogens in the milk following treatment was reduced, the number of quarters returning to normal milk was increased, and the number of cured quarters was increased. In should be noted that the use of antimicrobial agents for the treatment of **subclinical mastitis** at the end of lactation, known as **dry cow therapy**, is accepted worldwide and is based on scientific evidence using randomized clinical trials. Dry cow therapy is one of the principles applied in the effective control of bovine mastitis, in which much progress has been made since the early 1970s.

Treatment strategy

The treatment strategy will depend on whether the mastitis is **clinical** or **subclinical**, and the health status of the herd, including its mastitis history. Clinical mastitis is further categorized as **abnormal milk**, **abnormal gland** or **abnormal cow**, as described under Diagnosis. If treatment is indicated, the major decision is whether to administer antimicrobial agents parenterally or by intramammary infusion.

An important aspect of treatment is the accurate positive identification of the animal(s) to be treated, the recording of the relevant clinical and laboratory information, and the treatments being

used, and monitoring the response. Useful information would include:

- Cow identification
- Quarters affected
- Date of mastitis event
- Lactation number
- Date of calving
- Identification of pathogen(s)
- Treatment used, including dose, route and duration
- Milk withholding time and time when returned to the milking string
- Most recent level of milk production.

Options for treating cows with clinical mastitis include treating all cows with antimicrobial agents, treating none of the cows with antimicrobial agents or treating only specific cows with antimicrobial agents.[79] Treating all cows results in increased costs for those cows with clinical mastitis associated with pathogens not susceptible to the antimicrobial agent used, especially if the signs are likely to resolve before the milk withholding period has expired. Treatment of all cows is also associated with increased risk of violative residues in the bulk milk. Treating none of the cows with antimicrobial agents has animal welfare implications, in that an effective treatment is not administered to some cattle with clinical mastitis, and nontreatment allows Gram-positive pathogens to persist, increasing the probability of a recurrence of clinical mastitis or causing a herd epidemic of mastitis. Accordingly, nontreatment of all cases of mastitis is not a viable option. Treating only specific cows with antimicrobial agents requires an accurate method of determining which animals should be treated. However, clinical judgment and predictive models are too inaccurate to distinguish between clinical mastitis associated with Gram-negative and Gram-positive pathogens.[79] To select cows for antimicrobial therapy on the basis of bacteriological culture is costly and delays treatment; clinical judgment would still be necessary because bacteria are not isolated from 15–40% of milk samples from cows with clinical mastitis.

Veterinarians should always ask and answer four questions related to antimicrobial therapy in bovine mastitis:

- Is antimicrobial therapy indicated?
- Which route of administration (intramammary, parenteral or both) should be used?
- Which antimicrobial agent should be administered?
- What should be the frequency and duration of treatment?

Is antimicrobial therapy indicated?

The first decision is **whether to treat** a particular case with antimicrobial agents and whether supportive therapy is required. Therapy decisions should be made in context with the overall objectives of the lactating cow treatment protocol. The availability of approved, effective treatment products is an essential component of the program. A number of factors are important in determining which cases of mastitis should be treated during lactation. These factors include the type of pathogen involved, the type and severity of the inflammatory response, the duration of infection, the stage of lactation, and the age and pregnancy status of the cow.

Type of pathogen involved

There are marked differences in the bacteriological cure rates of the various major mastitis pathogens after therapy during lactation. The outcome of treatment during lactation is poor for cases of *S. aureus* mastitis. On the other hand, *S. agalactiae* responds extremely well to lactating cow therapy and all infected cows should be treated. Cases of mastitis associated with environmental organisms have reasonable, but variable, cure rates.

Type and severity of the inflammatory response

The predominant type of inflammatory process involved influences the objectives of the therapy program. Herds with clinical mastitis problems will aim at reducing clinical signs, returning the milk to saleable quality and avoiding residue violations. Herds with a predominance of subclinical mastitis are concerned with avoiding the spread of infection and reducing the prevalence of the major pathogens involved. Both types of herd have the primary objective of restoring the production potential.

The severity of the inflammatory response is also important in the selection of cases for mastitis therapy during lactation. Heat, pain and swelling of the quarter (abnormal gland) are clinical signs that indicate the need for antimicrobial therapy. Many producers, however, will treat any cow that shows clots in the milk (abnormal milk). There are no reports to verify that treatment of cows exhibiting abnormal milk only is efficacious and economically justifiable, although it is probable that treatment of clinical mastitis episodes of abnormal milk but normal gland due to *S. agalactiae* is efficacious and economic. Treatment success is lower in cows with high NAGase concentrations in milk compared to low NAGase concentrations.[80]

Duration of infection

For the contagious organisms, especially *S. aureus*, the duration of infection is an important determinant of its susceptibility to therapy during lactation. In chronic *S. aureus* mastitis, the organism survives intracellularly in leukocytes, becomes walled-off in small abscesses of mammary ducts, and has the ability to exist in the L-form state. At this point *S. aureus* is virtually incurable during lactation. With new methods of automated detection of subclinical intramammary infection such as in-line electrical conductivity measurement, new infections may be detected much earlier. The cure rate of *S. aureus* during lactation needs to be re-evaluated when treatment is administered early in the course of infection.

Stage of lactation

The stage of lactation is an important determinant of the benefit:cost ratio of mastitis therapy during lactation. It may be uneconomical to treat even cases with a high probability of cure during late lactation.

Age and pregnancy status of cow

The probability of a cure is greater in young cows, and age should be considered in selecting cases for mastitis therapy during lactation.[80] The economic aspects of treatment for late-lactation, nonpregnant cows are obviously different from those for midlactation pregnant cows.

A mastitis therapy program for lactating cows should be based on a complete understanding of the mastitis status of the herd, and individual cow treatment decisions should be consistent with the overall herd mastitis therapy program. A record system for treatment should be established so that it is possible to monitor the efficacy of the mastitis treatment program.

The udder health status in a particular herd will determine whether the lactating cow mastitis therapy strategy should be targeted at the individual cow level or at the herd level. The level of emphasis should clearly reflect the objectives of the therapy program. For example, a herd with low bulk tank milk SCC and sporadic cases of environmental mastitis should target the lactating cow therapy strategy at the cow level. The primary objectives would be to alleviate clinical signs, to achieve a bacteriological cure and to restore the cow's production. On the other hand, a herd with moderate to high bulk tank milk SCCs and a significant prevalence of contagious organisms should aim the program at the herd level. In this case, the objective would be to limit the spread of infection, markedly reduce or eradicate a specific pathogen and increase herd production. A clear statement of treatment philosophy (individual cow level or herd level) in a particular

herd is needed to direct establishment of well defined treatment protocols for mastitis in lactating cows.

Intramammary infection (mastitis) is identified by the presence of clinical signs or the results of a direct test (culture of milk) or indirect tests such as SCC, CMT or electrical conductivity. The detection of clinical or subclinical mastitis does not necessarily indicate that therapy should be administered, although animal welfare issues dictate that treatment must be administered to cattle with an abnormal gland or systemic signs (abnormal cow) because these animals are undergoing pain and discomfort. A decision to use treatment during lactation should be based on the likelihood of achieving the objectives of the therapy program. Several factors are important in the selection of cows for treatment. These factors can significantly influence the cure rate achieved with therapy, or the economic benefit realized.

The herd history of udder health will indicate the probable cause of clinical mastitis. Cows with mild cases of clinical mastitis (abnormal milk only) in herds with a low prevalence of contagious mastitis pathogens are likely to be affected with environmental pathogens[17] and commonly return to clinically normal milk in four to six milkings.[81] This has led to the development of treatment algorithms based on the results of culturing clinical cases using selective media. Using this approach, milk cultures are obtained from all cattle with clinical mastitis and plated using biplates or triplates. All cattle with abnormal glands or signs of systemic illness (abnormal cow) are immediately treated with antimicrobial agents and appropriate ancillary treatment, with subsequent antimicrobial treatment based on the preliminary culture results at 18–24 hours or the final culture results at 48 hours. In contrast, treatment is initially witheld from all cattle demonstrating abnormal secretion only; antimicrobial treatment is instituted based on the culture results. One such scheme recommends using intramammary antibiotics to treat affected quarters with *S. aureus*, coagulase-negative staphylococci and environmental streptococci, infusing intramammary antibiotics into all quarters of cows with one or more quarters infected with *S. agalactiae* and not administering antibiotics to cows with coliform bacteria or no growth.[82] When using this delayed approach to antimicrobial treatment, it is important that cattle with abnormal milk only are closely monitored and that antimicrobial treatment is immediately instituted when signs of an abnormal gland or abnormal cow are present. The major difficulty with implementing the delayed approach is the difficulty in transporting the milk sample to and receiving the results from the diagnostic laboratory in a time effective manner.

Which route of administration (intramammary, parenteral or both?)

The second decision is the route of administration. The goal of antimicrobial treatment is to attain and maintain an effective concentration at the site of infection. Three pharmacological compartments are recognized for infection by mastitis pathogens:

- Milk and epithelial lining of the ducts and alveoli
- Parenchyma of the mammary gland
- The cow[83] (Table 15.5).

In general, infections confined primarily to the milk and ducts (such as *C. bovis*, coagulase-negative staphylococci) are easily treated with intramammary antibiotics. In contrast, infections due to mastitis pathogens with potential for systemic infection (such as *E. coli*, *K. pneumoniae*, *M. bovis*) are best treated with parenteral antibiotics. Mastitis pathogens that are the most difficult to treat are those that are principally infections of parenchymal tissue (such as *S. aureus*, *A. pyogenes*); this is because it is more difficult to attain and maintain an effective antibiotic concentration at this anatomical site when administering antibiotics by the intramammary or parenteral routes.

Which antimicrobial agent should be administered?

The third decision is the antimicrobial agent. The selection of the antimicrobial class for the particular mastitis pathogen has traditionally been based on culture and susceptibility testing and, although some in vivo data are now available, the choice is still largely dependent on case studies rather than on controlled experiments. Culture and antimicrobial susceptibility testing of the pathogen is not necessarily a justifiable basis for selecting the antimicrobial agent to be used in individual cows, and the response to treatment of clinical mastitis in two recent studies[84,85] was unrelated to the results of in vitro susceptibility tests.

Antimicrobial agents are usually selected based on availability of labeled drugs, clinical signs in the cow, milk culture results for previous mastitis episodes in the herd, experience of treatment outcome in the herd, treatment cost and withdrawal times for milk and slaughter. Many veterinarians and researchers have also recommended the use of susceptibility testing to guide treatment decisions. The validity of agar diffusion susceptibility breakpoints derived from humans in the treatment of bovine mastitis has not been established and is extremely questionable because bovine mastitic milk pH, electrolyte, fat, protein and neutrophil concentrations, growth factor composition and pharmacokinetic profiles differ markedly from those of human plasma.[86] Moreover, antibiotics are distributed unevenly in an inflamed gland, and high antibiotic concentrations can alter neutrophil function in vitro and therefore have the potential to inhibit bacterial clearance in vivo.

Adequate databases of in vitro minimum inhibitory concentration (MIC)

[illegible]

Mastitis pathogen	Pharmacological compartment		
	Milk and ducts (abnormal milk)	**Parenchyma (abnormal gland)**	**Systemic (abnormal cow)**

values for clinical mastitis pathogens are currently unavailable, although adequate databases are available for subclinical mastitis isolates. Although we have a good knowledge of the pharmacokinetics of many parenteral antibiotics used to treat clinical mastitis, most pharmacokinetic data have been obtained in healthy cattle and it has not been determined whether pharmacokinetic values in healthy cows are the same as those in cows with clinical mastitis. In addition, pharmacokinetic values for many of the intramammary antibiotics used to treat clinical mastitis are unknown, and we have a limited understanding of the pharmacodynamics of antibiotics in treating mastitis. More importantly, the breakpoints currently recommended for all parenterally and almost all intramammarily administered antibiotics are based on achievable serum and interstitial fluid concentrations in humans after oral or intravenous antibiotic administration. The relevance of these breakpoints to achievable milk concentrations in lactating dairy cows after intramammary, subcutaneous, intramuscular or intravenous administration is dubious at best.[86]

Results from field studies are available to evaluate the validity of susceptibility breakpoints in guiding treatment of cows with clinical or subclinical mastitis. The results from these field studies suggest that the following antibiotics may have valid (but not necessarily optimal) breakpoints for treating clinical or subclinical mastitis associated with specific bacteria: parenteral penicillin G for subclinical *S. aureus* infections, intramammary cephapirin for clinical *Streptococcus* spp. infections, and parenteral trimethoprim–sulfadiazine for clinical *E. coli* infections. Of these three antibiotics, the breakpoints for penicillin G and cephapirin have only been validated for bacteriological cure, whereas the breakpoint for trimethoprim–sulfadiazine is validated for clinical cure.[84] Because duration of infection before treatment, antibiotic dosage, dosage interval and duration of treatment influence treatment outcome, many more field studies must be completed to validate the currently assigned antibiotic breakpoints for pathogens causing clinical mastitis.

To properly utilize the known pharmacokinetics of parenterally and intramammarily administered drugs, it is necessary to know something about their diffusion into mammary tissue, the degree of binding of a drug to mammary tissues and secretions, the ability to pass through the lipid phase of milk and the degree of ionization. All of these factors influence the level of the antibiotic in the mammary gland. For lactating cows the preferred treatment is one that maintains a MIC for 72 hours without the need for multiple infusions and without prolongation of the withdrawal time. The most successful antimicrobial agents for dry period treatment are those that persist longest in the udder, preferably as long as 8 weeks. These characteristics depend on the release time from the transport agent in the formulation, and the particle size and diffusion capabilities of the antibiotic.

The formulation of the preparation will affect the duration of the maintenance of the MIC. The third-generation cephalosporins (such as ceftiofur) and fluoroquinolones are the drugs of choice for use in cases in which the infection may be associated with either a Gram-positive or Gram-negative organism; however, these antimicrobial agents may not be able to be used to treat mastitis in some countries. Mixtures of penicillin and an aminoglycoside are also in common use for this purpose. Penicillin G and penethamate are favored for Gram-positive infections.

Of special importance are the beta-lactamase-producing strains of *S. aureus*, against which beta-lactam penicillins are ineffective; cloxacillin is a commonly used and effective intramammary formulation for these strains of *S. aureus*. The drugs that have the best record of diffusion through the udder after intramammary infusion are penethamate, ampicillin, amoxicillin, erythromycin and tylosin. Those of medium performance are penicillin G, cloxacillin and tetracyclines. Poor diffusers, which have a longer half-life in the udder because they bind to protein, include streptomycin and neomycin. Streptomycin is not much used now because of the high level of resistance to it, especially by *S. uberis* and *E. faecalis*.

What should be the frequency and duration of treatment?

The fourth decision is the **frequency and duration of treatment**. The frequency of administration for parenterally administered antimicrobial agents is dependent primarily on their pharmacokinetics and pharmacodynamics. Fluoroquinolones and aminoglycosides are **concentration-dependent** antimicrobial agents where increasing concentrations at the site of infection increase the bacterial kill rate. Macrolides, beta-lactams, and lincosamides are **time-dependent** antimicrobial agents where exceeding the minimum inhibitory concentration at the site of infection for a prolonged percentage of the interdosing interval correlates with improved efficacy.[87] In contrast, the frequency of administration for intramammary formulations is dependent primarily on the milking schedule, in that these agents are primarily cleared by milk removal. For example, the clearance of pirlimycin is strongly and positively correlated ($r = 0.97$) to 24-hour milk production at the time of dosing.[88] With all intramammary formulations being licensed based on the results of studies of twice-daily milking, the recent industry trend in some parts of the world towards thrice-daily milking has created uncertainty as to whether intramammary treatment should be repeated after every milking, or even whether once-a-day intramammary administration is as efficacious as twice- or thrice-daily administration.

Recent studies have confirmed long held beliefs that **appropriate antimicrobial therapy** (commonly called **extended or aggressive antimicrobial therapy**) for 5–8 days is much more effective in treating intramammary infections than label intramammary therapy (2–3 d). In other words, increasing the duration of antimicrobial administration increases treatment efficacy.[89–92] Extended antimicrobial therapy is opposed by producers because such treatment may be off-label and results in a longer milk withhold time, and consequently the amount of milk that has to be discarded. Extended therapy is opposed by dairying administrators because of the inevitable increase in the number of infringements of health regulations relating to antibiotic residues in milk. The inappropriately short treatment duration for most intramammary products has been a major hindrance to developing effective antimicrobial treatment protocols.

Intramammary antimicrobial therapy

For reasons of convenience and efficiency, antimicrobial udder infusions are in common use for the treatment of certain causes of mastitis in lactating cows, and for dry cow therapy. For example, the cure rate of *S. agalactiae* using intramammary infusions in lactating cows exceeds 95%. Disposable tubes containing suitable antimicrobials in a water-soluble ointment base are ideal for dispensing and for the treatment of individual cows. Multiple-dose bottles containing aqueous infusions are adequate, and much cheaper per dose when large numbers of quarters are to be treated, but repeated use of the same container increases the risk of contamination. The degree of diffusion into glandular tissue is the same when either water or ointment is used as a vehicle for infusion; the duration of retention within the gland depends on the vehicle.

Most antimicrobial agents currently available in the USA in commercial intramammary infusion products are active against the staphylococci and streptococci,[93] with cephapirin (a first-generation cephalosporin) having good

activity against coliform bacteria, and ceftiofur (a third-generation cephalosporin) having excellent activity against coliform bacteria.[94] Until recent years the emphasis was on the elimination of Gram-positive cocci from the udder, but Gram-negative infections, especially *E. coli*, have increased in prevalence to the point where a broad-spectrum preparation is almost essential for both lactation and dry period treatments.

The choice of antimicrobial agents for intramammary infusion should be based on:

- Spectrum of bacteria controlled
- Diffusibility through mammary tissue
- Cost.

Strict hygiene is necessary during treatment to avoid the introduction of bacteria, yeasts and fungi into the treated quarters; the use of a short cannula that just penetrates the external sphincter is preferred as it is less likely to introduce bacteria and leaves more of the keratin plug in place in the streak canal; the keratin plug has antimicrobial properties itself. Care must be taken to insure that bulk containers of mastitis infusions are not contaminated by frequent withdrawals and that individual, sterilized teat cannulas, usually part of commercial, single-dose ointment tubes, are used for each quarter. Bulk treatments are best avoided because of the high risk of spread of pathogens.

Infusion procedure

The teats must be cleaned and sanitized before infusing the quarter in order to avoid introduction of infection. The following steps are recommended:

- Clean and dry the teats
- Dip teats in an effective germicidal product. Allow 30 seconds contact time before wiping teats with an individual disposable towel (one towel/cow, use one corner of the towel for each teat)
- Thoroughly clean and disinfect each teat end with cotton soaked in 70% alcohol. Use a separate piece of cotton for each teat
- Prepare teats on the far side of the udder first, followed by teats on the near side
- Treat quarters in reverse order; near side first, far side last
- Insert only the tip of the cannula into the teat end (**partial insertion**). Do not allow the sterile cannula to touch anything prior to infusion. Most approved dry cow infusion products (and lactating tubes, too) are marketed with a dual cover that can be used for partial or full insertion
- Dip teats in a germicidal product after treatment
- Identify treated cows and remove them from the milking herd to prevent antimicrobials from entering the milk supply.

Diffusion of infused intramammary drugs is often impeded by the blockage of lactiferous ducts and alveoli with inflammatory debris. Complete emptying of the quarter by the parenteral injection of oxytocin (10–20 IU intramuscularly) followed by hand-stripping of affected quarters before infusion has been recommended in cases of clinical mastitis, but efficacy studies are lacking, the volume stripped is usually small and the procedure is painful to the cow. If stripping is performed, the intramammary infusion is given after the last stripping of the day has been done, avoiding any further milking of the gland until the next milking. Our current knowledge can be summarized by the following: 'To strip or not to strip, that is the question.'

Parenteral antimicrobial therapy

This should be considered in all cases of mastitis in which there is an abnormal gland or abnormal cow (fever, decreased appetite, or inappetence). The systemic reaction can usually be brought under control by standard doses of antimicrobial agents but a bacteriological cure of the affected glands is seldom achieved because of the relatively poor diffusion of the antimicrobial from the blood into the milk. However, the rate of diffusion is greater in affected than in normal quarters. Parenteral treatment is also recommended when the gland is markedly swollen and intramammary infusions are unlikely to diffuse to all parts of the glandular tissue. To achieve adequate therapeutic levels of an antimicrobial in the mammary gland by parenteral treatment it is necessary, for the above reasons, to use higher than normal dose rates daily for 3–5 days. Milk from treated cows must be withheld from the bulk tank for the stated period of time of that antimicrobial following the date of last treatment.

Treatment of lactating quarters

There are three situations to consider: the emergency single case of clinical mastitis requiring immediate treatment, the herd with a problem of too many clinical cases or intractable cases, but where the identity of the pathogen is known, and the cow with subclinical mastitis.

Emergency treatment when the type of infection is unknown

Cases of acute and peracute mastitis (abnormal cow) in lactating cows, and in dry cows close to calving, are serious problems for the field veterinarian. The need for treatment is urgent; it is not possible to wait for the results of laboratory tests to guide the selection of the most appropriate antibiotic. Clinical findings, season of the year and management practices may give a broad hint as to the specific bacterial cause, but in most such circumstances it is necessary to use a broad-spectrum approach to treatment.[95] Parenteral therapy with oxytetracycline (administered intravenously to increase bioavailability and therefore plasma and milk concentrations), a potentiated sulfonamide or similar broad-spectrum antimicrobial agent should be supplemented with intramammary infusion with a beta-lactamase-resistant antimicrobial such as a first-generation cephalosporin (cephapirin), a third-generation cephalosporin (e.g. ceftiofur), penicillin G–neomycin combination or other approved broad-spectrum intramammary infusion.[96] Parenteral ceftiofur is not effective in clinical mastitis episodes that have abnormal secretion or abnormal gland and secretion.[97]

Field studies show that, in herds in which clinical mastitis is often caused by environmental pathogens, intravenous administration of oxytetracycline, intramammary infusion of cephapirin and supportive therapy (including intravenous administration of flunixin meglumine or fluids) produces a higher rate of clinical and bacteriologic cure than supportive treatment alone.[96] In addition, antimicrobial treatment is more effective than supportive treatment alone.[86] In cows with clinical mastitis caused by *E. coli* the use of procaine penicillin G IM was no more effective than not using antimicrobial agents;[98] this result is expected based on penicillin's Gram-positive spectrum of activity. Knowledge of the likely causative agent is therefore helpful when making decisions about therapy of clinical mastitis episodes during lactation.

Provision of other supportive therapy such as fluids and electrolytes is also crucial to the survival of the cow and minimization of the severity of the mastitis and extent of permanent injury to the udder. The efficacy of frequent stripping, with or without intramammary infusion, is uncertain. NSAIDs decrease pain associated with an abnormal gland; in addition, they enhance recovery and reduce fever in severe cases.

Treatment when the infecting organism is known

A common situation encountered by a bovine practitioner is the dairy herd that has had an outbreak of clinical mastitis or has received a warning notice from the milk processor that the bulk milk SCC or bacterial count is above acceptable limits. The situation calls for a complete mastitis control program, including conducting an

investigation to determine the causative bacteria present, the source of the infection, hygiene in the milking parlor and the importance of risk factors such as milking machine management, plus recommended antimicrobial preparations selected on the basis of the causative agent. Treatment of a number of identified subclinical cases at the commencement of the program, and of individual cases subsequently, can be based on the known common infection in the herd. Among Gram-positive cocci, the response to antimicrobial agents is excellent for streptococci. For staphylococci a cure rate of 65% is about the best that can be expected, and unless there are good reasons for doing otherwise it is recommended that treatment be postponed until the cow is dry. Standard treatments for lactating cows include penicillin alone (100 000 units) or in combination with streptomycin (1 g) or neomycin (500 mg), and a combination of ampicillin (75 mg) and sodium cloxacillin (200 mg). Acid-resistant penicillins, e.g. phenoxymethylpenicillin, are probably best not used as mammary infusions because of their ability to pass through the human stomach, thus presenting a more serious potential threat to humans drinking contaminated milk. Because of the widespread and often indiscriminate use of penicillin, a large part of the mastitis that occurs is associated with penicillin-resistant bacteria, especially *S. aureus*. Treatment programs need to take this into account when recommendations are made about the antibiotic to be used.

Intramammary infections associated with **environmental streptococci** that manifest signs of clinical mastitis are usually acute but only moderately severe. In most of these cases the streptococci are sensitive to antimicrobial agents, and they often recover spontaneously with good management and nursing care. If not, they usually respond well to therapy. Bacteriological cure rates of 60–65% can be expected following a single intramammary infusion of a cephalosporin product. In one randomized controlled field trial of clinical mastitis associated with *Streptococcus* spp. or coliform bacteria, the clinical cure rate by the tenth milking was significantly higher when intramammary cephapirin, intravenous oxytetracycline, or both, were used along with supportive therapy (oxytocin and stripping of affected glands and, in severely affected cows, the use of flunixin meglumine and fluids) compared to supportive treatment alone.[99] These results indicate that, in herds in which clinical mastitis is often associated with environmental pathogens, antimicrobial therapy and supportive therapy may result in a better outcome than supportive therapy alone.

Treatment of subclinical mastitis

It is generally considered not advisable to treat subclinical mastitis during lactation. However, it is important to consider the causative organism and the udder health status of the herd. There are several situations in which lactational therapy of subclinical mastitis is indicated; for example, herds with *S. agalactiae* infections should consider several approaches to therapy during lactation. *S. agalactiae* infections respond well to therapy during lactation, with cure rates of 80–100% expected.[59] All approved intramammary therapy preparations are efficacious, including penicillin, cephalosporins, cloxacillin and erythromycin. In herds with a high prevalence of *S. agalactiae* mastitis, **blitz therapy** can be used for eradication of the pathogen, increased milk production and reduced penalties for high SCCs. There is, however, a risk of residue violation, problems with disposal of milk from treated cows and considerable costs involved. It is also important to insure that standard mastitis control procedures, such as postmilking teat disinfection and blanket dry cow therapy, have been implemented. The benefit:cost ratios for various approaches to blitz therapy of *S. agalactiae* infected herds have been studied.[59] The prevalence of infected cows, and their stage of lactation, are important determinants of the type of program selected.

Therapy of cows with subclinical mastitis due to *S. aureus* during lactation is much less rewarding. Under field conditions, cases of *S. aureus* are difficult to cure during lactation. Reported cure rates following intramammary therapy are between 15% and 60%. Lactational therapy of subclinical *S. aureus* mastitis using intramuscular penicillin along with intramammary amoxicillin infusion, compared with the intramammary infusion alone, increased the cure rate to 40%, which represented a doubling of the cure rate with intramammary therapy alone.[48] If treatment by this method is used in combination with data on the age of cow, stage of lactation, duration of infection and level of SCC, the economic benefit of treating some cases of *S. aureus* mastitis during lactation may be attractive.

Subclinical infections associated with environmental streptococci, and occasionally by coliform organisms, can be found in moderate numbers in some herds.[56] Although spontaneous cure rates are higher with these environmental infections, individual cows may merit treatment during lactation. In these cases, the previously listed factors should be used, and are important in the selection of cases to be treated.

Prepartum antibiotic treatment of heifers is of benefit in herds experiencing a high incidence of clinical mastitis in recently calved heifers. Coagulase-negative staphylococci are frequently isolated from late-gestation heifers, and intramammary treatment with sodium cloxacillin (200 mg) or cephapirin sodium (200 mg) 7 days before expected parturition is highly effective and economically beneficial.[100]

Anti-inflammatory agents

NSAIDs have been evaluated for the treatment of field and experimental cases of acute and peracute mastitis. NSAIDs have beneficial effects on decreasing the severity of clinical signs based on changes in rectal temperature, heart rate, rumen motility and pain associated with the mastitis, and are routinely administered as part of the initial treatment of cattle with severe clinical mastitis and marked systemic signs. On the basis of one comparative study, NSAIDs appear to ameliorate systemic abnormalities to a greater degree than corticosteroids.[101] The strongest evidence available to support the administration of NSAIDs is available for ketoprofen and phenylbutazone.

Ketoprofen at 2 g intramuscularly once daily combined with sulfadiazine and trimethoprim intramuscularly given daily to cows with acute clinical mastitis, and complete milking of affected quarters several times daily, significantly improved survival and milk production compared to cows not receiving the NSAID.[102] A reanalysis of the published results indicated that phenylbutazone at 4 g intramuscularly once daily combined with sulfadiazine and trimethoprim intramuscularly given daily to cows with acute clinical mastitis significantly improved the percentage of cows with milk production returning to more than 75% of previous levels compared to cows not receiving the NSAID.[103] However, intramuscular administration of phenylbutazone is not currently recommended because of the potential for myonecrosis. Dipyrone at 20 g intramuscularly once daily in the same study was not effective.[103]

There is no evidence that treatment of clinical cases with NSAIDs alters the inflammatory response in the udder,[101] although pretreatment of cattle with experimentally induced mastitis does alter the local (glandular) inflammatory response to infection. Flunixin meglumine concentrations are low in milk, which is consistent with its properties as a weak acid, which has difficulty crossing the blood–milk barrier.[104] Flunixin meglumine (2 mg/kg, intravenously, twice 24 h apart) did not alter the survival rate of dairy cows with severe *E. coli* or *S. uberis* mastitis compared to intravenous administration of 45 L of isotonic crystalloid fluids.[105] The one-time administration of

1 g of flunixin meglumine intravenously or 4 g of phenylbutazone intravenously, along with intramammary infusion of gentamicin (150 mg) at 12-hour intervals for four treatments, had no significant beneficial effect in cows with acute toxic mastitis associated with *E. coli* and *Klebsiella* spp.[106] However, the results of this study do not indicate a lack of effectiveness of flunixin meglumine or phenylbutazone because it is difficult for one dose of any NSAID to have a detectable effect on clinical signs in naturally occurring mastitis cases.

Supportive therapy

Supportive treatment, including the intravenous administration of large quantities of isotonic crystalloid fluids, is indicated in cattle with severe systemic illness. Large volumes of isotonic crystalloid fluids can be rapidly administered under pressure at 0.5 L/min through a 12-gauge catheter in the jugular vein, using a 7.5 L garden weed killer spray pump.[105] The administration of hypertonic saline followed by immediate access to drinking water is a practical method of providing fluid therapy to cows with severe mastitis, especially peracute coliform mastitis.[107] A dose of 4–5 mL/kg body weight (BW) of 7.5% saline is given intravenously over 4–5 minutes.[108] This is usually followed by the animal consuming large quantities of water. Circulating blood volume is increased and there is mild strong ion (metabolic) acidosis, improved renal function and changes in calcium and phosphorus homeostasis when compared to cows given a similar volume of 0.9% NaCl. Fluid therapy is covered extensively in Chapter 2.

Adjunctive therapy

Cytokines may be useful as adjunctive therapy with existing antimicrobials to improve therapeutic efficacy, particularly in lactating cows.[109] Cytokines are natural regulators of the host defense system in response to infectious diseases. The combination of a commercial formulation of cephapirin with recombinant interleukin-2 consistently improved the cure rate of treating *S. aureus* mastitis by 20–30% compared to use of the antimicrobial alone.[109]

Magnitude of response to therapy

The treatment of some causes of mastitis can be highly effective in removing infection from the quarter and returning the milk to normal composition. However, the yield of milk, although it can be improved by the removal of congestion in the gland and inflammatory debris from the duct system, is unlikely to be returned to normal in severe clinical cases, at least until the next lactation. The degree of response obtained depends particularly on the causative agent, the speed with which treatment is commenced, and other factors described above. A 'cure' may mean disappearance of clinical signs, elimination of the infectious cause, or both of those plus return to normal function and productivity. Which of these is the objective in any particular case or herd will influence the decisions to be made about treatment in an individual case of the disease.

Failure to respond to therapy of the lactating cow may be due to:

- The presence of microabscesses and inaccessibility of the drug to the pathogen
- Ineffective drug diffusion
- Inactivation of the antimicrobial by milk and tissue proteins
- Inefficient killing of the bacteria and intracellular survival of bacteria
- Increased antimicrobial resistance
- The development of L-forms of bacteria.

Dry cow therapy

Dry cow therapy is the use of intramammary antimicrobial therapy immediately after the last milking of lactation and is an important component of an effective mastitis control program.[110] Intramammary infusions at drying off **decrease the number of existing infections** and **prevent new infections during the early weeks of the dry period**. Dry cow therapy should be routinely administered and remains one of the cornerstones of an effective mastitis control program. **Blanket dry cow therapy** is treatment of all four quarters at drying off, compared to **selective dry cow therapy** based on treatment of only those quarters that are infected. When subclinical mastitis is very low in some herds, selective dry cow therapy can be considered, but nearly all herds use blanket dry cow therapy. The problem with selective dry cow therapy is the accuracy of available indirect tests to 'select' cows for treatment or non-treatment. Currently available indirect tests are not sufficiently accurate (the exception being quarter milk cultures) to be used as a basis for selective dry cow therapy.

Intramammary infusions approved for dry cow therapy contain high levels of antimicrobial agents in a slow-release base that maintains therapeutic levels in the dry udder for long periods of time. Most dry cow therapy infusion products are intended to eliminate existing infections due to *S. aureus* and *S. agalactiae* at drying off and to prevent new infections due to the same pathogens and environmental streptococci in the early dry period.

In herds with a high prevalence of contagious mastitis, dry cow therapy has been efficacious and economically beneficial in reducing the prevalence of intramammary infections. The consistent application of effective mastitis control procedures has reduced the prevalence of contagious pathogens and the bulk tank milk SCC (< 300 000 cells/mL) and owners of these herds questioned dry cow therapy because of the economics and the concerns of residues in the milk. Field trials in herds with a low prevalence of contagious mastitis indicate that dry cow therapy at the end of lactation increased 17-week milk production during the subsequent lactation and was economically beneficial compared to not treating them.[111] However, in the subsequent lactation, the incidence of clinical mastitis was not reduced nor were the SCCs significantly different from those of cows not treated at the end of lactation.

The most effective time to treat subclinical intramammary infections is at drying off. Dry cow therapy has the following advantages over lactation therapy:

- The cure rate is higher than that achieved by treatment during lactation
- A much higher dose of antimicrobial can be used safely
- Retention time of the antimicrobial in the udder is longer
- The incidence of new infections during the dry period is reduced
- Tissue damage by mastitis may be regenerated before parturition
- Clinical mastitis at calving may be reduced
- The risk of contaminating milk with antimicrobial residue is reduced.

Selection of a suitable dry period treatment should take into account the fact that Gram-negative infections are not common at that time because of the high concentration of lactoferrin in the dry secretions. Accordingly attention should be directed at the inclusion of a potent antibiotic against *Streptococcus* spp., beta-lactamase-producing *S. aureus*, and *A. pyogenes*. Cloxacillin, nafcillin, and cephalosporins are popular for the purpose; for example, a recommended treatment is cephapirin or sodium cloxacillin in a slow-release base with an expected cure rate of 80% against streptococci and 60% against *S. aureus*.

Most dry cow preparations maintain an adequate minimum concentration in the quarter for about 4 weeks, but some persist for 6 weeks. There is little, if any, value in treating cows again before the due calving date. There is always a possibility of introducing infection while

infusing an intramammary preparation and farmers are reluctant to break the teat canal seal, but it may be necessary to do so if summer mastitis is prevalent in the area.

Prepartum antimicrobial therapy in heifers

Intramammary infusion of a cephapirin dry cow therapy preparation into pregnant heifers 10–12 weeks prepartum eliminated over 90% of the intramammary infection due to *S. aureus*, *Streptococcus* spp., coagulase-negative staphylococci spp. and coliforms. The SCCs of cured quarters were comparable to uninfected control quarters after parturition.[112] At parturition, 24% of treated quarters were positive for the antimicrobial; however, no quarters were positive at 5 days postpartum.

Antimicrobial residues in milk and withholding times

Label instructions must be followed to insure that drug residues do not occur, especially from cows with a shorter than normal dry period. Antibiotic residue testing of the milk of a recently calved cow can be done if there is a suspicion of residues, but this is a misuse of a test designed for bulk tank milk testing and therefore suffers from problems with sensitivity and specificity.

Treatment and control of mastitis accounts for the largest percentage of antimicrobial use on dairy farms. Following treatment by the intramammary or parenteral route, the concentration of antimicrobial agents in the milk declines over time to levels that are considered safe and tolerable for humans. The duration of time for the concentrations to decline to acceptable limits is known as the **withholding time** or the **withdrawal period** during which the milk cannot be added to the bulk tank supply but must be withheld and discarded. The presence of residues in milk is a major public health concern that adversely affects the dairy industry, the practicing veterinarian and the perception the public has of the safety of milk for human consumption. The public perception of the safety of milk is crucial and veterinarians have a responsibility to respond to these concerns through public education and quality control of milk production.

Other serious consequences of antimicrobial residues in milk are their effect on the manufacture of dairy products and the potential development of antimicrobial sensitivity syndromes in humans. In most countries the maximum intramammary dose of antimicrobial agents is limited by legislation and the presence of detectable quantities of antimicrobial agents in milk constitutes adulteration. Attention has also been directed to the excretion of antimicrobial agents in milk from untreated quarters, after treatment of infected quarters and after their administration by parenteral injection or by insertion into the uterus. The degree to which this excretion occurs varies widely between animals and in the same animal at different points in the lactation period, and differs from one antibiotic to another. Milk from cows subjected to dry period treatment is usually required to be withheld for 4 days after calving. The use of any dry period treatments in lactating cows causes prolonged retention of the antimicrobial in milk and is a most serious violation of the legislation.

Veterinarians have the responsibility to warn farmers of the need to withhold milk, and both should be aware of the withholding times of each product, details of which are usually required to be included on its label. Marking the cow in some way to remind the farmer, by application of a leg band or placing dye on the udder, is advisable.

Antimicrobial residue tests

Several cowside tests are available to detect antimicrobial residues in the milk of cows that have been treated for mastitis.[113] The goal of cowside testing is to assist in the production of high-quality, antimicrobial-residue-free milk from dairy herds. To be consistent with the intent of a quality assurance program, cowside testing would be used only on cows recently treated with antimicrobial agents and only after appropriate milk withholding times had been followed. The ideal test would have a high sensitivity and high specificity.

Most of the cowside screening tests for antimicrobial residues are imperfect because of a high rate of false-positive results when used on field samples. The direct costs to producers can be high because of the unnecessary disposal of milk and imposition of fines and penalties. False-positive results also cause the unnecessary culling of some cows, and concern about the interpretation of positive assay results, the appropriateness of withholding periods and the safety of milk creates mistrust among consumers, producers, veterinarians and regulatory personnel. The specificity of four commercially available tests ranged from 0.78–0.95.[114] None of the test kits has been validated to meet performance standards for sensitivity and specificity. This applies to individual cow samples, bulk tank milk samples and tanker truck samples.

The presence of naturally occurring bactericidal products in the milk of cows with acute and convalescent mastitis is the most likely cause of the false-positive results of the tests (such as Delvo-test®) that are based on bacterial growth inhibition of beta-lactam antimicrobial agents.[113] Immunoglobulins, complement, lysozyme, lactoferrin and phagocytic cells are products of inflammation in the milk of cows with mastitis that can inhibit bacterial growth. The milk from cows with experimental endotoxin-induced mastitis is at increased risk for false-positive assay results using commercial residue tests.[114] The incidence of false-positive results is very low in milk from cows that have not had a history of mastitis or antimicrobial therapy.[115] Naturally occurring bactericidal products in mastitic milk can be removed by heating at 82°C for 5 minutes; this temperature does not denature antimicrobial agents present in milk.[116] Heat treatment therefore appears to provide a very practical way to reduce false-positive results on milk from individual cows.

A sample of milk can be submitted for antimicrobial residue testing up to three times. First, a producer may test a sample from a specific cow at the end of her withdrawal period. Second, milk is sampled at the tanker truck level. Third, should the tanker truck sample have positive results, bulk tank milk samples from each dairy herd that contributed to that tanker truck are tested.

There is a need for validation of the diagnostic assays used to detect antimicrobial residues in milk.[117] Acceptance of assays for regulatory purposes must be based on protocols that include field estimates of assay performance before the assays are used by the public. Three strategies have been suggested to balance public health concerns with economic concerns of dairy producers caused by false-positive results:

- Retest samples that yield positive results with a confirmatory assay of specificity close to 100%. Only those samples that also yield positive results on the second assay are considered to be positive for violative residues
- Recalibrate the assay to increase specificity. This will usually result in loss of sensitivity
- Use an alternative assay of higher specificity.[117]

It is suggested that regulatory monitoring of residues at a national level will be best served by use of a combination of at least two assays: initial screening with a highly sensitive and inexpensive assay followed by confirmation testing with an assay of high specificity (> 99%) that can quantify the concentration of the antimicrobial residue. All tanker samples that yield positive results with a screening assay should be rechecked with a quantitative assay. If the quantitative assay detects a concentration

greater than the safe level, safe concentration or tolerance level, only then would the milk be deemed to have violative residue and fines and penalties be imposed.[117] The complex dynamics of current milk residue tests discourage practitioners from recommending testing procedures to dairy producers.[118]

As an approximate guide, the recommended periods for which milk should be withheld from sale after different methods of antimicrobial administration are (in times after last treatment):

- Udder infusion in a lactating cow – 72 hours
- Parenteral injection, one only – 36 hours
- Parenteral injections, series of – 72 hours
- Antimicrobial agents parenterally in long-acting bases – 10 days
- Intrauterine tablet – 72 hours
- Dry cow intramammary infusion – to be administered at least 4 weeks before calving and the milk withheld for at least 96 hours afterwards.

Permanently drying off chronically affected quarters

If a quarter does not respond to treatment and is classified as incurable, the affected animal should be isolated from the milking herd or the affected quarter may be permanently dried off by inducing a chemical mastitis. Historically used methods, arranged in decreasing order of severity, are infusions of:

- 30–60 mL of 3% silver nitrate solution
- 20 mL of 5% copper sulfate solution
- 100–300 mL of 1:500, or 300–500 mL of a 1:2000 acriflavine solution.

If a severe local reaction occurs, the quarter should be milked out and stripped frequently until the reaction subsides. If no reaction occurs, the quarter is stripped out 10–14 days later. Two infusions of these solutions may be necessary.

The **best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone–iodine solution (0.5% iodine)** after complete milk-out and administration of flunixin meglumine (1 mg/kg BW, intravenously). This causes permanent cessation of lactation in the quarter but does not alter total milk production by the cow. If the goal is chemical sterilization, then three daily infusions of 60 mL of chlorhexidine suspension should be administered after complete milk-out. The majority of treated cows (5/7) returned to milk production in the quarter in the subsequent lactation.[119] The infusion of 60 mL of chlorhexidine, followed by milking out at the next subsequent milking and repeat of the infusion 24 hours after the initial treatment is also effective in making infused quarters nonfunctional within 14–63 days.[120] Histological evaluation of the infused quarters revealed that secretory tissues had involuted to a nonsecretory state and appeared similar to blind or nonfunctional quarters. However, as noted above, milk production may return in the gland in the subsequent lactation.

Mastitis pathogens of cattle

In the sections which follow, the special features of each mastitis associated with one or a group of pathogens will be described using the usual format of the book. Mastitis in cattle is categorized as being associated with contagious, teat skin opportunistic or environmental pathogens, and as being common or less common. The features that are unique to the diagnosis, treatment and control of each mastitis pathogen will be outlined but details applicable to all causes of mastitis have been presented above.

Mastitis of cattle associated with common contagious pathogens

STAPHYLOCOCCUS AUREUS

Synopsis

Etiology *Staphylococcus aureus* is a major pathogen of the mammary gland and a common cause of contagious bovine mastitis. *S. aureus* also causes mastitis in sheep and goats

Epidemiology Major cause of mastitis in dairy herds without an effective mastitis control program. Prevalence of infection 50–100%; prevalence of 1–10% in herds with low bulk tank milk SCCs, 50% in high-SCC herds, quarter infection rate 10–25% in high-SCC herds. Source of infection is infected udder; infection transmitted at milking. Chronic or subclinical *S. aureus* mastitis is of major economic importance

Clinical findings

- Chronic *S. aureus* mastitis is most common and is characterized by high SCC and gradual induration of udder, drop in milk yield and atrophy with occasional appearance of clots in milk or wateriness
- Acute and peracute *S. aureus* mastitis most common in early lactation. Acute swelling of gland with fever; milk is abnormal with thick clots and pus; gangrene of gland and teat in peracute form. Systemic reaction with anorexia, toxemia, fever, ruminal stasis

Clinical pathology Culture individual cow milk sample; indirect tests are high SCC and California Mastitis Test results

Necropsy findings Peracute, acute, and chronic (recurrent) clinical mastitis, subclinical mastitis common

Diagnostic confirmation Culture milk for pathogen

Differential diagnosis

- Peracute mastitis
- Peracute coliform mastitis
- *Arcanobacterium* (formerly *Actinomyces* or *Corynebacterium*) *pyogenes* mastitis
- Parturient paresis
- Acute and chronic mastitis. Not clinically distinguishable from other causes of mastitis. Must culture milk

Treatment

- **Lactating cows** – cure rates for lactating cows with subacute staphylococcal mastitis less than 50%. Intramammary infusions daily for at least 3 days, preferably 5–8 days
- **Peracute mastitis** – antimicrobial agents parenterally and intramammary that are beta-lactamase-resistant, fluid and electrolyte therapy
- **Dry cow therapy** – chronic or subclinical mastitis best treated at drying off with long-acting intramammary antimicrobial infusions that are beta-lactamase-resistant

Control

- Prevent new infections by early identification, culling infected cows and good milking procedures, including hygienic washing and drying of udders and teats before milking and postmilking germicidal teat dips. Regular milking machine maintenance. Consider segregation of infected cows
- Eliminate existing infections by dry cow therapy
- Immunization with vaccines may be possible in future

ETIOLOGY

Coagulase-positive *S. aureus* is a major pathogen of the bovine mammary gland and a common cause of contagious mastitis in cattle. *S. aureus* also causes mastitis in sheep and goats.

EPIDEMIOLOGY

Occurrence and prevalence of infection

Coagulase-positive staphylococci

Historically, *S. aureus* was one of the most common causes of bovine mastitis in dairy cattle worldwide. In the last 25 years, the prevalence of infection and the occurrence of clinical mastitis due to *S. aureus* has decreased in herds using effective mastitis control measures. However, surveys indicate that 50–100% of herds may be infected. In low-SCC herds, the prevalence of infection in cows ranges from 1–10%. In other herds, especially those with high SCCs, up to 50% of cows may be infected with *S. aureus*, with quarter infection rates ranging from 10–25%. The prevalence of infection of *S. aureus* in heifers at parturition can range from 5–15%. **The majority of intramammary infections due to *S. aureus* are subclinical.** The incidence of clinical mastitis due to *S. aureus* is dependent on its prevalence of infection in the herd. With an effective mastitis control program, the most common causes of clinical mastitis are the environmental pathogens. However, in some herds with a low rolling SCC, incidence of clinical mastitis due to *S. aureus* ranges from 190–240 cases/100 cows/year, with about 47% of the clinical cases being *S. aureus*.[1]

Source of infection and method of transmission

S. aureus is ubiquitous in the environment of dairy cattle. The infected mammary gland of lactating cows is the major reservoir and source of the organism.[2] The prevalence of intramammary infection in primiparous heifers at parturition ranges from 2–50% and may represent an important reservoir of infection in herds with a low prevalence of infection. The organism may be present on the skin of the teats and external orifices of heifers, bedding materials, feedstuffs, housing materials, nonbovine animals on the farm, and equipment. In herds with a high prevalence of infection (> 10% of cows), the organism was present in bedding, the hands and noses of dairy herd workers, insects and water supplies.[2] Transmission between cows occurs at the time of milking by contaminated milkers' hands and teat cup liners. Although *S. aureus* can multiply on the surface of the skin and provide a source of infection for the udder, the teat skin lesions are usually infected originally from the udder,

and teat skin is a minor source of infection.

The hornfly (*Hameotobia irritans*) is an important vector for transmitting *S. aureus* mastitis in heifers, particularly in herds with scabs on the teat ends of heifers.[3,4] Prevention of high populations of flies in heifers is therefore needed to decrease new infections in this group.

Risk factors

Animal risk factors

Several animal risk factors influence the prevalence of infection and the occurrence of clinical mastitis due to *S. aureus*.

Local defense mechanisms

Abrasions of the teat orifice epithelium are an important risk factor for *S. aureus* mastitis.[5] In experiments, teat canal infection or colonization may develop in 93% of experimentally abraded teat canal orifices compared to 53% in control quarters. Chapping of the teats and thickness of the teat barrel are correlated and significantly influence recovery of *S. aureus* from the skin.[6]

Colonization with minor pathogens

The presence of minor pathogens such as coagulase-negative staphylococci protects against new intramammary infections associated with the major pathogen *S. aureus*.[7] This may be the result of an elevated SCC or an antimicrobial-like substance provided by the coagulase-negative staphylococci that inhibits the growth of *S. aureus*. Conversely, quarters infected with coagulase-negative staphylococci may be more susceptible to new infections with *S. agalactiae*. Quarters that are infected with *C. bovis* are protected against *S. aureus* infection but not protected against most streptococcal species.

Parity of cow

The prevalence of intramammary infection and subclinical infection due to *S. aureus* increases with parity of the cow. This is probably due to the increased opportunity of infection with time and the prolonged duration of infection, especially in a herd without a mastitis control program.

Presence of other diseases

The presence of periparturient diseases such as dystocia, parturient paresis, retained placenta and ketosis has been identified as a risk factor for mastitis. The occurrence of sole ulcers in multiple digits may be associated with *S. aureus* in the first lactation.[8]

Heredity

Experimentally, the presence of certain bovine lymphocyte antigens increased the susceptibility to *S. aureus* infection[9] but heritability estimates of susceptibility after experimental challenge were low and unstable.

Immune system

The infection rate of *S. aureus* is dependent on the ability of the immune system to recognize and to eliminate the bacteria.[10] Staphylococcal antibodies are present in the blood of infected cows but they appear to afford little protection against mastitis associated with *S. aureus*. This may be due to the low titer of the antibodies in the milk. Antibody titers in the serum rise with age and after an attack of mastitis.

The development or persistence of *S. aureus* mastitis depends on the interaction between invading bacteria and the host's defense system, principally the somatic cells in an infected gland, which are more than 95% polymorphonuclear cells. The number of bacteria isolated from milk samples of *S. aureus*-infected mammary glands is characterized by a cyclic increase and decrease concomitant with an inverse cycling of the SCC. This relationship between SCC and numbers of bacteria indicates that the cells within the mammary gland have a central role in the pathogenesis of *S. aureus* infection.[11] There appear to be qualitative changes in the ability of the animal's somatic cells to phagocytose the bacteria. During the period of high SCC, the cells are able to kill bacteria 9000 times more efficiently than during the low-SCC period. The relative inability of the polymorphonuclear cells to kill bacteria during the low-SCC period may explain the source of reinfection. Phagocytosis and killing of the bacteria may also be inefficient because of low concentrations of opsonins, a lack of energy source, and the presence of casein and fat globules in the milk. The function of the intramammary polymorphonuclear cell (somatic cells) may also be affected by immunosuppression induced by cortisol and dexamethasone in treated cows.[12]

Environmental and management risk factors

Several herd-level management risk factors are important for the spread of *S. aureus*.[13] Poor teat and udder cleaning can allow spread of the organism among quarters of the same cow, and can allow contamination of milking units, which are commonly transferred among cows without washing or rinsing. The use of high-line parlors is a risk; this may be due to the greater fluctuation in vacuum, especially when units are removed, leading to a greater occurrence of teat end impacts in which bacteria in the milking unit may enter the teat canal to establish a new udder infection.

Extensive surveys reveal that management procedures that are most effective in reducing infection rates and cell counts associated with infections with *S. aureus* are:

- Postmilking teat dipping
- Maintaining a good supply of dry bedding for housed cows
- Thorough disinfection of the teat orifice before infusing intramammary preparations
- Milking clinical cases last.

Failure to use these management techniques will increase the risk of intramammary infection with *S. aureus*.

Pathogen risk factors

Virulence factors

S. aureus has several virulence factors that account for its pathogenicity and persistence in mammary tissue in spite of adequate defense mechanisms and antimicrobial therapy. **Most isolates from cattle appear to be host-adapted and different from human *S. aureus* isolates.** *S. aureus* has the ability to **colonize the epithelium** of the teat and the streak canal, and can adhere and bind to epithelial cells of the mammary gland. The specific binding is to the extracellular matrix proteins fibronectin and collagen, which can induce the epithelial cell to internalize the organism, protecting it from both exogenous and endogenous bactericidal factors. Some strains of *S. aureus* are capable of **invading bovine mammary epithelial cells** in culture, and the invasion process requires eukaryotic nucleic acid and protein synthesis as well as bacterial synthesis.[14]

Some strains of *S. aureus* produce **toxins**, some of which may cause **phagocytic dysfunction**. The beta toxin, or a combination of alpha toxins and beta toxins, is produced by most pathogenic strains isolated from cattle but its pathogenic significance is uncertain. The beta toxin damages bovine mammary secretory epithelial cells, increases the damaging effects of alpha toxin, increases the adherence of *S. aureus* to mammary epithelial cells and increases the proliferation of the organism.[15] All strains produce **coagulase** (hence the term coagulase positive *S. aureus*), which converts fibrinogen into fibrin; this appears to assist the invasion of tissues. **Leukocidin** produced by *S. aureus* may inactivate neutrophils.

Many staphylococcal strains (coagulase-negative and -positive) are able to produce an **extracellular exopolysaccharide layer** surrounding the cell wall.[16] This capsular structure and its production of slime have been associated with virulence against host defense mechanisms.

A major pathogenic factor is the ability of the organism to colonize and produce

microabscesses in the mammary gland so that it is protected from normal defense mechanisms, including phagocytic activity from neutrophils. The difficulty in removing staphylococci from an infected quarter is due largely to the bacteria's ability to survive in intracellular sites. There is also an ability to convert to a **nonsusceptible L-form** when exposed to antimicrobial agents, and to return to standard forms when the antimicrobial is withdrawn.

Genotype of strains

Phage typing and ribotyping can be used to classify strains from clinical and subclinical *S. aureus* mastitis.[17]

DNA fingerprinting techniques, using polymerase chain reaction, are also being used to differentiate various strains of the organism.[18] A large number of different types of *S. aureus* can be isolated from cases of bovine mastitis but a few types predominate within different countries.[19] Surveys have found that only a small number of genotypes cause most cases of *S. aureus* mastitis,[18] which may be useful information in determining the dynamics of infection in a herd and how infection spreads from cow to cow. Fine-structure molecular epidemiological analysis of *S. aureus* recovered from cows in the USA and Ireland indicates that only a few specialized clones of *S. aureus* are responsible for the majority of cases of bovine mastitis, and that these clones have a broad geographical distribution.[20] **A predominant strain is usually responsible for most clinical and subclinical *S. aureus* infections in a herd,**[21,22] and it is currently believed that *S. aureus* is a clonal organism that spreads from cow to cow. Moreover, most strains isolated from milk are different from strains isolated from the teat skin. In other words, most *S. aureus* strains isolated from mastitis demonstrate both host and site specificity.[22] This has important implications in the control of mastitis associated with *S. aureus*, as a rational and effective strategy for control of intramammary infections should be directed against clones that commonly cause disease.

Economic importance

The overall prevalence of mastitis due to *S. aureus* is much higher than for *S. agalactiae*, and the need for culling causes much greater economic consequences. The risk of new infections is of continuing concern. Response to treatment is comparatively poor, and satisfactory methods for the eradication of staphylococcal mastitis from infected herds have yet to be devised.

Zoonotic implications

The presence of *S. aureus* in market milk may present a degree of risk to the consumer because of the organism's capacity to produce enterotoxins and a toxic shock syndrome toxin, which cause serious food poisoning. Mastitic milk does not constitute any large risk for *S. aureus* enterotoxin food poisoning.[23]

PATHOGENESIS

The disease can be reproduced experimentally by the injection of *S. aureus* organisms into the udder of cattle and sheep but there is considerable variation in the type of mastitis produced. This does not seem to be due to differences in virulence of the strains used, although strain variations do occur, but may be related to the size of the inoculum used or, more probably, to the lactational status of the udder at the time of infection. It is possible to induce *S. aureus* infection in the bovine teat cistern; the teat tissues are able to mount a marked local inflammatory response but in spite of large numbers of neutrophils that invade the teat, they are unable to control the infection, except when the numbers of bacteria are low.[24]

Infection during early lactation may result in the peracute form of mastitis, with gangrene of the udder. During the later stages of lactation or during the dry period new infections are not usually accompanied by a systemic reaction but result in the chronic or acute forms. Chronic *S. aureus* mastitis in cows has been converted to the peracute, gangrenous form by the experimental production of systemic neutropenia.

In the **gangrenous form** the death of tissue is precipitated by thrombosis of veins causing local edema and congestion of the udder. *S. aureus* are the only bacteria that commonly cause this reaction in the udder of the cow, and the resulting toxemia is due to bacterial toxins and tissue destruction. Secondary invasion by *E. coli* and *Clostridium* spp. contributes to the severity of the lesion and production of gas.

The pathogenesis of acute and chronic *S. aureus* mastitis in the cow is the same, the variation occurring only in degree of involvement of mammary tissue. In both forms each focus commences with an acute stage characterized by proliferation of the bacteria in the collecting ducts and, to a lesser extent, in the alveoli. In **acute** mastitis the small ducts are quickly blocked by fibrin clots, leading to more severe involvement of the obstructed area.

In the **chronic** form there are fewer foci of inflammation and the reaction is milder; the inflammation is restricted to the epithelium of the ducts. This subsides within a few days and is replaced by connective tissue proliferations around the ducts, leading to their blockage and atrophy of the drained area. The leukocyte infiltration into the stroma, the epithelial lining and the lumina indicate an obvious deficiency of secretory and synthesizing capacity due to limitation of the alveolar lumina and the distension of the stroma area.

A characteristic of chronic *S. aureus* mastitis that is important in its diagnosis is the cyclical shedding of the bacteria from the affected quarter. Paralleling this variation is a cyclical rise and fall in the number of polymorphonuclear cells in the milk, and their capacity to phagocytose bacteria.[11] In some cases abscesses develop and botryomycosis of the udder, in which granulomata develop containing Gram-positive cocci in an amorphous eosinophilic mass, is also seen.

CLINICAL FINDINGS

Chronic *Staphylococcus aureus* mastitis

The most important losses are caused by the chronic form or subclinical form of mastitis. Although 50% of cattle in a herd may be affected, only a few animals will have abnormalities recognizable by the milker. Many cases are characterized by a slowly developing induration and atrophy with the occasional appearance of clots in the milk or wateriness of the first streams. The SCC of the milk is increased, as well as the CMT results of infected quarters, but the disease may go unnoticed until much of the functional capacity of the gland is lost. The infection can persist and the disease may progress slowly over a period of many months.

Acute and peracute *Staphylococcus aureus* mastitis

Acute and peracute staphylococcal mastitis are rare but do occur and can be fatal, even if aggressively treated.

Acute *S. aureus* mastitis occurs most commonly in early lactation. There is severe swelling of the gland and the milk is purulent or contains many thick clots. Extensive fibrosis and severe loss of function always result.

Peracute *S. aureus* mastitis occurs usually in the first few days after calving and is highly fatal. There is a severe systemic reaction with elevation of the temperature to 41–42°C (106–107°F), rapid heart rate (100–120 beats/min), complete anorexia, profound depression, absence of ruminal movements and muscular weakness, often to the point of recumbency. The onset of the systemic and local reactions is sudden. The cow may be normal at one milking and recumbent and comatose at the next. The affected quarter is grossly swollen, hard and sore to touch, and causes severe lameness on the affected side.

Gangrene is a constant development and may be evident very early. A bluish discoloration develops that may eventually spread to involve the floor of the udder and the whole or part of the teat, or may be restricted to patches on the sides and floor of the udder. Within 24 hours the gangrenous areas become black and ooze serum and may be accompanied by subcutaneous emphysema and the formation of blisters. The secretion is reduced to a small amount of bloodstained serous fluid without odor, clots or flakes. Unaffected quarters in the same cow are often swollen, and there may be extensive subcutaneous edema in front of the udder caused by thrombosis of the mammary veins. Toxemia is profound and death usually occurs unless early, appropriate treatment is provided. Even with early treatment the quarter is invariably lost and the gangrenous areas slough. Separation begins after 6–7 days, but without interference the gangrenous part may remain attached for weeks. After separation, pus drains from the site for many more weeks before healing finally occurs.

CLINICAL PATHOLOGY

Culture of individual cow milk

Bacteriological culture of milk is the best method for identifying cows with *S. aureus* intramammary infection.[25] A problem in the laboratory identification of *S. aureus* is that **bacteria are shed cyclically from infected quarters, so that a series of samples are necessary to increase overall test sensitivity**. The sensitivity of a single sample may be as low as 75%. Factors that have the greatest impact on the sensitivity of culture, in order of importance, are:

- The type of milk sample
- The volume of milk cultured
- The time interval between repeated milk sample collection strategies.[26]

Quarter samples taken on day 1 and repeated either on day 3 or 4, and cultured separately using 0.1 mL of milk for culture inoculum, were predicted to have sensitivities of 90–95% and 94–99%, respectively.[26] Repeated quarter samples collected daily and cultured separately gave a sensitivity of 97% and a specificity from 97–100%.[27] Culturing of composite milk samples instead of individual quarter samples increases the number of false-negative results in diagnosing *S. aureus* mastitis,[28] but the sensitivity of composite samples can be increased by using 0.05 mL of milk for inoculation. Freezing of milk samples before processing either does not affect the bacterial count or enhances it by about 200%; the latter response is attributed to fracturing of cells containing viable *S. aureus* bacteria. Bacterial counts of more than 200 cfu/mL are commonly used as a criterion for a positive diagnosis of infection.

Culture of bulk tank milk

The culture of 0.3 mL of bulk tank milk for *S. aureus* using special Baird–Parker culture media is a practical method for detecting the organism in bulk tank milk and monitoring its spread in dairy herds;[29] the sensitivity and specificity for detection of the bacteria ranged from 90–100%.

Somatic cell counts and California Mastitis Test

In an attempt to decrease the cost of sampling all quarters for culture, an alternative strategy is to use the SCC as a screening test in order to identify which cows to culture for *S. aureus*. For all intramammary infections, the sensitivity and specificity of SCC range from 15–40% and 92–99%, respectively. Composite milk sample SCCs have a low sensitivity, ranging from 31–54% for detecting cows with *S. aureus*.[27] Individual quarter SCCs have a higher sensitivity, ranging from 71–95% depending on the study and cutpoint chosen, but quarter sampling is impractical as SCC is usually performed on a composite sample.[30] Both composite and quarter milk SCC testing result in an unacceptably high proportion of infected cows being missed,[27,30] and are therefore not currently recommended as a screening test if the goal is to identify all cows with a *S. aureus* intramammary infection in the herd.

The CMT has also been used as a screening test to identify quarters or cows to culture. Using a CMT trace, 1, 2, or 3 to indicate the presence of an intramammary infection produced a range of sensitivities from 0.47–0.96 and specificities of 0.41–0.80.[30]

In summary, culture of quarter milk samples (preferably) or a composite milk sample is superior to a quarter SCC or CMT for the diagnosis of *S. aureus* intramammary infection.[30] Culture is strongly preferred if it is important to identify all positive cows in a herd because the sensitivity of indirect tests (such as SCC, CMT) is inadequate.

Enzyme-linked immunosorbent assays for antibody in milk

ELISA tests for detecting *S. aureus* antibody in milk have been developed[25,31] but are not widely used. Rapid laboratory tests incorporating these ELISAs, including a Staph-zym test, have demonstrated 84–90% accuracy in identifying staphylococci.[32]

Acriflavine disk assay

The acriflavine disk assay is a practical, accurate method for differentiating *S. aureus* isolates from non-*S. aureus* staphylococci.[33]

NECROPSY FINDINGS

In peracute staphylococcal mastitis, the affected quarter is grossly swollen and may contain bloodstained milk dorsally but only serosanguineous fluid ventrally. There is extreme vascular engorgement and swelling, often progressing to moist gangrene of the overlying skin. Bacteria are not isolated from the bloodstream or tissues other than the mammary tissue and regional lymph nodes. Histologically there is coagulation necrosis of glandular tissue and thrombosis of veins.

In milder forms of staphylococcal mastitis the invading organisms often elicit a granulomatous response. Microscopically, such 'botryomycotic' cases are characterized by granulomas with a central bacterial colony and by progressive fibrosis of the quarter.

Samples for confirmation of diagnosis

- Bacteriology – chilled mammary tissue, regional lymph node
- Histology – fixed mammary tissue.

DIFFERENTIAL DIAGNOSIS

Because of the occurrence of the peracute form in the first few days after parturition, the intense depression and inability to rise, the dairy producer may conclude that the cow has **parturient paresis**, which is characterized by weakness, recumbency, hypothermia, rumen stasis, dilated pupils, tachycardia with weak heart sounds and a rapid response to intravenous calcium gluconate. The mammary gland is usually normal in parturient paresis.

Peracute *S. aureus* mastitis is characterized by marked tachycardia, fever, weakness and evidence of severe clinical mastitis with swelling, heat, abnormal milk with serum and blood, and sometimes gas in the teat and often with gangrene of the teat up to the base of the udder. Other bacterial types of mastitis, particularly *E. coli* and *A. pyogenes*, may cause severe systemic reactions but gangrene of the quarter is less common.

Peracute coliform mastitis is a much more common cause of severe mastitis than *S. aureus* mastitis. The chronic and acute forms of staphylococcal mastitis are indistinguishable clinically from many other bacterial types of mastitis and bacteriological examination is necessary for identification.

TREATMENT

The bacteriological cure rates for the treatment of *S. aureus* mastitis with either intramammary infusion or parenteral antimicrobial administration are notoriously less than satisfactory, particularly in the lactating cow. Bacteriological cure rates after antimicrobial treatment seldom

exceed 50% and infections commonly persist throughout the lifetime of the cow. There are three likely reasons: inadequate penetration of the antimicrobial agent to the site of infection, formation of L-forms of *S. aureus*, and beta-lactamase production.

Inadequate penetration of antimicrobial agent

There is **inadequate penetration of the antimicrobial agent** into the site of intramammary infection in the lactating cow and the organism survives in phagocytes that are inaccessible. There may also be inactivation of the antimicrobial by milk and serum constituents, and the formation of L-forms of the organism during treatment, varying between 0% and 80% of bacteria.

Antimicrobial resistance

Antimicrobial resistant strains of *S. aureus* occur and are often beta-lactamase producers, the enzyme conferring resistance to beta-lactam antimicrobial agents such as penicillin G, penethamate, ampicillin and amoxicillin. Cloxacillin and nafcillin are effective, but only against Gram-positive bacteria; they are less effective against nonlactamase staphylococci. Clavulanic acid added to amoxicillin overcomes this beta-lactamase resistance. So does **cloxacillin** added to ampicillin, and this is made use of in a popular intramammary formulation. First- and third-generation cephalosporins and erythromycin are effective against beta-lactamase-producing staphylococci, and first- and third-generation cephalosporins are also effective against Gram-negative bacteria. A cephapirin dry cow product administered to heifers with *S. aureus* infections resulted in bacteriological cure and left the quarters clear well into their first lactation.[34] Intramammary cloxacillin and ampicillin is generally considered to be the preferred initial treatment for *S. aureus* mastitis because beta-lactamase production by *S. aureus* is sufficiently common.

Antimicrobial therapy for *S. aureus* subclinical mastitis during the lactating period is not economically attractive because of low bacteriological cure rates, discarding of milk during the withholding period and the lack of an economically beneficial increase in production following treatment. Dry cow treatment at the end of lactation is much more effective, being successful in 40–70% of cases, although treatment should be attempted in heifers infected early in lactation. Cows that are infected with *S. aureus* should be appropriately identified, segregated if possible and milked last or with separate milking units.[35] Culling of infected cows is also an option for consideration, but a detailed economic analysis of this popular recommendation is lacking.

Lactating cow therapy

The treatment of clinical cases of *S. aureus* mastitis using intramammary antimicrobial infusions is less than satisfactory but is often done. However, clinical recovery following therapy does not necessarily eliminate the infection and some of the published literature on cure rates has not made the distinction between clinical and bacteriological cure rates. In general, the cure rate depends on the duration of infection, the number of quarters infected, whether the strain of *S. aureus* is a beta-lactamase producer, the immune status of the cow, the antimicrobial agent administered and the duration of treatment. Current recommendations to ensure the best treatment success rate are to combine intramammary and parenteral antimicrobial treatment or **use extended intramammary treatment for 4–8 days**. Penicillin G is regarded as the antimicrobial agent of choice for *S. aureus* strains that are penicillin-sensitive.[22]

The following intramammary infusions, given daily at 24-hour intervals for three treatments (unless stated otherwise) have been used for the treatment of clinical cases of *S. aureus* mastitis, with expected clinical cure rates of about 30–60% in lactating cows. Subclinical cases are left until the cow is dried off:

- Sodium cloxacillin (200–600 mg for three infusions)
- Tetracyclines (400 mg)
- Penicillin–streptomycin combination (100 000 units – 250 mg)
- Penicillin–tylosin combination (100 000 units – 240 mg)
- Novobiocin (250 mg per infusion for three infusions)
- Cephalosporins – most strains of *S. aureus* are sensitive to cephapirin[36]
- Pirlimycin-extended therapy (two 50 mg doses, 24 hours apart, then 36-hour withhold, then cycle repeated twice, equivalent to infusing at 0, 24, 60, 84, 120, and 144 hours).

In a study of 184 cases of subclinical *S. aureus* mastitis in New York, commercially available intramammary infusions were not significantly more effective than untreated controls (43% bacteriological cure), with the following bacteriological cure rates: erythromycin (65%), penicillin (65%), cloxacillin (47%), amoxicillin (43%), and cephapirin (43%).[37]

A slightly more effective treatment for subclinical *S. aureus* intramammary infection, with a cure rate of 50%, is simultaneous intramammary infusion of amoxicillin (62.5 mg) and intramuscular injection of procaine penicillin G (9 000 000 units).[38] This study was the first to demonstrate that combined parenteral and intramammary therapy was more effective than intramammary infusion alone. Because of the persistence of the infection in each herd the final choice of the antimicrobial to be used should be based on a culture and susceptibility test; the latter is to determine whether the predominant *S. aureus* strain in the herd is a beta-lactamase producer; this is because **beta-lactamase-producing strains are harder to cure and require a specific antibiotic protocol**.[22] The bacteriological cure rate for penicillin-sensitive infections treated with parenteral and intramammary penicillin G was 76%, compared to beta-lactamase-producing strains treated with parenteral and intramammary amoxicillin–clavulanic acid (29%).[22]

The application of cytokines as an adjunct to antimicrobial therapy may help to increase the number of phagocytes in the mammary gland and enhance cell function. The experimental intramammary infusion of recombinant interleukin into infected or uninfected mammary glands elicited an influx of polymorphonuclear leukocytes exhibiting subsequent enhanced activity and increased the cure rate 20–30% in quarters infected with *S. aureus*.[39]

A novel method for decreasing the transmission of *S. aureus* within a herd is to **selectively cease lactation in infected quarters of lactating cattle.**[40] The best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone–iodine solution (0.5% iodine) after complete milk-out and administration of flunixin meglumine (1 mg/kg BW, intravenously). Therapeutic cessation of milk production in one quarter does not alter daily milk production but does decrease individual cow SCC and its contribution to the bulk tank milk SCC. The final outcome of selectively drying off infected quarters is a decrease in the rate of new intramammary infections in the herds and a lowering in the bulk tank milk SCC.

Peracute mastitis

Early parenteral treatment of peracute cases with adequate does of antimicrobials such as trimethoprim–sulfonamide or penicillin is deemed necessary to improve the survival rate. When penicillin is used the initial intramuscular injection should be supported by an intravenous dose of crystalline penicillin, with subsequent intramuscular doses to maintain the highest possible blood level of the antimicrobial over a 4–6-day period; tamethicillin or penthemate hydriodide are preferred to achieve this. Intramammary infusions are of little value in such cases because of failure of the drugs to diffuse into the gland. The intravenous administration of large quantities

of electrolyte solutions is also recommended. Hypertonic saline, as recommended for peracute coliform mastitis, has not yet been evaluated but may be indicated. Frequent massage of the udder with hot wet packs and milking out the affected gland is recommended. Oxytocin is used to promote milk-down but is relatively ineffective in severely inflamed glands. Surgical amputation of the teat may be indicated to promote drainage of the gland, but only in cows with necrotic teats.

Dry cow therapy

It has become a common practice to leave chronic *S. aureus* cases until they are dried off before attempting to eliminate the infection. The material is infused into each gland after the last milking of the lactation and left in situ. The major benefits of dry cow therapy are the **elimination of existing intramammary infections** and **prevention of new intramammary infections during the dry period**. In addition, milk is not discarded and bacteriological cure rates are superior to those obtained during lactation.

The factors associated with a bacteriological cure after dry cow therapy of subclinical *S. aureus* mastitis have been examined.[41] The probability of cure of an infected quarter *decreased* when:

- SCC increased
- Age of cow increased
- Another quarter was infected in the same cow
- The infection was in a hind quarter
- The percentage of samples that were positive for *S. aureus* was higher before drying off.

Cows with more than one infected quarter were 0.6 times less likely to be cured than cows with one infected quarter. The cure rate of quarters affected with *S. aureus* can be predicted using a formula which considers several cow factors and quarter factors.[41] The prediction of the probability of cure in an 8-year-old cow with three quarters infected with the organism and a SCC of 2300 000 is 36%. In a 3-year-old cow with one quarter infected and a SCC of 700 000, the probability of cure is 92%. This information is often available at drying off and can be used to select cows that are unlikely to be cured to be removed from the herd by designating them as 'do not breed' and culling when it is economically opportune.

Most intramammary antimicrobial infusions are satisfactory for dry cow therapy provided they are combined with slow-release bases. Bacteriological cure rates vary between herds from 25–75% and average about 50%.[42] The use of parenteral antimicrobials such as oxytetracycline along with an intramammary infusion of cephapirin did not improve the cure rate for *S. aureus*.[42]

CONTROL

Because of the relatively poor results obtained in the treatment of staphylococcal mastitis, any attempt at control must depend heavily on effective methods of preventing the transmission of infection from cow to cow. *S. aureus* is a contagious pathogen, the udder is the primary site of infection, and hygiene in the milking parlor is of major importance. To reduce the source of the organism, a program of early **identification, culling, and segregation** is important to control *S. aureus* mastitis in a dairy herd, although successful implementation of all three aspects is challenging. Satisfactory control of *S. aureus* mastitis has historically been difficult and unreliable; however, at the present time the quarter infection rate can be rapidly and profitably reduced from the average level of 30% to 10% or less.

The strategies and practices described under the control of bovine mastitis later in this chapter are highly successful for the control of *S. aureus* mastitis when applied and maintained rigorously. The control program includes:

- Hygienic washing and drying of udders before milking
- Regular milking-machine maintenance
- Teat dipping after milking. Teat dipping in 1% iodine or 0.5% chlorhexidine, either in 5–10% glycerine, is completely effective against *S. aureus* mastitis.[43] The program helps to eliminate infected quarters and reduces the new infection rate by 50–65% compared to controls. The disinfection of hands or use of rubber gloves provides additional advantages
- Dry cow treatment on all cows
- Culling cows with chronic mastitis
- Milking infected cows last (very difficult to implement in free stall housing or pasture feeding).

An alternative but radical control strategy when all else has failed is to permanently dry off the infected quarter using iodine infusion.

Immunization against *S. aureus* mastitis has been widely researched for 100 years. Different vaccines based on cellular or soluble antigens with and without adjuvants have been given to dairy cows but protection against infection and clinical disease has been unsatisfactory when used in the field. Currently available vaccines are autogenous bacterins (made to order using isolates from clinical cases on the farm) or contain one or more *S. aureus* strains that are believed to provide good cross-protection. The goals of such vaccines are to decrease the severity of clinical signs and increase the cure rate, particularly when administered to heifers before they calve. Vaccination has also been used simultaneously with antimicrobial therapy during lactation or at dry-off in an attempt to augment the cows immune response, with mixed success.[21] Development of an effective *S. aureus* vaccine remains one of the most important issues confronting control of infectious diseases in cattle.

STREPTOCOCCUS AGALACTIAE

Synopsis

Etiology *Streptococcus agalactiae* is a major pathogen of the mammary gland and a common cause of contagious bovine mastitis
Epidemiology Major cause of mastitis in dairy herds without an effective mastitis control program. Prevalence of infection 10–50% of cows and 25% of quarters. In herds with effective control program prevalence less than 10% of cows. Can be eliminated from herd with treatment and control. Highly contagious obligate pathogen. Infection is transmitted at milking
Clinical findings Individual repeated episodes of subacute to acute mastitis are most common. Gland is swollen, warm, and milk is watery and contains clots. Gradual induration of udder if not treated
Clinical pathology Culture of individual cow milk samples or bulk tank milk samples. Latex agglutination test
Necropsy findings Not important
Diagnostic confirmation Latex agglutination test for specific identification of organism
Differential diagnosis Cannot differentiate clinically from other causes of acute and chronic mastitis. Must culture milk
Treatment Mastitis associated with *S. agalactiae* in lactating cows is sensitive to intramammary therapy with wide variety of antimicrobial agents resulting in high rate of clinical and bacteriological cures. Blitz therapy (simultaneous treatment of all positive cows in a herd) commonly used to reduce prevalence of infection in herd
Control Eradication is possible. Identify and treat infected quarters, cull incurable cows. Premilking teat and udder sanitation, postmilking teat dipping, and dry cow therapy

ETIOLOGY

Streptococcus agalactiae. Infections with environmental streptococci are described in the next section.

EPIDEMIOLOGY

Occurrence and prevalence of infection

S. agalactiae was the major cause of mastitis before the antimicrobial era and is still a significant cause of chronic mastitis where control procedures for contagious mastitis are not used.[1] Herd prevalence rates of infection range from 11–47%. Typically, in a herd infected with the pathogen, the prevalence of infection could be as high as 50% of cows, but more recent surveys indicate much lower within-herd prevalences, ranging from 8–10%.[1] Where good hygienic measures and the efficient treatment of clinical cases are in general use, the prevalence of infection within a herd will be less than 10% of cows. Following the use of antimicrobial agents, *S. agalactiae* was superseded by *Staphylococcus aureus* as the major cause of bovine mastitis. In herds with a high bulk tank milk SCC, the probability is high that *S. agalactiae* infection is the most prevalent pathogen.

Source of infection

S. agalactiae is a highly contagious obligate parasite of the bovine mammary gland. The main source of infection is the udder of infected cows although, when hygiene is poor, contamination of the environment may provide an additional source. The teats and skin of cattle, milkers' hands, floors, utensils and clothes are often heavily contaminated. Sores on teats are the commonest sites outside the udder for persistence of the organism. The infection may persist for up to 3 weeks on hair and skin and on manure and bricks. The importance of environmental contamination as a source of infection is given due recognition in the general disinfection technique of eradication.

Transmission of infection

Transmission from animal to animal occurs most commonly by the medium of milking machine liners, hands, udder cloths and possibly bedding.

The streak canal is the portal of entry, although there is doubt as to how invasion into the teat canal and then gland occurs. Suction into the teat during milking or immediately afterwards does occur, but growth of the bacteria into the canal between milkings also appears to be an important method of entry. It is difficult to explain why heifers that have never been milked may be found to be infected with *S. agalactiae*, although sucking between calves after ingestion of infected milk or contact with infected inanimate materials may be sources of infection.

Risk factors

There is no particular breed susceptibility but infection does become established more readily in older cows and in the early part of each lactation. Poor hygiene, incompetent milking personnel and machinery that is faulty or maladjusted are important risk factors. **The most important risk factors are the failure to use postmilking teat dip and the selective or non-use of dry cow therapy**. The use of a common wash rag or sponge is also a risk factor. Inadequate treatment of clinical cases of mastitis is also a frequent risk factor in infected herds.

S. agalactiae has the ability to adhere to the mammary gland tissue, and the specific microenvironment of the udder is necessary for growth of the organism. The virulence of various strains of the organism is related to differences in their ability to adhere to the mammary epithelium. Bacterial ribotyping has been used to characterize strains of the organism to determine their geographical distribution.[2] The physical characteristics of the teat canal may influence the susceptibility to streptococcal infection.[3] The mechanisms used by *S. agalactiae* to penetrate the teat canal are influenced more by the diameter of the teat canal lumen, as reflected by the peak flow rate, than by teat canal length.

Economic importance

The disease is of major economic importance in milk production. In individual cows, the loss of production associated with *S. agalactiae* mastitis is about 25% during the infected lactation, and in affected herds the loss may be of the order of 10–15% of the potential production. Reduction of the productive life represents an average loss of one lactation per cow in an affected herd. Deaths due to *S. agalactiae* infection rarely if ever occur and complete loss of productivity of a quarter is uncommon, the losses being incurred in the less dramatic but no less important fashion of decreased production per cow.

PATHOGENESIS

When the primary barrier of the streak canal is passed, if bacteria are not flushed out by the physical act of milking they proliferate and invasion of the udder tissue follows. There is considerable variation between cows in the developments that occur at each of the three stages of invasion, infection and inflammation. The reasons for this variation are not clear but resistance appears to depend largely on the integrity of the lining of the teat canal. After the introduction of infection into the teat, the invasion, if it occurs, takes 1–4 days and the appearance of inflammation 3–5 days. Again there is much variation between cows in the response to tissue invasion, and a balance may be set up between the virulence of the organism and undefined defense mechanisms of the host so that very little clinically detectable inflammation may develop despite the persistence of a permanent bacterial flora.

The **development of mastitis** associated with *S. agalactiae* is essentially a process of invasion and inflammation of lobules of mammary tissue in a series of crises, particularly during the first month after infection, each crisis developing in the same general pattern. Initially there is a rapid multiplication of the organism in the lactiferous ducts, followed by passage of the bacteria through the duct walls into lymphatic vessels and to the supramammary lymph nodes, and an outpouring of neutrophils into the milk ducts. At this stage of initial tissue invasion,

a shortlived systemic reaction occurs and the milk yield falls sharply as a result of inhibition and stasis of secretion caused by damage to acinar and ductal epithelium. Fibrosis of the interalveolar tissue and involution of acini result even though the tissue invasion is quickly cleared. Subsequently, similar crises develop and more lobules are affected in the same way, resulting in a stepwise loss of secretory function with increasing fibrosis of the quarter and eventual atrophy.

The **clinicopathological findings** vary with the stage of development of the disease. Bacterial counts in the milk are high in the early stages but fall when the SCC rises at the same time as swelling of the quarter becomes apparent. In some cases bacteria are not detectable culturally at this acute stage. The SCC rises by 10–100 times normal during the first 2 days after infection and returns to normal over the next 10 days. The febrile reaction is often sufficiently mild and shortlived to escape notice. When the inflammatory changes in the epithelial lining of the acini and ducts begin to subside, the shedding of the lining results in the clinical appearance of clots in the milk. Thus the major damage has already been done when clots are first observed. At the stage of acute swelling, it is the combination of inflamed interalveolar tissue and retained secretion in distended alveoli that causes the swelling. Removal of the retained secretion at this stage may considerably reduce the swelling and permit better diffusion of drugs infused into the quarter. Inflammatory reactions also occur in the teat wall of affected quarters.

The variations in resistance between cows and the increased susceptibility with advancing age are unexplained. Hormonal changes and hypersensitivity of mammary tissue to streptococcal protein have both been advanced as possible causes of the latter. Local immunity of mammary tissue after an attack probably does not occur but there is some evidence to suggest that a low degree of general immunity may develop. The rapid disappearance of the infection in a small proportion of cows in contrast to the recurrent crises that are the normal pattern of development suggests that immunity does develop in some animals. The antibodies are hyaluronidase inhibitors and are markedly specific for specific strains of the organism. A nonspecific rise in other antibodies may occur simultaneously and this is thought to account for the field observations that coincident streptococcal and staphylococcal infections are unusual and that the elimination of one infection may lead to an increased incidence of the other.

CLINICAL FINDINGS

In the experimentally produced disease, there is initially a sudden episode of acute mastitis, accompanied by a transient fever, followed at intervals by similar attacks, which are usually less severe. In natural cases fever, lasting for a day or two, is occasionally observed with the initial attack but the inflammation of the gland persists and the subsequent crises are usually of a relatively mild nature. These degrees of severity may be classified as **abnormal cow** when the animal is febrile and off its feed, **abnormal gland** when the inflammation of the gland is severe but there is no marked systemic reaction, and **abnormal milk** when the gland is not greatly swollen, pain and heat are absent and the presence of clots in watery foremilk may be the only apparent abnormality. Induration is most readily palpable at the udder cistern and in the lower part of the udder, and varies in degree with the stage of development of the disease.

The milk yield of affected glands is markedly reduced during each crisis but, with proper treatment administered early, the yield may return to almost normal. Even without treatment the appearance of the milk soon becomes normal but the yield is significantly reduced and subsequent crises are likely to reduce it further.

CLINICAL PATHOLOGY

The **CAMP test**, which has served as the universally used means of identifying *S. agalactiae* for many years, has been displaced by a commercial **latex agglutination test**, which contains specific reagents necessary for the identification of *S. agalactiae* and is suitable for general laboratory use.[1] When used on isolates of samples from bulk tank milk, the sensitivity and specificity are 97.6% and 98.2%, respectively. An ELISA test correlates well with the bulk tank milk SCC and provides a suitable alternative.[1]

The critical judgment to be made is deciding when the quarter infection rate is so high that control or eradication measures are necessary. A decision can be made on the basis of the bulk tank milk SCC as an indicator of the prevalence of mastitis on a quarter basis, and on culture of the bulk tank milk sample to indicate that *S. agalactiae* is the important pathogen, but this approach is too inaccurate to be recommended. There seems to be no alternative to carrying out bacteriological culture and determining SCC on milk samples from individual cows or quarters. Milk samples collected for bacteriological examination for the presence of *S. agalactiae* can be stored in the frozen state. The number of samples that will be culturally positive when the stored frozen samples are thawed will either be unchanged or enhanced up to 200%; the latter response is attributing to fracturing of cellular debris containing *S. agalactiae*.

Culture from bulk tank milk samples

The presence of the organism in bulk tank milk is due to shedding of bacteria from infected quarters, with cyclic shedding being typical. The specificity of culture from bulk tank milk is very high; the sensitivity is much lower but can be increased by using selective media.

Total bacterial count

The total bacterial count in bulk tank milk can be markedly increased due to the presence of *S. agalactiae* mastitis in the herd. Samples of bulk tank milk from infected herds commonly contain bacterial counts in the range of 20 000–100 000 cfu/mL, because a cow in the early stages of infection can shed up to 100 000 000 bacteria/mL. The standard plate count can drop from 100 000 to 2000 cfu/mL after implementation of a modified blitz therapy and control program to control *S. agalactiae*.

Culture from individual cow samples

Composite milk samples are satisfactory, as the number of cows identified as positive does not increase by quarter sampling.[1] The sensitivity and specificity of a single culture from individual cows ranges between 95% and 100%.[1]

Somatic cell count

S. agalactiae produces high SCC in individual cows, which has a significant influence on the bulk tank milk SCC.

NECROPSY FINDINGS

The gross and microscopic pathology of mastitis associated with *S. agalactiae* are not of importance in the diagnosis of the disease.

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of *S. agalactiae* mastitis depends entirely on the isolation of *S. agalactiae* from the milk. Differentiation from other types of acute and chronic mastitis is not possible clinically.

TREATMENT

S. agalactiae is very sensitive to intramammary therapy using a wide variety of commercially available intramammary infusion preparations. Systemic therapy is also effective but offers no advantages over the intramammary route. Clinical cases should be treated whenever they occur because of the need to prevent transmission to uninfected quarters and cows. Subclinical cases identified at any stage of lactation should be treated

immediately because of the excellent response to treatment. Treatment of *S. agalactiae* mastitis with intramammary infusions will result in a high percentage of infections being eliminated economically and with few residual concerns, provided the milk withholding times are observed.

Infections at all stages of lactation have 90–100% cure rates with penicillin, erythromycin, cloxacillin and cephalosporins. Gentamicin, neomycin, nitrofurazone and polymyxin B have poor activity. Procaine penicillin G is universally used as a mammary infusion at a dose rate of 100 000 units. Higher dose rates have the disadvantage of increasing penicillin residues in the milk. A moderate increase in efficiency is obtained by using procaine penicillin rather than the crystalline product, and by using 100 000 units of penicillin in a long-acting base the cure rate (96%) is significantly better than with quick-acting preparations (83%).

To provide a broader spectrum of antimicrobial efficiency penicillin is often combined with other drugs that are more effective against Gram-negative organisms. A mixture of penicillin (100 000 units) and novobiocin (150 mg) provides a cure rate ranging from 89–98%.[4] It is necessary to maintain adequate milk levels for 72 hours: three infusions at intervals of 24 hours are recommended, but dosing with two infusions 72 hours apart, or one infusion of 100 000 units, in a base containing mineral oil and aluminum monostearate, gives similar results. As a general rule clinical cases should be treated with three infusions, and subclinical cases, particularly those detected by routine examination in a control program, with one infusion. Recovery, both clinically and bacteriologically, should be achieved in at least 90% of quarters if treatment has been efficient. Intramuscular administration of ceftiofur is not efficacious as a treatment to eliminate the organism, compared to intramammary infusion of penicillin (100 000 units) and novobiocin (150 mg) daily for two treatments.[4]

Other antimicrobial agents used in the treatment of *S. agalactiae* infections include the tetracyclines and cephalothin, which are as effective as penicillin and have the added advantage of a wider antibacterial spectrum, an obvious advantage when the type of infection is unknown. Neomycin is inferior to penicillin in the treatment of *S. agalactiae* mastitis, while tylosin and erythromycin appear to have equal efficacy. A single treatment with 300 mg of erythromycin is recommended as curing 100% of quarters infected with *S. agalactiae*. Lincomycin (200 mg) combined with neomycin (286 mg) and administered twice at 12-hour intervals also has good efficacy. In a study of 1927 cases of subclinical *S. agalactiae* mastitis in New York, all commercially available intramammary infusions were more effective than untreated controls (27% bacteriological cure), with the following bacteriological cure rates: amoxicillin (86%), erythromycin (81%), cloxacillin (77%), cephapirin (66%), penicillin (63%), hetacillin (62%), pirlimycin (44%).[5]

In dry cows, one infusion is sufficient, milk levels of penicillin remaining high for 72 hours. Cloxacillin eliminated the organism from 98% and 100% of infected cows in two different studies.[1]

Blitz therapy

The prevalence of subclinical mastitis due to *S. agalactiae* can be reduced more rapidly by treatment of infected cows during lactation than by dry cow therapy and postmilking teat dipping. *S. agalactiae* is one of the few pathogens causing subclinical mastitis that can be treated economically during lactation, and can be eliminated from herds with **blitz antimicrobial therapy followed by good sanitation procedures**. All cows are sampled and those that are positive are treated simultaneously with penicillin and novobiocin. Cows not responsive to the first treatment are identified and retreated or culled. Failure to institute sanitation procedures for the control of the pathogen may result in subsequent outbreaks of mastitis.[6]

If blitz therapy of all infected cows is not possible because of the short-term effect of lost milk production on income, a modified treatment protocol is recommended. The herd is divided into two groups, based on a composite milk SCC of 500 000. Those cows in the high category are treated with 300 mg of erythromycin, intramammarily. When lactating cow numbers reach their lowest point, all animals are treated with the same product. At drying off, cows are treated with 500 mg cloxacillin and 250 mg ampicillin.

CONTROL

Eradication on a herd basis of mastitis associated with *S. agalactiae* is an accepted procedure and has been undertaken on an area scale in some countries. The control measures as outlined later in this chapter are designed especially for this disease and should be adopted in detail. If suitable hygienic barriers against infection can be introduced and if the infection can be eliminated from individual quarters by treatment, the disease is eradicable fairly simply and economically.

The control program consists of:

- **Identifying infected quarters**
- **Treating infected quarters on two occasions if necessary**
- **Culling incurable cows**.

The control program is particularly applicable in herds where an unacceptable level of clinical cases is backed by a high incidence of subclinical infections. **Premilking teat and udder sanitation, postmilking teat dipping, and dry cow therapy** are vital aspects of the control program.

Vaccination

Vaccination against *S. agalactiae* has been attempted and elicits systemic hyperimmunity but no apparent intramammary resistance. Development of an effective vaccine will be difficult because of the multiplicity of strains involved and the known variability between animals in their reaction to intramammary infection.

Biosecurity

As with any eradication program a high degree of vigilance is required to maintain a 'clean' status. This is particularly so with mastitis due to *S. agalactiae*. Breakdowns are usually due to the introduction of infected animals, even heifers that have not yet calved, or the employment of milkers who carry infection with them. Most dairy farms in the USA are in an ongoing process of herd expansion or replacement acquisition by the addition of purchased animals. Introduction of contagious mastitis associated with *S. agalactiae*, *S. aureus* and *M. bovis* is a common result. It has been recommended that herd additions should be screened for these important pathogens;[7] however, currently available screening tests do not have perfect sensitivity.

MYCOPLASMA BOVIS AND OTHER *MYCOPLASMA* SPECIES

ETIOLOGY

A number of species of *Mycoplasma*, especially *M. bovis* and occasionally *Mycoplasma* species group 7,[1] *Mycoplasma* F-38, *Mycoplasma arginini*, *Mycoplasma bovirhinis*, *Mycoplasma canadensis*, *Mycoplasma bovigenitalium*, *Mycoplasma alkalescens*,[2] *Mycoplasma capricolium*,[3] *Mycoplasma californicum*[4,5] and *Mycoplasma dispar*,[6] have been isolated from clinical cases. Other mycoplasmas, not usually

Synopsis

Etiology *Mycoplasma bovis*, other *Mycoplasma* spp.
Epidemiology A highly contagious mastitis causing outbreaks of clinical mastitis. Most common in large herds with recent introductions. Transmitted within herds by bulk mastitis treatments and poor milking hygiene. Cows of all ages and any stage of lactation but those in early lactation most severely affected
Clinical findings Sudden onset of clinical mastitis in many cows, usually all four quarters, marked drop in milk production and may stop lactating, swelling of the udder and gross abnormality of the milk without obvious signs of systemic illness, eventually udders atrophy and do not return to production. Can cause clinical, subclinical and chronic intramammary infections. Calves suckling milk from infected cows may develop otitis media/interna
Clinical pathology Special culture and staining of milk techniques
Necropsy findings Purulent interstitial mastitis
Diagnostic confirmation Identification of pathogen in milk
Differential diagnosis Epidemiology and clinical findings are characteristic of mycoplasma mastitis. May resemble other causes of chronic mastitis unresponsive to treatment
Treatment Not responsive to commonly used mastitis treatments protocols. Identify and cull affected cows for slaughter
Control Prevent entry of infected cows into herd. Eradicate infection by culling affected cows

associated with the development of mastitis, also cause the disease when injected into the udder. There is also evidence of mastitis associated with *Ureaplasma* spp.[7] A striking characteristic of the mycoplasmas is that they seem to be able to survive in the presence of large numbers of leukocytes in the milk. Antibodies to the bacteria have not been detectable in sera or whey from animals infected with some strains, but complement-fixing antibodies are present in the sera of animals recovered from infection with other strains.

Acholeplasma laidlawii is not a mastitis pathogen, but it has been observed that a high proportion of bulk tanks will give positive cultural tests for it, especially during wet, rainy weather. This increase is accompanied by an increase of clinical mycoplasmal mastitis due to pathogenic mycoplasma. *A. laidlawii* is considered to be a milk contaminant in these circumstances.

The group of diseases, including mastitis, that are associated with *Mycoplasma* spp. in sheep and goats are dealt with separately.

EPIDEMIOLOGY

Occurrence and prevalence of infection

The disease has been recorded since the mid 1960s in the USA, Canada, UK, and Israel and has been observed in Australia. The quarter infection rate in infected herds varies widely.

Source of infection

The epidemiology of the disease has been incompletely characterized.[8] *Mycoplasma* mastitis occurs most commonly in large herds and in herds where milking hygiene is poor and when cows are brought in from other farms or from public saleyards. *Mycoplasma* mastitis usually breaks out subsequently after a delay of weeks or even months. The delay in development of an outbreak may be related to the long-term persistence of the organism (more than 12 months) in some quarters, and some cows become shedders of the organism without ever exhibiting signs of severe clinical mastitis. *M. bovis* was isolated from milk samples of 5–12% of cows during two lactations and two dry periods.[9]

M. bovis is capable of colonizing and surviving in the upper respiratory tract and the vagina, and extramammary colonization explains many of its epidemiological paradoxes. An interesting epidemiological observation is the detection of mycoplasmas and infectious bovine rhinotracheitis virus in affected udders at the same time. The virus could be the much sought-after unknown factor in the etiology of the disease. Outbreaks of mastitis are recorded concurrently with outbreaks of vaginitis and otitis media/interna vestibulitis.[10]

Transmission

Entry of the disease to a herd is usually by the purchase of animals and their introduction without quarantine. Transmission within a herd is most commonly at milking via machine milking or the hands of milkers. Transmission can also be through the use of bulk mastitis treatments administered through a common syringe and cannula.[11] Although the disease occurs first in the inoculated quarter there is usually rapid spread to all other quarters.

Hematogenous spread of *M. bovis* has been demonstrated.[12,13] Colonization of body sites other than the mammary gland is common, and *M. bovis* isolates from the respiratory and urogenital systems are frequently the same *M. bovis* subtypes that cause mastitis.[13]

Mycoplasma spp. group 7 has also been isolated from cases of pneumonia and polyarthritis in calves fed milk from cows with mycoplasmal mastitis.

Risk factors

Cows of all ages and at any stage of lactation are affected, cows that have recently calved showing the most severe signs and dry cows the least. There are several recorded outbreaks in dairy herds in dry cows,[14] one of them immediately after mammary infusions of dry period treatment that affected all quarters of all cows.

Experimental production of the disease[15] with *M. bovis* causes severe loss of milk production, a positive CMT reaction and clots in the milk.[16] Experimental infection produces little tissue necrosis but *Mycoplasma* are detectable in many tissues, including blood, vagina, and fetus, indicating that hematogenous spread has occurred. It is also apparent that spread of infection between quarters in one cow can be hematogenous. There are no significant pathological differences between mastitis produced by *M. bovigenitalium* and *M. bovis*; however, *M. bovis* remains the most common cause of mycoplasmal mastitis in dairy cattle.

Economic importance

The disease is a disastrous one because of the high incidence in affected herds and the almost complete cessation of production for the lactation. Many cows fail ever to return to milking; as many as 75% of affected cows may have to be culled.

PATHOGENESIS

This is a purulent interstitial mastitis. Although infection probably occurs via the streak canal, the rapid spread of the disease to other quarters of the udder and occasionally to joints suggests indicates that hematogenous spread may occur. The presence of the infection in heifers milked for the first time also suggests that systemic invasion may be followed by localization in the udder.

CLINICAL FINDINGS

In lactating cows, there is a sudden onset of swelling of the udder, a sharp drop in milk production and grossly abnormal secretion in one or more quarters. In most cases all four quarters are affected and a high-producing cow may fall in yield to almost nil between one milking and the next. Dry cows show little swelling of the udder. Although there is no overt evidence of systemic illness, and febrile reactions are not observed in most field cases in lactating cows, those that have recently calved show most obvious swelling of the udder and may be off their feed and have a mild fever. However, cows infected experimentally show fever up to 41°C (105.5°F) on the third or fourth day after inoculation, at the same time as the udder changes appear. The temperature returns

to normal in 24–96 hours. In some cases the supramammary lymph nodes are greatly enlarged. **The classic clinical presentation is severe clinical mastitis in multiple quarters of multiple cows with minimal systemic signs of disease.** A few cows, with or without mastitis, develop arthritis in the knees and fetlocks. The affected joints are swollen, with the swelling extending up and down the leg. Lameness may be so severe that the foot is not put to the ground. *Mycoplasma* may be present in the joint.

The secretion from affected quarters is deceptive in the early stages in that it appears fairly normal at collection; on standing, however, a deposit, which may be in the form of fine, sandy material, flakes or floccules, settles out leaving a turbid whey-like supernatant. Subsequently the secretion becomes scanty and resembles colostrum or soft cheese curd in thin serum. The secretion may be tinged pink with blood or show a gray or brown discoloration. Within a few days the secretion is frankly purulent or curdy but there is an absence of large, firm clots. This abnormal secretion persists for weeks or even months.

Affected quarters are grossly swollen. Response to treatment is very poor and the swollen udders become grossly atrophied. In infection with one strain of the *Mycoplasma*, many cows do not subsequently come back into production although some may produce moderately well at the next lactation. With other strains there is clinical recovery in 1–4 weeks without apparent residual damage to the quarter.

Mycoplasmal mastitis due to *M. bovigenitalium* may be very mild and disappear from the herd spontaneously and without causing loss of milk production.[17]

CLINICAL PATHOLOGY

The causative organism can be cultured without great difficulty by a laboratory skilled in working with *Mycoplasma*. Samples for culture should be freshly collected and transported at 4°C, and concurrent infection with other bacteria is common. Diagnosis at the herd level can be made by culturing bulk tank milk or milk from cows with clinical mastitis or increased SCC. However, the sensitivity of bulk tank milk culturing is poor (33–59%).[18,19] A marked leukopenia, with counts as low as 1800–2500 cells/μL, is present when clinical signs appear and persists for up to 2 weeks. Somatic cell counts in the milk are very high, usually over 20 000 000 cells/mL. In the acute stages the organisms may be able to be visualized by the examination of a milk film stained with Giemsa or Wright–Leishman stain. Species identification of *Mycoplasma* isolates is most commonly done using immunofluorescence and homologous fluorescein-conjugated antibody or an indirect immunoperoxidase test (immunohistochemistry). Speciation of the causative *Mycoplasma* species is recommended.

NECROPSY FINDINGS

Grossly, diffuse fibrosis and granulomatous lesions containing pus are present in the mammary tissue. The lining of the milk ducts and the teat sinus is thick and roughened. On histological examination the granulomatous nature of the lesions is evident. Metastatic pulmonary lesions have been found in a few long-standing cases.

Samples for confirmation of diagnosis

- Mycoplasmology – chilled mammary tissue, regional lymph node (special media)
- Histology – fixed mammary tissue.

DIFFERENTIAL DIAGNOSIS

A presumptive diagnosis can be made based on the clinical findings, but laboratory confirmation by culture of the organism is desirable. The facts that the organism does not grow on standard media and that other pathogenic bacteria are commonly present often lead to errors in the laboratory diagnosis unless attention is drawn to the characteristic field findings.

TREATMENT

The majority of *M. bovis* strains isolated from cattle are susceptible in vitro to fluoroquinolones, florfenicol and tiamulin.[20,21] Approximately half of the isolates are susceptible to spectinomycin, tylosin and oxytetracycline, and very few isolates are susceptible in vitro to gentamicin, tilmicosin, ceftiofur, ampicillin, or erythromycin.[20,21] The clinical relevance of these in vitro susceptibility data to treating mycoplasmal mastitis remains questionable.

Cows diagnosed with mycoplasmal mastitis should be considered to be infected for life. None of the commonly used antimicrobial agents appear to be effective and oil–water emulsions used as intramammary infusions appear to increase the severity of the disease. Parenteral treatment with oxytetracycline (5 g intravenously, daily for 3 days) has been shown to cause only temporary improvement. A mixture of tylosin 500 mg and tetracycline 450 mg used as an infusion cured some quarters.[22] Unless treatment is administered very early in the course of the disease, the tissue damage has already been done.

CONTROL

Prevention of introduction of the disease into a herd appears to depend upon avoidance of introductions, or isolating introduced cows until they can be checked for mastitis. A popular biosecurity recommendation is to culture the milk of all replacement cows for *M. bovis*, but the sensitivity and specificity of milk culture in cows with subclinical infections appears to be low. The disease spreads rapidly in a herd and affected animals should be culled immediately or placed in strict isolation until sale. Eradication of the disease can be achieved by culling infected cows identified by culture of milk and nasal swabs, especially at drying off and calving. When eradication is completed the bulk tank milk SCC is the best single monitoring device to guard against reinfection. An alternative program recommended for large herds is the creation of an infected subherd that is milked last. There appears to be merit in the frequent culturing of bulk milk samples as a surveillance strategy for problem herds and areas. Frequent culturing overcomes the poor sensitivity of bulk tank milk culturing. Cows with infected quarters are segregated into the subherd and cows developing clinical illness or decreased milk yield are culled.[23]

Intramammary infusions must be carried out with great attention to hygiene and preferably with individual tubes rather than multidose syringes. Most commercial teat dips are effective in control. Use of disposable latex gloves with disinfection of the gloved hands between cows may minimize transmission at milking.

Vaccination is a possible development but is unlikely to be a satisfactory control measure because the observed resistance of a quarter to infection after a natural clinical episode is less than 1 year. A *M. bovis* bacterin is commercially available in the USA that contains multiple strains of *M. bovis*. Autogenous bacterins have also been made for specific herds; however, no vaccine has proven efficacy for preventing, decreasing the incidence of, or decreasing the severity of clinical signs of mycoplasmal bovine mastitis.[24]

Mycoplasma are sensitive to drying and osmotic changes, but more resistant than bacteria to the effects of freezing or thawing. Amputating the teats of affected quarters may result in heavy contamination of the environment and is not recommended. Because *M. bovis* can cause respiratory disease, otitis media/interna and arthritis in calves, all colostrum and waste milk fed to calves should be pasteurized.

CORYNEBACTERIUM BOVIS

ETIOLOGY

Corynebacterium bovis is a common and very contagious pathogen that is most commonly associated with subclinical infection. However, *C. bovis* has been cultured from dairy cattle with clinical mastitis in 1.7% of cases[1] and, in a herd that had controlled contagious mastitis pathogens, *C. bovis* was the only pathogen isolated in 22% of clinical mastitis episodes.[2] There is considerable debate about the significance of *C. bovis* infections for mammary gland health and cow productivity. For this reason, *C. bovis* is classified as a **minor pathogen**.

EPIDEMIOLOGY

The main reservoir of infection appears to be infected glands and teat ducts, and *C. bovis* spreads rapidly from cow to cow in the absence of adequate teat dipping. *C. bovis* is extremely contagious and the duration of intramammary infection is long (many months). The prevalence of *C. bovis* is typically low in herds using an effective germicidal teat dip, good milking hygiene and dry cow therapy.

In vivo and in vitro studies have demonstrated that the bacteria has a predilection for the streak canal, and this predilection has been associated with a requirement for lipids (possibly in the keratin plug) for growth.[3] It is possible that *C. bovis* infection in the streak canal may compete with ascending bacterial infections for nutrients and thereby decrease the new intramammary infection rate. Alternatively, the mild increase in SCC associated with *C. bovis* infection might increase the ability of the quarter to respond to a new intramammary infection.

Intramammary infection with a minor pathogen induces a higher than normal SCC and thereby increases the resistance of the colonized quarter to invasion by a major pathogen. In particular, the lowest rate of intramammary infection with major pathogens is observed in quarters infected with *C. bovis*.[4]

CLINICAL FINDINGS

An intramammary infection with *C. bovis* is infrequently associated with clinical disease but usually causes a moderate increase in the SCC and a small increase in the CMT score. Milk production losses are usually not detectable, and the mastitis is typically a thicker than normal milk (abnormal milk); occasional cases also have a large firm gland (abnormal gland).[2] There are clear herd to herd differences in the apparent clinical pathogenicity of *C. bovis*, suggesting that strains of different virulence are present.

TREATMENT

C. bovis is very susceptible to penicillin, ampicillin, amoxicillin, cephapirin, and erythromycin, and most other commercially available intramammary infusions. There is no need for parenteral treatment. The duration of infection is prolonged (months) in animals not treated with antimicrobial agents.

CONTROL

Long-term intensive programs of teat dipping and dry cow therapy will markedly reduce the prevalence of *C. bovis*. Because of its status as a minor pathogen, specific control measures (such as vaccination) are not indicated.

Mastitis of cattle associated with teat skin opportunistic pathogens

COAGULASE-NEGATIVE STAPHYLOCOCCI

Because of the intense investigation of coagulase positive staphylococcal mastitis (*S. aureus*), coagulase-negative staphylococcal intramammary infections have come under closer scrutiny and are now among the most common bacteria found in milk, especially in herds in which the major pathogens have been adequately controlled. There is considerable debate about the significance of these pathogens for the mammary gland and for cow productivity. For this reason, these pathogens are classified as **minor pathogens**.

ETIOLOGY

Coagulase-negative staphylococci are common but minor contagious pathogens that include *Staphylococcus epidermidis, S. hyicus, S. chromogenes, S. simulans,* and *Staphylococcus warneri* that are normal teat skin flora, and *Staphylococcus xylosus* and *Staphylococcus sciuri* that come from an uncertain site.

EPIDEMIOLOGY

Coagulase-negative staphylococci are teat skin opportunistic pathogens and cause mastitis by ascending infection via the streak canal. Coagulase-negative staphylococci appear to have a protective effect against colonization of the teat duct and teat skin by *S. aureus* and other major pathogens,[1] with the exception of *E. coli* and the environmental streptococci.

Studies in the US found that 20–70% of heifer quarters are infected before parturition with coagulase-negative staphylococci,[2,3] but these infections are usually eliminated spontaneously or with antimicrobial therapy during early lactation. A survey of the prevalence and duration of intramammary infection in heifers in Denmark in the peripartum period found *S. chromogenes* in 15% of all quarters before parturition, but this decreased to 1% of all quarters shortly after parturition.[2] In Finland, coagulase-negative staphylococci are the most commonly isolated bacteria from milk samples of heifers with mastitis.[4] Infections with *S. simulans* and *S. epidermidis* occurred in 1–3% of quarters both before and after parturition.[2] Infection with *S. simulans* persisted in the same quarter for several weeks, but intramammary infections with *S. epidermidis* were transient.

Coagulase-positive *S. hyicus* and *Staphylococcus intermedius* have been isolated from some dairy herds and can cause chronic, low-grade intramammary

infection and be confused with *S. aureus*.[5] The prevalence of infection with *S. hyicus* was 0.6% of all cows and 2% of heifers at parturition; the prevalence of infection of *S. intermedius* was less than 0.1% of cows.

CLINICAL FINDINGS

Coagulase-negative staphylococci are usually associated with mild clinical disease (abnormal secretion only, occasionally abnormal gland) and are commonly isolated from mild clinical cases of mastitis and subclinical infections. For example, *Staphylococcus* spp. have been cultured from dairy cattle with clinical mastitis in 29% of cases,[6] and subclinical infections usually induce a moderate increase in SCC.

CLINICAL PATHOLOGY

Intramammary infections by minor pathogens such as coagulase-negative staphylococci result in a higher than normal SCC and thereby increase the resistance of the colonized quarter to invasion by a major pathogen.[7] Although these bacteria are capable of causing microscopic lesions, they are not nearly as pathogenic as *S. aureus*,[8] and necropsy reports are lacking.

TREATMENT

Spontaneous cure is common. Coagulase-negative staphylococci, including *S. chromogenes, S. hyicus* and others, are very susceptible to penicillin, ampicillin, amoxicillin, clavulanic acid, cephapirin, erythromycin, gentamicin, potentiated sulfonamides and tetracyclines. In a study of 139 cases of subclinical coagulase-negative staphylococcal mastitis in New York, the bacteriological cure rates of commercially available intramammary infusions were similar to that of untreated controls (72% bacteriological cure), with the following bacteriological cure rates: cephapirin (89%), amoxicillin (87%), cloxacillin (76%) and penicillin (68%).[9]

The use of a combination of novobiocin and penicillin, and cloxacillin as dry cow therapy for coagulase-negative staphylococci gave cure rates of over 90%.[10]

CONTROL

Implementation of a mastitis control program will be very effective in decreasing intramammary infection due to coagulase-negative staphylococci. Because of its status as a minor pathogen, specific control measures (such as vaccination) are not indicated.

Mastitis of cattle associated with common environmental pathogens

Environmental mastitis is associated with bacteria that are transferred from the environment to the cow rather than from other infected quarters. ***E. coli, Klebsiella* spp.** and **environmental streptococci** are the major pathogens causing environmental mastitis.

COLIFORM MASTITIS ASSOCIATED WITH *ESCHERICHIA COLI, KLEBSIELLA* SPECIES AND *ENTEROBACTER AEROGENES*

ETIOLOGY

Many different serotypes of *E. coli*, numerous capsular types of *Klebsiella* spp. (most commonly *K. pneumoniae*) and *Enterobacter aerogenes* are responsible for coliform mastitis in cattle. *E. coli* isolated from the milk of cows with acute mastitis cannot be distinguished as a specific pathogenic group on the basis of biochemical and serological test reactions. The incidence of antimicrobial resistance is also low in these isolates because they are opportunists originating from the alimentary tract, from which antimicrobial resistant *E. coli* are rarely found in adults. Other Gram-negative bacteria which are

Synopsis

Etiology Many different serotypes of *Escherichia coli*, numerous capsular types of *Klebsiella* spp. and *Enterobacter aerogenes*. These are commonly called coliform bacteria; other Gram-negative bacteria (such as *Pseudomonas aeruginosa*) can cause environmental mastitis but are not categorized as coliform bacteria.

Epidemiology Dairy cattle housed in total confinement or drylot; uncommon in pastured cattle. Most important mastitis problem in well managed, low-SCC herds. Quarter infection rate low at 2–4%. Incidence highest in early lactation. 80–90% of coliform infections result in clinical mastitis; 8–10% are peracute. Causes clinical mastitis rather than subclinical mastitis. Source of infection is environment between milkings, during dry period and prepartum in heifers. Isolates of *E. coli* are opportunists. Sawdust and shavings bedding contaminated with *E. coli* and *Klebsiella* spp. (particularly *K. pneumoniae*) major source of bacteria; much worse when wet (rainfall or high humidity). Coliform intramammary infection highest during 2 weeks following drying off and in 2 weeks prior to calving. Animal risk factors include:

- Low SCC
- Decrease of neutrophil function in periparturient cow
- High susceptibility in early lactation
- Contamination of teat duct
- Selenium and vitamin E status.

Outbreaks of coliform mastitis do occur, commonly associated with major change in management of the environment (introduction of sawdust for bedding may result in outbreaks of *Klebsiella* mastitis).

Clinical findings *Acute* – swelling of gland, watery milk with small flakes, mild systemic response, recovery in few days. *Peracute* – sudden onset of severe toxemia, fever, tachycardia, impending shock; cow may be recumbent. Quarter may or may not be swollen and warm, secretions thin and serous and contain very small flakes. May die in few days.

Clinical pathology Culture milk. Somatic cell count. Marked leukopenia, neutropenia and degenerative left shift. Bacteremia may occur, particularly in severely affected cattle.

Necropsy findings Edema, hyperemia, hemorrhages and necrosis of mammary tissue. Major changes in teat and lactiferous sinuses and ducts; invasion of organism into parenchyma not a feature of *E. coli*.

Diagnostic confirmation. Culture of organism from milk and high SCC.

Differential diagnosis

- Parturient hypocalcemia paresis
- Carbohydrate engorgement lactic acidosis

Other causes of acute and severe mastitis (must culture milk):

- Environmental streptococci
- *S. aureus* and *S. agalactiae*

Treatment Must consider status and requirements for each case based on severity. Use of antimicrobial agents is indicated in moderately to severely affected animals; efficacy uncertain in mild cases. Some infections become persistent if antibiotics are not administered. Severely affected cattle also need supportive fluid and electrolyte therapy (such as hypertonic saline), and possibly NSAIDs for endotoxemia.

Control Manage outbreaks by examination of environment. Improve sanitation and hygiene. Regular cleaning of barns. Dry bedding. Avoid crowding. Keep dry cows on pasture if possible. Replace sawdust and shavings with sand for bedding. Emphasize premilking hygiene, including premilking germicide teat dipping and keep cows standing for at least 30 minutes after milking. Core lipopolysaccharide antigen vaccine in dry period and early lactation to reduce incidence of clinical mastitis due to Gram-negative bacteria.

not categorized as coliforms but can cause mastitis include *Serratia*, *Pseudomonas*, and *Proteus* spp.

EPIDEMIOLOGY

Occurrence of clinical mastitis

The occurrence of coliform mastitis has increased considerably in recent years and is a cause for concern in the dairy industry and amongst dairy practitioners. Coliform mastitis occurs worldwide and is most common in dairy cattle that are housed in total confinement during the winter or summer months. Where cows are kept in total confinement in a drylot, outbreaks of coliform mastitis may occur during wet, heavy rainfall seasons. The disease is uncommon in dairy cattle that are continuously in pasture but it has been reported in pastured dairy cattle in New Zealand.

In contrast to contagious mastitis, environmental mastitis associated with coliform bacteria is primarily associated with clinical mastitis rather than subclinical mastitis. Clinical mastitis associated with environmental pathogens (including the environmental streptococci) is now the most important mastitis problem in well managed, low-SCC herds. In a survey of the incidence of clinical mastitis and distribution of pathogens in dairy herds in the Netherlands, the average annual incidence was 12.7 quarter cases per 100 cows per year. The most frequent isolates from clinical cases were *E. coli* (16.9%), *S. aureus* (14.4%), *S. uberis* (11.9%) and *S. dysgalactiae* (8.9%).[1]

The incidence of clinical coliform mastitis is highest early in lactation and decreases progressively as lactation advances.[2] The rate of intramammary infection is about four times greater during the dry period than during lactation. The rate of infection is also higher during the first 2 weeks of the dry period and during the 2 weeks before calving. 80–90% of coliform infections results in varying degrees of clinical mastitis in the lactating cow; approximately 8–10% of coliform infections result in peracute mastitis, usually within a few days after calving. The disease also occurs commonly in herds that concentrate calving over a short period of time.

Prevalence of infection

The prevalence of both intramammary infection and the incidence of clinical mastitis due to coliform bacteria has increased, particularly in dairy herds with a low prevalence of infection and incidence of clinical mastitis due to *S. aureus* and *S. agalactiae* as a result of an effective mastitis control program. Compared to other causes of mastitis, coliform infections are relatively uncommon and, in data based on herd surveys, the percentage of quarters infected with these pathogens is low. The percentage of quarters infected at any one time is generally low, at about 2–4%.

In the UK, about 0.2% of quarters of cows may be infected at any one time.[3] Surveillance of a dairy herd in total confinement in the USA indicated that infection with coliform bacteria by either day of lactation or day of the year never exceeded 3.5% of quarters, and this maximum was reached on the day of calving. However, coliform infections may cause 30–40% of clinical mastitis episodes. In herds with a problem, up to 8% of cows have been infected with coliform bacteria, and 80% of the cases of clinical mastitis may be due to coliform infections.[4]

Duration of infection

Coliform intramammary infections are usually of short duration. Over 50% last less than 10 days; about 70% less than 30 days; and only 1.5% exceed 100 days in duration.

Source of infection and mode of transmission

The primary reservoir of coliform infection is the dairy cow's environment (environmental pathogen); this is in contrast to the infected mammary gland, which is the reservoir of major contagious pathogens (*S. aureus* and *S. agalactiae*) and the main reservoir of infection in cattle with *M. bovis*. Exposure of uninfected quarters to environmental pathogens can occur at any time during the life of the cow, including during milking, between milkings, during the dry period and before calving in heifers.

Morbidity and case fatality

In dairy herds with low bulk tank milk SCCs the average herd incidence of clinical mastitis is 45–50 cases per 100 cows annually, with coliforms isolated from 30–40% of the clinical cases. This is similar to an average incidence of 15–20 cases of coliform mastitis per 100 cows in herds with low bulk tank milk SCCs.[5] Other observations indicate that the number of clinical cases of coliform mastitis varies from 3 to 32 per 100 cows per year but the average incidence in dairy herds can be as low as 6–8 per 100 cows per year.

Coliform mastitis is one of the most common causes of fatal mastitis in cattle. The case fatality rate from peracute coliform mastitis is commonly high and may reach 80% in spite of intensive therapy. Outbreaks of the disease can occur with up to 25% of recently calved cows affected within a few weeks of each other.

Risk factors

Pathogen risk factors

The isolates of *E. coli* from bovine mastitic milk are simply opportunist pathogens.[6] The isolates that cause coliform mastitis possess lipopolysaccharides (endotoxin), which form part of the outer layer of the cell wall of all Gram-negative bacteria. Coliform bacteria isolated from the milk of cows or from their environment have different degrees of susceptibility to the bactericidal action of bovine sera, with almost all the isolates that cause severe mastitis being serum-resistant.[7] Serum-sensitive organisms are unable to multiply in normal glands because of the activity of bactericidins reaching milk from the blood. Of the strains of *E. coli* isolated from cases of mastitis in cattle in England and Wales, only those that were serum-resistant were re-isolated from expressed milk following intramammary inoculation of lactating cows. Other observations indicate that serum-resistant coliforms have no selected advantage over serum-susceptible coliforms in naturally occurring intramammary infections. There are also somatic and capsular factors of coliforms that affect resistance to bovine bactericidal activity. Strains of *Klebsiella* that cause mastitis are also resistant to bovine serum. The fibronectin binding property of *E. coli* from bovine mastitis may be an important virulence factor that allows the organism to adhere to the ductular epithelium.

Environmental risk factors

All the environmental components that come in contact with the udder of the cow are considered potential sources of the organisms. The coliform bacteria are opportunists, and contamination of the skin of the udder and teats occurs primarily between milkings when the cow is in contact with contaminated bedding rather than at the time of milking. Feces, which are a common source of *E. coli*, can contaminate the perineum and the udder directly or indirectly through bedding, calving stalls, drylot grounds, udder wash water, udder wash sponges and cloth rags, teat cups and milkers' hands. Cows with chronic coliform mastitis also provide an important source of bacteria, and direct transmission probably occurs through the milking machine. Inadequate drying of the base of the udder and the teats after washing them prior to milking can lead to a drainage of coliform-contaminated water down into the teat cups and subsequent infection.

Bedding

Sawdust and shavings used as bedding that are contaminated and harbor *E. coli*, and particularly *K. pneumoniae*, are major risk factors for coliform mastitis. Cows bedded on sawdust have the largest teat end population of total coliforms and klebsiellae; those bedded on shavings have an intermediate number and those

on straw have the least. Experimentally, the incubation of bedding samples at 30–44°C (86–111°F) resulted in an increase in the coliform count; at 22°C (71°F) the count was maintained, and at 50°C (122°F) the bacteria were killed. Wet bedding, particularly sawdust and shavings, promotes the growth of coliform bacteria, especially *Klebsiella* spp.

The relationship between the bedding populations of Enterobacteriaceae was studied over a 12-month period in a dairy herd. The analyses revealed that rainfall bedding populations of *E. coli* and coliform mastitis incidence were statistically independent, while there was a strong association between rainfall and *K. pneumoniae* bedding populations and the incidence of *K. pneumoniae* mastitis. The lack of an association between bedding population of *E. coli* and coliform mastitis, along with the observation that cows are most susceptible immediately after parturition, suggest that the ability of the bacteria to penetrate the streak canal may be a factor of resistance in the cow and not a characteristic of the organism. Also, it appears that the cow in early lactation is not as susceptible to *K. pneumoniae* as to *E. coli*.

The ability of several different bedding materials to support the growth of environmental pathogens has been outlined under controlled conditions. Bedding materials vary in their ability to support growth of different pathogens, and under barn conditions it appears that high bacterial counts are influenced by factors more complex than type of bedding alone. Even clean damp bedding may support bacterial growth.

High populations of coliform bacteria on the teat end, unless accompanied by actual chronic quarter infection, are probably transitory and represent recent environmental contamination that would usually be eliminated by an effective sanitation program at milking time. However, any teat skin population, whether associated with infection in another quarter, from contaminated teat cup liners or from other environmental sources, must be considered as a potential source of new infection.

Animal risk factors

Factors that influence the susceptibility of cows to coliform mastitis include the SCC of the milk, the stage of lactation and the physiological characteristics and defense mechanisms of the udder (particularly the speed of neutrophil recruitment), teat characteristics, and the ability of the cow to counteract the effects of the endotoxins elaborated by the organisms.

Somatic cell count

Experimentally, an SCC of 250 000 cells/mL in the milk of a quarter may limit significant growth of bacteria and development of mastitis when small inocula of coliform organisms are experimentally introduced into the gland.[7] Somatic cell counts of 500 000 cells/mL provided complete protection.[8] Thus cows in herds with a low incidence of streptococcal and staphylococcal mastitis have a low milk SCC and are more susceptible to coliform mastitis. Dairy herds with low herd bulk tank milk SCCs may have a greater incidence of severe toxic mastitis than herds with higher counts.[8]

Neutrophil recruitment and function

Increased susceptibility to coliform mastitis in the periparturient cow is primarily due to impaired neutrophil recruitment to the infected gland.[9] In fatal cases of peracute mastitis in cows within 1 week after parturition there may be large numbers of bacteria in mammary tissues and an absence of neutrophilic infiltration. Other observations indicate a high correlation between poor preinfection chemotactic activity of blood neutrophils and susceptibility to intramammary *E. coli* challenge exposure.[10] Experimentally, in periparturient cows the inability to recruit neutrophils rapidly into the mammary gland following intramammary infection is associated with an overwhelming bacterial infection and peracute highly fatal mastitis.[9] The periparturient cows are unable to control bacterial growth during the first few hours after bacterial inoculation and consequently the bacterial load is much higher when neutrophils finally enter the milk. The lack of neutrophil mobilization could be due to:

- Failure to recognize bacteria
- Lack of production of inflammatory mediators
- A defect in the ability of the cells to move into the milk compartment.

In ketonemic cows, experimental *E. coli* mastitis is severe, regardless of preinfection chemotactic response.[11]

High levels of cytokines are present in the milk of cows that lack the ability to recruit leukocytes, which is evidence that the cells recognized the bacteria.[9] All of this suggests that the critical defect is in the neutrophils of the periparturient cow. Certain cell-surface receptors on leukocytes may be important defense mechanisms against *E. coli* polysaccharides.[12] Bovine mammary neutrophils possess cell surface C14 and C18 and lectin–carbohydrate interactions mediating nonopsonic phagocytosis of *E. coli*, which may be important in controlling these infections.

Selenium and vitamin E status

The positive effects of supplemental vitamin E and selenium on mammary gland health are well established. An adequate dietary level of selenium enhances the resistance of the bovine mammary gland to infectious agents. Experimentally induced intramammary *E. coli* infections are significantly more severe, and of longer duration, in cows whose diets have been deficient in selenium than in cows whose diets were supplemented with selenium. The enhanced resistance is thought to be associated with a more rapid diapedesis of neutrophils into the gland of cows fed diets supplemented with selenium, which limits the numbers of bacteria in the gland during infection.

Vitamin E is especially important to mammary gland health during the peripartum period. Plasma concentrations of alpha-tocopherol begin to decline at 7–10 days before parturition, reach nadir at 3–5 days after calving and then start increasing.[13] When plasma concentrations are maintained during the peripartum period by injections of alpha-tocopherol, the killing ability of blood neutrophils is improved.[14] The supplementation of the diets of dry cows receiving 0.1 ppm of selenium in their diets with vitamin E at 1000 IU/d reduced the incidence of clinical mastitis by 30% compared to cows receiving 100 IU/d. The reduction was 88% when cows were fed 4000 IU/d of vitamin E during the last 14 days of the dry period.[2]

There are also marked effects of dietary selenium on milk eicosanoid concentrations in response to an *E. coli* infection, which may be associated with the altered pathogenesis and outcome of mastitis in a selenium-deficient state.[15]

Stage of lactation and defense mechanism

Coliform mastitis occurs almost entirely in the lactating cow and rarely in the dry cow. The disease can be produced experimentally in lactating quarters much more readily than in dry quarters.[7] The difference in the susceptibility may be due to the much higher SCCs and lactoferrin concentrations in the secretion of dry quarters than in the milk of lactating quarters. Cows with known uninfected quarters at drying off may develop peracute coliform mastitis at calving, suggesting that infection occurred during the dry period. New intramammary infections can occur during the nonlactating period, especially during the last 30 days, remain latent until parturition and cause peracute mastitis after parturition.

The **rate of coliform intramammary infection** is highest during the 2 weeks following drying off and in the 2 weeks before calving. The fully involuted mammary gland appears to be highly resistant to experimental challenge by *E. coli* but it becomes susceptible during the immediate

prepartum period. More than 93% of *E. coli* intramammary infection associated with the nonlactating period originated during the second half of that period.[16]

Several physiological factors may influence the level of resistance of the nonlactating gland to coliform infection. The rate of new intramammary infection is highest during transitions of the mammary gland from lactation to involution and during the period of colostrum production to lactation. There can be a sixfold increase in coliform infections from late lactation to early involution but 50% of these new infections do not persist into the next lactation. Also, the rate of spontaneous elimination of minor pathogens is high during the nonlactating period. The difference in susceptibility or resistance to new intramammary infection may be due, in part, to changes in concentration of lactoferrin, IgG, bovine serum albumin and citrate, which are correlated with in vitro growth inhibition of *K. pneumoniae, E. coli*, and *S. uberis*.

There is also a slower increase in polymorphonuclear neutrophils in milk after new intramammary infection in early lactation than in mid and late lactation. These conditions may explain the occurrence of peracute coliform mastitis in early lactation. This suggests latent infection or, more likely, that infection occurred at a critical time just a few days before and after calving, when the streak canal became patent and the population of coliform bacteria on the teat end was persistently high because the cow was not being milked routinely and thus would not be subjected to udder washing and teat dipping. Coliform bacteria can pass through the streak canal unaided by machine milking – this may be associated with the high incidence of coliform mastitis in high-yielding older cows, which may have increased patency of the streak canal with age.

Newly calved cows can be classified as moderate or severe responders to experimentally induced coliform mastitis. Following infection there is a diversity of responses varying from very mild to very acute inflammation of the gland and evidence of systemic effects such as fever, anorexia and discomfort.[17] Losses in milk yield and compositional changes are most pronounced in inflamed glands and, in severe responders; milk yield and composition did not return to preinfection levels. It is proposed that the severe and long-lasting systemic disturbances in severe responders can be attributed to absorption of endotoxin.

In summary, coliform mastitis is more severe in periparturient cows because of inability to slow bacterial growth early after infection. This inability is associated with low SCC before challenge and slow recruitment of neutrophils.[9] There may also be deficits in the ability of leukocytes to kill bacterial pathogens.

Contamination of teat duct

The sporadic occurrence of the disease may be associated with the use of contaminated teat siphons and mastitis tubes and infection following traumatic injury to teats or following teat surgery. Several teat factors are important in the epidemiology of *E. coli* mastitis. It is generally accepted that *E. coli* is common in the environment of housed dairy cows and that mastitis can be produced experimentally by the introduction of as few as 20 organisms into the teat cistern via the teat duct. However, the processes by which this occurs under natural conditions are unknown. *E. coli* does not colonize the healthy skin of the udder or the teat duct.

The teat duct normally provides an effective barrier to invasion of the mammary gland by bacteria. As a result of machine milking there is some relaxation of the papillary duct, followed by gradual reduction in the duct lumen diameter in the 2 hours following milking. This period of relaxation after milking may be a risk factor predisposing to new intramammary infection.

Experimental contamination of the teat ends with a high concentration of coliform bacteria by repeated wet contact, however, does not necessarily result in an increase in new intramammary infection. The experimental application of high levels of teat end contamination with *E. coli* after milking repeatedly led to high rates of intramammary infection, which suggests that penetration of the teat duct by *E. coli* occurs in the period between contamination and milking. Milking machines that produce cyclic and irregular vacuum fluctuations during milking can result in impacts of milk against the teat ends, which may propel bacteria through the streak canal and increase the rate of new infections due to *E. coli* and outbreaks of peracute coliform mastitis.

Downer cows

Cows affected with the downer cow syndrome following parturient paresis, or recently calved cows that are clinically recumbent for any reason, are susceptible to coliform mastitis because of the gross contamination of the udder and teats with feces and bedding.

Other defense factors

Lactoferrin and citrate

The failure of lactoferrin within mammary secretions to prevent new infections and mastitis near and after parturition may be due to a decrease in lactoferrin before parturition. Lactoferrin normally binds the iron needed by iron-dependent organisms; these multiply excessively in the absence of lactoferrin. Also, citrate concentrations increase in mammary secretions at parturition and may interfere with iron-binding by lactoferrin.

Serum antibody to *E. coli*

The serum IgG_1 ELISA titers recognizing core lipopolysaccharide antigens of *E. coli* J5 in cattle are associated with a risk of clinical coliform mastitis. Titers less than 1:240 were associated with 5.3 times the risk of clinical coliform mastitis. Older cattle in the fourth or greater lactations were also at greater risk, even though titers increased with age. There is a titer-independent age-related increase in clinical coliform mastitis. Active immunization of cattle with an Rc-mutant *E. coli* (J5) vaccine resulted in a remarkable decrease in the incidence of clinical coliform mastitis.[18]

PATHOGENESIS

After invasion and infection of the mammary gland, *E. coli* proliferates in large numbers and releases endotoxin on bacterial death or during rapid growth when excess bacterial cell wall is produced. Endotoxin causes a change in vascular permeability, resulting in edema and acute swelling of the gland and a marked increase in the number of neutrophils in the milk.[7] The neutrophil concentrations may increase 40–250 times and strongly inhibit the survival of *E. coli*.[7] This marked diapedesis of neutrophils is associated with the remarkable systemic **leukopenia** and **neutropenia** that occurs in peracute coliform mastitis. The severity of the disease is influenced by:

- The degree of the pre-existing neutrophils in the milk
- The rate of invasion and total number of neutrophils that invade the infected gland
- The susceptibility of the bacteria to serum bactericidins that are secreted into the gland
- The amount of endotoxin produced.[19]

Stage of lactation

The severity of disease is dependent on the stage of lactation. Experimental infection of the mammary gland of recently calved cows with *E. coli* produces a more severe mastitis when compared with animals in midlactation. This may be due to a delay in diapedesis of neutrophils into the mammary gland of recently calved cows. Furthermore, because of this delay there may be no visible changes in the milk for up to 15 hours after infection, but the systemic effects of the endotoxin released by the bacteria are evident in the cow (fever, tachycardia, anorexia, rumen

hypomotility or atony, mild diarrhea). The net result is endotoxemia, which persists as long as bacteria are multiplying and releasing endotoxin. This persistent endotoxemia is probably a major cause of failure to respond to therapy compared to the transient endotoxemia in the experimental inoculation of one dose of endotoxin.

Neutrophil response

The final outcome is highly dependent on the degree of neutrophil response.[20] If the neutrophil response is delayed and growth of the organisms is unrestricted, the high levels of toxin produced could cause severe destruction of udder tissue and general toxemia. If the animal responds quickly there is often little effect on milk yield because the injury is confined to the sinuses without involvement of secretory tissues.[7] The ability of the neutrophils to kill *E. coli* varies among cows. Experimental infection of the mammary gland of cows with *E. coli* results in the stimulation of a long-lasting opsonic activity for the phagocytosis and killing of the homologous strain of the organism by neutrophils. Thus it is not opsonic deficiency that is the problem in early lactation but rather a **failure of rapid migration of neutrophils into the gland cistern**.

The rapidity and efficiency of the neutrophil response are major factors in determining the outcome.[21] If the neutrophil response is rapid, clinical disease will be mild or go undetected, self-cure will occur and the cow returns to normal; the milk may be negative for the bacteria. This may be one important cause of an increase in the percentage of clinical mastitis cases in which no pathogens can be isolated from the milk. Failure of the cow to mount a significant neutrophil response results in the multiplication of large numbers of bacteria, the elaboration of large amounts of endotoxin and severe highly fatal toxemia. In these cases, bacteria are readily cultured from the milk. In less serious and nonfatal cases, the recruitment of neutrophils does not fail but is delayed; this results in acute clinical mastitis with progressive inflammation and permanent loss of secretory function. The bacteria are not always readily eliminated from the infected gland by the neutrophils. Coliform bacteria may remain latent in neutrophils and, in naturally occurring cases, it is not uncommon to be able to culture the organism from the mammary gland during and after both parenteral and intramammary antibacterial therapy.

Numbers of bacteria in milk

The numbers of bacteria in the milk also influence the outcome. If bacterial numbers exceed 10^6 cfu/mL, the ability of the neutrophil to phagocytose is impaired. If the bacterial count is less than 10^3 cfu/mL at 12 hours postinfection, the bacteria will be rapidly eliminated and the prognosis will be favorable. This response is seen as a subacute form of the disease with spontaneous self-cure. If the neutrophil response is slow or delayed, the cow will exhibit more severe signs of coliform mastitis due to toxemia. This is most common in recently calved cows and is characterized clinically by a serous secretion in the affected quarter that later becomes watery, fever, depression, ruminal hypomotility and mild diarrhea. The prognosis in these cases is unfavorable. These more severe forms of coliform mastitis usually occur after calving and in the first 6 weeks of lactation. Cows with coliform mastitis in mid to late lactation generally generate a rapid neutrophil response rate and their prognosis is likely to be favorable.

Experimental endotoxin-induced mastitis

In an attempt to further understand the pathogenesis of coliform mastitis, the effect of experimentally introducing *E. coli* endotoxin into the mammary gland has been examined. The intramammary infusion of 1 mg *E. coli* endotoxin induces acute mammary inflammation and transient, severe shock from which cows recover within 48–72 hours.[22] Udder edema is apparent within 2 hours but begins to subside in 4–6 hours. The SCC increases within 3–5 hours and at 7 hours the count is 10 times normal. A mild systemic reaction with a transient fever occurs in some cows. High concentrations of interleukin-1 and interleukin-6 are detectable in the milk of infused glands, beginning 3–4 hours after infusion.[23] Milk concentrations of bovine serum albumin are increased from baseline levels to peak levels within 2 hours, indicating increased vascular permeability induced by inflammatory mediators. The infusion of endotoxin into the teat cistern of cows induces a rapid local inflammatory response of short duration with an influx of neutrophils into the teat cistern.[24]

The intramammary infusion of endotoxin results in a sequential increase of immunoglobulin in milk whey and of phagocytosis of staphylococci by milk polymorphonuclear cells. This is consistent with spontaneous recovery of cows with acute coliform mastitis. Endotoxin infusion can also result in increases in arachidonic acid metabolites such as thromboxanes, and cytokines,[23] which may be involved in mediation of local quarter inflammation and the systemic signs observed in acute coliform mastitis. Histamine, serotonin, leukotrienes and arachidonic metabolites are also released following experimental *K. pneumoniae* mastitis. There is also a marked increase in prostaglandin concentrations, which indicates that they may play a role in the pathogenesis of endotoxin-induced mastitis and that the use of NSAIDs may be of value therapeutically.

In **peracute coliform mastitis**, severe toxemia with fever, shivering, weakness leading to recumbency in a few hours, and mild diarrhea are common and probably due to the absorption of large quantities of endotoxin. For many years it was thought that bacteremia did not occur in severe cases of coliform mastitis. However, **bacteremia is present in 32–48% of naturally occurring cases of coliform mastitis**.[25,26] In experimental endotoxemia in cattle there is profound leukopenia (neutropenia and lymphopenia), a mild hypocalcemia and elevation in plasma cortisol concentration. Hypocalcemia also occurs in naturally occurring cases and is thought to be due to decreased abomasal emptying rate associated with the endotoxemia. Experimentally infused endotoxin is detoxified very rapidly after absorption into the circulation.

In the acute form, the systemic changes are usually less severe than in the peracute form. However, in both forms, there is marked agalactia and the secretions in the affected quarter become serous and contain small flakes. Coliform organisms are not active tissue invaders, and in affected cattle that survive the systemic effects of the endotoxin the affected quarter(s) will usually return to partial production in the same lactation, and even full production in the next. However, in some cows that survive the peracute form, subsequent milk production in the current lactation is inadequate and cows are commonly culled.

A retrospective analysis of cows with clinical and laboratory features of coliform mastitis revealed that 60% returned to produce a milk-like secretion in the affected quarters in the current lactation and 40% did not. However, only 63% of the former group and 14% of the latter group remained in the herd and produced milk in the next lactation. Some cows were culled during the current lactation for low milk production and other reasons, some died and others were culled for mastitis. Of the original 88 cows with coliform mastitis, only 38 (43%) remained in the herd and produced milk in the next lactation.[27]

CLINICAL FINDINGS

Peracute coliform mastitis in the cow is a severe disease characterized by a sudden onset of agalactia and toxemia. The cow

may be normal at one milking and acutely ill at the next. Complete anorexia, severe depression, shivering and trembling, cold extremities (particularly the ears) and a fever of 40–42°C (104–108°F) are common. Within 6–8 hours after the onset of signs the cow may be recumbent and unable to stand. At that stage, the temperature may be normal or subnormal, all of which may superficially resemble parturient paresis. The heart rate is usually increased up to 100–120 beats/min, the rumen is static, there may be a mild watery diarrhea and dehydration is evident. Polypnea is common and in severe cases an expiratory grunt may be audible because of pulmonary congestion and edema.

The **affected quarter**(s) is usually swollen and warm but not remarkably so, and for this reason coliform mastitis may be missed on initial clinical examination. The cow may be severely toxemic, febrile and have cold extremities before there are visible changes in the mammary gland or the milk. The mammary secretion is characteristic, and changes from the consistency of watery milk initially to a thin, yellow serous fluid containing small meal-like flakes that are barely visible to the naked eye and are best seen on a black strip plate used for gross examination of milk. Additional quarters may become affected within a day or two of the initial infection.

The course of peracute coliform mastitis is rapid. Some cows will die in 6–8 hours after the onset of signs; others will live for 24–48 hours. Those that survive the peracute crisis will either return to normal in a few days or remain weak and recumbent for several days and eventually develop the complications associated with prolonged recumbency. Intensive intravenous fluid therapy may prolong the life of the cow for up to several days but significant improvement may not occur and eventually euthanasia may appear to be the desirable course of action.

Acute coliform mastitis is characterized by varying degrees of swelling of the affected gland and variable systemic signs of fever and inappetence. The secretions of the gland are watery to serous in consistency and contain flakes. Recovery with appropriate treatment usually occurs in a few days.

Accuracy of clinical diagnosis

Various diagnostic schemes that use clinical parameters to differentiate cows with clinical mastitis due to Gram-negative bacteria from those with clinical mastitis associated with Gram-positive bacteria have been developed.[28–34] In general, all these schemes predict Gram-negative bacteria as the cause if the milk is watery or yellow, if the mastitis episode occurs in summer and if rumen motility is decreased or absent. Experienced clinicians are not much better at predicting the causative agent than inexperienced clinicians. The conclusion from all of these studies is that **clinical observations do not allow sufficiently accurate prediction of clinical mastitis pathogens** and should not be used as the sole criteria for deciding whether cows are treated with antibiotics, or even the class of antibiotic to be administered.[34] Even the best predictive algorithm was wrong 25% of the time if the prevalence of Gram-negative mastitis was 50%, which is too high an error rate to be used to guide treatment. For comparison, flipping a coin to attribute the causative agent as being Gram-positive or Gram-negative is wrong only 50% of the time!

An increase in the ability of a positive test to predict a Gram-negative bacterial infection as the cause for a clinical mastitis episode is provided by examining for the presence of endotoxin in milk (sensitivity (Se) = 0.72; specificity (Sp) = 0.95),[35] whether the segmented neutrophil count is less than 35% of the total leukocyte count (Se = 0.87; Sp = 0.71),[36] whether the segmented neutrophil count is less than 3200 cells/μL (Se = 0.93; Sp = 0.89),[36] and by culturing on selective media (Se = 0.60; Sp = 0.98).[37] The endotoxin test is a cowside test (**Limast-test®**) that is commercially available in Scandinavia. The test takes 15 minutes to run on milk samples and requires at least 10^4–10^5 cfu of Gram-negative bacteria for a positive test result.[35] Assessment of the white blood cell count and differential count is widely available in veterinary practice but is not a cowside test and is therefore not ideal. Both the milk endotoxin test and blood neutrophil count have adequate sensitivity and specificity for use to guide treatment decisions.

Chronic coliform mastitis is characterized by repeated episodes of subacute mastitis, which cannot be readily clinically distinguished from other common causes of mastitis.

Subclinical coliform mastitis is characterized by the presence of coliform organisms in the milk samples of cows without clinical evidence of mastitis. The prevalence of intramammary infection in quarters with coliform bacteria is low relative to contagious mastitis pathogens, ranging from 0.9–1.2%.

CLINICAL PATHOLOGY

Culture of milk

Milk samples should be submitted for culture to identify the causative agent, but antimicrobial susceptibility testing has not been validated and is currently not recommended to guide treatment decisions.[38] In the peracute case, the milk samples will yield a positive culture. In less acute cases, the milk sample may be negative because the neutrophils have cleared the bacteria.

Somatic cell count and CMT scores

In the experimental disease the SCC of milk from the inoculated quarter ranges from 14 000 000–25 000 000 cells/mL at 5 hours after inoculation. The CMT on secretions from affected quarters is usually +3.

Hematology

In peracute coliform mastitis there is hemoconcentration, a marked leukopenia, neutropenia and a degenerative left shift due to the margination of large numbers of neutrophils in response to endotoxin. There is also a moderate lymphopenia, monocytopenia and thrombocytopenia.[36] If the degenerative left shift, leukopenia and neutropenia become worse on the second day after the onset of clinical signs, the prognosis is unfavorable. An improvement in the differential white count on the second day is a good prognostic sign.

Endotoxin presence in milk and plasma

A commercially available cowside test (Limast-test®) for endotoxin is available in Scandinavia. The test takes 15 minutes to run on milk samples and is able to detect the presence of endotoxin and therefore Gram-negative bacteria, but does not differentiate between *E. coli* and *K. pneumoniae*.

Serum biochemistry

The biochemical abnormalities observed in naturally occurring cases include uremia, high aspartate aminotransferase activity and strong ion (metabolic) acidosis in fatal cases, while in surviving cases there were decreased concentrations of sodium, potassium and chloride, and strong ion (metabolic) alkalosis.[25,36]

NECROPSY FINDINGS

There is edema and hyperemia of the mammary tissue. In severe cases hemorrhages are present and are accompanied by thrombus formation in the blood and lymphatic vessels; there is necrosis of the parenchyma.

A study of the progressive pathological changes in experimental and natural cases of *E. coli* mastitis in cows reveals that damage is most marked in the epithelium of the teat and lactiferous sinuses and diminishes rapidly towards the ducts. In hyperacute cases, the organisms are largely confined to the ductular and secretory lumen and there is

little invasion of the parenchyma, despite the presence of large numbers of organisms. In some cases there may be intense neutrophil infiltration, subepithelial edema and epithelial hyperplasia of the sinuses and large ducts. In hyperacute cases in the immediate postpartum period, infiltration of neutrophils may be negligible. There is now some evidence that bacteremia may occur in coliform mastitis.[25]

Samples for confirmation of diagnosis

- Bacteriology – chilled mammary tissue, regional lymph node
- Histology – formalin-fixed mammary tissue.

DIFFERENTIAL DIAGNOSIS

- **Peracute coliform mastitis** in cattle is characterized clinically by a sudden onset of toxemia, weakness, shivering, often recumbency, fever in the early stages followed by a normal temperature or hypothermia in several hours, and characteristic gross changes in the milk, which usually is watery and contains some particles barely visible to the unaided eye. The peracute form of the disease is most common in recently calved cows
- **Parturient hypocalcemia paresis** occurs in recently calved cows. The weakness and recumbency resembles peracute coliform mastitis but the marked increase in heart rate, and dehydration and mild diarrhea if present, are not characteristic of parturient paresis and should prompt further clinical examination, particularly of the udder. In the early stages of coliform mastitis the changes in the milk may be just barely visible. Those clinical findings which are most useful to predict peracute coliform mastitis include watery consistency of milk, shivering, firmness of udder, tachycardia, polypnea, fever, weakness and mastitis of less than 24 hours' duration.[31] A marked leukopenia and neutropenia are characteristic of coliform mastitis, whereas in parturient paresis there is usually a neutrophilia and stress leukon (neutrophilia, no left shift, lymphopenia, monocytosis and eosinopenia). The differential diagnosis of recumbency in the immediate postpartum period is discussed under parturient paresis
- **Carbohydrate engorgement lactic acidosis** causes rapid onset of weakness, recumbency, diarrhea, dehydration, and ruminal stasis and resembles the clinical findings of shock in peracute coliform mastitis. However, the rumen contains an excess of watery fluid and the pH is below 5
- **Acute coliform mastitis** cannot be accurately differentiated from all other common causes of acute mastitis with abnormal gland and abnormal milk, including the environmental streptococci *S. uberis and S. dysgalactiae*, and the contagious pathogens *S. aureus* and *S. agalactiae*. Culture of the milk is necessary

TREATMENT

The treatment of coliform mastitis in cattle has been controversial but recent studies have clarified the **important role that antimicrobial agents play in treating severely affected cattle**. Historically, the treatment of coliform mastitis was based on the principles of treating a bacterial infection with varying degrees of inflammation. A combination of broad-spectrum antimicrobial agents administered parenterally and by intramammary infusion, fluid and electrolyte therapy, frequent stripping out of the affected glands with the aid of oxytocin, and anti-inflammatory drugs have been used with varying degrees of success based on empirical and anecdotal experience. Only a handful of clinical trials have evaluated the efficacy of therapeutic agents used in naturally occurring cases of coliform mastitis, especially for the peracute form of the disease.

Most of the controversy has centered on the rational use of antimicrobial agents.[4] The use of antimicrobial agents for the treatment of coliform mastitis has been questioned for several reasons:

- Clinical signs are primarily due to the effects of endotoxin in the mammary gland, with formation of endogenous inflammatory mediators within the udder and their subsequent release into the systemic circulation[39]
- The severity of clinical signs are correlated with the number of bacteria in the affected gland
- Most mild cases of coliform mastitis (abnormal milk but normal gland and cow) are self-limiting and resolve without antimicrobial therapy. However, a small percentage of these mild clinical cases develop persistent infection
- There is speculation that the use of bactericidal antimicrobial agents may result in the bolus release of large quantities of lipopolysaccharides in the mammary gland associated with a rapid kill of bacteria, but this has not been observed in any study to date. In contrast, endotoxin release occurs from rapid bacterial growth alone, which will be prevented by administration of an effective antibiotic
- Many, but not all, of the broad-spectrum antimicrobial agents currently approved for use in lactating cattle do not result in high enough concentrations in the milk when given parenterally.

Most of the antimicrobial agents currently used for the treatment of coliform mastitis in lactating dairy cows are not approved for use in food-producing animals.[40] Because of this extralabel use and the lack of pharmacokinetic data for adequate withholding times, the risk of drug residues in milk and meat is increased.

The prognosis in the peracute form of the disease is unfavorable if severe clinical toxemia is present. Severe depression, weakness, diarrhea and dehydration, recumbency and a heart rate over 120 beats/min are indicators of an unfavorable prognosis. The successful treatment of peracute coliform mastitis requires the earliest possible action and clinical surveillance until recovery is apparent.

Treatment trials using antimicrobial agents and untreated controls

Treatment trials with **experimentally induced** coliform mastitis in cattle during lactation have failed, for the most part, to demonstrate efficacy of antimicrobial therapy. This is because all experimental models used to date do not accurately reproduce the naturally occurring disease,[41,42] and not because antibiotics are ineffective. Accordingly, treatment efficacy should be based on the results of randomized field trials. The major considerations for antimicrobial use in coliform mastitis include:

- Early administration in order to decrease the exposure of the cow to endotoxin
- Ensuring appropriate withholding periods for milk and meat
- The benefit–cost ratio.[5]

The antimicrobial susceptibilities of *E. coli* isolates from coliform mastitis vary considerably; drug susceptibility determination is not routinely recommended because the breakpoints have not been validated and the bacteria come from diverse sources in the environment.

Parenteral antimicrobial agents

Broad-spectrum antimicrobial agents should be administered parenterally to cattle with systemic signs of disease (abnormal cow), preferably by the intravenous route initially, followed by intramuscular administration to maintain appropriate plasma concentrations. The first reason to administer parenteral antibiotics is that the **severity of clinical signs is correlated with the numbers of bacteria in milk from the affected gland**.[43] The second main reason to administer parenteral antibiotics is to **combat bacteremia, which is present in 32–48% of severely affected cattle**.[25,26,44] Based on pharmacokinetic/pharmacodynamic values, the results of experimentally induced and naturally acquired infections, and in vitro antimicrobial susceptibility testing (if this has any relevance to in vivo susceptibility), most *E. coli* isolated from the mammary glands of cattle are theoretically susceptible to

third-generation cephalosporins (such as ceftiofur), fourth-generation cephalosporins (such as cefquinome), fluoroquinolones, gentamicin, amikacin, trimethoprim–sulfonamide and oxytetracycline.

- **Ceftiofur** is a third-generation cephalosporin that is resistant to beta-lactamases and has excellent in vitro activity against *E. coli*. When given parenterally to cows with experimental coliform mastitis, ceftiofur did not produce drug concentrations in milk above the reported minimum inhibitory concentrations for coliform bacteria.[45] However, when administered to cows with naturally occurring coliform mastitis, ceftiofur-treated cows (2.2 mg/kg BW intramuscularly every 24 h) were three times less likely to die or be culled from the herd and had more saleable milk than nontreated cattle[44]
- **Cefquinome** is a fourth-generation cephalosporin that is resistant to beta-lactamases and has excellent in vitro activity against *E. coli*. Parenteral cefquinome therapy (1 mg/kg BW intramuscularly twice at 24 h apart), with or without intramammary cefquinome (75 mg, three times at 12 h intervals), increased the bacteriological cure rate and significantly improved clinical recovery and return to milk production in experimentally induced *E. coli* mastitis[46]
- **Enrofloxacin**, a fluoroquinolone with excellent in vitro activity against *E. coli*, given intravenously initially then subcutaneously (5 mg/kg BW) was effective in treating experimentally induced *E. coli* mastitis.[47-49] In general, parenterally administered enrofloxacin increased the rate of *E. coli* clearance from the infected mammary gland
- **Gentamicin** has been used on a extralabel basis for the treatment of acute and peracute coliform mastitis because more than 90% of isolates from milk from affected cows are sensitive in vitro.[40] However, the parenteral administration of gentamicin at 2 g intramuscularly every 12 hours until the appetite improved to dairy cows with mastitis predicted to be associated with Gram-negative bacteria did not result in significant improvement compared to cows with similar mastitis that did not receive an antimicrobial or received erythromycin[19]
- **Trimethoprim–sulfadiazine** (trimethoprim 4 g, sulfadiazine 20 g, intramuscularly every 24 h for 3–5 d) is efficacious in treating naturally acquired cases of coliform mastitis. The recovery rate of cows with clinical mastitis due to coliform bacteria susceptible to sulfonamide–trimethoprim was 89% compared to 74% in cows infected with coliforms resistant to the combination given parenterally, combined with NSAIDs and complete milking of affected quarters several times daily.[50] Sulfadiazine or sulfamethazine (sulfadimidine) are preferred to sulfadoxine because the latter produces much lower milk concentrations after parenteral administration
- **Oxytetracycline** (16.5 mg/kg BW intravenously every 24 hours for 3–5 d), combined with intramammary cephapirin (200 mg) and supportive care (intravenous or oral fluids, flunixin meglumine, stripping of the mammary gland) was more effective in treating coliform mastitis than similar treatment without antibiotics in cattle with naturally acquired mastitis.

Intramammary antimicrobial agents

Intramammary preparations of antimicrobial agents can be infused into the affected quarters after they have been stripped out completely at the start and end of the day. The initial choice of antimicrobial will depend on previous experience of treatment efficacy in the herd.

- **Ceftiofur**: based on clinical response and the results of antimicrobial susceptibility testing of coliform isolates from cows with naturally occurring mastitis (if relevant to in vivo performance), ceftiofur is an excellent choice for intramammary infusion in suspected cases of coliform mastitis[51]
- **Gentamicin**: the intramammary infusion of 500 mg of gentamicin did not affect the duration or severity of experimentally induced coliform mastitis.[40] The numbers of *E. coli* in the milk after intramammary inoculation were not affected by the intramammary infusion of gentamicin, despite maintaining a mean minimal gentamicin concentration in milk of 181 μg/mL between dose intervals.[40] The infusion did not affect the body temperature or the magnitude and duration of the inflammatory process in the glands as measured by the SCCs and peak albumin and immunoglobulin concentrations in the milk. It should be noted that gentamicin is not approved for use in the treatment of bovine mastitis and in some jurisdictions is not approved for any use.

A study of the efficacy of intramammary antibiotic therapy for the treatment of naturally occurring clinical mastitis associated with environmental pathogens found no difference in the short-term clinical or bacteriological cure rates between quarters infused with 62.5 g amoxicillin every 12 hours for three milkings or 200 mg of cephapirin every 12 hours for two milkings, and those treated with 100 units of oxytocin intramuscularly every 12 hours immediately before milking for two or three milkings alone.[52] However, the cost per episode of mastitis associated with the use of cephapirin was higher than the other two treatments, partly because of the longer milk withdrawal time (96 h) associated with the drug. The percentage of relapses was higher for cows in the oxytocin treatment group, especially when the mastitis-associated pathogen was an environmental *Streptococcus* sp.[53]

Stripping of affected quarter

An artificial intramammary environment has shown that milking 12 times daily could lead to elimination of *E. coli*,[54] suggesting that frequent stripping would be an effective treatment. Indeed, stripping (augmented by oxytocin) is a popular but largely unsubstantiated recommendation for treating severe cases of coliform mastitis.

Oxytocin at 10–20 units per adult cow given intramuscularly, followed by vigorous hand massage and hourly stripping of the affected quarter, may assist in removing inflammatory debris. Oxytocin doses higher than this are not needed, and intravenous administration is not needed because oxytocin is rapidly absorbed when injected intramuscularly. Oxytocin can be repeated and used as long as an effect is obtained.

Effective removal of coliform bacteria and endotoxin will minimize their local effects in the mammary gland and decrease the systemic signs of endotoxemia. The main problems with stripping are the labor involved, the small volumes produced, the potential for creating additional pain and discomfort for the cow (and the producer when the cow kicks!) and potential contamination of the environment if the secretion is stripped on to the ground. The role of frequent stripping, if any, in the treatment of clinical mastitis remains to be determined.

Fluid and electrolyte therapy

Fluid and electrolyte therapy are essential for the treatment of acute and peracute

coliform mastitis in order to counteract the effects of the endotoxemia. Isotonic polyionic electrolyte solutions (such as Ringer's solution) are given at 80 mL/kg BW for the first 24 hours by continuous intravenous infusion, and at a slower rate than that over the following days. For a mature dairy cow (400–600 kg) a total of 32–48 L is therefore needed in the first 24-hour period, with 20 L given during the first 4 hours and the remainder over the next 20 hours. A favorable response is usually clinically evident in 6–8 hours. If the animal has not improved after 5 days of intensive fluid therapy (the 5-day rule for clinical improvement), the prognosis for survival is poor.

The large amounts of isotonic fluids and electrolytes which have been advocated and used are expensive to administer by continuous intravenous infusion and require monitoring over many hours. A possible alternative is the use of small volumes of hypertonic saline, which can be transported easily and administered rapidly. **Hypertonic saline** can be safely administered to cattle with endotoxin-induced mastitis.[55] Hypertonic saline (7.2% NaCl) is given intravenously at 4–5 mL/kg BW intravenously over 4–5 minutes followed by immediate access to drinking water.[56] The changes following administration of hypertonic saline include transient expansion of the plasma volume, hypernatremia and hyperchloremia.[56] The intravenous administration of hypertonic saline to clinically normal cows with access to water increases circulatory volume rapidly, induces slight strong ion (metabolic) acidosis and increases glomerular filtration rate.[57] Fluid therapy is covered in detail in Chapter 2.

Anti-inflammatory agents

NSAIDs are frequently administered as adjunctive therapy in coliform mastitis, particularly in the peracute form of the disease.[39] **Ketoprofen** is the only currently available NSAID with documented efficacy in naturally acquired cases of coliform mastitis.

Ketoprofen has been evaluated as adjunctive therapy for the treatment of acute clinical mastitis in dairy cows, most cases of which were associated with Gram-negative pathogens.[58] All cases were treated with 20 g sulfadiazine and 4 g trimethoprim intramuscularly followed by one-half dose daily until recovery. Ketoprofen was given at 2 g intramuscularly daily for the duration of the antimicrobial therapy. Recovery rates for the nonblind contemporary controls and the blind placebo controls were 84% and 71%, respectively. In the nonblind controlled ketoprofen and placebo-controlled ketoprofen treatment groups, recovery rates were 95% and 92%, respectively. The odds ratio (OR) of recovery was significantly high in the placebo-controlled study (OR = 6.8), and high but not significant in the nonblind controlled study (OR = 2.6). It was concluded that ketoprofen significantly improved recovery rate in clinical mastitis. A similar clinical field trial evaluating the efficacy of phenylbutazone and dipyrone for the treatment of mastitis caused mostly by coliforms revealed a beneficial effect but no difference between the efficacies of the two drugs.[59] Neither phenylbutazone nor dipyrone is permitted for use in lactating dairy cattle in the USA, but their use is permitted in some countries.

The anti-inflammatory effect of either flunixin meglumine or dexamethasone was evaluated compared to controls in experimentally induced coliform mastitis. Dexamethasone at 0.44 mg/kg intravenously and flunixin meglumine at 1.1 mg/kg intravenously were both given 2 hours after inoculation of the *E. coli*, which is essentially a pretreatment administration because clinical signs are not evident at this time. Flunixin meglumine was also administered once 8 hours after the initial dose. Dexamethasone reduced the rectal temperature and the mammary surface temperatures, and prevented further increase in rectal temperature above 39.2°C. The response to flunixin meglumine was less than expected, which suggested that a higher dose of 2.2 mg/kg may be necessary in lactating dairy cattle. The administration of flunixin meglumine at 2.2 mg/kg intramuscularly or flurbiprofen at 2 mg/kg intravenously before clinical signs appeared in experimental *E. coli* mastitis abolished the febrile response during the first 9 hours after infection and lessened the decrease in rumen motility. Carprofen, a long-acting NSAID, reduced the fever, tachycardia and udder swelling associated with *E. coli*-endotoxin-induced mastitis.[60] The long-acting properties of carprofen may be considered a therapeutic advantage over flunixin meglumine, which requires frequent dosing.

Combination therapy

Fluid and electrolyte therapy and flunixin meglumine, in combination and individually, have been evaluated in a 3-year study of a large number of cows with toxic mastitis.[61] Cows were allotted to one of three groups:

- Fluid therapy (45 L of intravenous isotonic electrolyte solution) and flunixin meglumine at 2 g
- Fluid therapy intravenously only
- Flunixin meglumine only.

All cases were treated with parenteral and intramammary antimicrobial agents, oxytocin and calcium borogluconate. There was no significant difference in the rate of survival between the treatment groups, and 54% of the cows survived.

CONTROL

The control of coliform mastitis is characteristically difficult, unreliable and frustrating. Several cases of fatal peracute coliform mastitis may occur in a herd of 100 cows during a period of a year, in spite of the existence of apparently excellent management. The general principles of mastitis control that have been effective for the control of *S. aureus* and *S. agalactiae* mastitis have been unsuccessful for the control of coliform mastitis because infection of the mammary gland occurs by direct contact with the environment, usually between milkings. For the control of coliform mastitis, the emphasis is on the prevention of new infection. Core lipopolysaccharide antigen vaccines are useful and are discussed below.

Management of outbreaks

When an outbreak of peracute coliform mastitis is encountered the following procedures are recommended in an attempt to prevent new cases:

- Culture milk samples and obtain a definitive etiological diagnosis (in other words, **put a name to the causative pathogen**)
- Examine the bedding for evidence of heavy contamination with coliform bacteria. If sawdust or wood shavings are being used, replace with sand, if possible, or change more frequently
- Conduct a general clean-up of the stall and lounging areas
- Improve premilking hygiene
- Examine milking machine function
- Allow cows access to fresh feed immediately after milking to ensure that they remain standing for at least 30 minutes to allow time for the streak canal to close.

Housing and environment

The normal presence of coliform bacteria in every aspect of the cow's environment must be recognized but every effort must be made to avoid situations that allow a build-up of bacterial numbers. This is especially important in dairy herds that have been on a mastitis control program, resulting in a high percentage of cows with a low SCCs in their milk, which increases their susceptibility to coliform mastitis. The overall level of sanitation and hygiene must be improved and maintained in these herds.

Bedding

Most coliform infections in periparturient cows occur very early in the dry period or just before calving, and so efforts to

prevent infection should be centered on these periods. Management of the dry cow environment may provide the best opportunity for prevention of infection. While no reliable recommendations are available, cows that are housed during part or all of the day or night should be bedded on **clean** and **dry** bedding and not overcrowded, to prevent heavy fecal contamination. When possible, dry and preparturient cows are best maintained on pasture. There is an urgent need for the determination of optimum space and bedding requirements for the lounging areas of dairy cows kept under loose housing. Bedding should be kept as dry as possible. Excessively wet bedding should be removed from the back one-third of the stalls daily and replaced with fresh bedding. The addition of lime may decrease bacterial growth. Sawdust and shavings harbor more coliform bacteria than straw, and require special attention. The buildup of high numbers of coliform bacteria in the bedding of cow cubicles can be controlled by the daily removal of the sawdust from the rear of the cubicle and rebedding with clean sawdust, which is usually of low coliform count. The use of a paraformaldehyde spray on sawdust bedding reduced the coliform count for 2–3 days but it returned to its pre-disinfection level in 7 days. When outbreaks of coliform mastitis are encountered that are possibly associated with heavily contaminated sawdust or shavings, the bedding should be removed immediately and replaced with clean, fresh, dry straw. The use of sawdust or shavings as bedding should be avoided if possible. Sand is now considered to be the 'gold standard' and the most suitable alternative.

Regular daily cleaning of barns

This is necessary to minimize contamination of teats. In free-stall and loose-housing dairy barns, every management technique available must be used to insure that cows do not defecate in their stalls and increase the level of contamination. This requires daily raking of the bedding in free-stall barns and adjusting head rails to insure that cows do not lie too far forward in the stall and to insure that they defecate in the alleyway.

In dairy herds that are confined for all or part of the year, the level of contamination usually increases as herd size increases; commonly the ventilation is inadequate. This leads to excessively humid conditions, which promote the development of coliform bacteria in wet bedding. This will require increased attention to sanitation and hygiene.

Milking procedures

Postmilking teat dipping with a disinfectant has little effect on reducing the incidence of coliform mastitis because contamination of the teats occurs between milkings rather than at milking. Thus, one logical approach to the control of coliform mastitis is to reduce environmental contamination. In the event of gross fecal contamination of the udder and teats, additional time and care will be required at milking time. Premilking udder preparation can significantly influence milk quality. Lowest bacterial counts in milk are observed when the teats of cows are cleaned with water followed by thorough drying with paper towels, or when a teat disinfectant is applied to the teats followed by drying with paper towels. In addition, premilking teat disinfection in association with good udder preparation reduces the rate of intramammary infections by environmental pathogens by about 51% compared with good udder preparation only.[62]

Premilking teat disinfection

Many dairy producers have now incorporated premilking teat disinfection into their mastitis control strategy, and many different teat dips are being used.[62] Premilking teat dips containing 0.25% iodine, 0.1% iodophor, 0.25% iodophor and 0.55% iodophor–1.9% linear-dodecyl benzene sulfonic acid have been evaluated and have provided consistent results. Premilking and postmilking teat disinfection, in association with good udder preparation, are significantly more effective in prevention of environmental pathogen intramammary infection than good udder preparation and postmilking teat disinfection. No chapping or irritation of teats was observed. However, premilking teat disinfection did not reduce the incidence of clinical mastitis.

Postmilking external teat sealant

A latex barrier teat dip that formed a physical seal between the teat and the environment reduced the incidence of new coliform intramammary infections during lactation. The efficacy of this barrier product was thought to be due to the persistency of the dip on teats between milkings; however, it was not consistently successful. A barrier teat dip containing 0.55% chlorhexidine was effective in reducing intramammary infection associated with both environmental and contagious pathogens. The incidence of *E. coli* intramammary infections was reduced but the incidence of *Serratia* spp. and *Pseudomonas* spp. was increased, while the incidence of environmental streptococcal intramammary infection was unchanged by using the experimental barrier dip compared with the results using a 1% iodophor dip.

Nutrition

Vitamin E or selenium deficiency decreases neutrophil chemotaxis into the mammary gland and decreases the intracellular killing of bacteria by neutrophils. It is therefore important to ensure that vitamin E and selenium intakes are adequate; this is best achieved by daily ingestion of 1000 IU vitamin E and 3 mg selenium for dry cows and daily ingestion of 400–600 IU vitamin E and 6 mg selenium for lactating cows.

Prevention of infection during dry period

Considerable movement of coliform bacteria can occur from the teat apex into the teat sinus in cows that are not being milked, and so cows that are due to calve should be kept on grass or moved into a clean area at least 2 weeks before calving, their udders and teats washed daily if necessary, and teat dipping with a teat disinfectant begun 10 days before calving. This is particularly necessary for older cows and those that are known to be easy milkers. The teats of those cows that are 'leakers' just before calving may have to be sealed with adhesive tape or collodion to minimize the chance of infection.

Recumbent cows

Cows that are recumbent and unable to stand (e.g. the downer cow) should be well bedded on clean dry straw; their udders should be kept clean and dry, and the teats should be dipped with a teat disinfectant. Strict hygiene must be practiced when using teat siphons and teat creams, and strict asepsis observed when doing teat surgery.

Milking machine

Irregular vacuum fluctuations in the milking machine may induce coliform mastitis in quarters exposed to a high level of contamination. The operation and sanitation of the milking machine, especially those parts in direct contact with the teats, must therefore be examined.

Vaccination

Core lipopolysaccharide antigen vaccine

The vaccination of cows during the dry period and early lactation with core lipopolysaccharide antigen vaccine (such as the Re mutant *Salmonella typhimurium* or the Rc mutant *E. coli* O111:B4 (J5 vaccine)) provides one tool to reduce the incidence and severity of clinical coliform mastitis.[63] These vaccines are available in the USA and are based on mutated Gram-negative bacteria with exposed core antigens of lipopolysaccharide. The core antigen (lipid A component) is uniform between bacterial species possessing lipopolysaccharide and is immunogenic. On theoretical grounds, the Re mutant (*S. typhimurium*) should provide better

protection than the Rc mutant (*E. coli* J5) because the lipid A component is more accessible to the immune system; however, comparative studies of vaccine efficacy have not been performed.

The Re and Rc mutant vaccines are protective against natural challenge to Gram-negative bacteria, and in most, but not all studies, **reduce the incidence and severity of clinical Gram-negative bacterial mastitis in lactating dairy cows**. In a prospective cohort study in two commercial dairy herds, during the first 90 days of lactation, cows vaccinated with *E. coli* J5 vaccine were at five times lower risk of developing clinical coliform mastitis than unvaccinated cows. This is corroborated with the observation that cows with naturally occurring serum IgG ELISA titers higher than 1:240 against the Gram-negative core antigen of *E. coli* J5 had 5.3 times lower risk of developing clinical coliform mastitis than cows with lower titers. Vaccination reduced the severity of clinical signs following intramammary experimental challenge with a heterologous *E. coli* strain.[64] In cows vaccinated with the J5 bacterin at drying off, at 30 days after drying off and within 48 hours after calving, and challenged 30 days after calving with a strain of *E. coli* known to cause mild clinical mastitis, the duration of intramammary infection and local signs of mastitis were reduced compared to controls.[63] Also, the concentrations of bovine serum albumin in milk 24 hours after challenge were greater in control cows than in vaccinated cows.

A partial budget analysis of vaccinating dairy cattle with one core lipopolysaccharide antigen vaccine (the Rc mutant of *E. coli* or J5 strain) indicated that herd vaccination programs were predicted to be profitable when more than 1% of cow lactations resulted in clinical coliform mastitis[65] and predicted to be profitable at all herd milk production levels.

Core lipopolysaccharide antigen vaccines have the potential to have deleterious effects because of their endotoxin content. For instance, vaccination of late lactation and dry cattle with the *S. typhimurium* Re mutant transiently decreased leukocyte and blood segmented neutrophil concentration, but the decrease is probably clinically insignificant.[66] This response is typical for endotoxin administration. Vaccination of lactating dairy cattle with the *E. coli* Rc mutant decreased milk production by 7% at the second and third milkings after vaccination.[67] These two studies indicate that core lipopolysaccharide antigen vaccines should not be administered to diseased cattle or to healthy cattle in hot and humid weather, because of their decrease in cardiovascular reserve. The vaccines should not be administered at the same time as other Gram-negative vaccines.

ENVIRONMENTAL STREPTOCOCCI

Etiology *Streptococcus uberis*, *Streptococcus dysgalactiae* spp. *dysgalactiae*, other *Streptococcus* spp. most commonly; occasionally *Enterococcus* spp.

Epidemiology Common cause of subclinical and clinical mastitis in herds and countries that have controlled contagious mastitis. Responsible for approximately one-third of all cases of clinical mastitis in herds without contagious pathogens. Rate of infection high during first 2 weeks following drying off and 2 weeks before calving. Duration of infection usually short (<8 d). Prevalence of infection at calving: 11% of cows and 3% of quarters. Bedding materials (high in straw bedding) most important source of environmental streptococci; bacteria can be isolated from many different feedstuffs and several locations on cow (teats, rumen, feces, saliva, lips, nares). Bacterial numbers low in sand, which is bedding of choice

Clinical findings Abnormal milk, abnormal gland, usually no systemic signs. Recovery in two to three milkings

Clinical pathology Culture of milk

Necropsy findings Not applicable

Diagnostic confirmation Culture bacteria from milk and milk SCC

Differential diagnosis Cannot differentiate from other causes of subacute and acute mastitis without culture of milk

Treatment Antimicrobial intramammary infusions increase bacteriological cure rate and decrease percentage of relapses. Intramammary antibiotics should be administered to all clinical cases of mastitis due to environmental streptococci

Control Decrease exposure of teat end to pathogens by attention to environment, dry bedding, sand for bedding, premilking hygiene and premilking germicide teat dipping. Dry cow therapy with penicillin G, cloxacillin, erythromycin and first-generation (cephapirin) or third-generation (ceftiofur) cephalosporins. Application of an internal teat sealant of bismuth subnitrate at dry-off may decrease new infection rate in dry period

ETIOLOGY

Streptococcus uberis and *Streptococcus dysgalactiae* spp. *dysgalactiae* and the enterococci are the most commonly isolated environmental streptococci from intramammary infections. Other uncommon environmental streptococci involved in bovine mastitis include *Streptococcus equi* var. *zooepidemicus*,[1] *Streptococcus viridans*, *S. equinus* (*S. bovis*), *Streptococcus* spp. group G, *Streptococcus pyogenes* and *Streptococcus pneumoniae*. Both *S. uberis* and *S. dysgalactiae* are widespread in the animal's environment and on the skin of the teats. Two genotypes of *S. uberis* (*S. uberis* = type I; *Streptococcus parauberis* = type II), with marked differences in their capacity to invade quarters and to cause mastitis, have been identified.[2,3] *Enterococcus* spp. are also a common cause of environmental intramammary infections.[4] The streptococcal species most commonly isolated from intramammary infections all hydrolyze esculin (*S. uberis*, *Streptococcus* spp., *Enterococcus* spp.).

EPIDEMIOLOGY

Occurrence and prevalence of infection

In countries where the prevalence of intramammary infections due to the contagious pathogens *S. agalactiae* and *S. aureus* has been reduced or eradicated, the proportion of intramammary infections associated with **environmental streptococci** has increased markedly; these organisms are a leading cause of both subclinical and clinical mastitis in dairy cattle worldwide.[4,5] *S. uberis* is now a common cause of intramammary infection occurring during the dry period, with most clinical cases occurring during the first part of lactation. Many infections acquired during the dry period persist to lactation and contribute to the incidence of clinical mastitis in early lactation. The rate of new infection due to environmental streptococci is elevated during the first 2 weeks following drying off and the 2 weeks prior to calving; the rate of new infections is greater during the first month of lactation than during the remainder of the lactation. Approximately 50% of new infections occur during the dry period and 50% in the early part of lactation. The rate of new infections during the dry period is about five times greater than during lactation.[4] Based on data from surveys of milk samples over a 10-year period, the point prevalence of infection of environmental streptococci was 4% of quarters and 12% of cows.[6] The percentage in heifers at calving is similar to that in cows. The prevalence of environmental streptococci isolation at drying off and calving was 2.5% and 3.0%.[6] Environmental streptococcal intramammary infections are usually short-lived (< 28 days), with only a small percentage becoming chronic.[4,7]

The most important change in the epidemiology of bovine mastitis over the past decade has been the rise in the importance of environmental pathogens, mainly causing clinical mastitis, relative to contagious pathogens. Remarkable increases in both the coliforms and environmental streptococci as causes of clinical mastitis have occurred.[5] The percentage of clinical cases of mastitis from which environmental streptococci can be isolated ranges from 14% in Ontario to 26% in the UK. When expressed as a percentage of clinical cases from which a major pathogen was isolated, environmental streptococci are isolated in 37–45% of cases.

Source of infection

The environmental streptococci, especially *S. uberis*, have been isolated from bedding materials and the lips and tonsils of cows, with the abdominal skin of cows often harboring the largest population.[8] Some cows are permanently colonized with *S. uberis* and may pass large numbers of the bacteria in the feces. Fecal shedding is believed to play an important role in the maintenance of *S. uberis* populations on dairy farms, and is the likely source of large numbers of the organism in straw bedding on farms where this form of mastitis persists.[9,10] The numbers of environmental streptococci in organic bedding materials vary with the type of bedding. Large numbers of *S. uberis* are found in straw bedding and much lower numbers in sawdust and wood shavings. The numbers of streptococci recovered from the teats of cows bedded on sawdust are lower than those bedded on straw. Long straw used in calving box stalls or as bedding in loose housing can be a source of considerable exposure to environmental streptococci.

S. dysgalactiae can also be found in the environment of dairy cattle and has been isolated from the tonsils, mouth and vagina, and the mammary glands. It has characteristics of both a contagious and an environmental pathogen and some categorization schemes place it in the contagious category, although it is primarily an environmental pathogen. *S. dysgalactiae* is also associated with summer mastitis, which affects dry cows and heifers during the summer months. It has been isolated from the common cattle fly *Hydrotaea irritans*, which may be involved in the establishment and maintenance of bacterial contamination of teats. *S. dysgalactiae* may colonize the teat prior to infection with *A. pyogenes* and anaerobic bacteria such as *P. indolicus* and *F. necrophorum*.

Risk factors

Environmental risk factors

The major risk factor for environmental streptococci infection is **exposure of the teat end to mastitis pathogens in the environment**. Transmission is predominantly from the environment.[7] Exposure of uninfected teats to environmental streptococci can occur during the milking process, between milkings, during the dry period and prior to parturition in first-lactation heifers. The rate of new infections is greatest during the summer months in North America.[4]

Housing and management practices on dairy farms may contribute to contamination of bedding materials and exposure of teats to environmental streptococci. Housing facilities that predispose to the accumulation of feces on cows will increase the rate of exposure of the teat end to the pathogens. Straw bedding appears to increase the risk of *S. uberis* mastitis,[11] and an increase in *S. uberis* mastitis cases occurs when cows are housed in deep straw pack.

Pastured cattle are generally at reduced risk for environmental streptococcal mastitis when compared to cows in confinement housing. However, certain pasture conditions, such as areas under shade trees, poorly drained ground surfaces, ponds and muddy areas, may result in a high rate of exposure to the pathogens. The environmental streptococci are the most significant environmental pathogen in New Zealand dairy herds where cows spend almost 100% of their time on pasture.[12]

S. dysgalactiae is commonly isolated from heifers and cows in the dry period and is one of the most prevalent pathogens isolated from cases of summer mastitis. The spread of *S. dysgalactiae* between cows within dairy herds may occur directly or by way of the milking machine or environment.

Animal risk factors

The risk of new infections is influenced by the stage of lactation and parity of the cow. The **rate of new infection is highest during the 2 weeks following drying off and the 2 weeks prior to calving.** The high rates of new infection following drying off may be associated with the lack of flushing action of milking, changes in the composition of the mammary secretion, which may enhance the growth of the pathogens, and the lack of a keratin plug in the streak canal. The primary defense mechanisms for *S. uberis* are the length of the teat canal and the amount of keratin in the lining.[13] Antimicrobial dry cow therapy reduces the infection rate in the early part of the dry period but has no or little effect on

preventing infection with *S. uberis* at the end of the dry period. The increase in susceptibility to infection just prior to parturition may be associated with the lack of milking when the gland is accumulating fluid, loss of keratin plugs from streak canals, or immunosuppression of the periparturient period. The **rate of infection is also higher in older cows** than for either heifers or cows in second lactation, and highest during the summer months for both cows in lactation and cows in the dry period. This is in contrast to contagious pathogens, where exposure occurs primarily during the milking process.

Pathogen risk factors

S. uberis is ubiquitous in the cow's environment with multiple environmental habitats.[3] Consequently the mammary gland is exposed continuously to the pathogen during lactation and the dry period and infections are associated with a large variety of strains. Several virulence factors of *S. uberis* and *S. dysgalactiae* have been identified that are important in the pathogenesis of environmental mastitis. Antiphagocytic factors allow *S. uberis* to infect and multiply in the gland, and to adhere to and invade the mammary tissue.[14] Bovine mammary macrophages are capable of phagocytosis of the organism but certain strains of *S. uberis* are capable of resisting phagocytosis by neutrophils, because of their hyaluronic acid capsule.[15,16] The ability of *S. uberis* to invade the bovine mammary epithelial cells could result in chronic infection and protection from host defense mechanisms and the action of most antimicrobial agents,[17] which may explain the intractable response to therapy in some cases. However, most 'intractable' infections are due to an inappropriately short duration of treatment.

S. dysgalactiae behaves like both a contagious and an environmental pathogen and can invade bovine mammary epithelial cells, which may explain the persistence of infection.[18] Different biotypes of *S. dysgalactiae* have been identified,[19] and strains can possess several antiphagocytic factors, including M-like protein, alpha-2-macroglobulin, capsule and fibronectin binding, and virulence factors, including hyaluronidase and fibrinolysin.

An existing intramammary infection due to *C. bovis* is a risk factor for environmental streptococcal infection[20] through an unidentified mechanism.

Economic importance

The major economic losses associated with environmental streptococcal mastitis are caused by clinical mastitis resulting in lost production, milk withholding, premature culling, increased labor, and costs of therapy and veterinary services. 88% of the loss associated with clinical mastitis is attributed to loss of milk production and milk withholding. Pluriparous cows lost 2.6 times as much as first-calf heifers, and cows less than 150 days in milk lost 1.4 times more than cows more than 150 days in milk.

PATHOGENESIS

Infections with *S. dysgalactiae* artificially induced in goats are indistinguishable from mastitis associated with *S. agalactiae* and the pathogenesis is probably similar in all streptococcal mastitides.

In experimental infection of dairy cows with *S. uberis* there is acute inflammation, resulting in the accumulation of large numbers of neutrophils in the secretory acini in 24 hours.[21] After 6 days, the neutrophil response is still evident but there is cellular infiltration, septal edema, extensive vacuolation of secretory cells, focal necrosis of alveoli, small outgrowths of the secretory and ductular epithelium, and widespread hypertrophy of the ductular epithelium. The organism is present free or phagocytosed, in macrophages in the alveolar lumina, adherent to damaged secretory or ductular epithelium, in the subepithelium and septal tissue, and in lymphatic vessels and lymph nodes. The macrophage is important as the primary phagocytic cell but the marked neutrophil response may be ineffective as a defense mechanism. It is hypothesized that the marked neutrophil response following infection with *S. uberis*, rather than the organism, may be responsible for the most of the effects of the mastitis.[21] The current consensus is that environmental streptococci (with the possible exception of *S. dysgalactiae*) are not contagious pathogens.

CLINICAL FINDINGS

Approximately 50% of environmental streptococcal intramammary infections cause clinical mastitis during lactation. Clinical abnormalities occur in 42–68% of these infections in the same herd in different years.[4] The clinical findings are usually limited to abnormal milk or abnormal gland. In about 43% of cases the findings are limited to abnormal milk, 49% involve abnormal milk and an enlarged (abnormal) gland, and in only 8% of cases are there systemic signs with a fever and anorexia (abnormal cow). Clinical recovery commonly occurs in 24–48 hours.

CLINICAL PATHOLOGY

The laboratory diagnostic tests for these pathogens are the same as for *S. agalactiae*. All the environmental streptococci except *S. dysgalactiae* hydrolyze esculin on blood agar. Species can be differentiated with reasonable success using a variety of biochemical tests, such as the API20 Strep and serological grouping using specific antisera of Lancefield groups.[3] However, molecular biological techniques are needed for detailed epidemiological studies.[16] The **HYMAST® diagnostic kit** is available as a field test to distinguish between Gram-positive and Gram-negative bacteria in the milk of dairy cows with clinical mastitis.[5]

DIFFERENTIAL DIAGNOSIS

Streptococcus uberis mastitis in dry cows may be sufficiently severe to resemble mastitis associated with *A. pyogenes*. Diagnosis depends on cultural examination of the milk.

TREATMENT

Antimicrobial agents

The in vitro susceptibility of environmental streptococci to antimicrobial agents is high. Most isolates of *S. uberis* and *S. dysgalactiae* are susceptible to penicillin, novobiocin, amoxicillin and cephapirin. A high percentage (96%) are also susceptible to tetracycline, but susceptibility to aminoglycosides is much lower. Most cases of clinical mastitis associated with *S. uberis* and *S. dysgalactiae* respond well to intramammary infusions of penicillin, cephalosporins, cloxacillin, erythromycin and tetracyclines. Spontaneous cures can also occur. Clinical cases in lactating cows should be treated by at least two intramammary infusions 12 hours apart; this may produce clinical cure but fail to produce a bacteriological cure. Subclinical infections in **late lactation** may be left until the dry period. For clinical cases in the first 100 days of lactation there is substantial economic benefit from treatment. Some cases associated with strains of *S. uberis* appear intractable to treatment; extended treatment is necessary in these animals. Failure of treatment may be due to epithelial cell invasion and movement of the bacteria into subepithelial layers, possibly reducing the effectiveness of the antimicrobial. Extended therapy (for 5 or 8 days) with intramammary ceftiofur (125 mg), pirlimycin (50 mg) or penethemate hydriodide, dihydrostreptomycin sulfate and framycetin sulfate, every 24 hours, increases the bacteriological cure rate for cattle with experimentally induced *S. uberis* mastitis.[10,22–24] In a study of 1148 cases of subclinical environmental streptococci mastitis in New York, commercially available intramammary infusions were more effective than untreated controls (66% bacteriological cure), with

the following bacteriological cure rates: amoxicillin (90%), penicillin (82%) and cloxacillin (79%).[25]

Treatment using oxytocin and frequent stripping of the affected glands without intramammary antibiotic administration is not recommended because cure rates are much lower.[23,26] Moreover, not administering antimicrobial agents results in a higher relapse rate.[27,28] Many of the relapses were associated with the environmental streptococci and therefore **intramammary antimicrobial treatment should be routinely performed**. In particular, because clinical mastitis with an abnormal gland or abnormal cow induces some pain and discomfort in the cow, **withholding an effective treatment (antimicrobial agents) cannot be condoned on animal welfare grounds**.

Reinfection may occur quickly if the contributory causes are not corrected. Infections with *S. zooepidemicus* do not respond well to treatment with penicillin. Mastitis associated with *S. pneumoniae* responds well to local treatment with penicillin in large doses (300 000 units per infusion) but quarters allowed to go without treatment for any length of time suffer complete loss of function. All cases of mastitis associated with this bacteria should receive parenteral treatment with penicillin.

CONTROL

The control of mastitis due to environmental streptococci is achieved by **decreasing the exposure of pathogens to the teat end** and by **increasing the resistance to intramammary infections**. A specific control recommendation for environmental streptococci mastitis is not to bed on straw, but this may not be a practical or economic recommendation for some producers. If straw bedding is used, a reduction in the teat end exposure to *S. uberis* can result from frequent (daily) replacement of bedding.

Reducing the exposure of the teat end to pathogens depends on **maintenance of a clean and dry environment**. Special attention must be directed to the dry cow and close-up heifer housing, the calving area, lactating cow housing, and the milking parlor and milking hygiene. Organic bedding materials such as straw that support large numbers of environmental pathogens should be kept dry. **Sand is the ideal bedding material** because it has the lowest number of coliform and environmental pathogens. Wet and damp areas in the back part of free stalls and tie stalls promote exposure to environmental pathogens. Milking time hygiene should emphasize milking of clean, dry teats and udder, with a properly functioning milking machine. Predipping with a teat dip germicide may reduce environmental mastitis by as much as 50% but this reduction does not occur in all herds.

Dry cow therapy to prevent new infections has not been as successful for the control of all causes of environmental mastitis as it has been for contagious mastitis. However, dry cow therapy is more effective against the environmental streptococci than against coliform bacteria.[29] Application of an internal teat sealant of bismuth subnitrate at dry-off is effective in preventing infections associated with *S. uberis* during the dry period.[30,31]

A long-acting intramammary infusion dry cow therapy containing 250 mg cephalonium administered after the last milking of lactation reduced the incidence of new infections due to *S. uberis* from 12.3% to 1.2%.[32] Clinical infections during the dry period were most prevalent in quarters identified as having open teat canals. Fewer open teat canals were observed among treated quarters over the first 4 weeks of the dry period. It is proposed that the teat canal of treated quarters closed earlier than those of untreated quarters. Most of the new infections in the untreated controls occurred within the first 21 days of the dry period. Normally, the teat canal is dilated for up to 7 days after drying off, with a keratin plug then forming over the following 14–21 days. It is suggested that once a physical keratin seal has formed in the teat canal after drying off, an uninfected quarter has a very low risk of infection over the remainder of the dry period. Treated quarters had a lower incidence of new clinical infections during the next lactation and lower SCCs.

Vaccination

Experimentally, multiple intramammary vaccinations with whole killed *S. uberis* cells resulted in complete protection against experimental infection in cattle.[33] Bacteria could not be isolated from the quarters after challenge, and protection occurred in the absence of a marked neutrophil response. Preparations containing plasminogen activator may form the basis of a vaccine against *S. uberis*.[34] Vaccines are presently commercially unavailable,[16] and vaccination is not currently recommended as part of the control program for mastitis due to environmental streptococci.

ARCANOBACTERIUM PYOGENES

ETIOLOGY

Arcanobacterium pyogenes (formerly *Actinomyces pyogenes* and *Corynebacterium pyogenes*) causes two forms of severe clinical mastitis: sporadic cases of suppurative mastitis, mostly in housed cattle, referred to as **pyogenes mastitis**, and a clinically similar disease that occurs in outbreaks in cattle during the summer months in Europe and Scandinavia and is referred to as **summer mastitis**.[1] Successful transmission of infection has been performed, but the bacteria is rarely present in pure culture in the naturally occurring disease and is not the specific cause of summer mastitis. When the organism is applied to the teat skin at the end of the teat, infection of the quarter does not occur unless the teat end is injured,[2] when anaerobic bacteria are also involved in the infection.[3]

Synopsis: Mastitis of cattle associated with *Arcanobacterium pyogenes*

Etiology *Arcanobacterium pyogenes*, formerly known as *Actinomyces pyogenes* or *Corynebacterium pyogenes*
Epidemiology Important cause of sporadic suppurative mastitis, most common in dry cows or pregnant heifers. Outbreaks occur in Europe in summer (called summer mastitis) associated with seasonally active biting flies, such as *Hydrotoea irritans*. Other bacteria (*Streptococcus dysgalactiae* and *Peptostreptococcus indolicus*) may be required to initiate clinical mastitis
Clinical findings Gland is severely swollen and hard, usually only one quarter affected. Secretion from infected quarters initially watery with clots, later purulent. Initially severe systemic signs including fever, inappetence, tachycardia, depression, mortality rate up to 50%. In cattle surviving the initial infection, the affected quarter becomes abscessed, with drainage of purulent material at the base of the teat
Clinical pathology Culture of milk
Necropsy findings Abscesses in one gland and severe systemic reaction are strong presumptive necropsy findings of *A. pyogenes* mastitis
Differential diagnosis Cannot definitively differentiate from other causes of acute mastitis without culture of milk; however, presence of abscesses in mastitis is strongly suggestive of *A. pyogenes*
Treatment Responds poorly to treatment with parenteral procaine penicillin G or oxytetracycline and intramammary penicillin. Affected quarter is almost always lost for milk production
Control Intramammary infusion with dry cow preparation every 3 weeks during the dry period. Control fly populations. Isolate cows with draining abscesses

In summer mastitis the purulent material in the quarter usually contains *A. pyogenes* as a primary pathogen but the severity of the disease is determined by the presence of anaerobes such as *P. indolicus, S. dysgalactiae, F. necrophorum, P. melaninogenica, Fusobacterium* spp., a microaerophilic, Gram-positive coccus (Stuart–Schwan coccus)[4] and other Bacteroidaceae and *Micrococcus* spp. are also found. These bacterial species are found on the teats and conjunctiva and in the oral cavity of healthy cattle.[5] *F. necrophorum* was recovered almost exclusively from the oral cavity, *P. indolicus* and *A. pyogenes* most frequently from teat skin, and isolates of *P. melaninogenica* subsp. *levii* were evenly distributed between conjunctiva and teat tip samples. There is also a distinct seasonal pattern of the isolation of the pathogens, which corresponds closely to the seasonal activity of the fly *Hydrotoea irritans*.[2]

It has also been proposed that *S. dysgalactiae* is the primary cause, and the others secondary invaders,[6] but all these bacteria are capable of causing suppurative mastitis when infused into the udder. *A. pyogenes* alone establishes itself readily in mammary tissue after experimental introduction but causes only a subclinical disease, but inclusion of summer mastitis exudate provokes the classical syndrome of summer mastitis.[7] Experimental infections with *A. pyogenes* and *P. indolicus* cause a much more serious disease, and one less responsive to treatment if the infection is introduced into a dry quarter instead of into a lactating one.[8] The bacterial flora in cases of summer mastitis is quite variable. In some years in the UK, many cases are apparently due to pure infections of *M. haemolytica*.[9] In pyogenes mastitis, *A. pyogenes* is often found in pure culture but the other bacteria listed in summer mastitis are also common accompaniments. *Actinomyces ulcerans* is an uncommon cause of a subacute mastitis.

EPIDEMIOLOGY

Occurrence and prevalence of infection

Bovine mastitis associated with *A. pyogenes* occurs sporadically and is most common in dry cows or pregnant heifers, although lactating cows may also be affected. A high prevalence is also recorded in heifer calves as young as 2 months.[10] In the UK, Japan,[11] northern Europe, Florida and infrequently in a group of countries scattered all over the world, there is a much higher incidence of suppurative 'summer mastitis' during the summer months when nonlactating females are left at pasture and not kept under close observation. In the UK 20–60% of farms are affected, the same herds are affected each year and about 40% of farms never experience the disease.

Source of infection and mode of transmission

The portal of infection is unknown, although it is presumed to be via the streak canal. The method of spread is uncertain in sporadic cases but insects, especially biting ones such as *H. irritans*, appear to play an important role in outbreaks of 'summer mastitis'[2,5,12] in northern Europe. The prevalence of the disease is related to the peaks of the fly populations and the prevailing climate, especially the wind force and direction.

Risk factors

The incidence is much higher in wet summers and on heavily wooded and low-lying farms when the fly population is high. Dairy breeds are the predominant target, mostly at the end of gestation or in the first few days of the lactation. Heavy fly populations are a common accompaniment of an outbreak. It has been suggested that some triggering mechanism is needed before contamination of the teat and invasion and infection of the gland can occur.[5] The infection rate of *A. pyogenes* in udders is much less in housed cattle than in the same cattle at pasture. In Australia the disease occurs mostly in lactating cows and usually after injury or the development of black spot on the teat.[13] Outbreaks are also recorded in association with outbreaks of foot-and-mouth disease[14] and herpes mammillitis virus damage to the teats.

Economic importance

Summer mastitis is a serious disease in that the mortality rate without adequate treatment is probably about 50% and the affected quarters of surviving cows are always totally destroyed. In pyogenes mastitis the mortality rate is much less but the loss of the quarter means that the cow is culled.

PATHOGENESIS

It is suggested that the infection is carried from udder to udder by flies and that massive invasion of the mammary tissue occurs via the teat canal that is damaged. The greater part of the gland is affected at the first attack, causing a severe systemic reaction and loss of function of the entire quarter. The disease has been reproduced by inoculation of the mammary gland of pregnant heifers with *A. pyogenes, F. necrophorum,* and *P. indolicus*.[15] All animals developed moderate to severe clinical mastitis: four out of 10 animals recovered completely and had a normal lactation after calving. In six of 10 animals, the course of the disease was severe and affected quarters failed to produce milk after calving.

CLINICAL FINDINGS

Mastitis associated with *A. pyogenes* is usually peracute with a severe systemic reaction, including fever (40–41°C, 105–106°F), rapid heart rate, complete anorexia, and severe depression and weakness. Abortion may occur during this stage. In almost all cases only one quarter is affected, most commonly a front one. The teat is swollen and inflamed and the quarter is very hard, swollen and sore; the secretion is watery with clots early and later purulent, with a typical putrid odor. Affected cows usually carry a large fly population. If the cow survives the severe toxemia, the quarter becomes extremely indurated and abscesses develop, later rupturing through the floor of the udder, commonly at the base of the teat. These may be presented as being chronic cases but they are usually residual after an acute episode. True gangrene, such as occurs in staphylococcal mastitis, rarely if ever occurs in uncomplicated infections with

A. pyogenes but quarters may be so severely affected that sloughing occurs. Lameness in the hindlimb on the affected side occurs in some cases, and the limb joints may be swollen. The function of the quarter is permanently lost and cows that have calved recently may go completely dry. Severe thelitis with extreme thickening and obstruction of the teat is a common sequel. Partial or complete obstruction of the teat and damage to the teat cistern can also occur independently of an acute attack of mastitis. Fetal growth retardation is thought to be a feature of calves born to cows affected by summer mastitis during pregnancy.

CLINICAL PATHOLOGY

Isolation of the bacteria is required. Freezing of milk samples reduces the number of samples giving a positive cultural result.[16]

NECROPSY FINDINGS

Details of the pathology of the disease are not available.

DIFFERENTIAL DIAGNOSIS

The seasonal incidence of the disease in some areas, the acute inflammation of the quarter, the suppurative nature of the mastitis, the development of abscesses and the severe systemic reaction make this form of mastitis one of the easiest to diagnose clinically in cattle.

TREATMENT

Summer mastitis normally responds poorly to treatment and the affected quarter is typically lost for milk production. Failure of therapy is due to the extensive purulent processes in the udder and not to antimicrobial resistance. Bacterial isolates from cases of summer mastitis are susceptible to penicillin G and other beta-lactam antimicrobials.[17] However, penicillin G has limited distribution throughout the inflamed udder. Penicillin G given parenterally to experimental cases of summer mastitis was effective in about 40% of cases if treatment was initiated within 32 hours after inoculation.[18] In peracute cases parenteral treatment with sodium sulfadimidine or one of the tetracyclines is preferable and should be accompanied by repeated stripping of the quarter. Broad-spectrum antimicrobial agents are usually given by intramammary infusion but the quarter is almost always rendered functionless.

Affected quarters can also be treated by permanently drying the quarter off. The best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone–iodine solution (0.5% iodine) after complete milk-out and administration of flunixin meglumine (1 mg/kg BW, intravenously).[19] This causes permanent cessation of lactation in the quarter but does not alter total milk production by the cow.

Clearing of proteinaceous debris from the affected quarter may be aided by the intramammary application of proteolytic enzymes but the outcome as far as the quarter is concerned is unlikely to be much altered and amputation of the teat to facilitate drainage is a common treatment. Even with intensive therapy, at least 80% of quarters are rendered useless and many of those that respond are greatly reduced in productivity.

CONTROL

The question of control of this form of mastitis centers largely on 'summer mastitis'. Many prophylactic measures, including infusion of the quarter when the cow is dried off, sealing the teat ends with collodion and vaccination with toxoid, have been tried but with inconclusive results. The most favored technique is intramammary infusion with a dry cow preparation (e.g. cloxacillin 500 mg and ampicillin 250 mg in a long-acting base) at 3-week intervals during the dry period. Less frequent administration offers less protection.[20] An alternative intramammary infusion procedure is to use cephalonium at 4-weekly intervals.

Repeated spraying of the udder, for example automatically at watering points, with a contact insecticide[21] is commonly carried out during the fly season and is believed to be effective. An alternative to spraying is the use of insecticide-impregnated ear tags,[22] or pour-ons, but ear tags are decreasing in popularity. Careful daily examination of dry cows during the summer may enable affected quarters to be identified, the cows to be isolated and the quarters treated at an early stage and thus limit the spread of infection. In particular, cows with purulent material draining from an affected quarter need to be isolated from other cattle. Early treatment of teat lesions to limit bacterial colonization by bacteria, possibly transported by flies, is recommended. The known susceptibility of particular farms, and particular paddocks on those farms, demands proper care in planning the pasturing of dry cows during the danger period.

Mastitis of cattle associated with less common pathogens

PSEUDOMONAS AERUGINOSA

Mastitis in cattle and sheep associated with *Pseudomonas aeruginosa* is rare and occurs usually as sporadic cases after intramammary infusion with contaminated material.

ETIOLOGY

P. aeruginosa is the most common cause, although other *Pseudomonas* spp. can cause disease.

EPIDEMIOLOGY

P. aeruginosa is common in the environment of cattle. Occasionally a number of animals in the herd are affected, the infection usually originating in contaminated water used for washing udders.[1] The organism has the capacity to colonize inert materials such as loops of hose and the interior surface of water heaters, so that high bacterial concentrations may be in the water left in the hose between milkings. It may be an advantage in these circumstances to flush out the udder washing system before commencing each milking. Once the teats are contaminated, the entry of the organisms to the teats is facilitated by overmilking and by putting the milking cups on while the udder is still wet.[2] Serious outbreaks in cows have also occurred in association with the use of a suspected contaminated mastitis infusion[3] used as a dry period treatment. The cows became affected soon after calving.

Rarely, strains of this organism are highly virulent and cause fatal mastitis with generalized lesions. Less commonly still there is a high level of infection in a herd due to a contaminated water supply but with no clinical cases. Reinfection is common unless the source of infection is removed, even though there is apparent cure by treatment with spectinomycin.[4]

CLINICAL FINDINGS
The mastitis may be clinically severe and the mortality rate as high as 17% of affected cows, or it may be subacute or chronic. Clinically there is a severe systemic reaction, acute swelling of the gland and the appearance of clotted, discolored milk; the function of the gland is usually completely lost at the first attack, but recurrent crises may occur.

CLINICAL PATHOLOGY
Culture of the organism in the milk is necessary to confirm the diagnosis.

NECROPSY FINDINGS
The disease can be fatal and the gross and histological findings are similar to other causes of clinical mastitis in cows.

DIFFERENTIAL DIAGNOSIS

Bovine mastitis associated with *Pseudomonas aeruginosa* must be differentiated from the many other forms of acute mastitis associated with this species; this can be done only by bacteriological examination of the milk.

TREATMENT
Treatment with antimicrobial agents is generally unsuccessful. Third-generation cephalosporins such as ceftiofur, aminoglycosides such as gentamicin, and fluoroquinolones are most likely to be efficacious in treating affected animals. Daily intramammary infusions of streptomycin (1 g) or neomycin (0.5 g), or both combined with polymyxin B, for 4 days, have been used.

CONTROL
The standard control program described later in the chapter should control the disease in cows. The oral administration of an organic iodine compound and vaccination with a killed autogenous vaccine are credited with bringing the disease under control in one herd.

PASTEURELLA SPECIES

Mastitis associated with *Mannheimia* (formerly *Pasteurella*) *haemolytica* and *Pasteurella multocida* is common in ewes, occurring in a peracute gangrenous form, but is comparatively rare in cattle and goats.

ETIOLOGY
In cattle *M. haemolytica*[1] and *P. multocida* are the causative organisms; *M. haemolytica* has also been isolated from many cases of **summer mastitis** in the UK.[2]

EPIDEMIOLOGY
In cattle the disease is encountered rarely, and usually sporadically, but it may be a problem in individual herds, particularly where calves are reared by nurse cows.

CLINICAL FINDINGS
In cattle the mastitis is severe with fever, profound toxemic shock, weak pulse, tachycardia, and recumbency. The affected quarter is very swollen and the milk is watery, red-tinged and contains flakes. Disseminated intravascular coagulopathy may cause internal bleeding at many sites. All four quarters may be affected. There is complete cessation of milk flow in affected and unaffected quarters and subsequent fibrosis and atrophy. Newborn calves allowed to suck colostrum from affected cows may die of pasteurellosis.

Clinical pathology
Culture of the organism in the milk is necessary to confirm the diagnosis.

NECROPSY FINDINGS
The disease is not fatal in cows.

DIFFERENTIAL DIAGNOSIS

Bovine mastitis associated with *P. multocida* must be differentiated from the many other forms of acute mastitis associated with this species; this can only be done by bacteriological examination of the milk.

TREATMENT
In cattle, streptomycin administered by intramammary infusion is effective but tetracycline is preferred. Recurrence in quarters that appear to have recovered is not infrequent, and response to treatment is often poor.

CONTROL
The standard control program described later in the chapter should control the disease in cows.

NOCARDIA SPECIES

Nocardial mastitis is an uncommon occurrence in cattle and is manifest as an acute or subacute mastitis accompanied by extensive granulomatous lesions in the udder.

ETIOLOGY
Nocardia asteroides can be cultured from the milk of affected quarters, and the disease can be produced experimentally by this organism. Occasional cases of chronic mastitis associated with *Nocardia brasiliensis* and *Nocardia farcinica* have also been recorded.

EPIDEMIOLOGY
Occurrence
With rare exceptions, nocardial mastitis in cattle has been recorded as a sporadic infection affecting only one or two cows in a herd. Accidental introduction of the causative bacteria into udders when infusions are being administered may create a herd problem.[1] Nocardia is recorded as being a relatively common chronic mastitis in Cuba. Commencing in 1987, a large number of cases occurred in Canada. Confinement of dairy cattle in muddy pens has been associated with an increased incidence of nocardial mastitis.[2]

Source of infection and mode of transmission
The bacteria is a common soil contaminant and probably gains entrance to the udder when udder washing is ineffective or udder infusion is not carried out aseptically. Nocardia can survive in ineffective teat dips and may be spread by their use. The disease is most common in freshly calved adult cows, particularly if infusion of the udder with contaminated materials is carried out in the dry period. *N. asteroides* is capable of surviving in mixtures used for intramammary infusion for up to 7 weeks. There is one record of a massive outbreak with many deaths that was probably due to the use of a contaminated homemade udder infusion.[3]

Risk factors
A sharp increase in isolations of *N. asteroides* in milk samples at veterinary diagnostic laboratories in Canada[4] was related to the extensive use of a particular dry period treatment. Teat dips containing recommended concentrations of iodine or dodecylbenzene are effective against *N. asteroides* whereas those containing chlorhexidine acetate are not effective.[5] When the dip is contaminated during use it may spread the organism to other quarters and other cows.

Economic importance
The disease is a serious one in that there is extensive destruction of tissue, loss of production, and occasionally death of a cow. Also, there is a possibility that human infection may occur, as the organism may not be destroyed by usual pasteurization procedures.

PATHOGENESIS
The inflammation of the teat sinus and lower parts of the gland suggests invasion via the teat canal. Infection of mammary tissue results in the formation of discrete granulomatous lesions and the development of extensive fibrosis, the spread of inflammation occurring from lobule to

lobule. Infected animals are not sensitive to tuberculin.

When infection occurs early, in the first 15 days of lactation, the reaction is a systemic one with fever and anorexia. At other times the lesions take the form of circumscribed abscesses and fibrosis. There may also be infected foci in supramammary and mesenteric lymph nodes.[6]

CLINICAL FINDINGS

Affected animals may show a systemic reaction with high fever, depression and anorexia, but an acute or subacute inflammation is more usual. Fibrosis of the gland and the appearance of clots in a grayish, viscid secretion that also contains small, white particles is the usual clinical picture. The fibrosis may be diffuse but is usually in the form of discrete masses 2–5 cm in diameter. Badly affected glands become grossly enlarged, and may rupture or develop sinus tracts to the exterior. None of these cases recovers sufficiently to justify retention and all are eventually culled.

Laboratory examinations of herds in which cases occur may also reveal subclinical cases that have intermittent flare-ups.[7]

CLINICAL PATHOLOGY

The bacteria can be detected on culture of the milk. Small (1 mm diameter) specks are visible in the milk and, on microscopical examination, these prove to be felted masses of mycelia. Herds containing infected cows have been readily identified by culture of bulk milk samples.[8] A gentamicin–blood culture medium has good selectivity.[9] The normal blood agar plates need to be kept for an extended period of time in order to detect growth. Colonies may not appear until 72 hours.

NECROPSY FINDINGS

Grossly, diffuse fibrosis and granulomatous lesions containing pus are present in the mammary tissue. The lining of the milk ducts and the teat sinus is thick and roughened. On histological examination the granulomatous nature of the lesions is evident. Metastatic pulmonary lesions have been found in occasional long-standing cases.

Samples for confirmation of diagnosis

- Bacteriology – mammary tissue, regional lymph node
- Histology – formalin-fixed mammary tissue for light microscopy.

DIFFERENTIAL DIAGNOSIS

The appearance of the milk is distinctive but cultural examination is necessary for positive identification.

TREATMENT

The disease does not respond well to treatment. Erythromycin and intramammary miconazole are most effective but need to be used for 1–2 weeks.[7]

CONTROL

Invasion probably occurs via the teat canal from a soil-borne infection; proper hygiene at milking and strict cleanliness during intramammary infusion are therefore necessary on farms where the disease is enzootic. Treatment in late cases is unlikely to be of value because of the nature of the lesions, and in affected herds particular attention should be given to the early diagnosis of the disease.

Miscellaneous causes of bovine mastitis

BACILLUS SPECIES

Bacillus cereus and *Bacillus subtilis* are saprophytic organisms and only chance mastitis pathogens; they have been known to cause an acute hemorrhagic mastitis in cattle. *B. cereus* cases are often associated with contamination associated with teat injuries or surgery. The mastitis may also occur in cows at the time of calving and is associated with the feeding of brewers' grains in which the spores of *B. cereus* are present.

The infection is thought to occur during the dry period following the use of dry cow therapy preparations that may have been contaminated with the organism.[1] Infection probably occurs at the time of infusion but the acute mastitis does not occur until after parturition. *B. cereus* is a spore-former and may remain dormant in the mammary gland for long periods, unaffected by the presence of the antibiotic. In one outbreak, 62 of 67 cows infused with a dry cow infusion product contaminated with the organism developed acute hemorrhagic mastitis. Six cows died; the remainder survived but were subsequently culled and slaughtered because of recurrent mastitis, inadequate milk production and loss of weight.

Clinically there is peracute to acute mastitis affecting one or more quarters. There is severe swelling and pain and the secretions are red-tinged and serous in consistency. Initially there is a high fever (40–41°C, 104–106°F) and severe toxemia. Affected cows are weak and quickly become recumbent; death may occur in 24–36 hours. Gangrene may occur and, in cows that survive, portions of affected gland will slough out and a chronic relapsing mastitis will persist. Experimentally produced mastitis due to *B. cereus* causes toxemia, acute swelling of the quarter and clots in the milk. The mastitis persists in a chronic form and the quarter eventually dries up.[2]

The organism can usually be cultured from milk samples from affected quarters. At necropsy there is focal hemorrhagic necrosis of the mammary tissue, acute lymphadenitis and disseminated intravascular coagulation.

Treatment consists of intensive fluid therapy, a broad-spectrum antibiotic intravenously, and vigorous massage and stripping of the affected gland. Intramammary infusion of the most suitable antibiotic determined by culture and sensitivity is indicated but the results are often not good because of the presence of severe hemorrhage and necrosis and plugging of the lactiferous ducts. Prevention depends on the use of sterile techniques during teat surgery and the use of sterile intramammary infusions and instruments. In problem herds, autogenous bacterins have been prepared but not extensively evaluated.[3] If *B. cereus* infection is identified in the mammary glands of dry cows the recommended prevention program is infusion of each quarter with 750 mg neomycin and 375 mg framycetin.[4]

B. subtilis is recorded less frequently as a cause of acute mastitis. Infection is characterized by yellow or bloody milk, sometimes with clots, and the cow is febrile.[5]

CAMPYLOBACTER JEJUNI

Only one case has been recorded[6] but the incident is of some importance because of its zoonotic impact. Infection of the udder by the organism is easy to establish and the infection is persistent but subclinical for the most part. Other experimental cases have been recorded and campylobacters that have not been further identified[7] have also been observed in naturally occurring cases. These are characterized by fine granular clots in the milk, very high cell counts and a transient episode of fever and swelling of the quarter.

CLOSTRIDIUM PERFRINGENS TYPE A

This is a rare form of mastitis[8] characterized by high fever, swelling, and

superficial hyperemia of the affected quarter, followed later by gangrene, enlargement of the supramammary lymph nodes, a thin brown secretion containing gas, and subcutaneous emphysema. Early treatment with a broad-spectrum antibiotic can be successful,[9] but advanced cases are uniformly fatal

FUSOBACTERIUM NECROPHORUM

This is a rare type of mastitis but is likely to have a high incidence in the herd when it occurs. Mixed infections of *Fusobacterium necrophorum* appear to play an important role in summer mastitis due to *A. pyogenes* (see above). Affected quarters have a viscid, clotty, stringy secretion but there is little fibrosis. No systemic reaction occurs but treatment with a variety of antibiotics is unsuccessful.

HISTOPHILUS SOMNI

Histophilus somni (formerly *Haemophilus somnus*) has caused mild, chronic mastitis, an acute form with high fever and blood-stained milk, and a gangrenous form.[10,11]

LISTERIA MONOCYTOGENES

Listeria monocytogenes is being recorded with increasing frequency as a cause of bovine mastitis because of the zoonotic importance of the organism in dairy products. Most cases are subclinical and abnormal milk is rare.[12] The SCC is usually greater than 10^7 cells/mL milk. An ELISA test can be used to detect antibody in milk.[12] Culture of bulk milk samples is an adequate means of locating herds with infected cows.[13] Over a 23-year period in Denmark, the percentage of cows infected with the organism varied from 0.01–0.1% and that of herds with an infected cow from 0.2-4.2%.[14] Typing of the isolates from bovine mastitis and human clinical isolates revealed that 79% of bovine and 48% of human isolates shared common types. Identifying infected cows may not be easy because the mastitis is mild; the milk is normal in appearance but the quarter does lose productivity[15] and the milk carries a high SCC. The disease is characteristically unresponsive to treatment with penicillin, although the organism may be sensitive to the antibiotic in in vitro tests. The persistence of the clinical signs should arouse suspicion of *L. monocytogenes* as a cause.

MYCOBACTERIUM SPECIES

Tuberculous mastitis is described under tuberculosis. Other mycobacteria, especially *Mycobacterium lacticola*, have been isolated from cases of mastitis in cattle that occur after the intramammary infusion of therapeutic agents in oils.[16] The disease can be reproduced by the intramammary injection of the organism in oil but not when it is in a watery suspension. Subsequent oily infusions exacerbate the condition. Clinically there is tremendous hypertrophy of the quarter with the appearance of clots in discolored milk, but there is no systemic reaction. Affected animals do not show sensitivity to avian or mammalian tuberculin. No treatment is effective. It is suggested that the treatment of injured teats and quarters with oil-based intramammary preparations is inadvisable because of the risk of them already being infected with mycobacteria.

A mild, acute mastitis, self-terminating and unresponsive to treatment, has occurred in outbreak form.[17] It may be unassociated with intramammary infusion but is apparently predisposed to by stress and associated with an unidentified mycobacterium.

Mycobacterium fortuitum is encountered rarely as a cause of a severe outbreak of bovine mastitis. Infected quarters are seriously damaged and do not respond to treatment, and affected cows die or are salvaged.[18] The disease can be reproduced experimentally and affected animals show positive reactions to mammalian and avian tuberculosis and some sensitivity to johnin. Similar experiences are recorded with *Mycobacterium smegmatis*[19] and *Mycobacterium chelonei*.[20] The mammary secretion of affected quarters varies from pus to a watery fluid containing flakes and there is a high milk loss and irreparable damage to quarters. *M. smegmatis* causes hypertrophy of the gland of such proportions that all cases need to be culled.

SERRATIA SPECIES

Serratia marcescens causes mild chronic mastitis in which swelling of the quarters with clots in the milk appear periodically. *Serratia* mastitis occurs naturally and has been produced experimentally.[21] Neomycin (2 g initially followed by three daily doses of 1 g by intramammary infusion) is a satisfactory treatment. *Serratia liquefaciens* has caused a similar mastitis.[22] Most cases are sporadic but herd outbreaks caused by the use of contaminated sawdust as bedding and inadequate cleaning of the teats before milking may occur.[23]

FUNGI AND YEASTS

Trichosporon spp. can cause mastitis in cattle and is manifested clinically by swelling of the gland and clots in the milk. The infection rate is low and the fungi disappear spontaneously. Experimental transmission of the disease has been effected.

Cryptococcus neoformans, the yeast that causes human cryptococcosis, has caused acute mastitis in cattle[24] and buffaloes.[25] Contaminated infusion material and spread from other infected quarters are the probable sources of infection. Infection in humans drinking the milk is unlikely to occur because the yeast does not withstand pasteurization, but there may be some hazard to farm families. While there is no systemic reaction, the mastitis may be acute, with marked swelling of the affected quarter and the supramammary lymph node, a severe fall in milk yield and the appearance of a viscid, mucoid, gray-white secretion. Clinical mastitis persists for some weeks and, in many cases, subsides spontaneously, but in others the udder is so severely damaged that the cow has to be slaughtered. Systemic involvement occurs rarely. At necropsy, there is dissolution of the acinar epithelium and in chronic cases a diffuse or granulomatous reaction in the mammary tissue and lymph node. Similar lesions have been found in the lungs.

Many other yeasts, including *Candida* spp., *Saccharomyces* spp., *Pichia* spp., *Torulopsis* spp., and *Aspergillus fumigatus* have also caused mastitis in cattle. A survey of 91 bovine cases of fungal mastitis in the USA showed that 78% belonged to *Candida* spp.[16] The infection is probably introduced by contaminated intramammary infusions or teat cup liners.[26] Establishment of the infection is encouraged by damage to the mammary epithelium and stimulated by antibiotic therapy; for example *Candida* spp. utilize penicillin and tetracyclines as sources of nitrogen.

A fever (41°C, 106°F) is accompanied by a severe inflammation of the quarter, enlargement of the supramammary lymph nodes and a marked fall in milk yield. The secretion consists of large, yellow clots in a watery supernatant fluid. Lesions are limited to the walls of the milk cistern and there is no invasion of the mammary gland itself.[27] Usually the disease is benign and spontaneous recovery follows in about a week. In cases of infection by *A. fumigatus* or *Aspergillus nidulans* there are multiple abscesses in the quarter. These are surrounded by granulation tissue but the milk ducts are generally unaffected.

None of these infections responds well to antimicrobial therapy but treatment with iodides, either sodium iodide intravenously, organic iodides by mouth, or iodine in oil as an intramammary infusion, might be of value. A number of drugs, including cycloheximide, nystatin, polymyxin B, neomycin, and isoniazid, have been tested for efficiency against mastitis in cattle produced

experimentally by the infusion of *C. neoformans* but did not alter the clinical course of the disease. Merthiolate (20 mL of a 0.1% solution) as an infusion daily for 2–3 days is reported to have a beneficial effect if administered early in the course of the disease. Actinomycotic agents tested in vitro against fungi, mostly *Candida* spp., from cases of mastitis showed sensitivity to clotrimazole, nystatin, polymyxin, miconazole and amphotericin B, and least sensitivity to 5-fluorocytosine.[28] Miconazole (100 mg/L as an intramammary infusion, possibly supplemented by 400 mg doses given intravenously) is reported to produce good results.[29] Sulfamethoxypyridazine given parenterally (22 mg/kg BW for 2–3 d) has resulted in more than 50% clinical cures in quarters infected with *Candida krusei*.[30] A case of mastitis due to *A. fumigatus* has been successfully treated by concurrent intra-arterial injection and intramammary infusion of 100 mg of miconazole at each site. Clinical signs included fever, anorexia and depression, a hard, swollen, hot gland with clots in the milk, and a negative response to treatment with intramammary antibiotics.[31]

ALGAE

Prototheca trispora and *Prototheca zopfii* are algae that have been identified as causes of chronic bovine mastitis.[32,33] Reduced milk yield, large clots in watery milk and induration of the affected quarter may be the only clinical signs. Cases of this disease are usually sporadic but one severe outbreak is recorded.[34] The organisms are common isolates from animal environments.[35] Treatment is usually unsuccessful and affected cows should be culled; because of a high prevalence rate in many affected herds the loss to the farmer can be considerable.[34] Experimental transmission of the disease causes a progressive pyogranulomatous lesion in the gland and the organism can be isolated from draining lymph nodes.[36]

TRAUMATIC MASTITIS

Injuries to the teats or udder that penetrate to the teat cistern or milk ducts, or involve the external sphincter, are commonly followed by mastitis. Any of the organisms that cause mastitis may invade the udder after such injury, and in such cases mixed infections are usual. **All injuries to the teat or udder, including surgical interference, should be treated prophylactically with broad-spectrum antibiotics.**

Control of bovine mastitis

Improvement in udder health has been a major initiative of the dairy industry for over 40 years. The thrust of these efforts has been on the implementation and use of management techniques to limit the spread of major mastitis pathogens, thereby reducing the quarter infection rate. Detailed mastitis control strategies have been outlined and promoted by the National Institute for Research in Dairying (NIRD) and the National Mastitis Council (NMC). With proper implementation, these programs result in a dramatic decrease in the prevalence of common contagious mastitis pathogens. Herds that have successfully implemented a comprehensive mastitis control program also need to develop strategies to control infection with environmental organisms, as well as utilizing an effective monitoring system for new infections. Achievement of excellent udder health for the production of high-quality milk is a realistic and important goal for all aspects of the dairy industry.

The adoption of effective mastitis control programs has often been less than desirable, even with extensive research validation of the recommended control practices and with major extension efforts at both national and local levels. The reasons for this slow adoption of proven mastitis control strategies are not well documented, even though producers look to the veterinary profession for information on mastitis and its control.[1] If significant progress is to be made towards a general improvement in udder health status, veterinarians must become more active in organizing, conducting and monitoring comprehensive mastitis control programs.

Veterinarians usually become involved in mastitis control in one of the following circumstances:

- The herd is experiencing a higher than normal incidence of clinical cases
- The milk processing plant reports a higher than permissible total bacterial count or bulk tank milk SCC
- A farmer who is not carrying out the standard program of postmilking teat dipping and dry period treatment asks for advice – either as a single mastitis control program or, more probably, as part of a herd health management program.

The procedure is the same in all these situations, any variation being in terms of speed and intensity. It consists of an assessment of the herd's mastitis status and the implementation of a recommended mastitis control program.

Udder health improvement

The benefit of an integrated mastitis program is improved udder health; this improvement is progressive and can usually be observed within a few years after implementation at the herd level. In a closed, monitored herd applying the control measures there can be a reduction in the annual incidence of clinical mastitis from 130 cases/100 cows to a level of 35–40 cases/100 cows.[2] In the UK it is estimated that, since 1970, farms that have followed the recommended control procedures have reduced the average annual incidence of cases of clinical mastitis from 135 to 40 cases/100 cows each year, while the percentage of quarters remaining uninfected for a whole year has increased from 65% to 80% of the total quarters.[3] The control program has been most effective in reducing mastitis due to the contagious pathogens such as *S. aureus*, *S. agalactiae*, and *S. dysgalactiae*. These are now responsible for one-third or less of all clinical cases of mastitis compared to 30 years ago. This represents an annual reduction from about 90 to 12 cases/100 cows. The percentage of infected cows declined from 22% to 12% and the percentage of infected quarters from 7% to 3%. Methods now exist to control contagious pathogens and reduce the bulk

tank milk SCCs to below 400 000 cells/mL. With good management, the incidence of clinical mastitis can be kept low (7–21 cases/100 cows/year with dairy herds averaging 45 cows/herd) by culling any cow with chronic or recurrent mastitis and by paying great attention to housing and management standards.[4–6]

While the rate of contagious mastitis has been decreased with the program, the rate of infections and the incidence of mastitis associated with environmental pathogens such as *S. uberis* and the coliform bacteria has not decreased. **Approximately 65% of clinical cases are now due to environmental pathogens.** Organisms prevalent in the cow's environment currently cause the most costly types of mastitis in the USA.[7]

Economic benefits, incentives, and penalties

Mastitis is one of the most costly diseases in dairy herds. Some surveys indicate that the cost incurred by producers because of clinical mastitis is much higher than the cost of prevention.[7] An integrated mastitis control program has always been an excellent investment for the dairy farmer,[3] with a revenue to cost ratio of approximately 6:1,[3] most of the additional revenue being due to increased milk production.

Differential payments to farmers for milk quality are also an **economic** incentive to adopt a control program.[6] The widespread adoption of bulk tank milk SCCs as a measure of milk quality, and the adoption of payment schemes of increasing severity, has stimulated farmers to reduce their cell count. Many milk marketing cooperatives have established both penalty and incentive programs based on bulk tank milk SCC and total bacterial counts as global measures of milk quality.

Requirements

The requirements for a successful mastitis control program include a willing farmer, a capable diagnostic laboratory, an enthusiastic and knowledgeable veterinarian, a record keeping system, adequate milking machinery and adequate housing facilities.

The farmer must have health and production goals and be willing to achieve them by making a commitment to invest the resources to control mastitis. Wide variations in the costs of controlling and monitoring mastitis in herds are evident because of lack of client compliance with accepted recommendations for mastitis control.[8] There are also variations in the level of mastitis control procedures adopted by producers, which affect the success of a program. A survey of a large number of dairy herds in Ohio revealed that most herd managers teat dipped all cows after milking and used dry cow therapy.[9] However, other mastitis control practices were not as widely adopted. In addition, those herds classified as negative for contagious pathogens used predipping compared with herds classified positive for contagious pathogens, which did not. Predipping was also associated with a number of management factors, including having a clean and dry environment for the cows, cows with clean udders and teats, and minimal use of water in the milking parlor. A survey of Ontario dairy farms indicated that only one-third of producers used all five of the recommended mastitis control practices.[10] Lack of adoption may result from a lack of awareness of the economic returns from a complete program, adoption of a new practice only in response to a problem, or competition for liquid financial resources from other aspects of the enterprise.

The veterinarian must be knowledgeable about all aspects of mastitis and be willing to invest the time and effort required to provide sound advice based on the health and production information obtained from monitoring the herd. Some surveys of veterinarians indicate wide variations in their clinical approach to cases of mastitis in the field.[11] Many factors of importance for the clinical diagnosis of mastitis were not considered.

A data recording system that records all the udder health and production data, and the milk quality of each cow and the herd on a regular basis is a vital requirement. A diagnostic laboratory or milk recording agency that provides regular SCCs of individual cows is necessary to monitor udder health. The milking machine and the housing facilities must be adequate for the size of the herd. The animal attendants must be aware of the health and production goals of the herd and adhere to the principles of mastitis control.

OPTIONS IN THE CONTROL OF MASTITIS

The broad options for control are either eradication or decreasing the infection rate, and either legislative control or implementing a voluntary program.

Eradication

Complete eradication of bovine mastitis from a herd or geographical region is not a practicable target in most circumstances. The exception is mastitis due to *Streptococcus agalactiae*, which can be eradicated from individual herds by a blitz technique. The difficulty in attempting to eradicate mastitis is that the contagious causes of mastitis, *S. agalactiae* and *Staphylococcus aureus*, are so contagious, and the sources of infection so widespread, that adequate quarantine would be very difficult to maintain. In the case of *S. aureus* there is the additional difficulty of eliminating the infection from its intracellular sites in mammary tissue. The environmental infections, especially *Escherichia coli*, pose an even greater problem. They are so ubiquitous that reinfection would be almost immediate in cows housed in economically practicable surroundings.

Decreasing the infection rate

This is a practicable proposition, the degree of limitation being dependent on the need to maintain cost-effectiveness. One of the virtues deriving from this necessity is the concept that subclinical mastitis causes a continuous low-level leukocytosis in the milk that acts as a protective mechanism against other infetions. Present-day knowledge about immunity in the mammary gland suggests that control programs that reduce milk SCCs to unrealistically low concentrations may reduce the gland's resistance to clinical mastitis. Correspondingly, the complete elimination of common udder pathogens such as *S. agalactiae* and *S. aureus* is thought to increase the susceptibility of the udder to environmental pathogens, especially the coliforms. Another relevant example is the commonly encountered minor pathogen *Corynebacterium bovis*, which may be a significant microbial agent in maintaining the resistance of udders. The mastitic effect of this organism is too low to warrant action against it but the infection rate with major pathogens is significantly lower in quarters that harbor it than in those that do not.[12] An intensive program to disinfect udders could well eliminate *C. bovis* and increase susceptibility to other pathogens. There is good field evidence to suggest that this is in fact happening in North America and the UK. *C. bovis* is likely to be more important where cows are housed, or confined in straw yards, and therefore more exposed to teat contamination with coliforms. The criticism relates to the increasing numbers of clinical cases, often associated with Gram-negative organisms, that occur in herds that have achieved very low levels of udder infection, as indicated by very low bulk milk cell counts. The question of whether it is better practice to maintain some level of bacterial infection with innocuous organisms in the udder as a protection against more damaging pathogens, rather than to attempt complete bacterial sterilization, is still unresolved. For the time being it is generally agreed that decreasing the infection rate is the appropriate target.

Legislative control

Mastitis does not lend itself to eradication (as set out under Eradication above) and

so legislative control of the disease is not attempted.

A voluntary program

Most of what is done in mastitis control is by voluntary involvement by producers in programs aimed at reducing the incidence of mastitis and maintaining the infection rate at a low level. The justification for control of the disease is purely economic, and a control program must therefore be based on its applicability on each individual farm. Area or national control can only be in the form of providing incentives by educational and laboratory assistance to individual farmers who wish to participate. The value of a mastitis awareness program, and the part played by the two-way flow of information between farmers and the program operators is most apparent when an area campaign is conducted by a government or industrial sponsor.[6] Once a control program is in place it is customary for milk processors, aided in some places by government agencies, to encourage participation by paying incentives for bulk tank milk with low SCCs or bacteria counts, or refusing to accept milk for processing or, in some cases, refusing to transport milk that does not satisfy statutory requirements. This could be the first step in incorporating the program into planned health and production programs that promote mastitis control and maintenance of milk production at financially optimal levels. Mastitis infections in beef cattle herds are currently at too low a level for a mastitis control program to be financially advantageous.

PRINCIPLES OF CONTROLLING BOVINE MASTITIS

Dynamics of infection

The principles of a bovine mastitis control program are based on changing the dynamics of infection, which are as follows:[13]

Prevalence of infection is a function of the rate of new infection minus the rate of elimination
Rate of new infection is a function of the level of exposure times the number of susceptible quarters
Rate of elimination is a function of the number of infections times the efficacy of treatment plus spontaneous cure.

Successful control occurs when the level of infection is held low or is decreased, either by preventing new infections or eliminating existing infections.

The dynamics are not, however, so simple in reality. They vary with the susceptibility of the individual animal, which changes with **age** and **stage of lactation** and is **season-dependent.** The dynamics may vary with the pathogens involved, and the relative importance between herds can be very considerable and also vary with time. The duration of infection may be extremely different for different pathogens. *E. coli* causes mild to severe acute clinical disease but usually self-eliminates quickly; it is rarely found in subclinical infections. *S. agalactiae* and *S. aureus* are very persistent, and *S. aureus* responds poorly to treatment. The rate of elimination and the persistency of these pathogens are highly variable. Similarly, there can be large variations in the rate of new infections, which is very much related to the identifiable risk factors, including rate of teat contamination, mechanisms aiding teat penetration, and effectiveness of establishment and growth of bacteria in the mammary gland.

The success of a control program can be measured by the decrease in level of infection and the speed with which this is achieved. The farmer must be able to appreciate progress within a year in order to remain enthusiastic about application of the methods. The level of infection can be controlled significantly by lowering the rate of new infections, but the speed of change very much depends on the duration of the infection and is thus related more to the rate of elimination. No control procedures are available to prevent all new infections and only culling of chronically infected cows is absolutely successful in eliminating infections. Control schemes therefore require both prevention and elimination to give optimal effect, and that optimum will vary with each pathogen.

The specific components of a mastitis control program must be devised to fulfill three basic principles, which are to eliminate existing infections, prevent new infections and monitor udder health.

1. ELIMINATE EXISTING INFECTIONS

The control program must reduce the duration of infection in the cows. Antimicrobial therapy during the dry period is the best method of achieving this objective. Treatment during lactation can be useful to eliminate some existing infections, depending on the causative agent. Culling of chronic cases that are not eliminated with dry period treatment is also used to remove the most persistent existing infections. Further study needs to focus on development of treatment protocols and on cowside identification of the causative bacterial agent.

2. PREVENT NEW INFECTIONS

The control program must reduce the rate at which new infections occur. The dipping of all teats in an effective teat dip after each milking is the best method of reducing the new infection rate. Insuring that the milking machine is functioning properly and used correctly will result in less spread of infection. The dry period is the time of greatest risk of new infection, and blanket dry cow therapy or application of an internal teat sealant is efficacious in preventing new infections during the dry period. Environmental and nutritional management have also become important for the prevention of new infections. Specific recommendations for methods of reducing new infection rate depend upon the predominant pathogen in the herd.

3. MONITOR UDDER HEALTH STATUS

An ongoing program to monitor the udder health status of individual cows as well as the herd is needed to evaluate the effectiveness of the control efforts. Monitoring methods should also assist with specific decision-making, such as optimized treatment protocols or culling. In the five point mastitis control programs recommended by the NIRD and the NMC, monitoring was not emphasized. As udder health status improves, and as milk quality premiums and penalty programs become meaningful, there is a need to continuously monitor udder health.

MASTITIS CONTROL PROGRAMS

A major step forward in mastitis control occurred in 1970 with the publication of the results of controlled field studies carried out by the NIRD.[13] The **five-point control plan** was based on attacking the key areas in the dynamic processes of mastitis and the individual components of the plan were evaluated as efficacious by field testing in dairy herds. Its success has been well documented. **The five-point plan has been highly successful for the control of contagious mastitis but is not adequate for environmental mastitis.** The plan depends heavily on the motivation, education and financial commitment of the milkers and the herd owner to achieve good and consistent results.

The five-point mastitis control program is as follows:

1. Udder hygiene and proper milking methods
2. Proper installation, function, and maintenance of milking equipment
3. Dry cow management and therapy
4. Appropriate therapy of mastitis cases during lactation
5. Culling of chronically infected cows.

Five additional management practices are recommended to make a **ten-point mastitis control program,** which includes emphasis on an appropriate environment, particularly for the control of

environmental mastitis, and the keeping of records, monitoring udder health and setting goals for udder health status.

6. Maintenance of an appropriate environment
7. Good record keeping
8. Monitoring udder health status
9. Periodic review of the udder health management program
10. Setting goals for udder health status.

The ten-point mastitis control program satisfies the basic needs of the farmers, an essential prerequisite in the implementation of a voluntary program. The program is profitable, within the scope of the producer's technical skill and understanding, capable of being introduced into current management systems, and encourages farmers to continue the program by rapidly reducing the occurrence of clinical mastitis and the rejection of milk by milk processors on the grounds of quality.

The components of the recommended ten-point mastitis control program are the same for all situations. The exact level of severity at which it will be implemented depends on its cost-effectiveness; higher milk and cattle prices will justify higher financial inputs. The program has the virtues of simplicity, profitability and widespread applicability, and most countries with a significant dairy industry have devised their own variant of it to suit their own local needs, especially the targets of freedom from infection and other quality-control criteria. The ten-point program was designed primarily for the control of the common contagious mastitis pathogens and may encounter difficulties unless measures to control the environmental infections receive special attention.

THE TEN-POINT MASTITIS CONTROL PROGRAM

1. UDDER HYGIENE AND PROPER MILKING METHODS

The principles of a proper milking procedure include:

- Premilking udder hygiene
- Stimulation of milk letdown
- Efficient removal of the milk
- Postmilking teat disinfection.

These principles are important for controlling the spread of contagious pathogens and for preventing new intramammary infections associated with environmental organisms. There is much farm-to-farm and region-to-region variation in how these milking procedures are applied. Milking methods are often taught to milkers by observation of the current methods used on the farm, and milkers are seldom objectively evaluated, especially in family farm operations with only one or two farm employees.

Several important steps are necessary in establishing a milking management routine, including the following.

Establish and maintain a regular milking schedule in a stress-free environment

A management routine using twice-daily milking should strive for a 12-hour interval. In the same way, an 8-hour interval between milkings is necessary for thrice-daily milking. The milking schedule is obviously less important with robotic milking. Consistency is as important as maintaining these exact intervals. Any influence that may add stress to the milking environment is to be avoided. For example, harsh crowd gates, rough handling, barking dogs and people shouting can be associated with epinephrine release, which will counteract the effect of oxytocin for efficient milk letdown.

Insure that teats are clean and dry prior to milking

The major objective of premilking udder preparation and teat sanitation is to reduce the microbial population of teat skin, and particularly at the teat end. The aim of these techniques is to minimize the probability of new intramammary infection and have good milking performance. Milking time hygiene is extremely important because of the potential interaction between milking machine function and the microflora of teat skin. The incidence of intramammary infection is highly correlated with the number of mastitis pathogens on the teat end at milking.

Premilking cow preparation

Premilking cow preparation is a step in milking management where there is considerable variability between what is recommended and what is actually practiced. **The goal is to milk clean and dry teats**. Current recommended procedures for premilking udder preparation range from waterhose washing and manual drying of teats, to washing teats with a paper towel wetted in warm sanitized solution plus drying with a single service paper towel, to the use of premilking teat dipping in germicide plus paper towel drying. The additional step of premilking teat disinfection (predipping) has been incorporated as part of the milking routine on many dairy farms. It is argued that manual teat washing improves stimulation and the release of oxytocin for milk letdown, in addition to cleaning debris from the teats and teat ends. However, with properly functioning milking equipment, there is little evidence that the manual massage is necessary for good milk letdown. In milking parlors where hand-held spray washers are used, it is important to avoid wetting the udder. Excessive water use can lead to bacterial contamination of the teat cups, and to an increase in the incidence of mastitis. In addition to individual paper towels, the use of latex gloves is also recommended in order to minimize cow-to-cow contamination.

Udder hygiene score

An udder hygiene scoring system has been developed, with the udder being viewed from behind. Score 1 is an udder free of dirt, score 2 has 2–10% of the surface area dirty, score 3 has 10–30% of the surface area covered with dirt, score 4 has more than 30% of the surface area covered with caked on dirt.[14] A hygiene scoring system is repeatable and easy to use, but only hygiene scores for the udder and hind limbs were associated with cow composite milk SCCs.[15]

Premilking teat disinfection

Premilking teat disinfection, more commonly referred to as **predipping**, is used by some dairy producers as a component of a mastitis control program. Premilking teat disinfection with chlorhexidine in association with good udder preparation and postmilking teat disinfection can further reduce the occurrence of new intramammary infections during lactation.[16] The use of a 0.25% iodine premilking teat disinfectant is more effective against major pathogens than postmilking disinfection only.[17] The use of predipping is increasing as the predominant cause of mastitis shifts from contagious pathogens to environmental pathogens. Controlled studies on the effectiveness of predipping indicate significant merit in the use of iodine predipping for the reduction of udder infections due to environmental pathogens.[18,19] Some studies found that premilking teat dipping with 0.25% iodophor did not reduce the incidence of clinical mastitis due to environmental pathogens[19] and the use of 0.5% iodophor plus good udder preparation did not affect the prevalence of infection of coagulase-negative *Staphylococcus* spp., but the rate of clinical mastitis in the control group was 1.38 cases per 1000 cow-days compared to 1.06 cases per 1000 cow-days in the predipped group.[20] The benefit–cost ratio of 0.37 indicated that the benefit of reduced incidence of clinical cases of mastitis did not justify the added expense required to predip the herd.

Although premilking teat dipping with iodine-based sanitizers may play a role in reducing new intramammary infections, there are some precautions that should be

taken. The major concern is the potential for increased iodine residues in milk. Predipping with either 0.5% or 1% iodophor does not significantly increase milk iodine residues if a paper towel is used to dry the teats.[19] Without drying, iodine residues are significantly increased. In addition, predipping in combination with post-milking teat disinfection may increase the potential for residues.[21]

Implementation of predipping into the cow preparation methods may require significant management changes, such as the drying of teats. Some of the improvement in udder health associated with the implementation of a predipping program may be attributable simply to the milking of clean, dry teats. Prior to the commencement of predipping, attaching the unit to wet or dirty teats may have been common. Whatever management methods are adopted on a particular farm, premilking hygiene and udder preparation can have a significant effect on milk bacterial counts, and on the incidence of mastitis.[20] The overall objective is to have **clean and dry** teats ready for attachment of the milking unit.

Check foremilk and udder for mastitis

Early clinical mastitis can be detected by physical examination of the udder for swelling, heat or pain, and by using a strip cup or black plate to examine foremilk from each quarter of each cow prior to every milking. This step has been a standard NMC management recommendation but the supporting evidence has been inconsistent. The rate of implementation of foremilk stripping is widely variable and depends upon the management system used being used more commonly in milking parlor situations.

Checking foremilk has three major advantages:

- Detection of clinical mastitis (such as clotty, stringy or watery milk), as early as possible. Detection of abnormalities is enhanced if the milk is evaluated against a dark surface such as a black strip plate
- Forestripping theoretically aids in preventing new infections of the mammary gland by flushing pathogens from the teat streak canal prior to milking. Bacterial colonization of the teat canal may not represent a problem until the organisms gain access to the teat sinus beyond the rosette of Furstenburg
- Stimulation of the milk letdown process. This could be helpful in systems where minimal cow preparation is used, such as a premilking program consisting of only a dry wipe.

In tie-stall barns, a strip cup is necessary to avoid contaminating the stall bedding or the cow herself. In milking parlors, it is common to use the concrete floor surface for detection of abnormalities in the milk. In either case it is important to recognize the potential for cow-to-cow transmission of pathogens by milk contact from one teat to another. For this reason, forestripping is often implemented prior to the predipping or udder washing step.

Attach the milking unit properly

The milking unit teat cups should be carefully attached to the udder within 90 seconds of starting udder preparation. The milk letdown process that follows the release of oxytocin after udder stimulation is at maximum for 3–5 minutes. Some effects of the oxytocin may last up to 8 minutes. It is important to use this physiological event to its maximum for the most efficient removal of the milk. The proper timing of milking unit attachment has been shown to shorten milk-out time and increase lactation productivity. However, consistency in the time interval from stimulation to attachment of the unit is as important as the exact time.

When attaching the teat cups, it is imperative to minimize the amount of air drawn into the system. Excessive air inlet could result in vacuum fluctuations, which may predispose to milk aerosol impacts of the teat end and machine-induced infections.

The machine position and support should be adjusted as necessary during milking. This will insure that quarters milk out properly. The milking unit should hang on the cow as straight and level as possible. Improperly adjusted support could contribute to uneven milk-out, and to an unbalanced udder on some cows; in addition, there is an increased probability of liner slips and squawking, which in turn will increase the risk of new intramammary infections. The mechanics and importance of liner slips will be discussed with milking machine function later in this chapter.

The use of proper milking machine attachment and adjustment methods affects the number of milker units that can be efficiently handled per person. With a tie-stall barn pipeline milking system it is recommended that a maximum of three units per person be used. It is unlikely that producers who milk with more than three units in a tie-stall barn are using appropriate cow preparation and milking machine attachment methods.

Minimize machine stripping and avoid liner slips

The majority of milking-machine-induced intramammary infections occur near the end of milking. Liner slips occur with a greater frequency near the end of milking. During a liner slip, air sneaks in between the teat and liner (heard as a squawk), increasing the potential for small droplets of contaminated milk to be propelled backwards against the end of the other teats (teat end impacts). Over a sustained period of time, liner slips and milk impacts may result in an intramammary infection.

Machine stripping is the act of putting hand pressure on the milker unit at the end of milking, for the purpose of removing extra milk. Machine stripping is habit forming, and will eventually lead to increased milking time. It also increases the risk of squawking, liner slips and milk impacts.

Avoid overmilking or removing the unit under vacuum

As soon as a cow is milked out, the vacuum to the milker unit should be shut off and the teat cups should be removed. The milker unit should gently 'fall off' the teats, causing no irritation. Removing the unit under vacuum will cause milk and air to impact on to the teat ends. Overmilking should be avoided to prevent teat end irritation. The unit should be removed as soon as the first quarter is milked out. The risk of liner slip is also increased during overmilking but there is little evidence that overmilking will result in an increased rate of intramammary infection, unless liner slips and teat end impacts occur. The practice of removing teat cups individually is also discouraged.

Use an effective and safe postmilking teat germicide after every milking

Teat dipping or spraying with a germicidal solution immediately after every milking is an effective milking management practice to reduce the rate of new intramammary infections. **Postmilking teat antisepsis is regarded as the single most effective mastitis control practice in lactating dairy cows.**

Teat dipping is a simple, effective and economical means to reduce bacterial populations on teat skin. There is general agreement that the numbers and types of bacteria on teat skin have a direct relationship to the incidence and types of intramammary infections that develop in a herd. An effective teat dip, correctly used, will reduce the incidence of new udder infections by 50–90%.

There are several major classes of postmilking teat sanitizer, and many available products within each class. The classes of product vary widely in their composition, formulation and mode of action. Each product should be evaluated for its safety, efficacy, advantages and disadvantages. The most commonly used

teat dips in the USA and Canada fall into several major classes.

Iodophor formulations

Iodophor teat dips have been used extensively and marketed in a variety of formulations, ranging from 0.1–1.0% available iodine. The safety and efficacy of these products are well established.[21]

Chlorhexidine

Chlorhexidine teat dips are also widely used and effective for reducing new infections.[22] They are more efficacious in the presence of organic material than other classes of product. Chlorhexidines have a broad spectrum of antimicrobial activity and excellent persistence on teat skin.[18] Commercial preparations are formulated with a dye to make the product visible, and with glycerine to minimize teat skin irritation.

Linear dodecyl benzene sulfonic acid products

Linear dodecyl benzene sulfonic acid (LDBSA) teat dips contain an organic acid and are formulated with emollients. They are generally nonstaining, tolerant of organic matter and less irritating than most other products; their efficacy against major mastitis organisms is well established.

Quaternary ammonium compounds

A variety of quaternary ammonium chemicals, in combination with lanolin or glycerine, are available as teat dip germicides and are safe and effective. They are readily broken down in the environment and depend heavily upon proper formulation for effectiveness.

Sodium hypochlorite

Many dairy farmers prepare their own teat dip by dilution of commercial laundry bleach to a final concentration of 4% sodium hypochlorite. It is effective and extremely low-cost. However, these dips are not government approved, have a strongly disagreeable odor, and can be inactivated by organic material. There is also a risk of mixing errors, resulting in the potential for irritation of teats and milkers' hands.

External teat sealants (barrier teat dips)

A goal that has yet to be achieved is development of a barrier teat dip that provides an effective teat sealant for use in lactating cows and withstands environmental contamination but is easily removed with minimal premilking udder preparation. Latex and acrylic latex-based products have been developed to act as a physical barrier to the entrance of mastitis pathogens into the udder. These products were aimed at the prevention of coliform mastitis. However, it has proved to be difficult to remove the residual product from teats. Furthermore, the barrier product alone is not intended to be effective against other major mastitis organisms.

External teat sealants have been formulated in combination with disinfectants to provide protection as both a barrier and a germicide. A postmilking teat disinfectant containing 0.64% sodium hypochlorite in a gel formulation was an effective and safe teat dip preparation.[23] However, in experimental studies, barrier teat dips were no more efficacious in preventing new intramammary infections due to *S. aureus* and *S. agalactiae* than no teat dip or the use of a nonbarrier product.[24] In contrast to their current use in lactating dairy cows, external and internal teat sealants are being increasingly applied at dry-off (see Dry cow management and therapy, below).

Selection and use of teat disinfectants

With the extensive array of commercially available postmilking teat germicidal preparations, producers need some guidelines in order to make an appropriate selection for use on their farms. Manufacturers of teat dips should provide the producer with documentation of the efficacy and safety of each product. In the USA, teat dip products must be listed with the Food and Drug Administration (FDA). The FDA regulates teat dips for compliance with label accuracy and manufacturing quality, but efficacy data is not required for registration. In Canada, teat dips must be approved by the Bureau of Veterinary Drugs. This approval process requires extensive data on human safety, animal safety and the efficacy of each new teat dip submission. Standard protocols have been endorsed for the evaluation of teat dip efficacy under conditions of experimental challenge with mastitis pathogens, as well as under conditions of natural exposure in commercial dairy herds.

In the USA, iodine-based teat dips are the most commonly used product for postmilking disinfection, and an iodine-based teat dip in 10% glycerin is generally regarded as the gold standard teat dip against which all other teat dips are compared. Dairy producers should request information on effectiveness when selecting a teat dip. Veterinarians should assist producers with interpretation of the data. There is no evidence that changing teat dips on a regular basis is necessary to prevent the development of resistant mastitis bacteria. Monitoring several measures of udder health status will signal the need for a change in teat dip product. The teat dip selected must be compatible with other chemical preparations used in the milking management system.

Postmilking teat dips can be applied by dipping or spraying. In North America, **dipping has been the most popular method.** However, with the increase in herd size and parlor automation, there is an increase in the use of teat spraying. Spray and dip application of the same product result in equal efficacy, when done appropriately; however, it is easier to do a bad job of teat coverage with spraying than dipping. Under field conditions, the effectiveness of either method will depend upon adequate coverage of each teat. A general recommendation is that **as much of each teat should be covered as is possible, and no less than the lower half**.

Teat dips should be stored in a cool dry place and not allowed to freeze. Contamination should be prevented, and expiry dates observed. For economic reasons, producers are tempted to dilute commercially available products; however, their effectiveness and safety may not be maintained. **At the end of milking, unused teat dip solution should NOT be poured back into the original container.** Dipping devices should be cleaned regularly.

In cold weather conditions, precautions should be taken with respect to teat dipping. Dipped teats should be allowed to dry before cows are exposed to cold and windy conditions. This will minimize the occurrence of frostbite of wet teats.

Establish milking order and segregation programs

In herds with a significant prevalence of contagious pathogens, such as *S. aureus*, establishing a specific milking order may be helpful to limit the rate of new infections. This is a popular veterinary recommendation that is **difficult to implement** because it usually requires massive disruption of the milking procedure. In general, first-lactation heifers and fresh cows should be milked first. Cows with high SCCs, chronic clinical mastitis and current clinical cases should be milked last. The maintenance and management of both SCCs and clinical mastitis records becomes important to make milking order programs work.

In larger herds, cows are usually grouped according to stage of lactation and production level. For nutritional management reasons, it is often suggested to have high-, medium- and low-production groups. In herds with a high prevalence of *S. aureus* mastitis, it has been suggested that the problem of spread would be stopped by simply isolating infected cows and milking them last. In theory, segregation combined with culling and effective dry cow management should allow the prevalence of *S. aureus* to approach zero. However, the change in prevalence of *S. aureus* infection in unsegregated herds compared with

herds using a segregated program indicates no significant difference.[25] A more significant decrease in prevalence of *S. aureus* mastitis was found in herds that gave priority to a full milking hygiene program, in combination with dry cow therapy and culling. Segregation is not a simple, stand-alone solution to contagious mastitis problems.

Disinfect teat liners

Disinfection of the milking machine teat cup liners between cows has the potential of limiting the spread of contagious organisms from cow to cow since bacterial populations in liners can be greatly reduced by sanitization. However, there is considerably less documentation that flushing liners will result in major reductions in contagious mastitis problems.[26]

In tie-stall milking barns, **liner disinfection** is a laborious process that involves dipping the claw in a series of solutions. Liners must be put through a rinse, a disinfectant and another rinse to remove the germicide. The solutions should be kept hot and replaced when they become overly contaminated. Only two liners can be dipped at one time if the milk hose remains connected to the pipeline, in order to avoid an air lock in the claw, which will reduce the disinfection process. However, if the milk hose is disconnected from the milk pipeline, then all four liners can be dipped at one time. Even with these limitations, dairy herds with intensive management, utilizing individual cow SCCs and culture information, can effectively use liner sanitization to limit the spread of contagious pathogens. Electric hot pails are commercially available in order to maintain the disinfection solution at a sterilization temperature.

In large milking parlor operations, automatic **backflushing** of milking units between cows is commercially available but expensive to install. In conjunction with automatic take-offs, the claw is flushed with rinse water, followed by disinfectant, and again rinsed, immediately after the unit detaches from a cow. An alternative procedure (**cluster dunking**) involves back flushing the milking units with water until a clear stream is obtained and then dunking the milking units in a bucket containing disinfectant while avoiding trapping of air in the dunking process. Large numbers of pathogens can be removed from teat cups by the backflushing process but documented reductions in the new intramammary infection rate are not available. For instance, backflushing decreased the numbers of staphylococci and Gram-negative bacteria on liners by 98.5% and 99.5%, respectively, caused a small decrease in the number of new infections by *C. bovis*, but had no effect on the incidence of new infections by staphylococci, streptococci or coliforms.[27] Until backflushing has been demonstrated to decrease the new infection rate, the procedure cannot be a routine recommendation.

2. PROPER INSTALLATION, FUNCTION AND MAINTENANCE OF MILKING EQUIPMENT

The milking machine plays an integral role in the efficiency of the operation of a dairy farm, and it has direct contact with teat tissue. It must perform properly and consistently, twice or three times a day (or much more frequently in robotic milkers), day after day, year after year. For these reasons, it is important that the milking system is installed according to approved guidelines. Regularly scheduled maintenance should be carried out, and machine function should be evaluated by periodic analysis of the system. All persons in the milking management process should thoroughly understand the basic components, function and operation of the milking equipment. They should also be aware of the significance of regular equipment maintenance and of the importance of good milking techniques.

Milking system function and objectives

The milking system performs several basic functions to achieve its objectives. These are:

- Causing milk to flow from the teat by exposing the teat ends to a partial vacuum
- Massaging the teat in an effort to relieve the effects of a continuous milking vacuum
- Protecting the milk from contamination while it is transported to a storage device, which cools and stores the milk until it can be transported to the processing plant.

Components of a milking system

In order to carry out the basic functions and to achieve the objective of efficient removal of the milk with minimal opportunity for intramammary infection, milking and milk handling equipment requires three basic components. These are:

- A vacuum system
- A milk pipeline system
- A bulk milk tank for milk cooling and storage.

Considerable engineering expertise goes into the proper design, installation and function of milking equipment. For the purposes of understanding the basic principles of machine milking, a brief description of these three components will be provided.

The vacuum system

Vacuum pump

The function of milking equipment depends upon the creation of a partial vacuum. A **vacuum pump** is used to continuously remove some of the air from the various lines in the milking system. The amount of air removed determines the system vacuum level, which is important for proper function. The vacuum level is monitored using a gauge which is read in either kilopascals (kPa), millimeters of mercury (mmHg) or inches of mercury (in.Hg). If one-half of the air is removed from the system, the vacuum gauge will read 50 kPa (15 in.Hg) vacuum. Vacuum pumps are rated on the basis of the volume of air they can move when the intake vacuum is at 50.7 kPa (15.0 in.Hg). Cubic feet per minute (CFM) is the standard air flow measurement used. The CFM rating of a vacuum pump determines the number of milking units that can be used on the system. For example, in order to operate six units, the minimum vacuum pump capacity is 52 CFM.

Vacuum reserve tank

Since the vacuum pump continuously removes a constant amount of air from the system, a **vacuum reserve tank** is placed between the pump and the vacuum supply line. The purpose of this tank is to provide a common site for connecting the vacuum header lines and to provide a reserve of vacuum to help buffer the sudden admission of air into the system. For example, when a milking unit falls off a cow, there should be enough reserve vacuum to maintain the system function. The amount of reserve vacuum needed in a system is a function of pump capacity, pump performance, regulator operation and the degree of system leakage. Vacuum reserve tanks are usually constructed of PVC plastic and should not be less than 75 L capacity.

Vacuum regulator

A **vacuum regulator** or controller is an important component of the vacuum system. The function of the regulator is to keep the vacuum of the milking system at a preset level by responding to changing air admissions into the system. The regulator should be located in proximity to, or directly on, the vacuum reserve tank. The regulator should be sensitive, for a rapid response to changes in vacuum. Servo-diaphragm regulators are the most sensitive style available, and are highly recommended. An increase in vacuum pump capacity cannot compensate for poor regulator function. Likewise, a sensitive regulator cannot compensate for a deficiency in pump capacity. The two components must work well together.

It is recommended that two vacuum gauges be installed in the system, for the purpose of monitoring the system vacuum. One gauge should be located on the milking vacuum supply line, near the regulator. A second gauge is best situated at the far end of the vacuum pulsation line. A portable mercury manometer should be used on a regular basis to calibrate the accuracy of the system vacuum gauges, as well as to make adjustments to the vacuum regulator. The preferred vacuum system installation consists of two header lines from the vacuum reserve tank, continuing to form a completely looped pulsation line. The recommended vacuum lines are 76 mm diameter PVC pipe, adequately supported, slightly sloped in the direction of air flow, and with automatic drain valves. This line allows for attachment of the milking unit pulsators.

Pulsation system

A properly functioning pulsation system is critical to teat and udder health. The pulsator causes the chamber between the teat cup shell and the liner to alternate regularly from vacuum to air source. Pulsators are either electromagnetic or pneumatic. In an electromagnetic system, all pulsators function together off an electrical signal. An electronic control circuit turns current on and off to the electromagnet. Pneumatic pulsators run off the vacuum system, and use air to move a plunger or slide valve to cover and uncover the air passage, producing the pulsating action.

An understanding of the dynamics within the teat cup and the characteristics of pulsation is crucial to insuring that the objectives of mechanical milking are achieved. The chamber between the teat cup shell and the liner is regularly subjected to a vacuum source, whereas the inside of the liner is under stable milking vacuum at all times. The pulsation cycle involves a milk phase and a rest or massage phase. When air is admitted between the shell and the liner, the liner collapses around the cow's teat. The collapsed liner has a massaging action on the teat; this is called the **rest** or **massage phase**. Milk does not flow from the teat during this phase. When the pulsator opens, the space between the liner and the shell is exposed to system vacuum. This creates equal pressure on both sides of the liner, causing it to open. The cow's teat end is now exposed to milking vacuum. This vacuum, in combination with the internal pressure of milk letdown within the cow's udder, causes milk to be drawn out through the teat streak canal. This component of pulsation is called the **milk phase**. The process of milking involves repeatedly opening (milk phase) and closing (rest phase) the teat cup liner.

The **pulsation cycle** is measured by the time, in seconds, for the completion of one milk phase and one rest phase. The **pulsation rate** refers to the number of cycles completed by a pulsator in one minute. Pulsation rates range from 45–60 cycles per minute. The **pulsation ratio** is the length of time in each cycle that the pulsator is in its milk phase compared to its rest phase. A common pulsation ratio is 60:40, indicating that in each pulsation cycle the teat cup chamber will be milking 60% of the time and massaging the teat 40% of the time. Wide pulsation ratios can speed up milking time but can put undue stress on the teats and teat ends from insufficient rest, predisposing to new intramammary infections.

Pulsation phase refers to the method of pulsation for the whole milking unit, and is either simultaneous or alternating. In simultaneous pulsation all four teat cups milk at the same time and rest at the same time. With alternating pulsation, two teat cups milk while two teat cups rest, then alternate to complete the pulsation cycle. The alternating action may be from side to side, or from front to rear. Alternating pulsation has several advantages. It allows a more uniform milk flow into and out of the claw, which helps to minimize flooding of the claw, which can result in fluctuations in teat end vacuum. In addition, front/rear alternating pulsation allows for a wider pulsation ratio on the rear quarters, which encourages a more uniform and timely milk-out of all four quarters. For alternating pulsation systems with two different ratios, care must be taken to insure that air hoses are not reversed when attached to the claw.

Electromagnetic pulsators are unaffected by environmental temperature and can function at a constant preset pulsation rate and ratio. Pneumatic pulsators can be greatly affected by changes in temperature and system vacuum. They require more maintenance and constant checking of the settings. Thus, **electromagnetic pulsators using alternating pulsation are most commonly recommended**, particularly for high-producing cows with fast milk letdown.

If a teat cup is not positioned properly on a teat, the liner may slip down the teat and produce a 'squawking' sound. As this is happening, air is entering around the teat into the liner. The entrance of this air changes the system of stable milking vacuum within the claw and the other teat cups. These changes lead to droplets of milk being driven in a reverse direction back at the teat ends of the other teats. These are referred to as '**milk impacts**'. Repeated teat end milk impacts, particularly with milk contaminated by mastitis pathogens, can result in new intramammary infections.

The milk transport system

Milking parlors and stanchion barn pipelines have similar systems for transporting milk from the cow to the bulk tank. The components of the transport system will be described in the direction of milk flow. The rubber or silicone insert in each teat cup is referred to as a **liner** or **inflation**. The liner should milk cows safely, with a minimal number of squawks from downward slippage, and without the teat cup crawl action of riding up on the teats to the base of the udder. Liner performance depends upon many interrelated characteristics of the milking system. **Narrow bore liners are recommended**. Liners must be compatible with the teat cup shell. The most important management consideration with respect to teat cup liners is to **insure regular replacement, as recommended by the manufacturer.** As a general guideline, natural rubber liners last 500–700 cow milkings, synthetic rubber liners 1000–1200 cow milkings and silicone liners 5000–10 000 cow milkings. The desired milking inflation replacement interval (in days) can be calculated using the following formula:

Number of days between changes = ((Number of cow milkings/set of liners) × (Number of units))/((Number of cows milking) × (Number of milkings/day)).

Other rubber parts of the unit, such as the short air tubes on the claw, should be constantly checked for cracks or signs of wear. These problems could seriously affect air flow and liner pulsation. Proper storage in dark, cool conditions, as well as the correct use of cleaners and sanitizers, can affect the life of rubber parts.

The milk claw

The **milk claw** is an important component of the milking unit. The claw is the collection point for milk from the four teat cups and should have adequate capacity to handle peak milk flow without flooding. Each claw should have a means of shutting off the vacuum to the teat end, so that the unit is not removed under vacuum. Most claws have an air vent in the upper half to allow a predetermined quantity of air into the unit to facilitate milk flow away from the cow and into the pipeline. Claws should routinely be **inspected for cleanliness, plugged air vents and dented liner connectors**.

A long milk hose is used to carry milk from the claw to the pipeline. The hoses can be made of plastic, rubber or silicone. **They should be as short as possible**,

with an appropriate hose hanger. If the milk hose is crimped or allowed to loop, milk flows will be interrupted, which leads to irregular fluctuations in teat-end vacuum. The milk hose should attach to an inlet located in the top third of the milk pipeline, at the eleven or twelve o'clock position. Inlets should be self-draining, self-closing and should not cause milk flow restrictions that would result in irregular teat-end vacuum fluctuations.

The milk pipeline

The **milk pipeline** serves two important functions: transporting milk from the cow to the receiver jar and carrying air flow to provide milking vacuum to the teat end. Either glass or stainless steel can be used for milk pipeline construction. The milk line should form a complete circuit and must be rigidly supported from the floor in order to maintain the appropriate slope. It is generally recommended that **milk lines be installed as low as is practical**. In milking parlors, low pipelines are installed below udder level. In stall barns, high pipelines are used, but they should be no higher than 2 m above the cow platform. Milk moves by gravity through the pipeline to the receiver jar. The milk line must be self-draining and should have a continuous slope from the high point toward the milk receiver jar. The **correct slope** is important for the movement of milk and air during milking, as well as for proper cleaning of the system. In the construction of new tie-stall barns, it is recommended that the foundation, floor and gutter be sloped towards the milk house end. This will help to minimize pipeline height and to insure that line slope will facilitate drainage during milking and washing.

Line diameter is another important feature of milk pipeline design. In addition to line slope and the level of herd production, pipeline diameter will determine the number of milking units that a system can handle. Too many units will lead to milk line flooding and a reduction in air flow rate. Slugs of milk moving through the line is an obvious sign of milk line flooding. This problem will have a negative impact on milking time, herd production and udder health. The recommended minimum pipeline diameter is 51 mm (2.0 in.). At this pipeline size, high-producing herds should not use more than three milking units per pipeline slope. Thus, larger pipeline sizes are often recommended for new installations. Pipeline couplers or welds must prevent air leakage into the system.

Milk should flow into the receiver jar in a continuous, unimpeded fashion. When sufficient milk has accumulated, an electronic probe triggers the milk pump to transfer milk from the receiver jar to the bulk tank. A milk filter is inserted into the transfer system, as a mechanism to remove coarse impurities that may have entered the line. The receiver jar is connected to the main vacuum supply. A device called a sanitary trap is used to separate the 'air only' portion of the milking system from the 'milk handling' side of the system. The sanitary trap is designed to protect the vacuum supply from potential damage caused by the chemical cleaning and sanitizing solutions used to clean milk pipelines.

A milking system should have the capability of measuring the amount of milk from each cow. In older milking parlor systems, weight jars were often used for this purpose. They allowed for a quick visual means of monitoring individual cow production at each milking, as well as providing vacuum stability to the cow. However, they were expensive and represented a challenge to clean. More recently, milk metering systems have been developed that give an **electronic digital readout of the milk volume produced** at each parlor station. These systems can often be adopted to automatic data recording in an on-farm computer system. In stall barn pipeline installations, several types of mechanical milk meter are in use. It is important that any metering system not be restrictive to the flow of air and milk. These restrictions can cause a drop in teat-end vacuum and the occurrence of irregular teat end vacuum fluctuations. Increased milking time, incomplete milk-out and new intramammary infections can result.

Bulk milk tank

The bulk milk tank is the vessel used to cool and store raw milk until it is picked up by the bulk milk transport truck. All tanks must be of an approved sanitary design and construction. They must be of sufficient capacity to cool and store up to 3 days of milk production. The cooling capabilities of bulk milk tanks are clearly specified. Appropriate cleaning and sanitizing procedures for bulk tanks are critical, in order to prevent bacterial growth and contamination of raw milk.

Relationship of milking equipment to udder health

The milking machine can influence new intramammary infection rates in several ways:

- The milking machine may be a carrier of mastitis pathogens from one cow to the next
- The milking machine may serve as a pathway of cross-infection within cows
- Malfunctioning or improperly used equipment may result in failure to relieve congestion in teat tissue. Eventually, teat end damage and intramammary infection can occur
- Abrupt loss of milking vacuum may create changes in air movement of sufficient force to move pathogens past the streak canal defenses. This phenomenon, known as the impact mechanism, was described earlier.

The pathogenesis of new infections related to machine milking probably involves all four of these factors.[26] However, even though the milking system becomes the focus of many herd udder health investigations, there is little evidence that machine factors are of primary importance in most problem herds. It has been difficult to link milking machine factors and prevalence of herd infection. Mastitis has been difficult to produce experimentally by altering machine function.[28]

A great deal of research has been directed towards the identification of machine factors related to mastitis. Although many problems are identified, the only factors consistently associated with udder health problems are pulsation failure and the impact mechanism.

Appropriate pulsation is important for sufficient teat end massage. Although continuous vacuum will remove milk from cows' teats, eventually it will result in excessive congestion, edema and teat end damage. An adequate compressive load by the liner on the teat tissue is necessary to relieve the congestion. Mechanical failure of the pulsator, shortness of the liner barrel and a too-short liner rest phase are the most common examples of pulsation problems. The impact mechanism results from an abrupt loss of milking vacuum. Poor liner design has been shown to increase the frequency of liner slips. During a liner slip, a reverse pressure gradient occurs across the streak canal of the other three teats. Liner design has been shown to be very important in reducing the amount of slippage.[29] In combination with liner slips, the vacuum fluctuations that result from pulsation problems can lead to new intramammary infection.

Even with the myriad of potential machine problems, milking equipment is not usually the major risk factor for poor udder health.

Maintenance and evaluation of milking equipment

The most important aspect of udder health management related to milking equipment is the establishment of an appropriate evaluation, maintenance and service schedule. Farm personnel should

incorporate an inspection of the equipment into their regular milking process. Many of the problems discussed in conjunction with the description of milking system components can be discovered during this daily inspection. In addition, the producer should have milking equipment serviced on a regular basis. Items such as the vacuum pump, regulator, pulsators and sanitary trap would be included in this check list. Also included in this inspection will be regular changing of the teat cup liners and other rubber parts. It is common for equipment dealers to schedule a regular visit to each farm client for the purpose of conducting this periodic maintenance schedule and for dispensing chemical cleaners and disinfectants used in the udder health management program.

A complete milking system analysis should be conducted on a regularly scheduled basis. This regular analysis is perhaps just as important as the initial design and installation of the system. Many dairy cattle specialists believe that a regular independent analysis will insure proper equipment function. Milking system analysis can be conducted by equipment dealers, government extension staff, veterinarians or independent technicians. All these individuals need the appropriate knowledge and training. It is essential to use some type of systematic milking system analysis worksheet to record various performance measurements and to identify components requiring service or upgrading. A complete system analysis should be conducted at least once a year, and records should be kept for future reference.

3. DRY COW MANAGEMENT AND THERAPY

The proper management of dry cows and late-gestation heifers is an important component of a mastitis control program. The dry period offers a valuable opportunity to improve udder health while cows are not lactating. However, the beginning and the end of the dry period represent periods of increased risk of infection.[30] **The objective of udder health management during the dry period is to minimize the number of infected quarters at calving.** Two of the three major principles of udder health management must be met in order to achieve this objective. **Infections present at the time of drying off should be eliminated** and **the rate of new intramammary infections during the dry period must be minimized.** Thus dry cow therapy has a dual role in eliminating existing infections and preventing new infections during the dry period, and has been widely adopted by dairy farmers. If these two principles are followed, udders will be free of infection at calving and can be expected to produce a maximum amount of low-cell-count milk in the subsequent lactation. Intramammary administration of long-acting antimicrobial agents to all cows at drying off remains a routine recommendation.

Epidemiology of intramammary infection during the dry period

The development of effective udder health management strategies for the dry period requires an understanding of the epidemiology of intramammary infections in dry cows. This in turn requires an understanding of the incidence of new infections during the dry period and the types of pathogen involved. Risk factors that affect the susceptibility of dry cows should also be understood.

Incidence of new infections

The rate of new intramammary infections is significantly higher in the dry period than during lactation.[30] The greatest increase in susceptibility is during the first 3 weeks of the dry period. In this period, the new infection rate is many times higher than during the preceding lactation as a whole. A second period of heightened susceptibility occurs just prior to parturition. The reported rates of new intramammary infection in the dry period vary widely. Reasons for these differences include the diagnostic criteria used and the types of organism considered to be major pathogens. There are also important herd-level effects, such as the prevalence of existing infections at drying off and the method of dry-off. The average rate of new infections in untreated dry cows is expected to be between 8% and 12% of quarters.[30]

Types of pathogen causing new infections during the dry period

Contagious pathogens are transmitted among cows and quarters in association with the milking process. **Environmental pathogens** are primarily contracted from contamination with organisms in manure and bedding. **Teat skin opportunistic pathogens** are present on the teat, particularly the teat end. Contagious, environmental and teat skin opportunistic pathogens need to be considered in designing mastitis control schemes for the dry period.

Exposure to environmental pathogens is likely to continue throughout the dry period; thus prevention of new dry period infection with environmental agents represents a considerably greater challenge.[30] Herds that have implemented a basic mastitis control program still need to be aware of the importance of preventing environmental infections in the dry period. There are different rates of infection by the various environmental agents as the dry period progresses. For example, infections with environmental streptococcal species, *Klebsiella* spp. and *Enterobacter* spp. occur more frequently early in the dry period. On the other hand, *E. coli* infections tend to occur immediately before calving. Dry cow management strategies need to account for the risk of infection during the entire period from last milking until the next calving.

Risk factors that affect susceptibility in dry cows

Several factors contribute to the variation in susceptibility during the dry period. These factors include the following.

Teat end protection

The cessation of routine milking-time hygienic practices such as teat dipping allows bacterial subpopulations on teat skin to increase in number and diversity. *S. aureus* numbers are high immediately after drying off and environmental pathogens are more prevalent on teat skin late in the dry period and at calving time.[30] Teat end lesions increase the likelihood of intramammary infections during the dry period. A plausible mechanism to explain this association is that teat end lesions increase the surface area available for bacterial colonization while presenting a variety of environmental niches. For instance, quarters with cracked teat ends were 1.7 times more likely to develop a new intramammary infection during the dry period than unaffected quarters.[31]

The streak canal of the teat is more penetrable by bacteria during the early dry period. The keratin plug in the streak canal must form early and completely in the early dry period in order to prevent penetration and growth of bacteria and decrease the incidence of new intramammary infections. However, this natural internal teat sealant does not form in some cows, and delay in formation is common. For instance, in cows in New Zealand, 45% of teats are open on day 7 of the dry period, and 25% are still open on day 35 of the dry period.[32] Similar results were obtained in North American dairy cows.[31] Quarters that remain open during the dry period are 1.8 times more likely to develop a new intramammary infection than quarters that have developed an effective keratin plug.[31] Internal and external teat sealants are discussed further later in this chapter.

Swelling of the mammary gland, an increasing volume of secretion and leaking colostrum contribute to the high risk of new infection during the prepartum period.

Resistance mechanisms within the mammary gland

Throughout the dry period there are marked changes in the composition of mammary gland secretions and in the concentration of protective factors such as leukocytes, immunoglobulins and lactoferrin. These changes probably influence the variation in susceptibility to both environmental and contagious pathogens.

Substantial evidence exists that innate and acquired defense mechanisms are lowest from 3 weeks precalving to 3 weeks postcalving.[33] This lowered responsiveness includes aspects of systemic and mammary gland immunity that may account, in part, for the increased incidence of peripartum disease. Polymorphonuclear neutrophil function is impaired during the peripartum period and may contribute to the increased incidence of mastitis following calving. Diminished lymphocyte responsiveness around calving has also been observed.[33] The role of the cow in effectively transferring antibodies and cells to the mammary gland prior to parturition to insure high-quality colostrum is also an important function, and this may be affected by prepartum vaccination schedules and the ability of the animal to respond effectively.

Milk production at dry off

A high level of milk production at dry off increases the incidence of new intramammary infections at calving.[34] It is reasonable to assume that high milk production at dry-off will produce a higher intramammary pressure, thereby increasing the likelihood of an open streak canal early in the dry period. High milk production at dry-off will also decrease the concentration of protective fractions such as phagocytic cells, immunoglobulin and lactoferrin,[35,36] thereby decreasing resistance within the mammary gland. The finding that cows leaking milk following dry-off are four times more likely to develop clinical mastitis in the dry period[37] supports the concept that **increased milk production at dry-off increases the rate of new intramammary infections**.

Method of drying off

The industry standard method for cessation of lactation (drying off) is abrupt cessation of milking, whereby milking stops on the day scheduled for dry-off (all cows are usually scheduled to 'go dry' on the same day each week) in order to facilitate administration of dry cow intramammary antibiotics, vaccinations and vitamin E/selenium injections. Abrupt cessation is associated with a higher new intramammary infection rate in the dry period compared to intermittent cessation,[38,39] although the increase in prevalence is most evident in cows that are not dry treated. The best approach to dry off cows may therefore be intermittent milking, although additional studies are required before the industry standard is altered. In particular, the method of drying off is probably less important with blanket dry cow therapy.

Parity

Older cows are more likely to develop new intramammary infections during the dry period. This increased predilection may be due to increased milk production at dry-off, increased prevalence of abnormal teat placement (increasing exposure of the teat end to pathogens) or increased prevalence of open streak canals because older cows have higher milk production.

Risk factors that affect susceptibility in heifers

An increased risk for intramammary infection in the preparturient period in heifers is associated with the presence of *S. aureus* or *M. bovis* in the herd, calving in summer, high herd bulk tank milk SCCs, poor fly control, mastitic milk fed to calves and contact with adult cows.[40] Other risk factors are increased age at first calving, prepartum milk leakage,[41] blood in milk[42] and udder edema.[43]

Udder health management strategies for dry cows

Antimicrobial therapy (dry cow therapy)

Antimicrobial therapy at the end of lactation (dry cow therapy) has been one of the key steps in mastitis control programs and has become the most effective and widely used control method for dry cows. The efficacy and advantages of antimicrobial therapy are well known. The use of effective dry cow products results in 70–98% elimination of existing infections. However, elimination of *S. aureus* is less successful. **Dry cow therapy also reduces the incidence of new intramammary infections by approximately 80%**.[44]

Long-acting antimicrobial preparations have been formulated to **eliminate existing infections** and to **prevent new infections**. These preparations include benzathine cephapirin, benzathine cloxacillin and sustained-release formulations of erythromycin, novobiocin and penicillin. The withholding period for milk from animals treated with these dry cow formulations ranges from 30–42 days after treatment. It is important that the label directions be followed carefully for the recommended dosage level, required withdrawal period, storage guidelines and expiry dates. A general recommendation is that dry cow treatment should never be administered within 1 month of the expected calving date. Single-dose syringe preparations of dry cow antibiotic treatment are recommended. The risk of contamination by environmental bacteria and yeast is much higher for multiple-dose bottles than for single-dose syringes. If bulk containers are used, great attention should be paid to maintaining sterility.

The use of long-acting and short-acting antimicrobial intramammary infusions have been compared.[45] In some cases, short-acting antimicrobial agents were more effective than long-acting ones in eliminating infections due to *S. aureus* or treating cows infected with major pathogens diagnosed twice before drying off. Intramammary infusion of cephapirin sodium 15 days prepartum in heifers was effective in reducing intramammary infections during late gestation and reduced the occurrence of residues in milk during early lactation.[46] The milk of heifers that calve less than 15 days after treatment may contain antimicrobial residues.

Intramammary infusion is a widely used and highly recommended procedure for mastitis therapy; however, there is a potential for the introduction of pathogens during the infusion process. Insanitary infusion practices can introduce antibiotic-resistant environmental organisms into the udder. Infection with opportunistic microorganisms, such as yeast or *Nocardia* spp., may cause more extensive udder damage than the original organism for which treatment was being administered. Adequate teat end preparation and careful dry cow treatment procedures can reduce this risk. Dry cow treatment procedures should be carried out as follows:

- Milk out the udder completely
- Immediately following teat cup removal, dip all teats in an effective teat dip
- Allow the teat dip to dry. If necessary, remove excess dip from teat ends with a clean single-service paper towel
- Disinfect each teat end by scrubbing for a few seconds with a separate alcohol-soaked cotton swab. Start with the teats on the far side of the udder and work to the near side
- Infuse each quarter with a single-dose syringe of a recommended dry cow treatment. Start with the teats on the near side of the udder. Use the partial insertion method of administration into the teat streak canal. Preferably, a modified infusion cannula should be provided with the treatment product
- Dip all teats in an effective teat dip immediately following treatment.

The necessity of using appropriate dry cow treatment procedures cannot be

overemphasized. An increased incidence of *Nocardia* spp. mastitis has been associated with blanket dry cow therapy, especially neomycin-containing products. However, *Nocardia* spp. were not found as a contaminant of the suspected products. Teat end preparation by scrubbing with an alcohol-soaked cotton swab was protective against the occurrence of *Nocardia* spp. infection when teats were experimentally contaminated with organisms immediately before drying off.[47] Most commercial dry cow treatment products provide individually wrapped alcohol-soaked cotton swabs for use with each syringe. The use of good teat end preparation prior to intramammary infusion needs to be continually emphasized.

The method of intramammary infusion may be important. Partial insertion of the infusion cannula (up to 4 mm) results in fewer new intramammary infections and improved cure rates. The improvement with a short cannula is attributed to fewer organisms being delivered beyond the streak canal and decreased physical trauma to the streak canal. In addition, antimicrobial agents that are deposited within the streak canal should control local infections. Modified infusion cannulas for the convenient use of a partial insertion method of administration are now available for commercial dry cow products.

Another approach to preventing the problems associated with intramammary infusion would be the development of an effective systemically administered dry cow treatment. Preliminary results have indicated improved efficacy against *S. aureus* infections using a systemically administered quinoline antibiotic (norfloxacin nicotinate).

Blanket versus selective dry cow therapy

Three strategies for intramammary antimicrobial treatment of dry cows are available,[48] although the current recommendation for all herds is blanket therapy:

- **Blanket therapy** (treat all quarters of all cows)
- **Selective cow therapy** (treat all quarters of any cow infected in one or more quarters)
- **Selective quarter therapy** (treat infected quarters only).

Although blanket dry cow therapy is a cornerstone of any mastitis control program, there is some controversy concerning the need to treat all quarters of all cows (**blanket therapy**) or only those quarters or cows requiring treatment. The controversy has gained momentum as the implementation of udder health management practices has reduced the prevalence of infection. The major reasons for selective therapy are:

- To avoid the elimination of minor pathogens, which may make cows more susceptible to environmental agents
- To reduce the expense of treatment
- To address increasing consumer concern regarding the routine administration of antibiotics to food-producing animals
- To avoid the possible emergence of antibiotic-resistant organisms.[30]

Each of these reasons should be carefully considered in making a decision between blanket and selective dry cow therapy. Selective dry cow therapy is preferable provided that an accurate, practical and inexpensive method for selecting infected cows is available.[48] This is the major problem with selective dry cow therapy – in most herds the sensitivity and specificity of the test used for selection is not adequate.

As general udder health improves and bulk tank milk SCC remains low, producers question the need to continue dry treatment on all cows and are attracted by a potential reduction in costs for the purchase of dry cow treatment. However, selective therapy requires a decision as to which cows or quarters are to be treated. The sensitivity and specificity of currently available screening tests are inadequate as a basis for decisions concerning selective therapy. The history of the number of episodes of clinical mastitis, individual cow composite SCC during lactation and at dry off, CMT results during lactation or at dry-off and even bacteriological culture towards the end of lactation all result in leaving some infected cows untreated, but conversely result in the treatment of many uninfected cows. An important requirement for large-scale implementation of selective dry cow therapy is the development of a cheap, practical, sensitive and specific test to identify infected cows. The failure to prevent new intramammary infections during the dry period with the selective approach must also be considered. New infections in the dry period will become increasingly important as contagious pathogens are eliminated from herds. Finally, blanket dry cow therapy reduces new infection rates for quarters from approximately 14% to 7%. The increase in milk production alone resulting from prevention of these new infections provides enough return to offset the cost of treatment for all cows.

Information presently available indicates that the general recommendation should be for **routine treatment of all quarters of all cows at the time of drying off (blanket dry cow therapy)**. There is a need to identify important management practices to limit new infections in untreated dry cows and to develop new screening tests to determine which cows should be treated. New environmental management methods and modern information processing capabilities may lead to the development of better selective dry cow treatment programs. These may include the administration of ancillary therapeutic agents. For instance, the intramammary infusion of recombinant bovine interleukin-2 along with cephapirin sodium at drying off marginally increased the cure rate of intramammary infections associated with *S. aureus*, but not other pathogens, during the dry period compared with the administration of cephapirin only.[29] Interleukin did not affect the incidence of new intramammary infections for any pathogen group. However, the intramammary infusion of interleukin at drying off was associated with an increased incidence of abortion in dairy cows 3–7 days after the infusion.

Factors affecting the success of antimicrobial treatment of dry cows

Despite blanket dry cow therapy, some cows calve with infected quarters and some with clinical mastitis. Several risk factors affecting the results of dry cow treatment have been evaluated.[49,50] Some of these factors are:

- **Number of quarters infected**. With *S. aureus* infections, there is a significant decrease in cure rate as the number of quarters infected per cow increases. Quarters from cows with either three or four of their quarters infected have a very poor cure rate
- **Age of the cow**. As the age of the cow increases, the probability of *S. aureus* infections being cured by dry cow therapy decreases
- **Somatic cell count before drying off**. The cure rate of *S. aureus*-infected quarters diminishes as the SCC prior to treatment increases. Controlling for age and number of quarters infected, there was a significantly lower cure rate in quarters with an SCC of more than 1 000 000 cells/mL[49]
- **Herd of origin**. There is a distinct herd effect on the success of dry cow therapy. The cure rate of *S. aureus* has been shown to be higher in herds with good hygiene and with a low prevalence of *S. aureus* infections at drying off.[49]

There is considerable potential in using individual cow and herd-level information to predict the likelihood of a cure with dry cow therapy. For example, an older cow with three quarters infected with *S. aureus* and a persistently high SCC has a low probability of a cure. Continued

development of information management systems to assist with therapy and culling decisions will clarify the expectations of dry cow treatment.

Persistent *S. aureus* infections represent only one of the shortcomings of antibiotic treatment for dry cows. Most dry cow products are formulated for efficacy against Gram-positive cocci. These antibiotics are of limited usefulness against Gram-negative bacteria. In other words, new coliform infections would not be prevented by this therapy. Even though dry cow products are formulated for sustained activity, the provision of adequate protection during the critical prepartum period is questionable. The persistence of effective levels of antimicrobial agents has been evaluated for various dry cow treatments;[51] very few products have persistent activity until the time of calving.

Vaccination of the dry cow

Immunization and immunotherapy for the control and prevention of mastitis have been active areas of research.[52] Effective vaccines would have to eliminate chronic intramammary infections, prevent new intramammary infections or decrease the incidence or severity of clinical mastitis. Currently available mastitis vaccines may reduce the incidence and severity of clinical mastitis but have not eliminated chronic intramammary infections or prevented new intramammary infections. The inability of vaccines to prevent infection may be due to the wide variety of pathogens, inadequate specific antibodies or the failure of antibodies to enter the mammary gland prior to infection. Currently available vaccines should be used as adjuncts to other more effective control strategies.

Vaccines have been developed to reduce the incidence and severity of clinical mastitis associated with Gram-negative pathogens.[53] R-mutant bacteria have an exposed inner wall structure (core lipopolysaccharide antigens) that is highly uniform, even among diverse and distantly related Gram-negative bacteria. Vaccines containing killed R-mutant bacteria provide broad-spectrum immunity against a wide variety of unrelated Gram-negative bacteria. The most commonly used coliform mastitis vaccines are the Rc-mutant *E. coli* O111:B4, known as the J5 vaccine, and the Re-mutant *Salmonella typhimurium;* both of which are commercially available in the USA.[52] R-mutant vaccines have been efficacious in the reduction of the incidence and severity of clinical mastitis due to Gram-negative bacteria. More than 50% of large (> 200 cows) dairy herds and more than 25% of all dairy herds in the USA are using core lipopolysaccharide antigen vaccines.[54] No protection is provided against environmental streptococci and staphylococci, or the contagious pathogens.

No effective vaccines are currently available for the control of mastitis due to *S. aureus*, *S. agalactiae*, environmental streptococci, and *M. bovis*.

The use of recombinant bovine cytokines as adjuvants to enhance specific immunity in the mammary gland of cows after primary immunization against indicate an enhancement of specific immunity in the mammary gland, which may be effective in mastitis immunization protocols.

Management of the environment for dry cows

Dry cows should be provided with an environment that is as clean and dry as possible. If this is not feasible in confinement housing, it is probably better to maintain dry cows on pasture. Variations in the load of coliforms and environmental streptococci in the environment are important predictors of new infection rates. Minimizing the exposure to environmental bacteria will reduce the new infection rate. However, some pasture conditions promote the crowding of cows under shade trees. In hot, humid and muddy conditions, heavy contamination of such a small area can result in a significant risk of new environmental infections in the dry period. In good weather, it is ideal to hold parturient cows in a clean, grassy area where they can be observed and assisted if necessary.

In confinement housing systems for dry cows, it is important to provide adequate space, ventilation, bedding and lighting to insure cleanliness and comfort. Maternity (calving) stalls should be bedded with clean straw, sawdust or shavings. Other important procedures for managing the environment for dry cows include adopting an effective fly control program. Clipping the hair on the udders, flanks and inside the hind legs will help reduce contamination. **The words clean, dry, cold and comfortable summarize the ideal environment for dry cows.** The words clean and dry also summarize the goal for the teat before attachment of the inflation during milking.

Nutritional management of dry cows

A nutritionally balanced dry cow feeding program is important to insure udder health. A role has been suggested for specific nutritional factors in resistance to mastitis, especially over the dry period. Adequate levels of vitamin E and selenium in dry cow rations appear to be important for udder health at calving and in early lactation.[55] This effect may be mediated through enhanced resistance mechanisms. Other vitamins and minerals may be important in udder health, but their role is less well substantiated.

Nutritional management of dry cows is also important for reducing the risk of milk fever, which is an important predisposing factor to mastitis in fresh cows. Appropriate body condition can be achieved by good nutritional management in late lactation. The association between body condition, energy metabolism and udder health needs further clarification.

Internal teat sealants

As discussed previously in risk factors for infection in the dry period, **the keratin plug is a natural internal teat sealant** that provides an effective barrier to new intramammary infections. High milk production at dry-off increases the likelihood that the streak canal remains open and presumably compromises formation of the keratin plug, thereby increasing the risk of intramammary infection.[34]

A recent promising development in mastitis control has been **exogenous internal teat sealants** that are applied at dry off. The teat sealant product most extensively evaluated contains a heavy inorganic salt (**bismuth subnitrate**) in a paraffin wax base; this product does not have antibacterial properties but acts as a **physical barrier** to ascending intramammary infections. A New Zealand study involving 528 cows indicated that the internal teat sealant was retained for dry period lengths of more than 100 days, while producing a ten-fold decrease in the new intramammary infection rate, which was similar to that produced by dry cow intramammary infusion alone.[56] In contrast, a UK study involving more than 1000 cows indicated that bismuth subnitrate teat sealant alone decreased the number of new intramammary infections to a great extent than intramammary dry cow infusion alone.[57] The UK study had a greater incidence of new intramammary infections due to Gram-negative bacteria than the New Zealand study. A US study involving 437 cows found that an internal teat sealant at dry-off decreased new intramammary infections by 30% in the dry period and treated cows were 33% less likely to have a clinical mastitis episode between dry-off and the first 60 days of the subsequent lactation[58] compared to untreated quarters. The addition of an antimicrobial agent is a logical addition to the bismuth subnitrate internal teat sealant and has been a routine addition to the teat sealant for some years in Ireland.

Bismuth subnitrate internal teat sealants clearly show promise for the prevention of new intramammary infections during the dry period. However, because **bismuth subnitrate teat sealants do not eliminate**

existing intramammary infections, and an accurate method for determining the infection status of a quarter is unavailable (the exception being milk culture), the recommended application of internal teat sealants requires combined application with intramammary dry cow therapy. This combined therapy may be uneconomic. Widespread adoption of internal teat sealants will require an accurate test for determining intramammary infection status at dry-off. Finally, administration of internal teat sealants alone obviously requires proper aseptic technique.

External teat sealants

A longer-standing approach to providing a physical barrier to ascending infections is the use of external teat sealants, which were originally developed for use in lactating cows. The major problem with external teat sealants is the duration of adherence, which is too long for lactating cow use and too short for dry cows. Teat end lesions and teat length influence the adherence of external teat sealants.[31] Widespread adoption of external teat sealants will require a product that provides prolonged protection but is easily removed at calving.

Teat disinfection

Postmilking teat disinfection is a very effective means of reducing new infections in lactating cows. However, the efficacy of teat disinfection in decreasing the incidence of new intramammary infections in the dry period has been discouraging. Daily teat dipping for the first week of the dry period is not effective in reducing *S. uberis* infections. The lack of efficacy of teat disinfection needs to be contrasted to the efficacy of internal teat sealants.

Intramammary devices

Intramammary devices have been developed for use in preventing new infections in both lactating and dry cows. However, there is conflicting evidence as to the reduction in infection rate in quarters fitted with these devices, and such devices are no longer being investigated. The incidence of clinical mastitis may be less in cows fitted with these devices compared to control cows but the prevalence of subclinical infection is unaffected.[59] Intramammary devices induce a significant increase in postmilking SCC compared to control cows, and test-day SCCs may be higher than in control cows.

4. APPROPRIATE THERAPY OF MASTITIS DURING LACTATION

The early recognition and treatment of clinical cases remains an important part of a mastitis control program. Improvements in understanding of the epidemiology, pathophysiology, and response to therapy of various mastitis pathogens have clarified the role of intramammary and parenteral antimicrobial agents for of the treatment of clinical and subclinical mastitis during lactation. This is covered extensively earlier in this chapter.

5. CULLING CHRONICALLY INFECTED COWS

The final step of the five-point mastitis control program is the selective removal of cows with chronic intramammary infection from the herd. Most producers have interpreted this recommendation to mean that cows with recurrent episodes of clinical mastitis should be eliminated. For example, some herds have established that cows having three or more clinical cases of mastitis in a lactation will be culled (**the popular 'three strikes and out' approach**). However, very little research has been conducted to determine the effect of various culling strategies on herd udder health status, and on the incidence of clinical cases.

Nevertheless, culling chronically infected cows meets one of the three guiding principles of mastitis control, namely the elimination of existing intramammary infections. Through the use of available monitoring techniques and the establishment of a defined culling program, a valuable opportunity exists to improve udder health by culling.

In general, a record of chronic mastitis and severe fibrosis detected on deep udder palpation should be the basis of a recommendation to cull. Culling is an effective and documented mastitis control measure for some specific mastitis pathogens. For example, the removal of infected cows is a key element of the recommended mastitis control program for herds with a high prevalence of *S. aureus* infection. Removal of cows found to be infected with *S. aureus* accounted for more than 80% of the costs involved in the control program. Culling is also important in the control of other mastitis pathogens that respond poorly to antimicrobial therapy. Herds with mastitis cases associated with *M. bovis*, *Nocardia* spp., and *P. aeruginosa* should be aware of the benefits of culling infected cows.

A dairy herd culling program should be based upon consideration of the net present value of each cow in the herd as compared to the value of a replacement heifer.[60] The net present value depends on the age of the cow, her potential for milk production, the stage of lactation and her pregnancy status. Factors that determine the likelihood of treatment success, such as pathogen and duration of mastitis, as well as the cost of treatment, also need to be considered in calculating the net present value of the cow with mastitis. After consideration of the relative importance of udder health in the overall herd health management program, additional economic pressure may be applied to cows with a specific udder health status. For example, if a *S. aureus* control program is a major priority in the health management program, additional economic pressure should be applied in removal decisions of cows with known *S. aureus* infections. As health management data collection and analysis improve in sophistication, decision analysis methods and expert computer models will be used to provide this information automatically.

Biosecurity for herd replacements

Replacement animals may be purchased to increase herd size or to maintain cow numbers following culling. Biosecurity measures must be used to insure that herd replacements are not infected with contagious mastitis pathogens (specifically *S. aureus*, *S. agalactiae*, *M. bovis*). However, an economic analysis of the different components of a biosecurity program has not been performed, and it is likely that some components of currently used programs are not cost-effective.

An optimal biosecurity program includes knowing the herd of origin, knowing the cows and protecting the home herd.

Know the farm of origin

- Request a bulk tank milk culture from the farm of origin
- Request the following data:
  6–12 months of bulk tank milk SCC;
  bulk tank milk bacterial counts;
  6–12 months of records for clinical mastitis.

Know the cows

When purchasing single or small groups of animals the following prepurchase procedures are recommended:

- SCC and clinical mastitis records for each cow to be purchased
- Results of bacteriological culturing of quarter milk samples from each cow on arrival (if lactating) or at calving (if late-gestation) for *S. aureus*, *S. agalactiae* and *M. bovis*. In general, the sensitivity of a single milk culture to detect the presence of intramammary infections due to *S. agalactiae* is approximately 95%, for *S. aureus* it ranges from 30–86%, and for *M. bovis* it is 24%
- A physical examination of each cow, including udder, milk quality and teat ends.

Protect the home herd

Consider all purchased animals as potential health risks to the home herd by doing the following:

- Maintain all newly purchased animals in separate or isolated facilities until

diagnostic tests for udder health have been completed and there is no evidence of infection that may spread to the rest of the herd (usually < 14 d quarantine)
- Evaluate all herd replacements for evidence of antimicrobial residues in milk
- Milk all purchased animals last or with separate milking equipment until it is determined that they are free of infection
- Obtain results of bacteriological culturing of bulk tank milk samples or string samples for *S. aureus*, *S. agalactiae* and *M. bovis*; culturing should be done on more than one occasion because the sensitivity of bulk tank milk culturing is not 100%, and is less than 50% for *M. bovis*.

6. MAINTENANCE OF AN APPROPRIATE ENVIRONMENT

The multifactorial nature of mastitis has been emphasized throughout this chapter. Intramammary infection results from a complex interaction between the cow, the mastitis pathogens and the environment. Thus, the control of unfavorable environmental influences is extremely important in dairy herd udder health management programs.

Intramammary infection involves exposure of the teat surface to potentially pathogenic microorganisms, entry of the pathogens into the gland via the teat duct and establishment of the pathogens in the mammary tissue, producing an inflammatory response. Many environmental factors can influence this process of exposure, bacterial entry and establishment of infection. For example, the type of bedding and manure management can have a great impact on the contamination of teat skin with microorganisms. Housing design can have an impact on the prevalence of teat injuries, which will influence intramammary invasion by mastitis pathogens. Extreme climatic conditions, poor nutritional management and cow stocking densities will influence the immune system and the establishment of intramammary infection. A comprehensive udder health management program should involve steps to minimize the detrimental influences of the environment.

Global environmental influences

Worldwide, there are major differences in dairy herd health and production systems. For example, the type of animal used, economics of production, climatic conditions, housing structures and management methods are widely variable. These differences greatly affect the interaction of cows with their environment, even though the predominant causative organisms are the same under different systems. Thus, there are major variations in the relative incidences of different pathogens, and in the importance of various approaches to mastitis control.

Classification of environmental influences

The influences of the total environment can be divided into:

- **The external environment**. All aspects of the environment outside the housing facilities make up the external environment. This includes the regional differences in climate, geography and agricultural tradition. There are also local factors within a region that can have an important influence. These local factors include the topographical features of the land, natural shelters from the climate and the availability of pasture
- **The internal environment**. All environmental conditions inside the cow buildings make up the internal environment. The general internal environment includes the type of housing system, temperature, humidity and air quality. There are also specific internal environmental influences such as stall design, type of bedding, nutritional management and manure disposal. The milking environment has a major influence through the equipment, cow preparation methods and approach to general hygiene.

External environmental influences on mastitis control

There is minimal evidence that external environmental factors directly influence the incidence of mastitis; however, the external environment determines the way in which cows are housed, fed and milked. Through these associations, the external environment can be an important risk factor in problems with udder health in dairy herds.

Regional environment

The climate and geographical features of a region have implications for the prevalence of mastitis. The ambient temperatures and amount of rainfall often determine the types of housing and nutritional program used. Extremely hot or cold conditions interact with other predisposing management factors. In areas prone to severe rainstorms, teats may be exposed to wet or muddy conditions. The soil type, cropping policy and presence of other industries can also have an indirect impact on the prevalence of mastitis; for example, regions suitable for growing cereal grains will commonly use straw as a bedding material, which may favor the growth of environmental streptococcal organisms. In contrast, dairying areas close to the forestry industries may favor sawdust or shavings as bedding. The use of these materials may influence the incidence of coliform mastitis.

The socioeconomic structure and agricultural policy of a particular region can affect management factors known to influence udder health. These factors determine herd size and labor costs. Large herd sizes necessitated by economic conditions will dictate the housing, feeding and milking management practices employed. More recently, regional policy towards regulation of bulk tank milk SCC levels has had a profound impact on udder health status.[61]

Local environment

The local environmental factors such as the topography of the land, the presence of natural shelters and the type of pasture grown are thought to influence udder health status. However, direct scientific evidence is lacking. One important exception is 'summer mastitis', which affects nonlactating heifers and cows. This udder infection with *A. pyogenes* is greatly affected by the local environment, probably through the propagation of insects important in its transmission. Protected pastures increase insect populations and can result in a high incidence of infection.

Internal environmental influences on mastitis control

The incidence of new intramammary infections can be greatly affected by the management and facilities used in confinement dairying systems. General aspects of the internal environment exert their influence on all cows in the herd, such as the type of housing and milking system. Tie-stall barns pose different environmental stresses from a free-stall system. The air quality and noise levels can have an impact on animal health. The nutrient content of component feedstuffs can affect disease resistance.

Specific internal environmental factors exert their influence on an individual cow basis. For example, the stall design and tying system affect individual cows differently. Many epidemiological studies have revealed interactions between udder disease and internal environmental conditions. Most of these studies relate to European tie-stall and seasonal grazing systems. However, the results are generally relevant to most housing and management systems. Some of the most important general and specific influences of the internal environment are as follows.

Housing

Housing factors account for a great deal of the variation in udder health status between herds. In both tie-stall and free-stall barns, short and narrow stalls are

associated with increased incidence of teat tramps and mastitis. An appropriate partition between stalls is beneficial. Stanchions or neckstraps with chains can restrict the movement of the cow and increase the risk of teat injury. This occurs especially as cows are rising. In addition, the use of electrical cowtrainers has been associated with an increase in the rate of subclinical mastitis. The use of adequate amounts of a good bedding material will reduce mastitis incidence in both tie-stall and free-stall housing systems. Even though there are reports of specific bedding materials being associated with certain mastitis problems, the use of adequate amounts of properly maintained bedding is beneficial. Straw, shavings, sawdust, sand, shredded newspaper and other cushion systems have all been used effectively.

The climate and air quality maintained within a building can have a major influence on udder health. Draughty conditions, high relative humidity and marked changes in indoor temperature over a 24-hour period are factors that contribute to higher mastitis rates. Adaptation to adverse internal environmental conditions may cause stress, which can reduce the cow's defense mechanisms. Indoor climate, especially temperature and humidity, can also account for differences in the concentration of pathogenic organisms to which cows are exposed.

Nutritional management

A complex relationship exists between the quantity and quality of feed and udder health status. Improper nutritional management can result in an increase of new intramammary infections, the exacerbation of pre-existing chronic infections, and an increase in clinical mastitis. Several mechanisms have been suggested for this association. An improper anion to cation balance in the dry cow ration is a predisposing factor for periparturient hypocalcemia, which in turn increases the risk of new intramammary infections. Feeding programs that result in excessively fat or abnormally thin cows may affect resistance to disease. Also, there is some evidence that feeds high in estrogenic substances may be detrimental to udder health status.

The dietary concentration of some vitamins and minerals may have an important relationship to udder health. Studies have shown that intramammary infection is related to plasma concentrations of vitamin E and blood concentrations of selenium.[55] Dietary supplementation of vitamin E and selenium improved the natural resistance of the mammary gland to infection. Associations between udder health and the levels of vitamin A, beta-carotene, zinc and other nutrients have been proposed but are not well documented.

Management approach

Cow supervision, decision-making and general animal care by dairy herd managers may be important epidemiological factors in the relationship between environment and udder health. For example, lack of consistency in the performance and timing of various herd activities results in decreased udder health status. Irregular intervals between milkings should be avoided.

General hygiene

Even outside the milking environment, general hygiene can greatly influence the exposure of the udder and teats to pathogenic bacteria. The degree of hygiene achieved is directly related to the type of housing, the amount of bedding and the efficiency of manure removal. Worldwide trends towards increasing herd sizes and decreasing labor force necessitate more emphasis on the importance of cow hygiene.

Use of recombinant bovine somatotropin

It has been suggested that the use of bovine somatotropin may increase the incidence of clinical mastitis by an indirect mechanism that acts through increased milk production. Controlled field studies have shown that the use of bovine somatotropin is not associated with an increase in the incidence of clinical mastitis, milk discarded because of therapy for clinical mastitis, or culling for mastitis.[62]

Environmental control in an udder health management program

There is a strong association between herd udder health status and the number of stress factors operating within the herd. It has been proposed that mastitis occurs when stress factors exceed the cow's ability to adapt. It follows that a major objective of an udder health management program should be to limit the number and severity of environmental stress factors.

Veterinarians responsible for udder health management programs should have a good understanding of the importance of environmental management. The three major objectives of environmental control for improvement of udder health are:

To prevent contamination of the teat end
To prevent invasion of mastitis pathogens
To prevent pathogens from establishing in the mammary gland.

The important steps in achieving these three objectives have been discussed. For example, an adequate housing system and manure handling are important to limit bacterial contamination of the teats. The prevention of environmentally induced teat injuries will aid in preventing invasion of pathogens into the gland. The producer's approach to cow management, control of the nutritional program and insuring that the internal environment is appropriate, will all greatly improve host defense mechanisms and prevent intramammary pathogens from establishing within the gland.

7. GOOD RECORD KEEPING

Good record keeping involves the collection of useful data to monitor performance, calculation of appropriate indices and decision-making based on comparison to target levels. For acceptable performance the monitoring process is repeated and the cycle continues. If performance is not acceptable, further evaluation and analysis is carried out and a plan of action is instituted. Once again, the monitoring process carries on and the cycle continues. For many of the health management programs in food animal practice, a limiting factor is the availability of accurate and objective data. With respect to udder health, data have been readily available. Bulk tank milk SCC, individual cow composite SCC and bacteriological culture results are all accessible and useful. These data provide the information necessary to monitor udder health status and to make specific health management decisions. However, problems can still exist. Herds with a low prevalence of infection and very low bulk tank milk SCC can still have a high incidence of environmental infections and clinical mastitis cases. Thus, an important step in an effective udder health management program is the maintenance and use of mastitis records. The increasing adoption of computerized dairy health management record systems provides an opportunity to make effective use of clinical mastitis episode and therapy data. Even without a computerized system, manual records for clinical mastitis are easy to implement and use.

Objectives and uses of clinical mastitis records

The objective of maintaining computerized or manual records of clinical mastitis episodes is to complete the decision-making capabilities of a mastitis control program. The availability of this information will allow completion of the health management cycle over the entire spectrum of herd udder health situations.

There are several important uses of clinical mastitis records:

To assess the risk factors associated with clinical mastitis episodes

- To evaluate lactational and dry cow therapy programs
- To provide information useful in the evaluation of net present value of individual cows for the purposes of culling decisions. Without the ready availability of accurate data surrounding mastitis events, decisions associated with therapy, culling and the removal of risk factors are difficult to make.

Recording clinical mastitis data

There is a limited amount of specific data necessary to make effective use of mastitis records as a health management tool. The cow identification, date of the clinical episode occurrence, type of therapy used and the date that milk withholding will be complete are the essential pieces of information. If a manual record system is used, it will be important to add the lactation number, the date of calving and the most recent test date production. A standard form that calculates the distribution of clinical episodes by lactation number and by stage of lactation is desirable. These are the same distributions often provided with an individual cow SCC report. A record form that allows the recording of treatment used, the number of days treated, milk withholding periods and an estimate of the costs associated with clinical mastitis has been described.[63,64]

Using clinical mastitis monitoring systems

Since clinical mastitis is a common event in dairy production, it is ironic that these records have not traditionally been kept. The key to overcoming this hurdle is the regular use of this information for health management decisions. Some of these uses and decisions are as follows.

Cow versus herd clinical mastitis problems

Calculation of the percentage of cows affected in the herd and the average number of clinical episodes per affected cow will aid in determining if the clinical mastitis is more of an individual cow problem or a herd-level issue.[65]

Probability of recurrence of clinical mastitis in the same lactation

The number of animals with repeat cases of mastitis divided by the total number of clinical cases gives an estimate of the likelihood of recurrence. The same calculation can be made for specific parity groups. This information can be useful to characterize the problem, and for culling decisions.

Stage of lactation and seasonal profile

If clinical mastitis data is collected consistently over a considerable period of time, potentially useful problem-solving information can be derived. For example, calculating days in lactation at first occurrence can help to identify specific risk factors for new intramammary infections. There is a higher proportion of clinical occurrences during the first few weeks after calving. However, analysis of clinical mastitis records might yield a different stage-of-lactation profile. In these cases, the evaluation of potential nutritional, environmental or other stress factors would be indicated. There may be different immediate and long-term solutions that should be implemented.

Analysis of clinical mastitis records over several years may identify a significant seasonal pattern, such as the documented seasonal pattern for bulk tank milk SCC data and antibiotic residue violations. Action may be necessary to deal with seasonal environment and housing problems that impact upon new infection rates.

Days of discarded milk

It is very common for producers to have an aggressive attitude towards the treatment of clinical mastitis. This approach may result in huge economic losses if waste milk is not fed to calves. These losses are largely the result of discarded milk during the clearance of antibiotic residues from treated cows. Calculating the days of discarded milk may suggest that the mastitis therapy program during lactation should be evaluated. Establishment of an appropriate treatment program and careful selection of cows for therapy might significantly decrease the need for discarding milk. In addition, cows that are responsible for a large percentage of the discarded milk should be identified for selective removal. The calculations from mastitis records that can help to clarify these issues include:

- Total days of discarded milk for the herd
- Days of discarded milk per episode
- Days of discarded milk by lactation number
- Accrued days of discarded milk for individual cows.

8. MONITORING UDDER HEALTH STATUS

An important step missing from early mastitis control programs was the monitoring of udder health status. Although intuitively it appears necessary to chart the progress of any program, it is only quite recently that monitoring has been included as an integral component of udder health management. **Monitoring is now recognized as the third key principle of mastitis control.** The development of objective, inexpensive and efficient methods of monitoring udder health has made it much easier to complete the health management cycle for this component of herd programs.

The implementation of SCC measurement on bulk tank milk and on individual cow samples has been widespread throughout the major dairy regions of the world. Since SCC is objective and standardized, it can be used to evaluate the progress of regional control programs. This has allowed rapid improvement in udder health compared to most of the other components of dairy health management programs. Regional authorities have established new regulatory limits and targets for milk quality performance.

Implementing an effective system of monitoring udder health involves:

- Monitoring udder health at the herd level
- Monitoring udder health of individual cows
- Use of cowside diagnostic tests.

This discussion will emphasize the use of monitoring methods for decision-making and problem-solving in udder health management programs. Monitoring of udder health should be done at the **herd level** and **individual cow level**.

Monitoring udder health at the herd level

The monitoring of bulk tank milk provides the best method to evaluate the overall udder health status of dairy herds and the effectiveness of mastitis control programs. **Herd-level monitors of udder health include bulk tank milk SCC, bulk tank milk bacteriological culture and herd summaries of individual cow SCC data.** Analysis of clinical mastitis records is also useful for monitoring udder health at the herd level.

Bulk tank milk somatic cell counts

Most milk marketing organizations and regional authorities regularly measure SCC on bulk tank milk as a monitor of the milk quality and udder health status of each herd. Many of these agencies use bulk tank milk SCC for penalty deductions or incentive payments. Improvement in bulk tank milk SCC is associated with improvement in other measures of milk quality such as bacterial counts, inhibitor test violations and milk freezing point.[66] Countries and regions set milk quality targets using this SCC data, with milk being rejected from processing plants when the bulk tank milk SCC exceeds 400 000–1 000 000 cells/mL, depending on the country.

Several management practices are associated with low, medium and high SCC in bulk tank milk.[67] Postmilking teat disinfection and dry cow therapy are most

frequently associated with herds with a low bulk tank milk SCC. In herds with a low bulk milk SCC, more attention is given to hygiene than in herds with a medium or high bulk tank milk SCC. Cubicles, drinking buckets and cows are cleaner in herds with a low bulk tank milk SCC. Cleaner calving pens and cubicles for herds with low bulk tank milk SCC coincide with the observations that bedding for lactating cows and in maternity pens is drier for herds with a low bulk tank milk SCC. In herds with a high bulk tank milk SCC, a higher percentage of cows are culled because of a high SCC.

The incidence of clinical mastitis in dairy herds may not be different among those with low, medium and high bulk tank milk SCC.[68] However, clinical mastitis associated with Gram-negative pathogens such as *E. coli*, *Klebsiella* spp., or *Pseudomonas* spp. occurs more commonly in herds with a low bulk tank milk SCC. Clinical mastitis associated with *S. aureus*, *S. dysgalactiae*, and *S. agalactiae* occurs more often in herds with a high bulk tank milk SCC. Systemic signs of illness associated with clinical mastitis occur more often in herds with a low bulk tank milk SCC. In herds with a high bulk tank milk SCC, more cows with a high milk SCC were culled. In herds with a low bulk tank milk SCC, more cows were culled for teat lesions, milkability, udder shape, fertility and character than in herds with a high bulk tank milk SCC. In herds with a low bulk tank milk SCC, cows were culled more for export and production reasons.

Herd average of weighted individual cow somatic cell count

The arithmetic mean of individual cow SCC values, weighted by the cow's milk production, is also a good measure of the general udder health status of the herd. It should be noted that the high degree of variability of SCC measurements makes it inappropriate to compare this mean directly with the bulk tank milk SCC.

Other herd-level somatic cell count monitors

There are several other calculations using individual cow SCC data that are useful for monitoring herd udder health. In general, these indices attempt to use mathematical calculations to reduce the impact of individual cows and to measure the change over time. These summaries are used to assist producers in the use of individual cow SCC information at the herd level. These indices include the following.

Herd average somatic cell count linear score

The use of linear score can simplify SCC interpretation and buffer the effects of individual cows with very high values. Thus, the herd average of SCC linear score is a very useful monitor of herd udder health status. A realistic goal for most dairy herds is an average linear score of less than 3.0, equivalent to fewer than 100 000 cells/mL. It is not correct to estimate herd production loss from the average linear score using the individual cow linear score–production loss relationship developed for bulk tank milk SCC.[69]

Percentage of herd over somatic cell count threshold

Interpretation of SCC and linear score requires the choice of a threshold value for classification of cows as positive and negative. The threshold value used ranges from 200 000–400 000 cells/mL. A useful herd goal for subclinical mastitis is to have less than 15% of cows with SCC values greater than 200 000–250 000 cells/mL (prevalence). A second goal is to have fewer than 5% of cows developing new subclinical infections each month (incidence).

Percentage of herd changing somatic cell count to over threshold

Most uses of SCC data focus upon the determination of current udder health status. In other words, SCC is used as an estimate of the prevalence of existing infections in the herd; however, an important objective of a mastitis control program is to minimize the number of new intramammary infections. The change in the SCC of individual cows from month to month can be used as an estimate of the rate of new infections, and the use of SCC data in this way has been evaluated.[70] Using SCC changes from month to month as a test for the rate of new infections has low sensitivity and high specificity. More research is needed on the usefulness of SCC to monitor the occurrence of new infections.

A popular way to represent these data graphically is to plot the SCC value (or linear score) for the current month on the y axis and the SCC value (or linear score) for the preceding month on the x axis. This graphing arrangement is preferred because the current SCC value is dependent, in part, on the previous SCC value. Using this graphical approach, individual SCC values in the upper left quadrant are new infections, values in the upper right quadrant are persistent infections and values in the lower right quadrant are resolved infections.

Bacteriological culture of bulk milk

Although SCC is widely used for monitoring udder health status in dairy herds, decision-making often requires information about the prevalence of specific pathogens. With the regular collection of bulk tank milk samples for the purposes of quality monitoring programs, culturing of bulk tank milk is an attractive alternative to culturing milk from individual cows. Bulk tank milk culture has been formally evaluated as a mastitis screening test.[71] For the major mastitis pathogens, bulk milk culture had a low sensitivity. Even in herds infected with *S. agalactiae*, repeated bulk milk cultures were necessary to detect positive herds. Mastitis pathogens of greatest interest are contagious pathogens, such as *S. agalactiae*, *S. aureus*, *M. bovis*, and *C. bovis*.

The **standard plate count** (plate loop count) provides an estimate of the total numbers of aerobic bacteria in bulk tank milk and is an important measure of milk quality and udder health. It is most commonly used to evaluate the efficiency of cleaning the milking system. **A standard plate count of less than 10 000 cfu/mL can be achieved on most farms and less than 5000 cfu/mL should be the goal.** Standard plate counts higher than 10 000 cfu/mL indicate milking of cows with dirty teats or mastitis, poorly sanitized milking equipment or delayed cooling of milk in the bulk tank. Many herds routinely have bacteria counts of 1000 cfu/mL or less. Total bacterial counts have some value as an early warning system because up to 50% of violations of the standard are associated with mastitis-related bacteria. For example, bacterial counts in the milk of acute clinical cases may be as high as 10 000 000 cfu/mL. Milk from subclinically infected quarters may contain 1000–10 000 cfu/mL, and normal quarters yield less than 1000 cfu/mL. In nonmastitic cows, higher counts, up to six times higher, are seen in housed cows than in pastured cows.

The **preliminary incubation count** is an estimate of the total number of cold-loving bacteria. As such, the preliminary incubation count provides an index of milk production on the farm. A preliminary incubation count below 50 000 cfu/mL can be achieved on most farms, with less than 10 000 cfu/mL being the goal. The preliminary incubation count should be less than 3–6 × the standard plate count.

Herd-level measures of clinical mastitis

The **incidence of clinical mastitis, calculated as cases per 100 cows per year**, can provide a rough assessment of new intramammary infections.[72] The **goal is less than two new cases per 100 cows each month** (equivalent to < 24% of cows affected each year). Calculation of the total treatment days can provide a herd-level assessment of the approach to therapy of clinical mastitis, as well as an estimate of the economic losses.

In a random sample of dairy herds in the Netherlands, the following risk factors were associated with a higher incidence of clinical mastitis:[73] one or more cows leaking milk, one or more cows with trampled teats, no disinfection of the maternity area after calving, consistent use of postmilking teat disinfection, Red and White cattle as the predominant breed, and an annual bulk tank milk SCC of less than 150 000 cells/mL. Factors associated with a higher rate of clinical mastitis caused by *E. coli* included cows with trampled teats, no disinfection of the maternity area after calving, consistent use of postmilking teat disinfection, use of a thick layer of bedding in the stall and the stripping of foremilk before cluster attachment. Factors associated with a higher rate of clinical mastitis caused by *S. aureus* included Red and White cattle as the predominant breed, cows with trampled teats, stripping of foremilk before cluster attachment, no regular disinfection of the stall, no regular replacement of stall bedding and an annual bulk tank milk SCC of less than 150 000 cells/mL.[73] Teat disinfection appeared to increase the incidence of clinical mastitis associated with *E. coli*, which may be explained by the higher incidence around calving and during early lactation, when the resistance of cows is low combined with an increase in the numbers of environmental bacteria associated with maternity pens.

Monitoring udder health of individual cows

Earlier in this chapter, one direct (culture) and several indirect tests for intramammary infection were described. Currently, four methods are widely used to detect subclinical mastitis: culture of composite or quarter samples, SCC values of composite or quarter samples, and CMT and electrical conductivity of quarter samples. Currently, cow level data (culture or SCC) are the most commonly used of these four monitoring tools, but the usefulness of these tests varies depending upon their cost, sensitivity, specificity, convenience and availability.

Bacteriological culture of milk

Culture of aseptically collected milk samples has been a cornerstone of mastitis control programs. Extensive diagnostic laboratory systems have been developed for the culture of milk. For many years, milk bacteriology has been recognized as the gold standard of mastitis diagnostic tests. The sensitivity and specificity of milk bacteriology are now being examined and, as the costs of laboratory procedures have risen, there is an increasing need to justify diagnostic expenses. However, there is still an important need for information concerning the predominant types of mastitis organism active in a herd.

Several schemes have been proposed for obtaining a pathogen profile of the mastitis pathogens in a herd. The following suggestions are offered as the most appropriate times to collect samples for milk bacteriology:

- **Pretreatment milk samples from clinical cases**. Samples should be frozen, collected at a herd visit, and submitted for culture
- **Cows that have an increased SCC**. At each scheduled herd visit, each cow that has increased in SCC over a preset threshold is sampled and the sample is submitted for culture
- **A composite milk sample from each lactating cow in the herd**. This whole-herd culture would be conducted annually, or more frequently depending upon the herd situation. This method is most appropriate for herds having problems with contagious pathogens, but the economics of this approach have not been determined
- **Culture of cows at a specific management event**, for example milk culture at drying off and at the first milking after calving, can be useful for assessment of the dry cow management program.

The cost-effectiveness of any one or a combination of these methods of obtaining a bacteriological profile of a herd's milk will depend on the current situation in the herd. For the vast majority of dairy herds, the routine culture of cows for subclinical mastitis diagnosis is not cost-effective. In fact, herds with a low bulk tank milk SCC and a low incidence of clinical mastitis episodes can conduct an efficient udder health management program without culturing milk. It is very wise, however, to collect pretreatment milk samples from clinical mastitis cases. These samples can be frozen without significant alterations of the culture results for most pathogens.[74] The samples are collected at a scheduled herd visit and submitted to the laboratory. In most herds, this approach will give a meaningful bacteriological profile of the herd and assist in assessment of the treatment protocol.

C. bovis is not a common cause of clinical mastitis on most farms but is frequently found in random milk samples. Because *C. bovis* is highly infectious and susceptible to teat disinfection, it has been suggested that *C. bovis* prevalence could be used as an indicator of teat-dipping efficiency in a herd, either of the intensity of the dipping or of the efficacy of the dip. The fact that *C. bovis* is limited in its colonization to the streak canal makes it valuable as a monitor of teat disinfection.

Somatic cell counts

Several management decisions can be based on individual cow composite SCC. Before any decisions can be made using SCC, criteria must be established to categorize cows based on their SCC results. This involves establishing threshold values or other criteria. The **recommended threshold is 250 000 cells/mL in herds with a low prevalence (< 5%) of subclinical mastitis**, providing a sensitivity of 0.55 and specificity of 0.96. In comparison, the **recommended threshold is 200 000 cells/mL in herds with a high prevalence (40%) of subclinical mastitis**, providing an apparent sensitivity of 0.73–0.89 and a specificity of 0.86. A clinically more appropriate approach is to calculate likelihood ratios using test sensitivity and specificity, estimated herd prevalence and a spreadsheet. Cows are identified for further investigation based on their SCC, using three different methods:

- **Change in SCC to over the threshold**. A cow with a marked increase in SCC from one month to the next would be identified as potentially being infected
- **Persistently elevated SCC**. Cows with a persistently elevated SCC month after month would be identified for management intervention. The lactation average linear score and the lifetime linear score are also useful in this respect. This information is especially useful if dry period therapy has already been unsuccessful for the cow in question
- **Percentage contribution to herd average**. An estimate of the percentage of the SCC in bulk tank milk contributed by each problem cow can be calculated using individual cow test-day milk weights and SCC data. It should be noted that cows with high milk production and intermediate SCC levels can make a significantly higher contribution to SCC than some cows with a very high SCC but low production. It is not uncommon for a few problem cows to be responsible for more than 50% of the cells in the bulk tank, particularly in small herds. In most circumstances, the cows with the highest percentage contribution merit immediate action.

With these methods of identifying individual cows based on SCC results, several udder health management decisions can be made, including:

- **Selection of cows for milk bacteriological culture**. The importance of having a good bacteriological profile of the

intramammary infections in the herd has been emphasized. Several lactation events are suggested as useful times to collect milk for bacteriology. One such event is a clinical mastitis episode. Selection of cows for culture can also be based on an elevated SCC

- **Selection of cows for dry cow treatment**. Blanket dry cow therapy is currently recommended for most herds. However, herds that use selective dry cow therapy need a suitable screening test in order to make therapy decisions; such a test is currently unavailable, although individual cow SCC may be of some help in this decision-making process. Cows with a very high SCC have significantly lower cure rates after dry cow treatment than cows that are infected but have a lower SCC. The SCC can be used as a general indicator of the expected success of dry cow treatment[49]
- **Treatment during lactation**. The development of a treatment protocol and the criteria for selecting cows to treat during lactation are presented above. Treatment on the basis of a change in individual cow SCC from month to month is not economically justifiable. Many other factors need to be considered for a cost-effective treatment decision, and SCC could be one of these criteria
- **Evaluation of the response to treatment**. Individual cow SCC data can be used as a preliminary evaluation of the mastitis therapy program. With good records on clinical cases and the treatment administered, individual cow SCC data in the months following treatment can be used as a general indicator of the response to therapy. Spontaneous cures and new infections will confound this evaluation but with data from multiple farms and over a considerable time period a low-cost preliminary evaluation can be achieved

Culling decision. The lifetime average SCC or linear score of an individual cow is useful additional information in making specific culling decisions.[69] In conjunction with milk culture results, the SCC data are useful to help establish a cow's net present value. An elevated SCC month after month serves to emphasize that culling is the only method of elimination of some chronic cases of mastitis. Removal of these cows eliminates a source of infection for the rest of the herd, as well as assisting in general improvement in the quality of the bulk tank milk

- **Alter the milking order**. It is generally recommended that infected cows be milked last, although this is often impractical for freestall and pasture-based dairy enterprises. Individual cow SCC can be used to establish a milking order in tie-stall barns. Alternatively, some large herds establish a special milking string for infected cows. These milking order and segregation programs can be based upon SCC results, but cows with an elevated SCC but no intramammary infection may be incorrectly classified. In segregation programs these false-positive cows may be at increased risk
- **Management procedures to limit the effect of individual cows**. There is some evidence that machine disinfection after milking infected cows may limit the spread of contagious pathogens. In an intensively managed tie-stall herd, it is possible to manually disinfect the milking unit between cows. In order to maximize the efficiency of this labor-intensive step, individual cow SCC can be used to identify the cows after which machine disinfection would be useful. Another management method involves using the milk from specific cows for feeding calves. In situations where there are significant financial incentives for low SCC bulk milk, removal of the milk from one or two cows can have an impact on the amount of premium received. Individual cow SCC values can be used to identify specific cows that should be eliminated from the bulk tank. Precautions need to be taken to prevent intersucking between calves receiving this high SCC milk
- **Use of individual cow SCC in economic decision analysis**. The relationship between individual cow SCC and milk production losses has been well established. SCC values can be used to estimate the economic losses from subclinical mastitis. This information may be extremely useful in calculating the potential economic benefit of implementing a new udder health management strategy.

Problem-solving using individual cow somatic cell counts

A simple approach to problem-solving involves defining the problem by **answering the questions: who, when, where and what is involved** in the situation. Individual cow SCCs provide an inexpensive consistent source of information to answer these questions. This process is completed by dividing the herd into subgroups and calculating the percentage of cows with SCCs over a threshold (250 000 cells/mL) in each group.

- **Who is affected?** The herd can be subdivided based upon several defining characteristics. These include production level, genetic factors (sire) and other characteristics such as having a previous clinical mastitis episode. A gradual increase in the proportion of elevated SCC would normally occur as lactation number increases. Thus, a higher percentage of older cows are expected to have elevated SCCs than first- and second-lactation animals. A high proportion of elevated SCC values in heifers would suggest a problem in the replacement program or a breakdown of hygiene in the immediate periparturient period for first-calf heifers. A markedly elevated percentage of high-SCC cows in older animals suggests that infections have become chronic and that the culling strategy should be re-evaluated
- **When does high SCC occur?** It is appropriate to examine SCC distributions according to stage of lactation and season of the year. Normally there is a gradual increase in the prevalence of elevated counts as the lactation progresses. If the prevalence of cows with elevated SCCs is high in early lactation, it suggests a problem with dry cow management or with new infections occurring around the time of calving. If the distribution of cows over threshold shows a dramatic increase during lactation, cow-to-cow transmission of contagious organisms is suspected. Measures of new infection rate are also helpful in solving these problems. The percentage of cows over threshold in the herd can be charted over time. It is expected that this indicator will indicate the same seasonal trends as found in bulk tank milk SCC in the population. For example, the percentage of the herd over threshold should be highest in the fall and lowest in the spring. An increase in this index in the spring would contradict the population trend and should be investigated
- **Where are the affected cows located?** The distribution of cows with elevated SCC according to their location in the tie-stall barn, in milking strings or according to milking order may provide evidence

for some risk factors for new infections. A mastitis problem due to environmental pathogens in a free-stall operation can be difficult to solve. Calculating the percentage of cows with a SCC greater than 250 000 cells/mL for each milking group can help to determine where the problem is most severe. If a specific milking order is followed, as is the case in most tie-stall systems, the distribution of cows with elevated counts according to milking order can demonstrate weaknesses in milking hygiene

- **What is the problem and why has it occurred?** The information obtained by answering the questions **who**, **when** and **where** in the problem-solving process can go a long way toward defining **what** the problem is. Prevalence distributions can be combined with the incidence of clinical mastitis, information from milk cultures and an estimate of the financial losses, in order to complete the picture. Subsequently, specific solutions will be aimed at **why** this problem might exist.

With the development of computerized dairy health management records systems, the epidemiological analysis of udder health information can be greatly simplified. Ultimately, specific risk factors would be automatically tested for statistical significance. In addition, the relative importance of many potential risk factors would be evaluated.

9. PERIODIC REVIEW OF THE UDDER HEALTH MANAGEMENT PROGRAM

Many aspects of mastitis control, such as milking management and therapy of clinical cases, become routine practices. However, changes continue to occur in the udder health status of the herd, environmental conditions and available technology. With these changes, the current udder health management program may no longer be appropriate. New employees may be introduced and it is possible that various steps are not being appropriately implemented. In some dairy herds, management practices are passed on from previous generations without critical examination. Mastitis results from a continually evolving relationship between microorganisms, the cow and the environment. Any program intended to limit problems from these relationships needs to be re-evaluated on a regular basis.

An effective udder health management program should undergo regular periodic review. This process of appraisal should involve the producer and the herd veterinarian, although input may be sought from various farm management advisors. The review should be objective and thorough, but simple and easy to conduct. The use of a standard investigation form structured on the 10 steps of the mastitis control program is recommended. The same standard form can be used for the investigation of problem herds.

10. SETTING GOALS FOR UDDER HEALTH STATUS

The establishment of realistic targets of performance for various udder health parameters is the final component in an udder health management program. These goals are important to determine whether there have been shortfalls in the milk quality and udder health performance. The goals should be realistic and achievable, as well as having economic significance. In addition, the targets must be easily measured and should be accepted by all members of the farm management and labor team.

The setting of appropriate goals for mastitis control efforts is crucial for completion of the health management cycle. In some cases, the target will be the industry reference value, however in most situations it will be a farm-specific level of performance.

Relationship of udder health to productivity and profitability

Mastitis is generally considered to be the most costly disease facing the dairy industry. The reduced profitability is due to two major factors:

- Reduced milk production associated with subclinical mastitis accounts for approximately 70% of the economic loss
- The treatment costs, culling and reduced productivity associated with clinical mastitis are responsible for the remaining losses.

Production losses from increased somatic cell count

It is well accepted that milk production decreases as SCC increases, but the relationship between SCC and milk production is curvilinear for individual cattle but approximates a straight line when a logarithmic transformation (such as linear score) is used. Estimates of the milk production losses range from 3–6% with each one unit increase of linear score above 3. The loss in first-lactation heifers is greater than that in older cows. A general rule of thumb would suggest that there is 5% loss for each unit of linear score increase above a linear score of 3.

There is also a relationship between bulk tank milk SCC and milk production in that a linear decrease in herd milk production with an increase in bulk tank milk SCC. Estimates of the production loss range from 1.5–3.0% for each increase of 100 000 cells/mL over a baseline of 150 000 cells/mL. Using an average of these estimates, daily milk and dollar losses can be calculated from bulk tank milk SCC and herd production levels.

Clinical mastitis and lost productivity

Economic losses associated with the treatment of clinical mastitis arise from the cost of drugs, veterinary services and milk discarded. In addition, decreased milk production, premature culling and replacement heifer costs are also significant. However, more than 80% of the loss attributed to a clinical episode involves the discarding of nonsaleable milk and decreased milk production.

ASSESSMENT OF THE COST-EFFECTIVENESS OF MASTITIS CONTROL

Dairy producers look to their veterinarian for information and services related to mastitis and its control. With this motivation, veterinarians should be able to implement comprehensive udder health management programs on the majority of dairy farms. In order to achieve a high rate of implementation of mastitis control strategies, it may be necessary to demonstrate the cost:benefit ratio of the suggested practices before they are adopted. A reassessment of their impact over time may also be useful.

Mastitis control is feasible, practical, and cost-effective. The economics of the efforts of a mastitis control program in a herd can be estimated. There are several steps necessary to complete this assessment.

1. Programs for monitoring udder health and for establishing achievable goals must be in place for an economic assessment
2. The losses resulting from mastitis must be quantified. The amount of reduced milk production resulting from increased SCC is calculated. In addition, costs associated with the discarded milk and treatment of clinical cases must be estimated
3. The udder health management program to be implemented must be described. An accounting system should be established to calculate the costs associated with this program
4. Using an estimate of the potential loss for a hypothetical herd with no mastitis control efforts, the profitability of the herd's current udder health management program is determined
5. By estimating the costs of implementing new udder health

management measures, the remaining potential profits from mastitis control can be calculated.

This economic assessment is done using a computer spreadsheet program. With such a computer program, veterinarians can simply and rapidly input actual values for a particular farm, and assess the economic circumstances. The impact of each element of control can be considered from the point of view of a cost–benefit ratio. The results of economic assessment will vary widely from farm to farm, but usually the following conclusions are made:

- Mastitis will remain a costly disease, even with implementation of properly applied, effective control programs
- Loss of milk production attributable to subclinical infection will remain a major cause of economic loss due to mastitis in most herds
- Proper application of simple, inexpensive mastitis control procedures will have a significant impact on profitability, and will bring higher returns on investment.

Miscellaneous abnormalities of the teats and udder

LESIONS OF THE TEAT AND UDDER SKIN

Several diseases are characterized clinically by lesions of the skin of the teats and udder. These diseases are most common in dairy cattle and are of economic importance because teat lesions cause pain and discomfort during milking, and udder edema and udder rot are very common in heifers at calving.

The skin of the wall of the teat and the skin surrounding the teat canal orifice must be inspected closely in order to observe lesions and palpated in order to detect lesions covered by scabs. It may be necessary to superficially irrigate and gently wash teat lesions with warm 0.9% NaCl solution in order to see the morphology and spatial arrangement of the lesions. The entire skin of the cranial, lateral and posterior aspects of the udder should be examined by inspection and palpation. Lesions may be restricted to the lateral aspects of the udder and teats, as in photosensitization, or completely surround the teats, as in pseudocowpox.

In North America, the most common viral diseases of the teats of cattle, which result in vesicles or erosion of the teats, include pseudocowpox and bovine herpes mammillitis, with vesicular stomatitis occurring occasionally. The vesicular diseases of the teats are particularly important because they require differentiation from the exotic vesicular diseases such as foot-and-mouth disease. The appearances of the lesions of each of these diseases are similar, which makes clinical diagnosis difficult. However, in most cases, the morphological and epidemiological differences in the lesions in groups of animals aid in the diagnosis.

In pigs, **necrosis of the skin of the teats of newborn piglets** may occur in outbreak form. Abrasion of the nipples of baby pigs raised on rough nonslip concrete may be observed as acute lesions or be apparent only when the piglets mature and are found to have deficient teat numbers, as described under agalactia.

The skin of the mammary gland and teats of lactating ewes may be affected by the lesions of **contagious ecthyma**, which are transmitted from the lips of

suckling lambs. **Ulcerative dermatosis** of the teats in lactating ewes has lesions similar to those of herpes mammillitis in cows. It is a disease of housed ewes and may be initiated by bedding on infected straw. Mastitis and teat deformity are common sequels. The etiology varies from *Staphylococcus aureus* to coagulase-negative staphylococci or *Pasteurella* spp.[1]

LESIONS OF THE BOVINE TEAT

Traumatic injuries to teats are very common and range from superficial lacerations to deep lacerations into the teat cistern with the release of milk through the wound. Accidental trampling of a teat by a cow may cause amputation of the teat.

Chapping and cracking of the skin of the teats is common in dairy and beef cattle. The cracks in the skin are often linear and multiple and are painful when palpated or when the milking machine teat cups are applied to the affected teats. Cracks of the skin of the teats initiated by milking machine action can be aggravated by environmental factors to create chapping of the teats. The condition is common when adverse weather conditions follow turn-out in spring. Linear lesions appear on the teat wall near the teat–udder junction and extend transversely around the teat. The addition of **10% glycerin** to the teat dip provides an excellent method of improving teat skin condition.

Frostbite of teats occurs in dairy cows housed outdoors during severely cold weather without adequate bedding. The skin of the teats is cold, necrotic and oozes serum. Usually the front teats are more severely affected than the rear teats because the latter are less exposed to adverse ambient temperatures.

Teat end lesions are common in dairy cattle.[2] Lesions include teat canal eversion, teat canal prolapse, prolapse of the meatus, eversion of the meatus and teat orifice erosion. Limited information is presently available as to the mechanism of development for these lesions and their clinical significance; one study found no association between the presence or absence of a teat end lesion and intramammary infection.[2]

It is normal to see a 2 mm wide white ring around each teat orifice of machine milked cows. The first stage of a teat orifice abnormality occurs when this ring undergoes hypertrophy, keratinization, and radial cracking. Progression leads to increased hypertrophy, secondary bacterial infection, scab formation, eversion of the distal teat canal and eventually teat orifice erosion. Improper milking machine function can produce teat orifice abnormalities. Excessive or fluctuating vacuum levels, faulty teat cup liners, incorrect pulsation ratios and other faults attributed to inadequate maintenance and careless use of milking machines have been shown to cause teat injury. A high milking vacuum combined with a relatively low pulsation chamber vacuum can result in bruising and hemorrhage of the teat end teat wall by the slapping action of the liner.

Black spot (black pox) is a sporadic lesion of the teat tip characterized by a deep, crater-shaped ulcer with a **black spot** in the center. Lesions occurring at the ends of the teats commonly involve the teat sphincter. This abnormality is caused in most cases by excessive vacuum pressure or overmilking in teats that are naturally firm and have pointed ends. There is no specific bacteriology, although *Fusobacterium necrophorum* is commonly present and *S. aureus* is frequently isolated from the lesions. The latter occur only on the teats and take the form of deep, crater-shaped ulcers with raised edges and a black spot in the center. The lesions are confined almost entirely to the tip of the teat, usually invade the sphincter and are responsible for a great deal of mastitis. Lesser lesions of teat sphincters are listed under vacuum pressure in bovine mastitis control.

The lesions are painful, leading to kicking by the cows, sometimes repeated kicking off of the teat cups, and to blockage of the sphincter. *Arcanobacterium pyogenes* mastitis is a common sequel.[3] The lesions are poorly responsive to treatment even if the machine error is corrected.

Treatment of black spot is usually by topical application of ointments: Whitfield's, 10% salicylic acid, 5% sulfathiazole and 5% salicylic acid, 5% copper sulfate are all recommended. An iodophor ointment, or iodophor teat dip with 35% added glycerol, is also effective but treatment needs to be thorough and repeated and milking machine errors need to be corrected.

Thelitis or inflammation of the tissues of the teat wall leading to gangrene is a common complication of gangrenous mastitis, most commonly associated with peracute *S. aureus* mastitis. The skin of the teats is cold, edematous and oozes serum. The subcutaneous aspects are commonly distended with gas. The skin is commonly dark-red to purple-black. Sloughing of the skin may be evident.

Inflammation of the wall of the teat (thelitis) is a nonspecific lesion usually associated with traumatic injury to the lining of the teat cistern. The wall of the cistern is thickened, hardened, painful and, in chronic lesions, irregular in its internal lining. The lesion can be felt as a dense, vertical cord in the center of the teat tip. The lesions have historically been intractable to treatment, which usually consists of intramammary antibiotics and refraining from milking. The recent application of teat endoscopy has assisted in identifying cattle that are most likely to respond to medical or surgical treatment.

Enzootic nodular thelitis of alpine cows in Switzerland[4] is characterized by nodular lesions in the teat wall. The lesions are multicentric nodules containing atypical mycobacteria. A similar disease in French cattle is characterized by tuberculoid granulomas on the teats and lower udder that contain acid-fast mycobacteria, including *Mycobacterium terrae*.[5]

Corpora amylacea are inert concretions of amyloid that may become calcified and detached from the mammary tissue so that they cause blockage of the teat canal and cessation of milk flow. They are formed as the result of stasis due to blocked mammary tissue ducts and resorption of the milk fluids.

Papillomatosis of the teats is caused by bovine papillomavirus and is characterized clinically by small, white, slightly elevated nodules of 0.3 cm diameter or elongated tags 1 cm long that are removable by traction.

Pseudocowpox is characterized clinically by painful localized edema and erythema with a thin film of exudate over the edematous area. Vesicle formation is uncommon. Within 48 hours of onset of signs, a small orange papule develops, shortly followed by the formation of an elevated, small, dark-red scab. The edges of the lesion then extend and the center becomes umbilicated; at 1 week the lesion measures approximately 1 cm in diameter. By 10 days the central scab tends to desquamate, leaving a slightly raised circinate scab commonly termed a 'ring' or 'horseshoe' scab. One teat may have several such lesions, which coalesce to form linear scabs. The majority of lesions desquamate by 6 weeks without leaving scars, although occasionally animals develop chronic infection.

Photosensitization of the teats (photosensitive thelitis) is a local manifestation of generalized photosensitization but occasionally photosensitive thelitis is the first clinical abnormality detected by the producer. There is a characteristic erythema and hardness of the unpigmented or white parts of the lateral aspects of each teat. The medial aspect is soft and cool. The teats are also painful and in the early stages apparently irritable, because affected cows will also stand in ponds or waterholes in such a way that the teats are immersed, and then

rock backwards and forwards. They will also brush the sides of the udder with the hind feet in a way that could suggest the stamping movements of abdominal pain. In cases where the photosensitization is related to the induction of parturition by the administration of corticosteroids, the skin lesions are usually restricted to the teats. In cases due to other causes there are usually obvious lesions of photosensitive dermatitis on the dorsal aspects of the body but confined to the white parts.

LESIONS OF THE BOVINE TEAT AND UDDER

Thermal burns of the skin of the udder and teats may occur in mature cattle exposed to grass fires. The hairs of the udder and base of the teats are singed black. Thermal injury to the skin varies from marked erythema of the teats to blistering and necrosis and weeping of serum.

Bovine herpes mammillitis is characterized by the formation of variable-sized vesicles, severe edema and erythema of the teat with subsequent erosion of the teat epithelium. The vesicles rupture within 24 hours, and copious serous fluid often exudes from the dermis. Fever and depression are common, particularly in young animals. Scabs form over the lesions by the fourth day and the epithelium is re-established under the scab by the third week, although the trauma of milking may delay healing, especially when secondary infection occurs. Scar formation on recovery is uncommon. Lesions may be present on several teats and the base of the udder.

The epidemiology of infection within a herd is consistent with the presence of carrier animals, which may shed virus during times of stress, particularly in the periparturient period. There is a seasonal incidence of clinical disease that has been related to the activity and presence of insect vectors.[6] Experimental studies indicate that transmission requires virus inoculation at or below the level of the stratum germinativum of the teat or udder skin, and therefore trauma associated with milking, teat cracks or biting flies (such as *Stomoxys calcitrans*) is a requirement for infection to be transferred.[7]

Diagnosis is made on the basis of clinical signs in multiple animals. Virus may be isolated from aspirating the fluid from vesicles before they rupture. Serology has been performed in order to identify a three- to fourfold rising titer but is not widely available and many animals seroconvert early in the disease process.[8]

Treatment is general supportive, including the application of topical antiseptics. Cattle that develop a thickened teat due to secondary bacterial infections are likely to develop clinical mastitis and treatment success of affected quarters is poor. Standard control measures for mastitis should be implemented, including isolation of clinically active cases. There is one report that suggested iodine-based teat dips are virucidal[9] and therefore may be of assistance in decreasing transmission.

LESIONS OF THE BOVINE UDDER OTHER THAN MASTITIS

Udder impetigo associated with *S. aureus* is characterized by small, 2–4 mm diameter pustules at the base of the teats that may spread to involve the entire teat and the skin of the udder. This disease is of importance because of the discomfort it causes, its common association with staphylococcal mastitis, its not uncommon spread to milkers' hands and the frequency with which it is mistaken for cowpox. The lesions are usually small pustules (2–4 mm diameter) but in occasional animals they extend to the subcutaneous tissue and appear as furuncles or boils. The commonest site is the hairless skin at the base of the teats, but the lesions may spread from here on to the teats and over the udder generally. Spread in the herd appears to occur during milking and a large proportion of a herd may become affected over a relatively long period. The institution of suitable sanitation procedures, such as dipping teats after milking, washing of udders before milking and treatment of individual lesions with a suitable antiseptic ointment, as described under the control of mastitis, usually stops further spread. An ancillary measure is to vaccinate all cows in the herd with an autogenous bacterin produced from the *S. aureus* that is always present. Good immunity is produced for about 6 months but the disease recurs unless satisfactory sanitation measures are introduced.

What appears to have been an exaggerated form of this disease has been reported in a recently gathered herd of cows. It is assumed that the cows were very susceptible and that the *S. aureus* present was very virulent. In addition to the signs described above, there was a high prevalence of clinical mastitis and a generalized exudative epidermitis reaching from the escutcheon to the thighs.

Sores of bovine teat skin in Norway, characterized by the presence of *S. aureus* and referred to as 'bovine teat skin summer sore' are thought to be caused by cutaneous invasion by *Stephanofilaria* spp. nematodes. The differential diagnosis of discrete lesions on bovine teat skin is dealt with in the subject of cowpox.

Udder rot (udder cleft dermatitis, flexural seborrhea) of cattle occurs most commonly in dairy heifers that have calved recently. Lesions are present in three locations: on the caudodorsolateral aspect of the udder where it comes into contact with the medial aspect of the thigh, between the halves of the udder (udder cleft dermatitis) or on the ventral midline immediately cranial to the udder. Lesions are usually detected during foot trimming or milking. Udder edema is believed to play an important role in development of lesions on the caudodorsolateral aspect of the udder, because these occur most commonly in periparturient dairy heifers. In contrast, udder cleft dermatitis occurs most commonly in older dairy cattle and the etiology remains uncertain.[10]

In lesions of all three anatomical sites, there is severe inflammation and a profuse outpouring of sebum. Extensive skin necrosis may develop, characterized by a prominent odor of decay. The irritation and pain of the caudodorsolateral lesion may cause the animal to appear lame when walking, and the animal may attempt to lick the affected part. Shedding of the oily, malodorous skin leaves a raw surface beneath, which heals in 3–4 weeks. Some animals with lesions on the caudodorsolateral aspect of the udder benefit from resolution of udder edema and mechanical debridement using a towel drawn repeatedly across the inguinal area. In advanced cases, a soft tissue curette is used to facilitate debridement of necrotic material. The efficacy of topical treatment is unknown. Lesions in the other two sites are usually asymptomatic.

Blood in the milk is usually an indication of a rupture of a blood vessel in the gland by direct trauma (such as getting caught on top of a wooden fence or the result of a kick) or more commonly by capillary bleeding in heifers with udder edema. Although in the latter circumstance the bleeding usually ceases in 2–3 days, it may persist beyond this period and render the milk unfit for human consumption. The discoloration varies from a pale pink to a dark chocolate brown and may still be present 7–8 days after parturition. Rarely, the blood loss may be sufficiently severe to require treatment for hemorrhagic shock (see Ch. 2).[11] Treatment is often requested, although the cow is clinically normal in all other respects. Intravenous administration of calcium borogluconate or parenteral coagulants is widely practiced but efficacy studies are lacking and it is difficult to believe that either treatment has therapeutic value. Difficulty may be experienced in milking the clots out of the teats, but they will usually pass easily if they are broken up by compressing them inside the teat. The presence of blood-

stained milk in all four quarters at times other than immediately postpartum should arouse suspicion of leptospirosis or diseases in which extensive capillary damage occurs. Cases of blood in the milk are usually sporadic in occurrence but there are records of herds with over 50% of cows affected. No clotting defects were evident.

UDDER EDEMA

Edema of the udder at parturition is physiological but it may be sufficiently severe to cause edema of the belly, udder, and teats in cows and mares. In most cases the edema disappears within a day or two of calving, but if it is extensive and persistent it may interfere with sucking and milking. A 10-level scale of severity has been devised and could be applied in assessing the effects of treatment (Table 15.6).[12] Edema is a prominent sign in inherited rectovaginal constriction of Jersey cows, and is described under that heading.

Udder edema is most severe in peri-parturient heifers, and the mechanism for its development is not well understood. Hypoproteinemia is not a precursor of udder edema. It is a common recommendation that the amount of grain fed in the last few weeks of pregnancy be limited, and there is evidence that heavy grain feeding predisposes to the condition, at least in heifers. High sodium or potassium intakes increase the incidence and severity of udder edema,[13] especially in housed cattle; the disease often disappears when cows are turned out to pasture. The tendency for udder edema may be heritable in some herds and selection against bulls that sire edematous daughters is thought to be worthwhile.[14] Such a tendency could be mediated through a complex interaction between sex steroids, which are thought to play a role in the etiology.[15] There is also a reduction in blood flow through, and an increase in blood pressure in, the superficial epigastric or milk veins of cows with chronic edema, through an unidentified mechanism.[16]

Table 15.6 Scale used in grading udder edema

Score	Definition
0	No edema apparent
1	Edema in the base of the udder around one or two quarters
2	Edema in the base of the udder around two or three quarters
3	Edema covering the lower half of the udder
4	Edema beginning to show in the midline and umbilicus
5	Extensive fluid accumulation along the midline and umbilicus
6	Edema covering entire udder. Median suspensory ligament crease has disappeared
7	Midline fluid accumulation extended to the brisket
8	Midline fluid accumulation extended dorsally. The subcutaneous abdominal vein is indistinguishable
9	Fluid accumulation extended to the thighs
10	Severe edema. Marked fluid accumulation in the vulva. Edema extensive in all of the areas mentioned above

Source: from Tucker WB et al. J Dairy Sci 1992; 75:2382.

A mild form of udder edema is the presence of a hard localized plaque along the ventral abdomen immediately cranial to the udder after parturition in heifers. This is common and relatively innocuous but may interfere with milking or ventral abdominal surgical repair of a left displaced abomasum. If the mild udder edema occurs repeatedly over a number of lactations it may result in permanent thickening of the skin (scleroderma) of the lateral aspect of the udder.[17] Hot fomentations, massage and the application of liniments are of value in reducing the hardness and swelling. A chronic form of the disease is recorded from New Zealand but no credible etiological agent has been proposed.

If udder edema is severe, one or more of the following empirical treatments is recommended. Milking should be started some days before parturition, but colostrum from heifers should be discarded as it is likely to be of poor quality. After parturition, frequent milking and the use of diuretic agents is recommended. Corticosteroids appear to exert no beneficial effect. Acetazolamide (1–2 g twice daily orally or parenterally for 1–6 d) gives excellent results in a high proportion of cases, the edema often disappearing within 24 hours. Chlorothiazide (2 g twice daily orally or 0.5 g twice daily by intravenous or intramuscular injection, each for 3–4 d) is also effective. Furosemide is the most potent diuretic agent and should be administered parenterally (1 mg/kg BW, intramuscularly or intravenously; 5 mg/kg BW orally) in severe cases of udder edema,[18–20] but prolonged use can result in hypokalemia, hypochloremia and metabolic alkalosis. The use of diuretics before calving may be dangerous if considerable fluid is lost. When there is a herd problem, detection of the cause is often difficult.

An outbreak of udder edema in ewes has been recorded.[21] Affected animals were afebrile, bright and clinically normal except for the udder, which within 24 hours of lambing was white, cool, and firm, with edema. The milk was normal grossly and laboratory tests detected no abnormalities. Most ewes recovered within 5–10 days of lambing.

Hard udder or indurative mastitis in goats is described under the heading of caprine arthritis–encephalitis, and that in ewes under maedi.

RUPTURE OF THE SUSPENSORY LIGAMENTS OF THE UDDER

Rupture of the suspensory ligaments occurs most commonly in adult cows and develops gradually over a number of years. The cause is thought to be severe udder edema at calving, with excessive weight on the udder causing breakdown of the udder attachments, particularly the median suspensory ligament. The result is that the teats on affected cows are not vertically aligned but point more laterally. When rupture of the suspensory ligament occurs acutely, just before or after parturition, the udder drops markedly and is swollen and hard, the teats point laterally and serum oozes through the skin. Severe edema occurs at the base of the udder. The condition may be confused with gangrenous mastitis or abdominal rupture due to hydrops allantois on cursory examination. Partial relief may be obtained with a suspensory apparatus but complete recovery does not occur.

AGALACTIA

The most important cause of agalactia in farm animals is mastitis–metritis–agalactia (MMA) in sows. The general principles that apply there apply also to the less common cases of agalactia that occur in all species. There is partial or complete absence of milk flow, which may affect one or more mammary glands. The condition is of major importance in gilts and sows, although it occurs occasionally in cattle. The importance of the disease in gilts and sows derives from the fact that piglets are very susceptible to hypoglycemia. The condition may be due to failure of letdown or absence of milk secretion.

The causes of **failure of letdown** include painful conditions of the teat, sharp teeth in the piglets, inverted nipples that interfere with sucking, primary failure of milk ejection, especially in gilts, and excessive engorgement and edema of the udder. In many sows the major disturbance seems to be hysteria, which is readily cured by the use of tranquilizing drugs. Treatment of the primary condition and the parenteral administration of oxytocin, repeated if necessary, is usually adequate.

Ergotism may be a specific cause of agalactia in sows and has been recorded in animals fed on bullrush millet infested with ergot.

Apparent **hormonal defects** do occur, particularly in cattle. Sporadic cases occur in which cows calve normally and have a normal udder full of milk but fail to let it down when stimulated in the normal way. A single injection of oxytocin is often sufficient to start the lactation. In rare cases repeated injections at successive milkings are required. There is one report of a number of cows in a herd being affected.[22] The cows were under severe stress for a number of reasons and had depressed serum cortisol levels. In heifers and gilts there may be complete absence of mammary development and, in such cases, no treatment is likely to be of value. In animals that have lactated normally after previous parturitions, the parenteral administration of chorionic gonadotrophin has been recommended but often produces no apparent improvement.

Mares grazing fescue may fail to lactate after parturition because of inhibition of prolactin release.

Milk drop syndrome

This is a herd syndrome in which the milk yield falls precipitately without there being any clinical evidence of disease, especially mastitis, or obvious deprivation of food or water. Heat stress (particularly the combination of heat and humidity), summer fescue toxicosis and leptospirosis due to *Leptospira hardjo* are among the more common causes.

'Free' or 'stray' electricity as a cause of failure of letdown

Free electrical current is common in dairies, especially recently built ones. The problem is most common when a herd moves into a new shed but it also occurs with alterations to electrical equipment and wiring or with ordinary wear and tear to it. The stray current is present in the metallic part of the building construction, much of which is interconnected. Cows are very sensitive to even small amperages and are highly susceptible because they make good, often wet contact with the metal and with wet concrete on the floor. People working in the dairy are not likely to notice the electrical contact because they are usually wearing rubber boots. The voltage present would be too low to be of much interest to the local power authority, and an independent technician may be necessary to carry out the examination, which should be carried out while the milking machine is working. The effects of free electricity in the milking shed may be:

- Fatal electrocution, stunning causing unconsciousness, frantic kicking and bellowing, all manifested when the animal contacts the electrified metal, as set down under the heading of electrocution

Table 15.7 Diagnosis of free electricity problems

Normal	0–0.50
Suspicious	0.50–0.75
Mild reactions	0.75–1.50
Strong reactions	1.50–3.50
Critical reactions	3.50–5.0
Life at risk	5.0

- Restlessness, frequent urination, defecation, failure to let milk down, in tie-stalls frequent lapping at the water bowl but refusing to drink. The abnormal behavior may be apparent only when the cow is in a particular position or posture
- Startled, alert appearance with anxiety, baulking, refusal to enter the milking parlor
- Failure of letdown leads to lower milk production and recrudescence of existing subclinical mastitis leading to appearance of clinical signs.

In spite of the many field observations of these abnormalities experimental application of AC current up to 8 mA causes changes in behavior but not in milk yield or letdown.[23]

Recommended guidelines for a diagnosis of free electricity problems are set out in Table 15.7.[24] For simplicity it can be assumed that cows will behave abnormally if the free voltage exceeds 1 V AC, although 2 V and a current of 3.6–4.9 mA does not reduce milk production.[25] A safer threshold is 0.35 V AC as a maximum.[26] A proper voltmeter is necessary to make a diagnosis and in most circumstances a qualified electrician is necessary for the exercise.

The development of voltages in the metalwork of the milking shed can arise from many factors. Obvious short circuits from faulty wiring are the least common cause. Most cases are due to accumulation of relatively low voltages because of increased resistance in the earth or ground system, thus neutral to earth voltages. Reasons for the accumulation include a poor earthing or grounding system, grounding rods that are too short to reach the water table, insufficient grounding rods, or dry seasons lowering the water table. The problem may be intermittent and even seasonal, depending on climatic conditions that facilitate the passage of current through the cow as an alternative grounding system.

NEOPLASMS OF THE UDDER

Neoplasms of the bovine udder are particularly rare and have moderate malignancy.[27] A fibrosarcoma originating within or close to a mammary gland has been observed to have high malignancy.[28] Primary teat fibroma and fibrosarcoma in heifers have been satisfactorily treated by surgical excision.[29] Malignant mammary carcinoma occurs occasionally in mares.[30] A mammary adenocarcinoma and ovarian granulosa cell tumor have been recorded in an aged Toggenburg goat.[31] Neoplasms of the skin of the udder may spread to involve mammary tissue.

The commonest neoplasm of cows' teats is viral papillomatosis. It is esthetically unattractive and may play a part in harboring mastitis organisms on the teat skin. It is dealt with in detail under the heading of papillomatosis. Similar papillomata occur on the teat and udder skin of lactating Saanen goats. Rarely, these lesions may develop a squamous-cell carcinoma lesion of low malignancy.[32]

TEAT AND UDDER CONGENITAL DEFECTS

The common sporadic defects in cows are supernumerary teats, fused teats with two teat canals opening into one teat sinus, hypomastia, absence of a teat canal and sinus[33] and absence of a connection between the teat sinus and the udder sinus; in sows insufficient and inverted teats are the common errors. Supernumerary teats are common (up to 33%) in Simmental and Brown Swiss heifers and are removed surgically.[34] A high prevalence of defects is recorded in Murrah buffaloes[35] and inheritance of hypomastia, rudimentary teats and angulation of teats is suspected in cows.[36]

Traditionally sows are required to have at least 12 functional teats[37] and sows deficient in this regard are likely to be culled. Reasons for the deficit include inherited shortage (teat number is highly heritable), misplaced teats (usually too far posteriorly to be accessible to the piglets) or unevenly placed, inverted teats, either congenital or acquired as a result of injury, vestigial nipples that do not acquire a lumen, cistern or gland, and normal-sized teats that are occluded. Inverted teats in sows may be so because they lack a teat upturn, the teat duct opening directly into the mammary gland cistern.[38]

Mastitis–metritis–agalactia syndrome in sows

The mastitis–metritis–agalactia (MMA) syndrome (also called toxemic agalactia, farrowing fever, lactation failure, periparturient hypogalactia syndrome (PHS), or postpartum dysgalactia syndrome (PPDS)) occurs in sows between 12 and 48 hours (sometimes 72 h) after farrowing and is characterized clinically by anorexia, lethargy, restlessness, lack of interest in the piglets, fever, swelling of the mammary glands and agalactia. Most affected animals respond to therapy within 12–24 hours. Pathologically, there are varying degrees of mastitis. In some sows the level of oxytocin may be half the level in unaffected sows. The disease is of major economic importance when outbreaks occur because the inadequate milk production leads to high piglet mortality from starvation and secondary infectious diseases. In cases of subclinical MMA there is often a failure to achieve weaning weights (<4 kg at 24 d). The term mastitis–metritis–agalactia was originally developed to describe sows with agalactia that had swollen udders, assumed to be due to mastitis, and the appearance of a vulval discharge, assumed to be due to metritis. Necropsy of spontaneously occurring cases has frequently confirmed the presence of mastitis but the incidence of metritis has been insignificant.

The prevalence of the condition appears to have reduced recently with the increased attention to hygiene in the farrowing house and the use of more porous and less traumatic floorings. When it does occur it can be quite common, with up to 11–58% of the sows being affected.[1] A recent case definition[2] suggests that the pathognomonic signs are poor piglet growth and sow rectal temperatures greater than 39.5°C.

ETIOLOGY

The etiology is unclear. Several different cause-and-effect relationships have been proposed, based on clinical and epidemiological observations, but only infectious mastitis has been substantiated. The list of proposed causes includes infectious mastitis, metritis, overfeeding during pregnancy, nutritional deficiencies, constipation and endocrine dysfunction. The composite view of this is that there are potential sources of bacterial infection with subsequent endotoxin absorption that lead to the subsequent systemic signs. There is a very considerable farm effect in the appearance of the condition as sow care and management are so important.

A major problem in the determination of the etiology is the difficulty of being precise in the description of the clinical findings of the abnormal mammary glands of affected sows. The common clinical findings are:

- Swelling of the glands
- Agalactia
- Toxemia
- Fever.

There is considerable overlap in the clinical findings from one affected sow to another but the lesion present in the mammary glands may vary from uncomplicated physiological congestion and edema to severe necrotizing mastitis.

Ringarp[3] published the classic work on this disease based on 1180 cases of postparturient illness in sows in which agalactia was present. At least five causes of agalactia or hypogalactia were recognized which are as follows (the incidence of each group as a percentage of the total cases is given in brackets):

- **Eclampsia** (0.6%), usually of older sows, responding to calcium and magnesium therapy
- **Failure of milk ejection reflex** (3.3%), affecting primarily first-litter gilts and usually treated satisfactorily with oxytocin
- **Mammary hypoplasia** (1.5%) in gilts, resulting in deficient milk secretion
- **Primary agalactia** (6%), in which reduced milk supply is the only abnormality
- **Toxic agalactia** (88.6%), the most important numerically and economically. It is characterized by anorexia, depression, fever, swelling of the mammary glands and a course of 2–4 days. Mastitis was commonly present but there was no evidence of metritis.

Infectious mastitis is suggested as a major cause in many clinicopathological investigations and there is a greater incidence of intramammary infection in affected sows compared to normal sows. Peracute mastitis in sows is readily recognized as a clinical entity but less severe infections may result in small foci of inflammation within the gland that cannot be detected on clinical examination.

Escherichia coli and *Klebsiella pneumoniae* have been recovered from the mammary glands of naturally affected cases and both bacterial species are associated with histopathological changes of mastitis. Experimental intramammary inoculation of sows with field isolates of *E. coli* and *K. pneumoniae* has resulted in cases of lactation failure and mastitis that closely resemble naturally occurring cases. Unfortunately, they cannot always be demonstrated in the plasma of affected sows and neither can endotoxin. *Streptococcus* spp. and *Staphylococcus* spp. have also been isolated, but these are frequently isolated from healthy glands unassociated with pathological changes. It is unlikely that *Mycoplasma* spp. are important.

Coliforms are the most significant pathogens isolated from sows with mastitis. Pathological examination of affected sows that were euthanized within 3 days after parturition revealed the presence of varying degrees of mastitis, and *E. coli* and *Klebsiella* spp. were the most common organisms recovered. A recent study has shown that *E. coli* strains from mastitis in sows are highly variable in serotype, biochemical profile, virulence factors and random amplified polymorphic DNA (RAPD) type. No relationship between serotypes, virulence factors and RAPD types was found.[4] Toxic agalactia can be produced experimentally by the introduction of *E. coli* endotoxin into the mammary gland of sows at parturition. The clinical, hematological, and serum biochemical changes are similar to those that occur in naturally occurring cases of

toxic agalactia. *E. coli* endotoxin acting at the level of the hypothalamus can suppress prolactin release, which results in a pronounced decline in milk production. Experimental *Klebsiella* mastitis in sows is an excellent model for the study of toxic agalactia due to infectious mastitis.

Agalactia may also be the result of a deficiency of prolactin. Prolactin levels may be dramatically reduced by even the smallest amounts of endotoxin. Any factor that interferes with the release of prostaglandin from the uterus may affect the increase in prolactin that must occur to stimulate lactogenesis immediately prior to parturition.[5]

In summary, field observations have suggested many different causes and predisposing factors, including infectious mastitis, nutritional disturbances, metabolic disorders and the stress of farrowing in total confinement in a crate. Based on the examination of spontaneously occurring cases, infectious mastitis appears to be a major cause. Both prolactin and oxytocin release can be stopped by stressors and toxins from bacteria such as *E. coli*.

EPIDEMIOLOGY

Occurrence

The disease occurs most commonly in sows at farrowing or within the first 48 hours after parturition. It is most common in sows that farrow in crates indoors and only occasionally occurs in sows farrowing outdoors, which may be a reflection of the greater number of pigs raised in confinement. A peak incidence during the summer months has also been observed. The disease will often occur in one batch and then disappear again for months, which suggests that some unidentified factor may be affecting a whole group.

Morbidity and case fatality

Morbidity and mortality data are not readily available nor precise because of the difficulty of making a reliable clinical diagnosis. Epidemiological observations indicate that the risk of sows developing toxic mastitis increases with increasing age up to the third or fourth litter. The population incidence of toxic agalactia ranges from 4–10% of all farrowings while the herd incidence may vary from 0–100%. Some surveys report an overall incidence of 6.9% of all farrowings with a range from 1.1% to 37.2%. The incidence rates in Swedish herds ranges from 5.5% in small herds to 10.3% in large herds.[6] In Denmark, an incidence rate of 9.5% from a total of 80 000 farrowings, independent of herd size, has been reported.[6] In a survey of 70 herds in Norway over a period of 2 years, the incidence rate was about 17.5%[7] and there was no consistent relationship between disease incidence and herd size.[8,9] Sporadic outbreaks of the disease may occur in which almost all sows farrowing over a period of several weeks or a few months may be affected and then suddenly no further cases develop for no apparent reason.

The fatality rate is usually less than 2%, but piglet losses due to starvation and crushing may be as high as 80%. It is not a major cause of sow mortality.[10] The disease does not usually recur in the same animal, which may suggest that immunity develops and possibly that affected sows should not necessarily be culled because of the disease.

Risk factors

The risk factors that have been proposed based on field observations include overfeeding during pregnancy, a drastic change of feed at farrowing, insufficient time for the sow to adjust to the farrowing crate after being transferred from the gestation unit and constipation of the sow at farrowing.

Animal risk factors

The initiating factors have not been identified. The incidence of the disease may also be higher in sows with larger litters than sows in the same herd that remain healthy, and in those with a higher number of stillbirths and pigs found dead after birth.[6]

Each section of the mammary gland of the sow is divided into a separate anterior and posterior section, each with its own teat cistern and teat canal. In a sow with 14 teats there are 28 potential portals of entry for environmental infectious agents and perhaps it is little wonder that mastitis should occur commonly immediately after parturition when the teat canals have become patent. Bacteria in the gut and in endometritis have been proposed as a source of endotoxin, particularly as **beta-hemolytic streptococci** and coliforms have been associated with the condition.

Some clinicopathological examinations of affected sows have revealed the presence of a slightly enlarged, flaccid uterus from which coliform and streptococcal organisms can be recovered. However, pathological evidence of metritis in affected sows is uncommon; the organisms that can be recovered are commonly present in the reproductive tract of normal sows after parturition and their recovery from vaginal mucus is difficult to interpret.

Constipation of sows at farrowing time has been suggested as a cause but has not been substantiated. However, clinical and pathological examinations of both spontaneously occurring cases of agalactia and experimental agalactia induced by the introduction of *E. coli* endotoxin into the mammary gland have been unable to support the observation of constipation. Both sick and normal sows defecate less frequently from 1 day before farrowing until 2 days later. There is no difference in the weight of feces in the terminal colon and rectum between sick and normal sows. Low exercise has also been suggested as a cause and this also contributes to constipation. The role of water intake or lack of it and stress or disturbance during parturition has also not been investigated.

The nursing behavior of the sow and the sucking behavior of the piglets may provide an explanation for the pathogenesis and clinical findings of some cases of agalactia in sows. Successful ejection of milk by the sow is dependent on proper stimulation of the sow's udder by the piglets followed by a complex response by the sow. A period of time ranging from 15–45 minutes must elapse from the last successful milk ejection to the next. Failure of milk ejection may occur in up to 27% of sows that attempt to suckle their piglets within 40 minutes after the previous milk ejection. The failure of milk ejection in sows within the first few crucial adjustment days after farrowing might possibly contribute to the cause of mastitis and engorgement of the mammary glands. The possible causes of failure of milk ejection, even when a suitable interval has elapsed since the previous milk ejection, include:

- Environmental or other animal noises and disturbances
- Uncomfortable farrowing crates
- High environmental temperatures
- Insufficient time to adjust to the farrowing crate.

Management and dietary factors

The disease occurs under management, environmental and sanitation conditions ranging from very poor to excellent; however, the possible relationship between the level of bacterial contamination in the farrowing barn and on the skin of the sow and the incidence of the disease has apparently not been examined. Dirty conditions greatly increase the bacterial contamination of the udder.

Digestive disturbances and certain feeding practices have been associated with the disease. Sows that have been on high-level feeding during pregnancy appear to be susceptible to the disease, especially if they are subjected to a change of feed immediately prior to parturition. Also, any management practice that results in a marked change in feed intake at or near farrowing may appear to precipitate the disease. A sudden change of feed severe enough to result in gastrointestinal stasis has

been used to reproduce the condition experimentally.

The effects of different feed allowances during late pregnancy may affect the incidence rate of the disease. Feeding sows during the last 15 days of gestation a diet at a level of 3.4 kg daily compared to 1.0 kg daily resulted in an incidence rate of 26.6% and 14.0%, respectively.[6] The explanation for the effects of feeding is unknown. It has been proposed that intense feeding may promote toxin production in the alimentary tract but how this is related to mastitis is unknown. Another hypothesis suggests that increased feeding in late gestation may intensify the initiation of lactation and result in udder engorgement and increased susceptibility to intramammary infection.[6] A further suggestion is that moldy food may play a part, but this has never been proved.

The clinical status of the mammary glands, the bacteriological findings and the total cell count and its percentage of polymorphonuclear leukocytes and pH in colostrum and milk secretion during the first 3 weeks of lactation of sows on high or low feeding regimes during late pregnancy have been examined.[11] *E. coli* infection was present in 80% of the sows affected with toxic agalactia and 30% of the healthy sows. The *E. coli* were eliminated at between 3 and 8 days of lactation and were not isolated from sows examined at the time of weaning.[12] The different feeding regimes did not influence the total cell count, the polymorphonuclear cells or the pH in milk from bacteriologically negative glands or glands with *E. coli* mastitis. The two feeding regimes had no influence on total cell count, the percentage of polymorphonuclear cells or the pH of colostrum and milk of healthy sows.[13]

PATHOGENESIS

The pathogenesis of infectious mastitis due to *E. coli* or *Klebsiella* spp. is probably similar to that of bovine mastitis in which the infection gains entry through the teat canal and invades the mammary tissue causing mastitis. Endotoxemia occurs accounting for the fever initially, and the depression, anorexia and agalactia, even in glands that are unaffected.[14] The lipopolysaccharide endotoxins acting at the level of the hypothalamus and hypophysis suppress the release of prolactin which results in a marked decline in milk production.[15,16] The endotoxin may also have a direct inhibitory effect on the mammary gland. There is a higher prevalence of bacterial endotoxin in the blood of affected sows compared to control animals. The endotoxin can be detected in the blood of about 33% of sows affected with coliform mastitis.[14] However, the oral administration of endotoxin daily to prepubertal gilts did not result in any clinical abnormalities.[17] Experimentally, mastitis can be produced in sows by contamination of the skin of the teats with *K. pneumoniae* either shortly before or after parturition. The clinical signs are similar to those described for MMA; mastitis is present in more than 50% of the mammary gland subsections and a marked leukopenia and degenerative left shift occurs. A total of 120 organisms is sufficient to produce the mastitis when the organisms are inoculated into the teats. In recent experimental infections with *E. coli* it was shown that the time of infection of the mammary gland relative to parturition and the number of circulating neutrophils at the time of infection influenced the development of clinical coliform mastitis in the sow.[18] Similarly parturition allows the penetration of vaginal organisms further up the reproductive tract and the absorption of endotoxin reduces F2α in the uterus and this stimulates prolactin, which may contribute to the hypogalactia and agalactia.

If noninfectious acute painful swelling of the mammary glands accompanied by agalactia occurs in the sow as a result of the possible noninfectious factors that were described earlier, the pathogenesis is unclear. It is difficult to synthesize a pathophysiological mechanism that would explain how stress, overfeeding, changes in diet or constipation could result in acute swelling of the mammary gland in sows.

CLINICAL FINDINGS

Sometimes there may be a delay in parturition of more than 5 hours. The sow is usually normal, with a normal milk flow, for the first 12–18 hours after farrowing. Normally, the sow will suckle her piglets for about 20 seconds once an hour. One of the first indications of the disease is the failure of the sow to suckle her piglets. She is uninterested in the piglets, generally lies in sternal recumbency and is unresponsive to their squealing and sucking demands. Litters of affected sows are more noisy and are generally scattered around the pen searching for an alternative food supply. Such piglets may drink surface water or urine in the pen and infectious diarrhea may occur. If sucking is permitted, it does not progress from the vigorous nosing phase to the quiet letdown stage, and it is accompanied by much teat-to-teat movement by the piglets. Many piglets may die from starvation and hypoglycemia. A failure to grow at more than 105 g/d is a sure sign of piglet problems. Some sows are initially restless and stand up and lie down frequently, which contributes to a high mortality from crushing and trampling.[19,20]

Affected sows do not eat, drink very little and are generally lethargic. The body temperature is usually elevated and ranges from 39.5–41°C (103.1–105°F), especially if there is mastitis. Mild elevations in body temperatures of sows in the first 2 days after parturition are difficult to interpret because a slight elevation occurs in normal healthy sows.[21] This is known as uncomplicated farrowing fever. However, temperatures above 40°C (104°F) are usually associated with acute mastitis that requires treatment. One detailed investigation of the disease in Sweden concluded that 78% of sows with a temperature exceeding 39.5°C had clinical evidence of mastitis. It is suggested that a temperature of 39.4°C at 12–18 hours after farrowing is an appropriate threshold at which to give preventive treatment for the disease. The heart and respiratory rates are usually increased.

Initial temperatures greater than 40.5°C (104.9°F) are usually followed by severe illness and toxemia. Normally, the sows get better within 3 days, but not always if the temperature is very high.

The characteristic findings are present in the mammary glands and consist of varying degrees of swelling and inflammation. In most cases, several sections are affected, which results in the appearance of diffuse involvement of the entire udder. Individual sections are enlarged, warm and painful, and may feel 'meaty' and lack the resilience of normal mammary tissue. There may be extensive subcutaneous edema around and between each section, which results in a ridge of edema on the lateral aspects of the udder extending for its entire length. The skin overlying the sections is usually reddened and is easily blanched by finger pressure. The teats are usually empty and may be slightly edematous. A few drops of milk may be expressed out of some teats after gentle massage of the section or the administration of oxytocin but rarely can a normal stream of milk be obtained. In severe cases of mastitis the milk contains flakes and pus or is watery.

The feces are usually scant and drier than normal but whether or not constipation is present in most cases is uncertain. The inappetence and anorexia and failure to drink normally could account for the reduced volume of feces. Constipation with impaction of the rectum with large quantities of feces is uncommon in sows and when it does occur as the only abnormality it has little effect on appetite and milk production.

A vaginal discharge is normal following parturition, and normal sows frequently expel up to 50 mL of a viscid, nonodorous,

clear mucus that contains variable amounts of white material within the first 3 days following farrowing. Tenacious strands of this discharge may also be observed within the vagina. The presence of this discharge has been misleading and has been interpreted as evidence of the presence of metritis. Necropsy examination after euthanasia of affected sows has failed to reveal evidence of significant metritis. The clinical diagnosis of metritis in sows is difficult but generally large quantities of dark-brown, foul-smelling fluid are expelled several times daily, accompanied by severe toxemia. This is uncommon in sows. Diagnosis is usually on clinical signs.

CLINICAL PATHOLOGY

Examination of milk

The number of somatic cells in the milk from sows with mastitis will range from 2–20 $\times 10^9$/mL compared to the normal of less than 2×10^9/mL. Significant numbers of bacteria are present in the milk of more than 80% of sows with toxic agalactia. Milk obtained for laboratory examination and culture should be taken after thorough cleaning and disinfection of the teats to minimize contamination by skin flora. However, because mastitis may be present in only one or a few of the mammary gland subsections in the sow and because it is often impossible to clinically identify affected subsections and distinguish them from unaffected adjacent glands, which may be swollen and agalactic because of continuous swelling, a valid assessment of intramammary infection is not possible unless milk samples are obtained from each subsection. Subclinical mastitis may not be easy to detect with cells not reaching 2×10^9/mL but 75% may be polymorphs. Normally, milk is around 1×10^9/mL.

Hematology and serum biochemistry

Some hematological and biochemical changes are present in affected sows but may not be marked enough to be a routine reliable diagnostic aid. In severe cases of infectious mastitis, a marked leukopenia with a degenerative left shift is common. In moderate cases there is a leukocytosis and a regenerative left shift. The serum biochemical changes that occur in naturally occurring cases and in the experimental disease are recorded. The plasma cortisol levels are commonly elevated, which may be due to a combination of the stress of parturition and infectious mastitis. The plasma protein-to-fibrinogen ratio is lower than normal and the plasma fibrinogen levels are commonly increased in severe cases that occur 8–16 hours after parturition.

NECROPSY FINDINGS

Neither lesions in the udder nor the reproductive tract are consistent. If they are found, the most important lesions are in the mammary gland. There may be extensive edema and some slight hemorrhage of the subcutaneous tissue. Grossly, on cross-section of the mammary tissue there is focal to diffuse reddening and often only one subsection of a mammary gland may be affected. Histologically, the mastitis may be focal or diffuse in distribution and the intensity of the lesion varies from a mild catarrhal inflammation to a severe purulent and necrotizing mastitis usually involving more than 50% of all the mammary glands. There are no significant lesions of the uterus when compared with the state of the uterus in normal healthy sows immediately after parturition. The adrenal gland is enlarged and heavier than normal, presumably due to adrenocortical hyperactivity. In a series of spontaneous cases, *E. coli* and *Klebsiella* spp. were most commonly isolated from the mammary tissues. The abscesses of the mammary glands of sows examined at slaughter are not sequelae to coliform mastitis but rather probably due to injuries and secondary infection.

Samples for confirmation of diagnosis

- Bacteriology – mammary gland, regional lymph node
- Histology – formalin-fixed mammary gland.

DIFFERENTIAL DIAGNOSIS

The characteristic clinical findings in toxic mastitis and agalactia are a sudden onset of anorexia and lack of interest in the piglets, acute swelling of the mammary gland, hypogalactia or agalactia, a moderate fever and a course of about 2 days. The mammary secretion from mastitic glands may be watery or thickened and contain pus, and the cell count will be increased up to 20×10^9/mL. The acute swelling and agalactia of infectious mastitis must be differentiated from other non-infectious causes of acute swelling or 'caking' of the mammary glands, which also results in agalactia as follows:

- **Agalactia due to a failure in milk letdown** is most common in first-litter gilts and is characterized by a fullness of the mammary glands but an inability of the gilt to suckle her piglets in spite of her grunting at them. The gilt is usually bright and alert and systemically normal. The response to oxytocin is dramatic and repeat treatment is rarely necessary
- **Farrowing fever** is characterized clinically by loss of appetite, inactivity and a body temperature of 39.3–39.9°C (102.7–103.8°F) with minimal detectable changes of the mammary gland
- **Parturient psychosis of sows** is characterized by aggressive and nervous behavior of the sow after the piglets are born. The sow does not call the piglets and does not allow them to suck. When the piglets approach the sow's head, she will back away, snap and make noisy staccato nasal expirations. Some sows will bite and kill their piglets. The mammary gland is usually full of milk but the sow will not let it down. Ataractic drugs and/or short-term general anesthesia are indicated and the response is usually excellent. Some sows need repeated tranquilization or sedation for the first few days until the maternal–neonatal bond is established
- **Other causes of agalactia** accompanied by enlargement of the mammary gland include **inherited inverted teats** and **blind teats** due to necrosis of the teats occurring when the gilt was a piglet. These are readily obvious on clinical examination. The sharp needle teeth of piglets may cause the sow to refuse to suckle her piglets. The sow attempts to suckle but leaps up suddenly, grunting and snapping at the piglets. The piglets squeal and fight to retain a teat, thus causing more damage to the teats, which is obvious on clinical examination. Other causes of agalactia accompanied by systemic illness include **retained piglets** and infectious disease such as outbreaks of **transmissible gastroenteritis** and **erysipelas.** The common causes of agalactia in pigs where there is lack of mammary development include **ergotism**, **immature gilts** and **inherited lack of mammary development**. These are set out in Figure 15.1.

TREATMENT

Most affected sows will recover within 24–48 hours if treated with a combination of antimicrobials, oxytocin and anti-inflammatory agents. The treatment should begin when the temperature reaches 39.4°C.[22]

Antimicrobials are indicated in most cases because infectious mastitis and metritis are the two most common causes of the disease. The choice is generally determined by previous experience in the herd or region but broad-spectrum antimicrobials are indicated because *E. coli* and *Klebsiella* spp. are the most common pathogens involved. They should be given daily for at least 3 days.[23] Usually ampicillin, tetracyclines, trimethoprim–sulphonamide, or enrofloxacin is used.

As soon as possible after the disease is recognized every effort must be made to restore normal mammary function through the use of oxytocin and warm water massaging of the affected mammary glands.

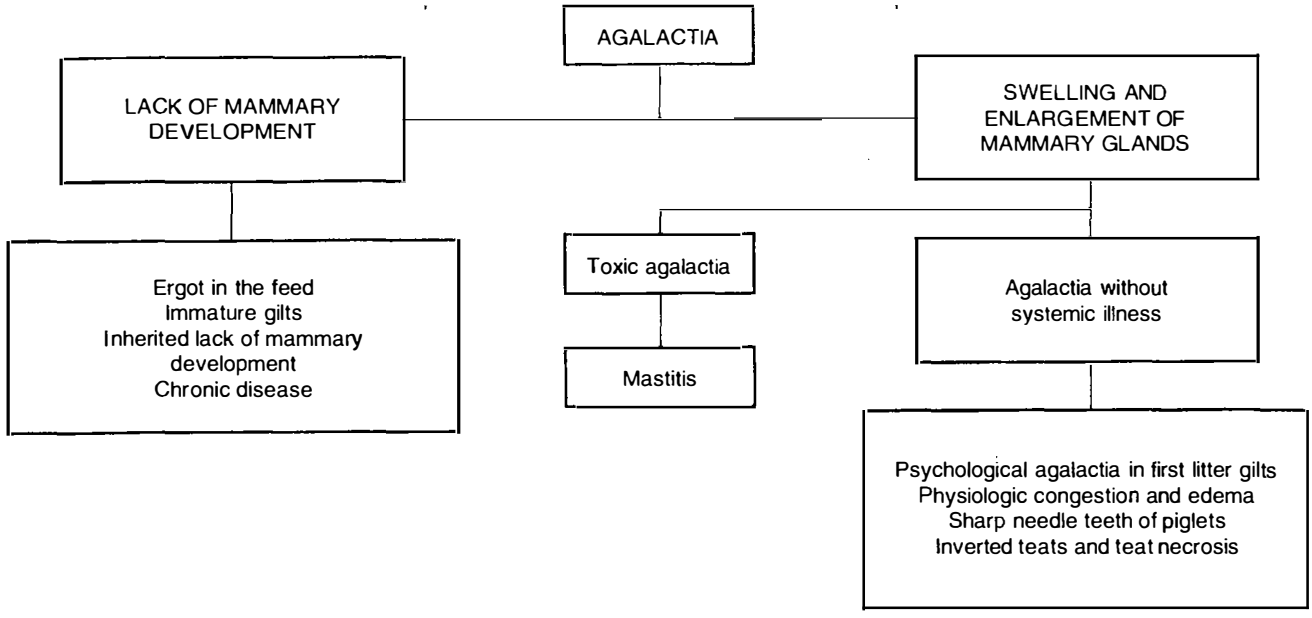

Fig. 15.1 The causes of porcine agalactia.

Oxytocin 30–40 U intramuscularly or 20–30 U intravenously, is given, frequently, to promote the letdown of milk. If there is a beneficial response the piglets should be placed on the sow if she is willing to allow them to suck. This will assist in promoting milk flow. Massage of the mammary glands with towels soaked in warm water and hand milking for 10–15 minutes every few hours may assist in reducing the swelling and inflammation and promote the flow of milk. It will also relieve the pain and encourage the sow to suckle her piglets. Intramuscular injections of oxytocin may be repeated every hour, along with massaging of the glands with warm water. Failure of milk letdown or a low response following the use of oxytocin may be due to a reduced sensitivity of the sow to oxytocin during the first week of lactation. In the normal, healthy sow the peak response to oxytocin occurs in the second week of lactation and gradually decreases to a low response at the eighth week.

The use of a long-acting carba oxytocin analog is being explored as a possible substitute for oxytocin. Oxytocin has an effect for about 14 minutes, while the analog has an effect for about 6 hours. Preliminary results of its use in agalactic sows indicate superior results compared to oxytocin.

Anti-inflammatory agents are in common use for their anti-inflammatory effect but are rarely used on their own; flunixin meglumine has been shown to be beneficial and ketoprofen to alleviate pyrexia and endotoxemia. Recently, meloxicam and oxytocin were shown to reduce mortality compared to flunixin only.[24] Plasma cortisol levels are increased in the experimental disease and for this reason may be contraindicated. However, field reports suggest that their use along with antimicrobials and oxytocin provides a better response than when they are not used. Corticosteroids used alone do not appear to prevent the disease or enhance recovery. To be effective they must be used in combination with antimicrobials and oxytocin. Dexamethasone at the rate of 20 mg intramuscularly daily for 3 days for sows weighing 150–200 kg has been recommended.

Supplementation of piglets

The hypoglycemic piglets must be given a supply of milk and/or balanced electrolytes and dextrose until the milk flow of the sow is resumed, which may take 2–4 days, and most important of all must be kept warm until body reserves are re-established. Piglets should receive 300–500 mL of milk per day divided into hourly doses of 40–50 mL given through a 12–14 French plastic tube passed orally into the stomach. A solution of balanced electrolytes containing 5% glucose can also be given for 1–2 days if a supply of cows' milk is not available. Condensed canned milk diluted with water 1:1 is a satisfactory and readily available supply of milk. In severe cases where the return to milk production and flow are unlikely, the piglets should be fostered on to other sows. If these are unavailable, the use of milk substitute fortified with porcine gammaglobulin is recommended to prevent the common enteric diseases. This is discussed under colibacillosis. Many more piglets are treated for diarrhea when the sows are treated for MMA, perhaps up to 19% compared to up to 9% normally.[1]

CONTROL

It has been difficult to develop a rational approach to control because the disease has been considered to be a complex syndrome caused by several different factors. However, the control of infectious mastitis would seem to be of major importance. The routine use of antibiotics and oxytocin without indication does not appear to be helpful.[24] Farrowing crates should be vacated, cleaned, disinfected and left vacant for a few days before pregnant sows are transferred from the dry sow barn and placed in the crates. Pregnant sows should be washed with soap and water before being placed in the crate. Farrowing crates must be kept clean and hosed down if necessary, particularly a few days before and after farrowing to minimize the level of intramammary infection. In problem herds, it may be necessary to wash and disinfect the skin over the mammary glands immediately after farrowing. All in/all out in the farrowing area with proper cleaning and disinfection facilitated by batch farrowing will reduce the disease. An opportunity for exercise will help, as under outdoor conditions (sows in paddocks) the condition is rare.

To minimize the stress to the sow of adjusting to the farrowing crate and the farrowing facilities, the sow should be placed in the crate at least 1 week before the expected date of farrowing.

The nature and composition of the diet fed to the sow while in the farrowing crate should not be changed. In order to minimize the risk of toxic agalactia, it is recommended that the daily feed allowance be related to body condition score. It may be necessary to reduce the feed to

1 kg/day (from 100 d gestation) before farrowing.[25] The daily intake (compared to the intake during the dry period) may be increased on the day after the sow has farrowed and in increments thereafter as the stage of lactation proceeds. The inclusion of bran at the rate of one-third to one-half of the total diet for 2 days before and after farrowing has been recommended to prevent constipation. In some herds the use of lucerne meal or other vegetable protein at the rate of 15% of the diet may help control the disease. However, under intensified conditions it may be impractical to prepare and provide these special diets on a regular basis. While field observations suggest that a bulky diet at the time of farrowing will minimize the incidence of toxic agalactia, there is little scientific evidence to support the practice.

Antimicrobial agents used prophylactically have apparently been successful in controlling some outbreaks. A trimethoprim–sulfadimidine and sulfathiazole combination at 15 mg/kg in feed from day 112 of gestation to day 1 after farrowing may reduce the prevalence. Using oxytocin early may also help. In a recent study where *E. coli*, streptococci and staphylococci were the most cultured pathogens, marbofloxacin(10% solution) was found to be superior to amoxicillin. All *E. coli*, were susceptible to the former but 32% were resistant to the latter antibiotic.

The use of prostaglandins for the induction of parturition in sows has not been associated with a marked consistent change in the incidence of the disease. Some field trials have shown a reduction, while others have had no effect.

Mastitis of sheep

ETIOLOGY

Most cases (80–90%) of clinical mastitis are due to *Staphylococcus aureus*, the remainder to *Streptococcus agalactiae* and *M. haemolytica*, with rare occurrences of *Escherichia coli* and *Histophilus somni*. (formerly *Histophilus ovis*). Coagulase-negative staphylococci are a major cause of subclinical mastitis in sheep.[1] Sheep at pasture are the only species other than dairy cattle in which outbreaks of mastitis due to *S. aureus* and *M. haemolytica* occur. A small percentage of cases are associated with *Clostridium perfringens* A, *Pseudomonas* spp., or *Corynebacterium pseudotuberculosis*. *Acholeplasma oculi* is pathogenic and can cause mastitis and agalactia.[2] Mycoplasma serogroup II is pathogenic in sheep when inoculated experimentally.[3]

EPIDEMIOLOGY

Occurrence

Clinical mastitis in ewes occurs about equally immediately after weaning or close to parturition. In pastured ewes the prevalence is low and due usually to *M. haemolytica* or *Staphylococcus* spp. In housed ewes many cases are due to teat injury, especially when the sheep are housed on abrasive floors, such as expanded metal.

Up to 10% of ewes used for milk production have subclinical mastitis.[4] Clinical mastitis in pastured ewes averages only about 2% per year, but mastitis causes up to 10% of all ewe deaths.

The forms of loss in milk sheep are the same as those for dairy cattle. In meat and fiber sheep the losses take the form of deaths, due usually to gangrenous mastitis, and to decreased growth in the neonates.[5] Where sucking lambs have access to supplemental feed the effect of subclinical mastitis on lamb performance is negligible.[6]

Although in most European countries sheep are used for mutton and wool production, in Greece nearly all ewes are milked commercially for the production of Greek feta cheese. Any factor that adversely affects the quantity and quality of ovine milk is of great financial interest. The prevalence of subclinical mastitis in sheep in Greece varies between flocks from 29–43%.[7] Coagulase-negative staphylococci and *S. aureus* were isolated in 44% and 33% of the positive milk samples, respectively.

Staphylococcal mastitis

The most prevalent mastitis pathogen of the ewe is *S. aureus*.[8] The incidence of clinical mastitis may be as high as 20%; the mortality rate varies between 25% and 50%, and affected quarters in surviving ewes are usually destroyed. Chronic mastitis can result in a 25–30% reduction in milk yield from affected udder halves.[9] The disease can be a very important one in those countries in which ewes' milk is a staple article of diet. The disease is probably spread from infected bedding grounds, the infection gaining entry through teat injuries caused by sucking lambs.

Other staphylococcal mastitides in ewes include *Staphylococcus epidermidis*; many clinically normal quarters show a high rate of infection with coagulase-negative staphylococcus.[10] Experimental infection with *Staphylococcus chromogenes* causes clinical mastitis, *Staphylococcus simulans* causes subclinical mastitis and *Staphylococcus xylosus* causes a transient increase in the SCC.[11]

Streptococcal mastitis

The disease can be reproduced by the introduction of *S. agalactiae* into the mammary glands and occurs naturally in sheep used as milking animals. The infection originates from an infected udder and is transmitted to the teat skin of other females by milking machine liners, milkers' hands, wash cloths and any other material that can act as an inert carrier. Also listed as occasional causes are *Streptococcus dysgalactiae* and *Streptococcus uberis*.

Mannheimia mastitis

Peracute, gangrenous mastitis associated with *Mannheimia* spp. is the common mastitis of ewes. *M. haemolytica* can be isolated from affected quarters and the disease can be reproduced experimentally[12,13] by the intramammary infusion of cultures of the organism. *S. aureus*, *Arcanobacterium pyogenes*, and streptococci are often present as secondary invaders.

Mannheimia mastitis occurs sporadically in the western USA, Australia, and Europe in ewes kept under systems of husbandry varying from open mountain pasture to enclosed barns. Mastitis is most common in ewes suckling large lambs 2–3 months old. Infection is thought to occur through injuries to teats, perhaps caused by

overvigorous sucking by big lambs. *Mannheimia* mastitis occurrence is not related to hygiene, many outbreaks occurring in sheep at range but, because of the sheep's habit of sleeping at night on often used bedding grounds, it is possible that transmission occurs by contact with infected soil or bedding.

PATHOGENESIS

The mechanisms of pathogenesis are similar to those for bovine mastitis.

CLINICAL FINDINGS

In milking ewes clinical mastitis is similar to that in cows, with acute and subacute forms manifested by swelling of the gland and wateriness and clots in the milk. Most clinical cases seen by the veterinarian are in brood ewes, and take the form of gangrenous mastitis, affecting one or both halves.

Staphylococcal mastitis

In sheep there is a strong similarity between this form of mastitis and that associated with *M. haemolytica*. They are both peracute, gangrenous infections. The ewe is usually recumbent and profoundly toxic, and the affected gland and the surrounding area of belly wall are blue-green in color and cold to the touch. A few drops of clear, bloodstained liquid is all that can be expressed from the udder. A fatal clinical course of 1–2 days is usual.

Mannheimia mastitis

An acute systemic disturbance, with a high fever (40–42°C, 105–107°F), anorexia, dyspnea and profound toxemia, accompanies acute swelling of the gland and severe lameness on the affected side. This lameness is an important early sign and is useful in locating affected animals in a group. The udder is at first hot, swollen and painful and the milk watery, but within 24 hours the quarter is discolored blue-black and cold, with a sharp line of demarcation from normal tissue. The secretion is watery and red and contains clots. The temperature subsides in 2–4 days, the secretion dries up entirely and the animal either dies of toxemia in 3–7 days or survives with sloughing of a gangrenous portion of the udder, followed by the development of abscesses and the continual draining of pus. Usually only one side is affected. Cases of pneumonia due to the same organism may occur in lambs in flocks where ewes are affected.

Clostridial mastitis

Clostridium perfringens A is a rare and highly fatal cause of acute mastitis in ewes. Clinical signs of infection are principally hemolytic and are characterized by hemoglobinuria, jaundice and anemia, plus fever, anorexia and recumbency. The affected quarter is swollen, painful and hot and contains watery, brown, flocculent secretion.[14]

Caseous lymphadenitis and mastitis

Suppurative lesions associated with *Corynebacterium pseudotuberculosis* are found commonly in ovine mammary glands, but they usually involve only the supramammary lymph nodes and are not true mastitis, although the function of the mammary gland may be lost when the infection has spread from the lymph node to mammary tissue.

Pseudomonal mastitis

Naturally occurring pseudomonal mastitis in ewes is likely to be gangrenous and lethal[15] and accompanied by severe lameness in the hindlimb on the affected side. Infected intramammary infusions or milking machine malfunction[16] are the usual means of introducing the infection.

CLINICAL PATHOLOGY

Determination of the SCC is useful for the prediction of mammary gland infection in sheep.[7] Bacteriologically negative ewe's milk has 2–3% somatic cells, 10–17% lymphocytes, 10–35% neutrophils and 45–85% macrophages.[17] In milking ewes milked by machine, SCCs and CMT scores resemble those in dairy cows.[18] However, a universally accepted value has not yet been set for the ewe. The SCC in normal ewes' milk may range from 500 000–1 000 000 cells/mL. However, more than 95% of milk samples from normal ewes have a total content of less than 500 000 cells/mL. In one survey of milk samples from sheep, mean SCC from mastitis-negative samples was 1500 000 cells/mL.[8] All mastitis-positive samples had somatic cells in excess of 2 000 000 cells/mL and it is suggested that the threshold level for subclinical mastitis in ewes should be close to 1 500 000 cells/mL.[8] The CMT is a reliable indicator of the SCC of ewes' milk and of the level of infection, and it, the SCC and the NAGase all correlate well with the microbiological findings in mastitic quarters. Infection with Maedi–Visna virus does not appear to alter milk SCC in the ewe.

NECROPSY FINDINGS

The gross appearance of the affected glands varies with the agent involved and the duration of the process.[19] In general, the swollen, hemorrhagic, and/or gangrenous nature of fatal acute ovine mastitis is glaringly obvious. A purulent exudate is sometimes present, especially in the case of chronic *C. pseudotuberculosis* infection.

Samples for confirmation of diagnosis

Bacteriology – chilled mammary gland for aerobic culture; anaerobic culture if *Clostridium* sp. is suspected.

DIFFERENTIAL DIAGNOSIS

Mannheimia mastitis is peracute and resembles mastitis associated with *S. aureus*. A similar disease in ewes has been ascribed to *Actinobacillus lignieresii*. Suppurative mastitis associated with *C. pseudotuberculosis* is chronic in type and no systemic signs occur. Differentiation from clostridial mastitis is also necessary.

TREATMENT

Broad-spectrum parenteral and intramammary antimicrobial agents are effective. Although ewes probably require smaller doses of intramammary infusions than cows it is customary to use ordinary cow-type mammary infusion treatments; this may, however, result in a much longer period during which the milk in the quarter has a higher level of antibiotic than is desirable.[20] The treatment of ewes with peracute gangrenous mastitis is as unsatisfactory in terms of results as in cows. Systemic treatment is necessary and requires larger doses than normal to achieve significant levels in the mammary secretion.

CONTROL

Removal of sources of infection in sheep flocks necessitates culling some ewes with affected udders but even rigid culling usually fails to completely eradicate the disease.

Control programs for milking sheep flocks could easily be arranged by adapting the one described for cows. Dry period treatment with intramammary infusions of cephapirin benzathine is being used;[21] infusion of both halves greatly reduces the subsequent new infection rate.[22] For suckling ewes in flocks with a bad history of mastitis another recommended prophylaxis is the infusion of each half with sodium cloxacillin at weaning.

Staphylococcal mastitis

It is possible that vaccination could be an effective method of control for staphylococcal mastitis. A bacterin toxoid has proved moderately effective in reducing the incidence of the disease. Two injections of the vaccine are necessary. Vaccination against staphylococcal mastitis in ewes has been on trial for some time. The latest vaccine, consisting of killed *S. aureus* cells, toxoided staphylococcal beta-hemolysin plus dextran sulfate as an adjuvant, appears to provide some protection against experimental infection.[23] Prophylactic infusion of each half of the udder within a few days of weaning, using half of a tube of dry cow treatment of penicillin and streptomycin, has also given good results. The frequent changing

of pasture areas and culling of affected ewes should also help to control the spread of infection.

Mannheimia mastitis

Polyvalent hyperimmune serum and a formolized vaccine have been shown to be of value in prophylaxis. An autogenous vaccine of killed *M. haemolytica*[24] appears to confer excellent immunity and should be effective in a flock where the disease is occurring.

Mastitis of goats

Goats are much less frequently affected by contagious mastitis than cattle, but mastitis is an important sign in many of the infectious diseases associated with *Mycoplasma agalactiae* and *Mycoplasma mycoides* var. *mycoides*. Details of the other infections encountered are fragmentary and inconsistent; coliform organisms, for example, are listed as not occurring and as being most common. Coagulase-negative staphylococci are a common finding in clinically normal halves[1] and appear to cause persistent infection.[2]

In some surveys, *Staphylococcus aureus* and *Escherichia coli* are the most commonly isolated pathogens from mastitic goats.[3] Other infections are *Pseudomonas* spp., *Staphylococcus hyicus* (much less pathogenic than *S. aureus*),[4] *Streptococcus dysgalactiae*, *Streptococcus pyogenes*, *Streptococcus intermedius*, *Arcanobacterium pyogenes*, *Bacillus coagulans*, and *Bacillus licheniformis*.[5] *Klebsiella pneumoniae*, *Corynebacterium pseudotuberculosis*, *M. haemolytica*, and *Actinobacillus equuli* have also been isolated from mastitic goats.[3] *Nocardia asteroides* causes a systemic reaction and granulomatous lesions in the udder and lungs.[6]

The prevalence of infection in goats ranges from 10%[3] to 30%.[7] Prevalence of infection in different herds may range from 7–34% of glands and 17–44% of goats.

Staphylococcal mastitis

This is the most common cause of mastitis in goats. In the experimentally produced disease associated with *S. aureus* in goats the pathogenesis is very similar to that in the cow except that there is a marked tendency for the staphylococci to invade and persist in foci in the interacinar tissue. As in cattle, some staphylococci in goats' milk produce enterotoxins and the toxic shock syndrome toxin and are likely to cause food poisoning in humans. Latex agglutination tests are available for the identification of the enterotoxins.[8]

Streptococcal mastitis

Goats are uniformly susceptible to *Streptococcus agalactiae*; mastitis associated with it does occur but to a lesser extent than in cattle. In flocks of milking goats the infection is passed from infected quarters to others by means of the milker's hands, the teat cups of milking machines and wash cloths used to disinfect the udder before milking. *Streptococcus zooepidemicus* causes chronic suppurative mastitis in does, and artificially induced infections with *S. dysgalactiae* are indistinguishable from mastitis associated with *S. agalactiae*. The pathogenesis is probably similar in all streptococcal mastitides.

Pseudomonas mastitis

Experimental pseudomonas mastitis in goats is acute, with extensive necrosis and fatal septicemia.

Summer mastitis

Summer mastitis associated with *A. pyogenes* has been produced experimentally in goats with udder lesions typical of acute suppurative mastitis. Nonlactating goats developed a severe mastitis, lactating animals only a moderate one.

Other infections

Mastitis in goats is associated with an organism tentatively identified as *M. haemolytica*. *Yersinia pseudotuberculosis* has caused mastitis in an aborting goat doe that probably experienced a bout of systemic yersiniosis. The infection would have had zoonotic implications.[9] Granulomatous lesions in the mammary glands and in internal organs have been observed in goats experimentally infected with *Cryptococcus neoformans*.

CLINICAL FINDINGS

Clinical mastitis in goats is similar to that in cattle, subclinical, chronic, acute and peracute gangrenous forms occurring. Particular care is needed in the clinical examination of goat's milk because of its apparent normality when there are severe inflammatory changes in the udder.

Somatic cell counts in milk of goats are higher than in cattle or sheep but vary widely.[10] The counts increase with stage of lactation with or without intramammary infection.[11] Lower mature equivalent milk production and increased parity are also associated with an increase. Parity of milking does does not affect SCC, standard plate count and major milk components.[12] The count is highest in lactating goats during October, December and January.[11] Much of the variation was not due to intramammary infection. Non-infected goats may have a SCC of more than 1 000 000 cells/mL. These variations make their value as a guide to diagnosis in this species controversial.[13] A physiological threshold of 500 000 cells/mL has been suggested;[14] however, a count of more than 1 000 000 cells/mL can be regarded as positive for mastitis.[15] Some observations indicate that the most discriminating threshold for diagnosis of infection is 800 000 cells/mL.[2] The Fossomatic instruments and infrared milk analyzers must be calibrated with goat milk standards for more reliable and accurate analysis of milk.[16]

In staphylococcal mastitis infected halves have higher NAGase and CMT tests than normal halves but they and the lactate dehydrogenase and antitrypsin tests give very variable results and are not considered to be reliable. Two of the difficulties encountered are that the efficiency of the tests is not so good in the colostral period, and that halves adjoining affected halves give higher than normal results.[17]

Treatment and control

Treatment and control of mastitis techniques to be used in goat does can be adapted from those used for cattle, with the details of dry period and lactational treatments supplied by a laboratory culture. If the cow dose rate is used, retention of the antibiotic in the udder will be prolonged and the withholding period will need to be increased. Antibiotic residue tests for screening bovine milk adequately identify goat's milk that is free of antibiotic residues.[18] Vaccination against *S. agalactiae* in goats causes a rise

in serum antibodies that may provide a degree of immunity. Intravenous flunixin meglumine (two doses at 2.2 mg/kg BW 8 hours) was a more effective antipyretic agent in goats with experimentally induced coliform mastitis than intravenous dexamethasone (0.44 mg/kg BW once).[19]

Mastitis of mares

Mastitis in mares is rare. *Corynebacterium pseudotuberculosis*, *Pseudomonas aeruginosa*, *Streptococcus zooepidemicus*, *Streptococcus equi*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella* spp., and *Neisseria* spp. are all recorded.[1,2] Beta-hemolytic streptococci have been found in the milk of many normal, just-foaled mares.[3]

Clinical cases occur at any time during the lactation and many occur in non-lactating mares. Many mares with typical signs of severe swelling and soreness of the udder, but without abnormal milk, are first observed when a sick foal has not sucked for 24 hours. In streptococcal mastitis there may be severe local pain and moderate systemic signs. In most cases both halves are affected. Gangrenous mastitis similar to that in cows occurs occasionally.

Severe cases, sometimes accompanied by fever, depression, and anorexia, show swelling, pain, and heat in the affected half, ventral edema and clots in the milk; the mare is lame in the leg on the affected side. Gangrene and sloughing of the ventral floor of a gland may occur.

Because of the high frequency of Gram-negative bacteria as causative agents in mares, treatment should include a broad-spectrum antibiotic in an intramammary infusion plus intensive parenteral antibacterial treatment. Trimethoprim–sulfonamide preparations are generally satisfactory. Hot packs and frequent milking are also recommended.

PART 2

SPECIAL MEDICINE

Diseases associated with bacteria – I

16

Introduction to infectious disease

The infectious diseases are of major importance in agricultural animals. Accordingly the bacterial, viral, fungal, protozoal and parasitic diseases account for a major portion of this book. The infectious diseases are capable of affecting many animals in a short period of time and the case fatality rate in some diseases can be very high and the economic losses may be very large. Certain infectious diseases, especially the viral diseases, are endemic in some countries and pose a threat to other countries considered to be free of them. The veterinary profession has made a major contribution in developing reliable diagnostic techniques and effective control procedures for many of these diseases. Some of the infectious diseases assume major importance because they are directly transmissible to humans.

REPORTABLE DISEASES (OIE LISTINGS)

Several infectious diseases of livestock have the potential for serious and rapid spread, implications for international trade and/or risk for significant zoonotic disease. Because of the nature of these diseases and the risk to regional or national animal health, their control is beyond the capability of the individual practitioner and requires the intervention of state and possibly national veterinary personnel and organizations. In most countries, diseases of this nature are listed as **reportable diseases** or **notifiable diseases** and these must be reported (notified) to the state or national veterinary authority immediately they are diagnosed.

A world organization for animal health, called the Office International des Épizooties (OIE), has been in existence for many years and its major objectives have been the collection, analysis, and dissemination of scientific veterinary information on animal diseases of significant veterinary importance. Member countries have traditionally reported to the OIE, on a regular basis, the occurrence, or absence, of these diseases in their respective countries. The purpose has been to ensure transparency in the global animal disease and zoonotic disease situation, and to provide expertise and encourage international solidarity in the control of animal diseases.

The OIE has established a **Terrestrial Animal Health Code (Terrestrial Code)** where the majority of the reportable diseases are specifically detailed, including their clinical presentations, distribution amongst member countries and methods for diagnosis.[1] The purpose of the Terrestrial Code is to assure the safety of international trade in terrestrial animals and their products by detailing the health measures to be used by the veterinary authorities of importing and exporting countries. The purpose is to avoid the transfer of agents pathogenic for animals or humans while also avoiding unjustified sanitary banners. It constitutes a reference within the World Trade Organization (WTO) Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement) as an international standard for animal health and zoonoses.[2,3]

Traditionally, the OIE has classified animal diseases in two lists.

List A diseases (Box 16.1). These are transmissible diseases that have the potential for very serious and rapid spread, irrespective of national borders, that are of serious socioeconomic or public health consequence and that are of major importance in the international trade of animals and animal products. The presence of a list A disease in a country may limit or prevent its international trade of animals and animal products. In most countries the control and regulation of list A diseases are under the control of the federal veterinary authorities. Private practitioners have the responsibility to immediately report the occurrence, or

Box 16.1 List A diseases for cattle, swine, horses, sheep and goats

Transmissible diseases that have the potential for very serious and rapid spread, irrespective of national borders, that are of serious socioeconomic or public health consequence and that are of major importance in the international trade of animals and animal products

- Foot and mouth disease
- Swine vesicular disease
- Vesicular stomatitis
- Classical swine fever
- African swine fever
- Peste des petits ruminants
- Lumpy skin disease
- Bluetongue
- African horse sickness
- Rinderpest
- Contagious bovine pleuropneumonia
- Rift Valley fever
- Sheep pox and goat pox

suspicion of their occurrence, to state or federal regulatory authorities

- **List B diseases** (Box 16.2). These are transmissible diseases that are considered to be of socioeconomic and/or public health importance within countries and that are significant in the international trade of animals and animal products. The control of these diseases varies between countries and between diseases in this list, but most countries require that they be reported to state or federal authorities if they are diagnosed.

2005 single list

In 2005 the OIE reorganized the diseases in the Terrestrial Code to a single list (Box 16.3). In part, this was done in response to concerns that the administration and listings of diseases had led to unfair trade restrictions on certain countries. The new listing is accompanied by the expectation of better international cooperation in the detection and control of animal disease, and support for developing countries in the diagnosis and control of these diseases is proposed. There is also the recognition that many of the recent emerging, or re-emerging, diseases of animal origin have zoonotic potential. The overriding criterion for inclusion of a disease in the OIE single list remains its potential for international spread, but other criteria include a capacity for significant spread within naïve populations and zoonotic potential.[1–3] There has been agreement that the occurrence of certain listed diseases in a country does not necessarily preclude trade by that country in animal products. One of the reasons is that the disease may be absent from certain regions of the country that have geographical or ecological

Box 16.2 List B diseases for cattle, swine, horses, sheep and goats

Transmissible diseases that are considered to be of socioeconomic and/or public health importance within countries and that are significant in the international trade of animals and animal products

Affecting more than one animal species

- Anthrax
- Aujeszky's disease (pseudorabies)
- Echinococcosis/hydatidosis
- Heartwater
- Leptospirosis
- New world screwworm (*Cochliomyia hominivorax*)
- Old world screwworm (*Chrysomyia bezziana*)
- Paratuberculosis (Johne's disease)
- Q fever
- Rabies
- Trichinellosis

Cattle

- Bovine anaplasmosis
- Bovine babesiosis
- Bovine brucellosis
- Bovine cysticercosis
- Bovine genital campylobacteriosis
- Bovine spongiform encephalopathy
- Bovine tuberculosis
- Dermatophilosis
- Enzootic bovine leukosis
- Hemorrhagic septicemia
- Infectious bovine rhinotracheitis/ infectious pustular vulvovaginitis
- Malignant catarrhal fever
- Theileriosis
- Trichomonosis
- Trypanosomosis (tsetse-transmitted)

Swine

- Atrophic rhinitis of swine
- Enterovirus encephalomyelitis
- Porcine brucellosis
- Porcine cysticercosis
- Porcine reproductive and respiratory syndrome
- Transmissible gastroenteritis

Horses

- Contagious equine metritis
- Dourine
- Epizootic lymphangitis
- Equine encephalomyelitis (Eastern and Western)
- Equine infectious anemia
- Equine influenza
- Equine piroplasmosis
- Equine rhinopneumonitis
- Equine viral arteritis
- Glanders
- Horse mange
- Horse pox
- Japanese encephalitis
- Surra (*Trypanosoma evansi*)
- Venezuelan equine encephalomyelitis

Sheep and goats

- Caprine and ovine brucellosis (excluding *Brucella ovis*)
- Caprine arthritis/encephalitis
- Contagious agalactia
- Contagious caprine pleuropneumonia
- Enzootic abortion of ewes (ovine chlamydiosis)
- Maedi-visna
- Nairobi sheep disease
- Ovine epididymitis (*B. ovis*)
- Ovine pulmonary adenomatosis
- Salmonellosis (*Salmonella abortus-ovis*)
- Scrapie

Box 16.3 2005 single list of diseases notifiable to the Office International des Epizooties

characteristics that would not support the disease – an example would be areas of a country that did or did not support the vectors for bluetongue. It is also recognized that management systems may allow freedom from disease and that consequently there could be trade from production systems using these management methods – an example would be the disease and security status in a high health swine unit compared to free-range pigs in the same area.[2,3] There is also the recognition that many of the recent emerging, or re-emerging diseases of animal origin have zoonotic potential.

We have listed the old List A and List B categorizations of diseases as these categories are familiar to practicing veterinarians and we suspect that they will be referred to, as such, in the lifetime of this edition of this book. We further believe that there was some meaning for practicing veterinarians, in terms of disease significance and emergency response, in the old List A and List B categorization that is not evident in the new single listing, which, although it might be politically correct, has less impact for those who practice clinical veterinary medicine at the level of the farm. We have reservations concerning the new single listing and reservations about some of the diseases selected for listing. There are several examples, but three will suffice. We question how a disease such as leptospirosis, generically essentially a universal infection in farm animals, can be equated and placed in a single list with a disease such as foot and mouth disease. We question how African horse sickness, with its huge potential for spread outside Africa, can be compared with the ubiquitous, and usually clinically insignificant, equine rhinopneumonitis. We question the inclusion of a disease such as atrophic rhinitis in the swine list of diseases and the exclusion of a disease such as pleuropneumonia, but more importantly, we question why atrophic rhinitis should be equated in economic, or response, importance to African swine fever.

DIAGNOSIS OF INFECTIOUS DISEASES

The clinical and laboratory diagnosis of the infectious diseases can be difficult. However, with the appropriate laboratory support and suitable samples, most of them can be diagnosed definitively. For each disease certain samples must be submitted to the laboratory for isolation or demonstration of the specific pathogen.

Clinical and epidemiological findings will usually result in a tentative diagnosis and a rule-out list of possible diagnoses. When herd or area **population epidemics** occur, a detailed examination of the epidemiological characteristics of the disease is often useful in helping to make a diagnosis and in advising on the best treatment and control procedures. Particular attention should be given to the epidemiological aspects of the history, for example:

- The **descriptive epidemiology** including the distribution in age or other groups
- The morbidity and case fatality and population mortality rates
- The seasonal incidence
- Relationship to other species
- Recent changes in management
- Vaccination history
- Nutritional history
- Disease in previous years
- Source of imported animals
- Known risk factors for the diseases under consideration
- The treatments used and the success rate.

The epidemiological behavior of the epidemic includes an examination of the manner of spread of disease between individuals and groups of animals, the age of animals affected, the length of the course of the disease and the estimated incubation period. It may be necessary to establish a prospective survey or surveillance studies on sentinel herds to monitor the spread of the disease. field investigation may include the examination of nearby herds or other species, such as wildlife or humans, that may be sources of the infection.

When an infectious disease is suspected, **laboratory investigations** will aid in diagnosis and differential diagnosis. The veterinary literature contains a large number of reports of the development of antibody-detection or antigen-detection tests for individual animal diseases. Most of these have not been validated in a significant number of animals for sensitivity and specificity in disease detection, and most are not available commercially or available on line in diagnostic laboratories. Those that are on line vary between countries and between laboratories within countries. The practitioner should consult the appropriate diagnostic laboratories to determine the tests that are available and the laboratories' definition of the sensitivity and specificity of the test to be used. The recommended techniques of investigation and the common differential diagnoses are given for each disease.

- Clinical, hematological, clinical chemistry and immunological examinations, as appropriate, should be done on as many clinically affected animals as possible. Similar examinations should be conducted on normal animals that have been in close contact with the affected animals. The detection of latent carriers among clinically normal animals may require special laboratory tests. Repeated visits and examinations may be necessary to determine the presence and rate of seroconversion in an affected herd as an indication of the rate and direction of spread
- Tissue samples from necropsies and from live animals (biopsies) and discharges, feces and urine should be submitted for isolation or demonstration of the suspected pathogen.

The responsibility of the veterinarian in the case of infectious diseases is to advise the owner of the **risks of spread** to other animals or populations and the need for treatment and/or control. In the case of notifiable diseases, the government regulatory authorities must be notified immediately. Every precaution must be taken to prevent the spread of the disease to nearby herds or other geographical areas. Veterinarians have the responsibility to advise the owner of zoonotic risk of the disease to the farm family and farm workers. Veterinarians also have a responsibility to alert their clients to the possibility that an infectious disease may be approaching geographically and to take the necessary precautions. The **control** of infectious diseases is dependent on a knowledge of the etiology and epidemiological characteristics of the disease. The basic principles of disease control are:

- Reduce the infection pressure
- Eliminate or minimize risk factors that can be influenced
- Increase the nonspecific immunity
- Increase the specific immunity.

Any one or a combination of the following may be effective for the control of a specific infectious disease:

- Insure adequate colostral immunity in the newborn
- Identify affected animals, isolate them from the normal animals and treat or dispose of them as indicated, or return them to the herd if they are considered to be safe
- Prevent the introduction of infected animals into herds previously considered free of the disease. Quarantine all animals imported into a herd for a period of 30–60 days. Serological testing may be done on the imported animals
- Determine the source of the infection and remove it if possible. Sources include infected animals, feed and water supplies, wildlife and contaminated environments
- Control by the use of mass medication of feed and water supplies may be appropriate with some diseases
- Clean and disinfect animal houses and grounds regularly – this is essential. When animals occupy a barn for prolonged periods (weeks or months) without a clean-out and disinfection, the buildup of infectious agents increases almost geometrically and the incidence of disease will increase correspondingly
- Provide an optimal environment for housed animals. This includes adequate ventilation, the prevention of overcrowding and effective removal of manure
- Establish primary breeding stock through the use of specific-pathogen-free animals obtained by hysterectomy or cesarean section and rearing them under controlled conditions; this program may be indicated for the control of diseases such as enzootic pneumonia of swine
- Vaccinate susceptible animals against endemic diseases; this should be part of a regularly scheduled herd health program that includes vaccination of the pregnant dam for the enhancement of colostral immunity in the newborn
- Avoid stress associated with long transportation, inclement weather and undernutrition
- Base effective control of intestinal parasites on measures designed to prevent or limit contact between parasite and host. The strategies are to: a) prevent the build-up of dangerous numbers of larvae on pastures; and b) anticipate the periods during which large numbers of larvae are likely to occur and remove susceptible animals from heavily contaminated pastures before these periods. These aims can be achieved using three interrelated approaches: grazing management, the use of anthelmintics and dependence on the acquisition of immunity.

Diseases associated with *Streptococcus* species

Mastitis associated with *Streptococcus agalactiae*, *Streptococcus dysgalactiae*, *Streptococcus uberis*, and *Streptococcus zooepidemicus* is dealt with in Chapter 15. Strangles in horses, neonatal streptococcal infections, disease associated with *S. zooepidemicus* in horses and streptococcal cervical abscesses of pigs are dealt with later in this section.

Other miscellaneous diseases in which streptococci appear to have etiological significance include septicemic infections of swine, sheep and calves, pneumonia in calves, meningoencephalitis and otitis media in feeder pigs, lymphangitis in foals and infectious dermatitis of piglets.

SEPTICEMIA

- Acute streptococcal septicemia of adult sows and their litters occurs sporadically. The onset is sudden and death occurs in 12–48 hours. Clinically there is weakness, prostration, fever, dyspnea, dysentery and hematuria. At necropsy, petechial and ecchymotic hemorrhages are present throughout all organs. Animals that survive for several days show extensive edema and consolidation of the lungs. The infection spreads rapidly and the mortality rate may be very high unless the drug sensitivity of the organism, usually *S. zooepidemicus* or *Streptococcus equisimilis*, is determined and appropriate treatment instituted
- Experimental inoculation of *S. zooepidemicus* into horses causes fever, depression, anorexia, abnormal lung sounds, joint inflammation accompanied by mild–severe lameness, emaciation and a leukocytosis[1]
- *Streptococcus pneumoniae* is the apparent cause of septicemia with sudden death in calves
- In ruminants of all ages *Streptococcus suis*, usually a pathogen in pigs, causes a bacteremia with localization in many organs, including lungs, joints, bones, and meninges[2]
- In sheep and goat flocks, septicemia due to *S. zooepidemicus* causes up to 90% mortality in lambs and kids. *S. dysgalactiae* is a common cause of polyarthritis in lambs.

ENTERITIS

Streptococcus (Enterococcus) durans has been isolated from a foal with enteritis and has caused mild enteritis and diarrhea in foals infected orally. This organism has also been isolated from outbreaks of diarrhea in neonatal pigs[3] and disease has been produced in gnotobiotic piglets.[4] *Streptococcus entericus* sp. nov. has been isolated from the intestine of a cow with enteritis but its causal significance is not known.[5]

PNEUMONIA

- A syndrome of pneumonia and fibrinous pleuritis and pericarditis is caused in lambs by *S. zooepidemicus*
- Pneumonia in calves may be associated with *S. pneumoniae*, and unidentified streptococci are common invaders in viral pneumonia of calves. Infections in calves with *S. pneumoniae* may have public health significance; the isolation of identical strains of the organism from the lungs of calves dying of the disease and from the throats of their human attendants suggests that interspecies transmission may occur. Calves may be immunized either by the use of antiserum or through vaccination of their dams with a polyvalent aluminum hydroxide-adsorbed vaccine
- *S. pneumoniae* is also associated with inflammatory disease of the lower respiratory tract of horses,[6] sometimes in association with a virus and sometimes with *S. zooepidemicus*[7]
- Streptococcal pneumonia can be a complication of systemic corticosteroid therapy in horses.[8]

MENINGOENCEPHALITIS

Meningoencephalitis is a common complication of streptococcal septicemia of the newborn but *S. suis* is a specific cause in pigs and is dealt with under that heading. Streptococcal meningitis is restricted to the neonate in all species except piglets with *S. suis* and rarely lambs where sporadic meningitis in 3–5-month-old lambs occurs. Streptococcal meningitis and brain abscess may be a rare complication in horses of sinusitis and rhinitis.[9]

LYMPHANGITIS

An ulcerative lymphangitis, caused in many instances by *S. zooepidemicus*, has been observed in foals from 6 months to 2 years of age and may be confused with

ulcerative lymphangitis associated with *Corynebacterium pseudotuberculosis*.

DERMATITIS

Infectious dermatitis (contagious pyoderma) of pigs is characterized by the formation of pustules about the face and neck, and to a lesser extent the trunk. Streptococci and staphylococci are present in the lesions and spread appears to occur through abrasions, especially in young pigs that fight and have not had their needle teeth removed. The disease may be confused with exudative epidermitis.

ARTHRITIS IN LAMBS

In the UK, *S. dysgalactiae* is a significant cause of outbreaks of arthritis in lambs, especially during the first 3 weeks of life. It occurs more commonly in lambs that are lambed indoors. Affected lambs are lame in one or more legs and are often found recumbent. There is minimal joint swelling in the initial stage of the disease and for this reason differential diagnoses include nutritional myopathy, swayback and spinal abscess. Infection is present in any joint but most common in the tarsal and atlanto-occipital joints. Some die with systemic disease and myocarditis. Survivors may be chronically lame.[10]

GENITAL TRACT INFECTIONS

Streptococcal infections of the genital tract, including *S. zooepidemicus*, occur commonly, especially in mares, in which the disease is thought to be spread by coitus and is accompanied by a high incidence of abortion, sterility and neonatal infection in foals.[11,12]

Foals from infected mares may be affected each year. Although streptococcal metritis occurs in sows, there appears to be no relationship between uterine infection and neonatal septicemia. Abortions in sows may be associated with infection with beta-hemolytic streptococci.

One of the important features of streptococcal diseases is their lack of susceptibility to control by vaccination. Vaccines against strangles of horses, *S. suis* in piglets and cervical adenitis of pigs are available, but results with them are equivocal. When the vaccines are properly prepared and carefully and intelligently applied the results are good. However, it is apparent that the streptococci are not good antigens and that the vaccines made with them lack the ease of application and safety that one expects with, say, the clostridial vaccines.

STRANGLES (EQUINE DISTEMPER)

Synopsis

Etiology *Streptococcus equi* subsp. *equi*
Epidemiology Highly contagious disease that affects horses of all ages but is most common in young animals. Prolonged carrier state in asymptomatic animals
Clinical signs Acute onset of fever, anorexia, depression, submandibular and pharyngeal lymphadenopathy with abscessation and rupture, and copious purulent nasal discharge. Metastatic infection in other organ systems
Clinical pathology Culture of *S. equi* from nasal and abscess discharges. Polymerase chain reaction (PCR) of nasal, pharyngeal or guttural pouch swabs. High serum antibody titer to SeM
Lesions Caseous lymphadenopathy with rhinitis and pharyngitis, pneumonia and metastatic infection in severe cases
Diagnostic confirmation Culture of *S. equi*
Treatment Systemic administration of penicillin. Local treatment of abscesses
Control Isolation and quarantine of cases and new admissions to barns and stables. Detection of carrier status by PCR and/or culture of guttural pouch washings. Vaccination may reduce the case attack rate and severity of disease

ETIOLOGY

Streptococcus equi subsp. *equi* (*S. equi*) is a Gram-positive coccobacillus that produces a beta-hemolysin, evident as a zone of clear hemolysis surrounding colonies growing on blood agar. There is evidence that *S. equi* is a biovar or genovar of *S. zooepidemicus*.[1] *S. equi*, which is highly host-adapted to Equidae, demonstrates no serological variation, although genetic analysis demonstrates the existence of clones that vary geographically.[2] There is variation in virulence related to the amount of M protein and hyaluronic capsule produced.[3] An atypical milder form of the disease is associated with a capsule-deficient variant of *S. equi*.

EPIDEMIOLOGY

Occurrence

Strangles occurs in horses, donkeys, and mules worldwide. Outbreaks are seen relatively frequently on breeding farms and in polo and racing stables, when the infection is introduced by new arrivals that are often asymptomatic, and in horses taken to fairs and riding schools. An **incidence** of 35% over a 3-year period is reported for horse studs in Australia.[4]

Strangles can affect horses of any age, although the **morbidity rate** is usually greater in younger horses such as foals and weanlings.[5] Age-specific attack rates of strangles of 18% for brood mares, 48% for 1-year-old horses and 38% for foals during an outbreak on a breeding farm are reported, although higher morbidity rates (100%) can occur, especially in young horses.[5,6] The risk of occurrence of an outbreak of strangles increases with the size of the group of horses: farms with 100 or more horses have a 26 times greater risk of experiencing an outbreak than farms with fewer than 15 horses.[4]

The **case-fatality rate** without treatment is about 9%, but with adequate early treatment may be as low as 1–2%. Deaths are usually due to pneumonia.[5,7]

Source of infection and transmission

S. equi is an obligate parasite of horses and all infections are attributable to transmission from infected horses, either directly or by fomites. **Nasal and abscess discharge** from infected animals that contaminates pasture, tack, stalls, feed and water troughs, grooming equipment, and hands and clothes of grooms and veterinarians is often the source of infection for susceptible horses. *S. equi* can survive in the environment for at least 2 months, and fomite transfer is important in transmission of infection.[8] Direct transmission from infected animals to susceptible animals occurs through contact.

Approximately 10–40% of horses that recover from the clinical disease have **persistent infection** of *S. equi* in the pharynx and guttural pouches for many months and are an important source of infection.[9,10] Horses with **clinically inapparent disease**, such as some cases of guttural pouch empyema, may shed the organism for over 3 years.[9] The period of infectivity is important in terms of the length of quarantine that needs to be imposed on horses that have apparently recovered from the disease. Because shedding of *S. equi* may be intermittent, repeated culture of nasopharyngeal swabs or use of PCR examination of guttural pouch washings may be necessary to document the carrier status of individual horses.[10] Endoscopic or radiographic examination of clinically inapparent shedders may demonstrate lesions in the guttural pouches, paranasal sinuses, or pharynx.[11] However, some persistent carriers of *S. equi* do not have detectable abnormalities of the nasopharynx. The clinically inapparent nature of the infection makes detection of carriers problematic, especially

when considering introduction of horses into a previously closed herd in which strangles is not endemic.

Animal risk factors

Strangles is more common in young or naive horses, although the disease can occur in horses of any age. Animals that have previously had the disease are less likely than naive animals to develop the disease on subsequent exposure.[3,6,12] A proportion (approximately 25%) of horses that recover from the disease do not develop a protective immune response and are susceptible to reinfection and a second bout of strangles.[3,6] Resistance to the disease is associated with the production of **serum and mucosal IgG antibodies** to the streptococcal **M protein**.[6] The presence in the nasopharynx of antibodies to streptococcal M protein is thought to be important in conferring resistance to the disease.[3] Serum IgGb antibodies specific for SeM protein, which is important in the antiphagocytic activities of *S. equi*, are produced by most but not all horses during convalescence. Similarly, IgA and IgGb against SeM protein are detectable on nasal and pharyngeal mucosa after *S. equi* infection but not after intramuscular administration of vaccines containing M protein.[13] Serum bactericidal activity alone is not considered to be a good indicator of resistance to the disease, especially if it is induced by administration of a vaccine.[1,3] Antibodies similar to those found in the nasopharynx after infection with *S. equi* are present in colostrum and milk of mares that have recovered from the disease, are passed to foals via the colostrum and are secreted into the foal's nasopharyngeal mucosa.[12] These acquired antibodies are important in mediating the resistance of young foals to the disease.[12]

Although **strong immunity** occurs immediately after an attack, this immunity wanes with time and a horse may suffer further disease if the organism is virulent.

Importance

Strangles is one of the most important diseases of horses in developed countries, accounting for up to 30% of reported infectious disease episodes.[1] The disease is important not only because of the deaths that it causes but more importantly because of the disruption of the management of commercial horse establishments, the time necessary to treat affected horses and the esthetic unpleasantness of the running noses and draining abscesses.

PATHOGENESIS

Virulence of *S. equi* is attributable to the presence of **M proteins** on the surface of the bacteria, a hyaluronic acid capsule and the production of a leukocidal toxin.[2] M proteins are associated with *S. equi* adhesion to oral, nasal, and pharyngeal tissues, invasion of pharyngeal tonsils and associated lymphoid structures, and evasion of the innate host immune response.[13] *S. equi* produces two M proteins – SeM and SzPSe. SeM is unique to *S. equi* and plays a dominant role in resistance of the organism to phagocytosis.[14] Variations in structure of M protein are associated with decreased virulence.[15] The M proteins interfere with the deposition of complement component 3b on the surface of the bacteria and bind fibrinogen, both of which reduce the susceptibility of the bacteria to phagocytosis by neutrophils.[16,17] The antiphagocytic activity of *S. equi* reduces the efficacy of neutrophils in engulfing and destroying the bacteria.

The capsule of *S. equi* is associated with resistance to non-immune phagocytosis and pathogenicity. Strains of *S. equi* that do not produce a capsule do not induce disease, although they are able to infect guttural pouches and cause seroconversion in experimental studies.[18]

Following exposure of the oral and nasopharyngeal mucosal surfaces to *S. equi*, bacteria lodge in the **pharyngeal and tonsillar lymphoid tissues** where they multiply rapidly. There is no evidence of colonization of mucosal surfaces and streptococci can be detected in pharyngeal tonsils within hours of exposure.[19] The binding of *S. equi* to pharyngeal cells is caused by fibrinogen binding proteins associated with M protein.[14] The resistance of *S. equi* to non-immune phagocytosis results in accumulation of large numbers of organisms surrounded by degenerating neutrophils. Release of streptolysin S and streptokinase may contribute to tissue damage by directly injuring cell membranes and indirectly through activation of plasminogen.[19] Bacteremia may occur. Migration of neutrophils into the lymph nodes causes swelling and abscessation, with associated disruption of lymph drainage and development of edema in tissues drained by the affected nodes. Swelling of retropharyngeal lymph nodes may interfere with deglutition and respiration. Most abscesses eventually rupture and drain and the infection resolves with the development of an effective immune response. Nasal shedding of *S. equi* usually begins 4–7 days after infection, or 2 days after onset of fever, and persists for 2–3 weeks in most horses but up to years in exceptional horses. Cessation of shedding accompanies development of an effective serum and mucosal immune response.[12]

Death is usually due to pneumonia caused by aspiration of infected material, although other causes of death include asphyxiation secondary to upper airway swelling and impairment of organ function by metastatic infection. Rare deaths also occur as a result of infarctive purpura hemorrhagica in horses infected with *S. equi*.[20]

Metastatic infection of the heart valves, brain, eyes, joints, and tendon sheaths or other vital organs may occur and cause a chronic illness and eventual death. Metastatic infection may occur because of bacteremia or extension of infection along chains of lymph nodes. Purpura hemorrhagica may occur as a sequela to *S. equi* infection and is associated with high serum antibody titers to SeM.

CLINICAL FINDINGS

The disease manifests as an acute disease of varying severity, chronic infection of retropharyngeal lymph nodes and guttural pouches, and as chronic disease associated with metastatic infection of organs distant to the upper respiratory tract. The severity of the acute disease varies with the age and immune status of the animal, and size of the inoculum and duration of exposure to infection. The term strangles derives from the enlarged retropharyngeal lymph nodes and guttural pouches causing respiratory distress in severely affected equids.

Acute disease

The acute disease is characterized by mucopurulent nasal discharge and abscessation of submandibular and retropharyngeal lymph nodes. After an **incubation period** of 1–3 weeks the disease develops suddenly with complete anorexia, depression, fever (39.5–40.5°C, 103–105°F), a serous nasal discharge, which rapidly becomes copious and purulent, and a severe pharyngitis and laryngitis.[21,22] Rarely there is a mild conjunctivitis.

Lymphadenopathy becomes apparent as the submandibular lymph nodes enlarge and palpation elicits a painful response. The pharyngitis may be so severe that the animal is unable to swallow and there is a soft, moist cough. The head may be extended.

The febrile reaction commonly subsides in 2–3 days but returns as the characteristic abscesses develop in the lymph nodes of the throat region. The affected nodes become hot, swollen, and painful. **Swelling of the retropharyngeal lymph nodes** may cause obstruction of the oro- and nasopharynx with subsequent respiratory distress and dysphagia. Death by asphyxiation may occur at this time in severe cases. Obvious swelling of the nodes may take 3–4 days to develop; the glands begin to exude serum through the overlying skin at about 10 days and rupture to discharge thick, cream-yellow pus soon afterwards. Average cases run a course of 3 weeks, severe cases may last as long as 3 months.

Retropharyngeal abscesses may rupture into the guttural pouches, resulting in

guttural pouch empyema and ultimately in prolonged infection and formation of chondroids. Retropharyngeal lymph node abscessation may not be apparent on external evaluation and can often only be detected by radiographic or endoscopic examination of the pharynx. Infection of retropharyngeal lymph nodes and guttural pouches is important in persistent infection and carrier status of some horses.

If the infection is particularly severe, many other lymph nodes, including the pharyngeal, submaxillary, parotid and retrobulbar nodes, may abscess at the same time. Local abscesses may also occur at any point on the body surface, particularly on the face and limbs, and the infection may spread to local lymphatic vessels causing obstructive edema. This occurs most frequently in the lower limbs, where edema may cause severe swelling. Abscess formation in other organs probably occurs at this time.

An atypical form of the disease may occur and is characterized by widespread subclinical infection and a mild disease. Affected horses have a transient fever for 24–48 hours and a profuse nasal discharge, and are anorexic. A moderate enlargement of the mandibular lymph nodes occurs in only about one-half of the affected horses.

Strangles in burros is a slowly developing debilitating disease. At postmortem examination the characteristic lesions consist of caseation and calcification of abdominal lymph nodes.

Complications

Complications occur in about 20% of cases.[5,6] The most common fatal complication is the development of **suppurative necrotic bronchopneumonia**, which probably occurs secondary to the aspiration of pus from ruptured abscesses in the upper airway, or metastatic infection of the lungs.[23]

Extension of the infection into the **guttural pouches**, usually as a result of rupture of retropharyngeal lymph nodes into the medial compartment, causes empyema, which may lead to the formation of accretions of inspissated pus (chondroids). Involvement of the guttural pouches is evident clinically as distension and, after resolution of other signs, unilateral or bilateral nasal discharge. Guttural pouches of affected horses should be examined endoscopically for evidence of retropharyngeal abscessation or guttural pouch empyema or chondroid formation.

Retropharyngeal lymphadenopathy may impair the function of the **recurrent laryngeal nerves,** with subsequent unilateral or bilateral laryngeal paresis and consequent respiratory distress.

Metastatic infection ('bastard strangles') results in the formation of abscesses in any organ or body site but most commonly in the lungs, mesenteric lymph nodes, liver, spleen, kidneys, and brain. Clinical signs depend on the organ affected and the severity of the infection, but intermittent fever, chronic weight loss and sudden death due to rupture of abscesses into a body cavity are common manifestations of metastatic infection. Rectal examination or percutaneous ultrasonographic examination may reveal intra-abdominal abscesses in some horses with metastatic abscesses in the abdomen. Peritoneal fluid from these horses is often abnormal.

Metastatic infections may occur in the **central nervous system**. Extension of infection to the meninges results in suppurative meningitis characterized clinically by excitation, hyperesthesia, rigidity of the neck, and terminal paralysis. Abscesses in the brain cause a variety of clinical signs, depending on location of the abscess, including severe depression, head pressing, abnormal gait, circling, and seizures.[24] Metastatic infections of the ocular and extraocular structures, heart valves and myocardium, joints, bones, tendon sheaths, and veins may occur.

Purpura hemorrhagica can occur as a sequela to *S. equi* infection.[20,25]

Two myopathic syndromes occur with *S. equi* infection in horses.[26] **Muscle infarction**, which may be extensive, is assumed to result from immune-mediated vasculitis associated with purpura hemorrhagica.[20] Often the muscle lesions in these horses are associated with other lesions consistent with severe purpura hemorrhagica, including infarctions in the gastrointestinal tract, skin and lungs. **Rhabdomyolysis and subsequent muscle atrophy** results in signs of muscle disease, including stilted gait and elevated serum activity of creatine kinase and other muscle-derived enzymes, and is assumed to be due to cross-reactivity of anti-SeM antibodies with myosin.[26]

Myocarditis and glomerulonephritis have been suggested as sequelae to *S. equi* infection but have not been conclusively demonstrated to occur.

CLINICAL PATHOLOGY

Hematological abnormalities during the acute phase of the disease include leukocytosis with a neutrophilia reaching a peak as the lymph nodes abscess. **Hyperfibrinogenemia** is characteristic of both the acute and chronic disease. Hematological and biochemical abnormalities associated with metastatic infection depend on the site of the infection and its severity. Leukocytosis with a **hyperproteinemia** attributable to a polyclonal gammaglobulinemia is characteristic of metastatic and chronic abscessation. **Hypoalbuminemia** may be present. Serum biochemical profile may reveal evidence of specific organ dysfunction. There may or may not be an anemia, which may be due to the hemolytic effect of streptolysin O, immune-mediated hemolysis, or anemia of chronic disease.

A commercial test that measures the **serum IgG antibody titer to SeM** has been developed and has been used to determine response to vaccination, suitability for vaccination and presence of metastatic infection.[19,27] The test is not useful in diagnosis of the acute disease. Serum antibody titers to SeM are very high (> 1:12 800) in horses with metastatic infection or purpura hemorrhagica.

PCR testing is useful to detect shedding of *S. equi* DNA. The test is reported to be more specific than culture for detection of *S. equi* shedding.[10] The PCR does not differentiate between live and dead *S. equi* and false-negative results occur in the presence of large numbers of *S. equi*. PCR testing should be considered an adjunct to routine culture for detection of *S. equi*.

Culture of nasal, pharyngeal, guttural pouch, or abscess discharge will usually yield *S. equi* in horses with active disease or in carriers. Abscesses may rapidly become contaminated with *S. zooepidemicus*, which may impede isolation of *S. equi*.

NECROPSY FINDINGS

In the rare fatalities that occur, necropsy examination usually reveals suppuration in internal organs, especially the liver, spleen, lungs, pleura, and peritoneum. When the last is involved, it is usually as a result of extension from abscesses in the mesenteric lymph nodes. The microscopic changes of abscessation and suppurative lymphadenitis are uncomplicated. The widespread ecchymotic hemorrhages of purpura hemorrhagica are not specific to this infection, but *S. equi* should always be investigated as a potential cause of such lesions.

Samples for confirmation of diagnosis

- Bacteriology – swab of abscess wall, enlarged lymph node (CULT).

DIAGNOSTIC CONFIRMATION

Confirmation of strangles depends on the isolation of *S. equi* from nasopharyngeal swabs and discharges from abscesses. Shedding of *S. equi* in nasal discharges begins 1–4 days after the onset of fever, and ruptured abscesses often become contaminated with *Streptococcus zooepidemicus* and *S. equisimilis*.

TREATMENT

The **specific treatment** of choice for *S. equi* infection of horses is **penicillin**, either as

DIFFERENTIAL DIAGNOSIS

See Table 16.1 for a list of differential diagnoses of infectious upper respiratory tract disease of horses. Pneumonia should be differentiated from pleuropneumonia associated with transport or other stress. Chronic weight loss due to metastatic infection should be differentiated from equine infectious anemia, parasitism, inadequate nutrition and neoplasia, especially gastric squamous cell carcinoma, alimentary lymphosarcoma and granulomatous enteritis.

procaine penicillin G (22 000 IU/kg intramuscularly every 12 h) or potassium or sodium penicillin G (22 000 IU/kg intravenously every 6 h). Tetracycline (6.6 mg/kg intravenously every 12–24 h) and sulfonamide–trimethoprim combinations (15–30 mg/kg orally or intravenously every 12 h) may be efficacious but should only be used if penicillin cannot be administered. Aminoglycosides, such as gentamicin or amikacin, and the fluoroquinolones are not effective.

There is considerable debate about the treatment of horses with strangles. Folklore and anecdotal reports suggest that antibiotic treatment of horses with strangles is contraindicated because it promotes the development of metastatic infection. There is no experimental or empirical evidence to support this contention and horses with strangles should be treated with therapeutic doses of an appropriate antibiotic, such as procaine penicillin, for a period of time sufficient to effect a cure, as appropriate.

Treatment for *S. equi* infection depends on the stage of the disease:[28]

- Horses with **early clinical signs** including fever, anorexia, depression, and purulent nasal discharge should be isolated and treated with therapeutic doses of penicillin for at least 5 days. The purpose of treatment is to prevent further development of the disease in the affected animal, and to minimize environmental contamination with *S. equi* and transmission to other horses. Treatment should start as soon as clinical signs are observed and the full course of treatment should be completed to minimize the chances of recrudescence of the infection. Treatment at this stage causes rapid resolution of fever, anorexia, nasal discharge, and lymphadenopathy in individual horses and may abort an incipient outbreak of the disease in a

Table 16.1 Differential diagnosis of diseases of the upper respiratory tract of horses

Disease	Epidemiology	Clinical signs: Respiratory tract	Clinical signs: Other	Diagnosis and clinical pathology
Strangles (*Streptococcus equi* infection)	Incubation period 4–8 d. Course 10–21 d. Spreads by inhalation or ingestion. Mostly young horses in recently commingled groups. Long period (many months) of inapparent infection in some horses	Copious, purulent nasal discharge. Cranial lymphadenitis and rupture. Moist cough. Obstruction of pharynx can cause dyspnea	Severe illness with suppuration, fever. Atypical cases show involvement of other organs. Serious sequelae include pneumonia, metastatic spread of infection, mesenteric abscess or purpura hemorrhagica	*S. equi* in nasal, pharyngeal or guttural pouch swabs, oropharyngeal pus or lymph node abscess pus. PCR of nasal, pharyngeal or guttural pouch swabs. High SeM antibody titer in chronic disease or convalescence. Leukocytosis. Hyperfibrinogenemia
Equine viral arteritis (EVA)	Incubation period 1–6 d. Course 3–8 d. Some deaths	Serous/purulent nasal discharge. Slight cranial lymphadenitis, cough. Conjunctivitis, purulent with edema or petechiae. Dyspnea	Severe disease. Anasarca. Ventral edema, prepuce, legs, scrotum. May be diarrhea, jaundice. Up to 50% of mares abort	Virus in blood at fever peak. Serology. Leukopenia
Equine viral rhinopneumonitis (EHV-1)	Incubation period 2–10 d. Course 2–5 d. Cough may last as long as 3 weeks	Serous/purulent nasal discharge. Slight cranial lymphadenitis, coughing, conjunctivitis. Mild respiratory disease; in young	Abortion in mares. Virus may cause myelopathy	Virus in nasal discharge or peripheral blood buffy coat. PCR of nasal discharge or blood. Tissue culture and serological tests. Leukopenia. Virus in intranuclear hepatic inclusions of fetus
Equine viral rhinopneumonitis (EHV-4)	Incubation period 2–10 d. Course 2–5 d. Cough may last as long as 3 weeks	Serous/purulent discharge. Slight cranial lymphadenitis, coughing, conjunctivitis	Mild respiratory disease; in young horses	Virus in nasal discharge. Tissue culture and serological tests. Leukopenia
Equine influenza (H3N8 rarely H7N1)	Incubation period 2–3 d. Course 7 d. Cough may persist 3–4 weeks. Enzootic, worldwide (not Australia). Explosive outbreaks. 80–100% morbidity in young	Nasal discharge slight, serous only. Slight cranial lymphadenitis. Severe cough. No conjunctivitis and no respiratory distress	Minimal extra-respiratory signs. Temperature 39–41°C (102–105°F)	Virus in nasal discharge. Good serological tests available. Rapid ELISA test for viral antigen in nasal secretions. PCR of nasal secretions
Equine rhinitis virus	Incubation period 3–8 d. Rapid spread, high morbidity (70%). Solid immunity after natural infection. Excreted in urine	Pharyngitis, pharyngeal lymphadenitis, nasal discharge serous to mucopurulent. Cough persists 2–3 weeks	Mild disease. Emphasis on coughing. Fever to 39.5°C (103°F)	Equine rhinitis virus on tissue culture. Serological tests available
Equine adenovirus	Many inapparent infections. High proportion of population serologically positive	Mild respiratory signs in adults. Fatal pneumonia in Arabian foals with combined immunodeficiency	Transient softness of feces. In mares can cause abortion without clinical illness	Adenovirus in oropharyngeal swabs. Serological tests available

ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

stable or yard. However, treated horses may not develop a protective immune response and consequently may be at risk of reinfection if exposed to *S. equi* after completion of the course of treatment, leading one authority to recommend that only severely affected animals be treated[28]

- Horses with submandibular **lymph node abscessation** but without other clinical abnormalities probably do not require antibiotic treatment. Such horses should be isolated and efforts made to aid maturation and rupture of affected lymph nodes
- Systemic antibiotic therapy with penicillin is indicated in horses with **advanced signs of strangles**, including prolonged fever, depression, anorexia or dyspnea resulting from retropharyngeal lymphadenopathy. Retropharyngeal abscessation frequently responds to antimicrobial therapy, although surgical drainage may be required in some instances[29]
- Horses with **metastatic infection** require systemic penicillin therapy in combination with specific therapy for the complication. Pulmonary and mesenteric abscesses are problematic because they are usually not amenable to surgical drainage, and prolonged antimicrobial therapy is required to effect a cure
- **Guttural pouch empyema** requires either surgical drainage or repeated flushing of the affected pouch through the pharyngeal openings.[11] Removal of pus and inspissated material in the guttural pouches can be achieved under endoscopic guidance. Alternatively, rigid or flexible indwelling catheters can be inserted for repeated flushing of the pouches with sterile isotonic electrolyte solutions (such as 0.9% NaCl) and topical medications. Substances and solutions that are irritating or injurious to mucus membranes, such as iodine, hydrogen peroxide and similar irritant compounds, should not be infused into the guttural pouches. Combined topical and systemic administration of potassium benzyl penicillin may be beneficial.[30] Chondroids can often be removed using wire snares. Horses with metastatic or guttural pouch infections should be isolated
- Treatment of **purpura hemorrhagica** is dealt with elsewhere
- Management of horses that have been **exposed to** horses with strangles is controversial. Some authorities recommend treatment of such in-contact horses with penicillin until affected horses are isolated and no longer are a source of infection. However, close examination of exposed animals, including monitoring rectal temperature, and treatment of horses at the first sign of illness is probably a more reasonable approach.

Ancillary treatment consists of administration of nonsteroidal anti-inflammatory drugs (NSAIDs) to reduce swelling and provide pain relief, application of hot poultices to encourage rupture of abscesses, provision of intravenous hydration in animals unable to drink, and wound care, including cleaning of ruptured abscesses and application of petroleum ointment to surrounding skin to prevent scalding. Horses with severe upper airway obstruction may require placement of a short-term tracheotomy.

CONTROL

The principles of control measures include the prevention of transmission of *S. equi* from infected horses (cases or carriers) to susceptible animals and enhancement of resistance to infection and disease.

Prevention of transmission

Preventing introduction of strangles to herds free of the disease is difficult, especially when there is frequent movement of horses in and out of the herd. Close attention should be paid to the health of horses introduced to herds free of the disease and, although this is an imperfect safeguard, the owner or manager of horses to be introduced to a herd should be questioned about the likelihood of exposure of the horse to strangles. Ideally, horses should be isolated for 3 weeks before introduction to a herd that is free of the disease and should have washings of the guttural pouches performed on three occasions at weekly intervals. The washings should be examined by culture and PCR for the presence of *S. equi*. Clearly, this requirement, while ideal, is demanding of time, space and labor, is expensive and would be difficult to implement as a routine practice.

Methods to control transmission of *S. equi* on affected premises are detailed in Table 16.2.[19]

Table 16.2 Aims and associated measures used to control transmission of *Streptococcus equi* in affected premises and herds

Aim	Measure
Prevention of spread of *S. equi* infection to horses on other premises and to new arrivals on the affected premises	Stop all movement of horses on and off affected premises immediately and until the outbreak is controlled Horses with strangles and their contacts should be maintained in well demarcated quarantine areas Clustering of cases in groups allow parts of the premises to be allocated as contaminated or clean
Establish whether clinically recovered horses are carriers	At least three nasopharyngeal swabs or washings taken at weekly intervals from all recovered cases and their contacts and examined by culture and PCR Horses that are consistently negative are returned to the clean area
Investigate apparently healthy horses from which *S. equi* is recovered	Endoscopic examination of the upper airways and guttural pouches
Eliminate *S. equi* from guttural pouches	Treatment of guttural pouches, as detailed under 'Treatment'
Prevention of infection of uninfected horses by *S. equi* from infected horses	Personnel should have dedicated protective clothing when dealing with infected horses Personnel should not deal with infected and uninfected horses. If this is not possible, then infected horses should be dealt with after uninfected horses Strict hygiene should be implemented, including provision of disinfection facilities for personnel and diligent and thorough cleaning of stables and barns. If practicable, equipment should be destroyed after use with infected horses Organic material should be removed from stables and then appropriate phenolic disinfectants or steam should be applied. This cleaning should be repeated Feces and waste from infected animals should be composted in an isolated location Uninfected horses should not be introduced to pastures used to house infected horses for 4 weeks Water troughs should be disinfected daily. Horse vans should be thoroughly cleaned and disinfected after each use

PCR, polymerase chain reaction.

- Infected animals should be isolated immediately
- All potential sources of fomites – including pails, brooms, grooming brushes and blankets – should be thoroughly cleaned and disinfected and the bedding burned. Disinfection with phenolic compounds is preferred because they retain their activity in the presence of some organic matter, whereas bleach and quaternary ammonium compounds are inactivated by organic material[31]
- Emergency prophylactic treatment, using injections of benzathine penicillin every 48 hours in foals and yearlings that are most susceptible, has been used but most treated animals develop strangles when the treatment is discontinued.[28] This method of prophylaxis is not recommended
- People who care for affected horses should, ideally, avoid contact with susceptible animals. If this is not practical, then strict isolation protocols, including the wearing of protective boots and clothes that are changed between affected and normal horses, should be implemented
- Newly introduced animals should be quarantined for 3 weeks and observed for signs of strangles. Rectal temperature should be monitored twice daily
- Horses with elevated temperatures should have nasopharyngeal or guttural pouch swabs cultured
- Ideally, recovered animals should not be mingled with susceptible animals for a period of several months. The optimum length of a quarantine period has not been determined, but it should be recalled that prolonged shedding (several months to years) occurs in horses with lesions of the guttural pouch. Animals without such lesions can shed *S. equi* for at least 60 days.

Enhanced resistance

The majority of horses develop solid immunity to strangles after recovery from the spontaneous disease. This immunity lasts for up to 5 years in approximately three-quarters of recovered horses.[6] Maximum resistance to disease probably requires both systemic and mucosal immunity to a variety of *S. equi* factors including, but not limited to, M protein.[19,32]

The efficacy of **vaccination** of adult horses with *S. equi* bacterins or M protein extracts of *S. equi* administered intramuscularly is controversial. Administration of M protein vaccines elicits an increase in the concentration of serum opsonizing antibodies but does not confer a high degree of resistance to natural exposure.[3] Anecdotal and case reports suggest that vaccination is not effective. However, in a controlled field trial, vaccination with an M protein commercial vaccine three times at 2-week intervals reduced the clinical attack rate by 50% in a population of young horses in which the disease was endemic.[33] Horses vaccinated only once were not protected against strangles.[33] This result suggests that, in the face of an outbreak, vaccination may reduce the number of horses that develop strangles but will not prevent strangles in all vaccinated horses. A common vaccination protocol involves the administration of an M protein vaccine intramuscularly for an initial course of three injections at 2-week intervals, with further administration of the vaccine every 6 months in animals at increased risk of contracting the disease.[34] On breeding farms, vaccination of mares during the last 4–6 weeks of gestation and of the foals at 2–3 months of age may reduce the incidence of the disease.[35]

The vaccines are administered by the intramuscular route and frequently cause swelling and pain at the injection site.[34] **Injection site reactions** are usually less severe with the M protein vaccines. Injection into the cervical muscles may cause the horse to be unable to lower its head to eat or drink for several days – injection into the pectoral muscles is preferred for this reason. There are reports of **purpura hemorrhagica**, the onset of which was temporally associated with administration of a *S. equi* vaccine. Owners should be clearly warned of the limited efficacy and potential side-effects of vaccination.

Foals that receive adequate high-quality colostrum from exposed or vaccinated mares have serum and nasopharyngeal mucosal immunoglobulins (IgGb) that provide them with resistance to *S. equi* infection.[6] This passive immunity wanes at approximately 4 months of age. Vaccination of brood mares 1 month before foaling increases colostral IgG antibodies to M protein, and presumably serum and mucosal immunoglobulin concentrations in their foals,[3] but the efficacy of this approach in preventing strangles in foals is not reported.

An **intranasal vaccine** of an avirulent live strain of *Streptococcus equi* has recently been developed and appears useful. The vaccine is composed of a live variant (strain 707-27) that does not possess a capsule and is therefore avirulent when administered intranasally. Anecdotal reports suggest that recent manipulation of the genome by deletion of genes HasA and HasB, associated with formation of the capsule, has increased the genetic stability of the vaccine strain.[36] The live attenuated vaccine should only be administered intranasally to healthy horses. The efficacy of the vaccine in field situations, safety in the face of an outbreak and in pregnant mares, incidence of adverse effects and risk of reversion to virulence have not been reported. It should not be used in potentially exposed horses during an outbreak of the disease. Intramuscular injection of the vaccine results in the formation of abscesses. The vaccine should not be administered to horses concurrently with intramuscular administration of other vaccines because of the risk of contamination of needles and syringes with *S. equi* vaccinal strain and subsequent development of abscesses at injection sites.

Vaccination by **submucosal** injection of a modified live vaccine is reported to provide short-lived (90-day) immunity to disease.[37] The commercial form of the vaccine is administered into the submucosal tissues of the upper lip and is recommended for use in horses at moderate to high risk of developing strangles.[38] At present there is no evidence of reversion of the vaccinal strain to virulence, and horses developing strangles subsequent to vaccination have all been infected with virulent strains of *S. equi*, apparently before development of immunity as a result of vaccination.[38]

STREPTOCOCCUS ZOOEPIDEMICUS INFECTION

Streptococcus equi var. *zooepidemicus* (*S. zooepidemicus*) is one of the bacteria most commonly isolated from the upper respiratory tract of clinically normal horses.[1] Almost all horses harbor a number of antigenic types of *S. zooepidemicus* in their tonsils, and this may be the source of opportunistic infections of other body systems, including the lungs.[1] Pneumonia in an individual horse is usually associated with a single strain of *S. zooepidemicus*, based on variants of the M-protein-like compound SzP.[1] However, there are a large number of SzP phenotypes and it does not appear to be an important determinant of invasiveness or epizootic capability.[1] *S. zooepidemicus* is also frequently isolated from horses with pleuropneumonia, endometritis, neonatal septicemia, abortion, and mastitis, suggesting a role for this organism in the pathogenesis of these diseases.[2,3] *S. zooepidemicus* is likely important in the development of respiratory disease in foals and adult horses.[4–7] *S. zooepidemicus* was isolated from 88% of foals with clinical evidence of lower respiratory tract disease, and isolation of the organism was associated with an increased proportion of neutrophils in bronchoalveolar lavage fluid,[4] suggesting a causal role for this organism. Similarly, the number of *S. zooepidemicus* isolated from tracheal aspirates of adult horses is directly proportional to the number of neutrophils in the aspirate and the probability that they have a cough.[5,8,9] The association of *S. zooepidemicus* and inflammatory airway disease in race horses is independent of previous viral infection, suggesting a role for *S. zooepidemicus* as a primary pathogen.[7] Presence and number of colony forming units (cfu) of *S. zooepidemicus* in tracheal aspirates of horses is significantly associated with the risk of the horse having inflammatory airway disease.[7,10] Adult horses dying of pneumonia associated with transportation often yield *S. zooepidemicus* on culture of lung lesions and the disease can be reproduced experimentally.[6,11] These results clearly demonstrate a role for *S. zooepidemicus* in the pathogenesis of respiratory disease of horses. However, it is unclear whether *S. zooepidemicus* is a primary cause of disease, a secondary contaminant or an invader of airways compromised by viral infection or other agents.

Clinical signs of *S. zooepidemicus* infection of the lower respiratory tract of foals and horses include coughing, mild fever, mucopurulent nasal discharge, and increased respiratory rate. Endoscopic examination of the trachea and bronchi reveals erythema and presence of mucopurulent exudate.[4,5] Tracheal aspirates or bronchoalveolar lavage fluid of affected horses or foals have an increased (>10%) proportion of neutrophils. *S. zooepidemicus* is a frequent isolate from the cornea of horses with ulcerative keratitis.[12]

Treatment consists of the administration of antimicrobials including penicillin (procaine penicillin, 20 000 IU/kg every 12 h) or the combination of a sulfonamide and trimethoprim (15–30 mg/kg orally every 12 h). Control consists of isolation to prevent spread of infectious respiratory disease and vaccination to prevent viral respiratory disease.

NEONATAL STREPTOCOCCAL INFECTION

Etiology Various *Streptococcus* spp.
Epidemiology Neonatal foals, calves, lambs, piglets
Signs Acute painful swelling of joints, lameness, fever. Signs of meningitis, omphalophlebitis, ophthalmitis. Sudden death
Clinical pathology Culture organism from joint fluid
Necropsy findings Fibrinopurulent synovitis, purulent meningitis and omphalophlebitis
Diagnostic confirmation Recovery of organism from joint fluid
Differential diagnosis Other infectious causes of arthritis, meningitis and omphalophlebitis
Treatment Antimicrobials, usually penicillin
Control See 'Principles of control and prevention of infectious diseases of newborn farm animals' in Chapter 3

ETIOLOGY

Streptococci are an important cause of septicemia, polyarthritis, meningitis, polyserositis, endocarditis, and unexpected death in the neonates of all farm animal species. Meningitis associated with streptococcal infection is restricted to the neonate in all species except piglets, where outbreaks can occur in pigs after weaning, and lambs infected with *S. suis*, where meningitis can occur as a sporadic disease at 3–5 months of age. Historically, there are reports of isolates of most of the Lancefield groups of beta-hemolytic streptococci, of non-beta-hemolytic streptococci and of viridans group streptococci from neonatal disease in farm animals. Commensal skin streptococci can occasionally cause disease in presumably immunocompromised neonates.[1] However, the majority of neonatal disease is associated with a limited number of streptococcal species, although there can be geographical variation in their relative prevalence within animal species.

In **foals,** *S. equi* (*S. equi* subsp. *equi*) and *S. zooepidemicus* (*S. equi* subsp. *zooepidemicus*) are the most common streptococcal species recovered from septicemic disease and polyarthritis and are also a cause of placentitis and abortion in mares.[2–4] *S. equisimilis* (*S. dysgalactiae* subsp. *equisimilis*) is a less common isolate.

S. suis and *S. equisimilis* are the most common species incriminated in **piglets.** *S. suis* is especially important and is presented separately in the next section. Other Lancefield groups have been associated with sporadic disease.[5] In **calves**, *S. dysgalactiae* and *S. uberis* are the common streptococcal isolates from synovial fluid of neonatal calves with arthritis.[6,7]

S. dysgalactiae is also reported to be the most common cause of outbreaks of arthritis in neonatal lambs in Great Britain.[8,9]

Streptococci can also contribute to purulent infections at local sites, such as navel ill of all species or otitis media in neonatal calves.[10]

EPIDEMIOLOGY

Occurrence and prevalence

The importance and relative prevalence of streptococcal infections in neonatal disease varies among countries and with surveys.

Streptococci are a common cause of postnatal infections of **foals,** representing 50% of such cases in some surveys[10] but with a lower prevalence in others.[4,11] Up to 20% of abortions in mares are due to placentitis from streptococcal infection. Streptococcal septicemia due to beta-hemolytic streptococci may occur in foals under 5 days of age that have been stressed and have failure of transfer of passive immunity.[12]

In **calves**, neonatal infections with streptococci are usually sporadic and less

common than infections with Gram-negative bacteria and may be predisposed by failure of transfer of passive immunity. In **lambs**, *S. dysgalactiae* is associated with outbreaks with high morbidity and in Great Britain is reported to be the cause of over 70% of cases of polyarthritis in lambs during their first 3 weeks of life. Despite the high attack rate in these outbreaks, it is rare for more than one of twins or triplets to have disease.[8,9] Streptococcal arthritis associated with *S. suis* infection in piglets is a common disease and is covered in a separate section.

Source of infection

The source of the infection is usually the environment, which may be contaminated by uterine discharges from infected dams or by discharges from lesions in other animals. *S. dysgalactiae* is reported to survive for up to a year on clean straw, as opposed to wood shavings, which do not support the persistence of the organism.[8]

The portal of infection in most instances appears to be the umbilicus, and continued patency of the urachus is thought to be a contributing factor in that it delays healing of the navel. In piglets there can be high rates of infection associated with infection entering through skin abrasions such as carpal necrosis resulting from abrasive floors or facial lesions following fighting.[13] Contaminated knives at castration and tail docking, or contaminated ear taggers, can result in infection and disease. Other mechanical vectors include the screwworm fly (*Cochliomyia americana*).

The organism can be isolated from the nasopharynx of the sow, and direct infection from the sow to the piglet is suggested by some epidemiological data.

Economic importance

Affected foals and other species may die or be worthless as working animals because of permanent injury to joints. There is also loss due to condemnation at slaughter.[14]

Zoonotic implications

S. zooepidemicus is associated with human infections, particularly nephritis, and many human infections can be traced back to the consumption of contaminated animal food products. Some strains of *S. equisimilis* can also infect humans.[15]

PATHOGENESIS

The infection spreads from the portal of entry to produce a bacteremia that is not detectable clinically. The period of bacteremia is variable but it may last several days in piglets. A terminal acute fatal septicemia is the common outcome in animals under 1 week of age but in older animals suppurative localization in various organs is more common. Arthritis is the most common manifestation, with synovitis and invasion of medullary bone of the epiphysis with microabscessation and ischemic necrosis of bone. Other manifestations of infection include ophthalmitis in foals and calves, meningitis and endocarditis in piglets, meningitis in calves, and endocarditis and sudden death in lambs. Streptococcal endocarditis can be produced by the intravenous inoculation of group L *Streptococcus*. Lesions are well established within 5 days, the left heart is most commonly affected, and myocardial and renal infarction occur.

CLINICAL FINDINGS

Foals

Foals do not usually show signs until 2–3 weeks of age. The initial sign is usually a painful swelling of the navel and surrounding abdominal wall, often in the form of a flat plaque, which may be 15–20 cm in diameter. A discharge of pus may or may not be present and a patent urachus is a frequent accompaniment. A systemic reaction occurs but this is often mild, with the temperature remaining at about 39.5°C (103°F). Lameness becomes apparent and is accompanied by obvious swelling and tenderness in one or more of the joints. The hock, stifle, and knee joints are most commonly affected but in severe cases the distal joints are involved and there is occasionally extension to tendon sheaths. Lameness may be so severe that the foal lies down most of the time, sucks rarely and becomes extremely emaciated. There may be hypopyon in one or both eyes.

Recovery occurs if treatment is begun in the early stages. When joint involvement is severe, particularly if the abscesses have ruptured, the animal may have to be destroyed because of the resulting ankylosis. Death from septicemia may occur in the early stages of the disease.

Piglets

Arthritis and meningitis may occur alone or together and are most common in the 2–6-week age group. More commonly, several piglets within a litter are affected. The arthritis is identical with that described in foals above. With meningitis there is a systemic reaction comprising fever, anorexia and depression. The gait is stiff, the piglets standing on their toes, and there is swaying of the hindquarters. The ears are often retracted against the head. Blindness and gross muscular tremor develop, followed by inability to maintain balance, lateral recumbency, violent paddling and death. In many cases there is little clinical evidence of omphalophlebitis. With endocarditis the young pigs are usually found comatose or dead without premonitory signs having been observed.

Lambs

Lameness in one or more limbs of lambs up to 3 weeks of age is the common presenting sign of infection with *S. dysgalactiae* but approximately 25% of lambs can be initially recumbent. With this infection there is not major joint swelling in the early stages and myopathy or delayed swayback may be initial considerations. In contrast with outbreaks that occur following docking the incubation period is short, usually 2–3 days, and there is intense lameness, with swelling of one or more joints appearing in a day or two. Pus accumulates and the joint capsule often ruptures. Recovery usually occurs with little residual enlargement of the joints, although there may be occasional deaths due to toxemia.

Calves

These show polyarthritis, meningitis, ophthalmitis, and omphalophlebitis. The ophthalmitis may appear very soon after birth. The arthritis is often chronic and causes little systemic illness. Calves with meningitis show hyperesthesia, rigidity, and fever.

CLINICAL PATHOLOGY

Pus from any source may be cultured to determine the organism present and its sensitivity to the drugs available. Bacteriological examination of the uterine discharges of the dam may be of value in determining the source of infection. The success rate with blood cultures is not very high but an attempt is worthwhile. The identification of the causative bacteria is important but the sensitivity of the organism may mean the difference between success and failure in treatment. The specific identity of the streptococcus should be determined.

NECROPSY FINDINGS

Suppuration at the navel and severe suppurative arthritis affecting one or more joints are usual. Abscesses may also be present in the liver, kidneys, spleen, and lungs. Friable tan masses of tissue are common on the heart valves of affected piglets and this valvular endocarditis may also be observed in other species. Peracute cases may die without suppurative lesions having had time to develop. Necropsy findings in the meningitic form in pigs include turbidity of the cerebrospinal fluid, congestion of meningeal vessels and the accumulation of white, purulent material in the subarachnoid space. Occasionally this exudate blocks the flow of cerebrospinal fluid in the ventricular system, causing internal hydrocephalus. Histologically there is infiltration of the affected tissue by large numbers of neutrophils, usually accompanied by fibrin deposition.

Samples for confirmation of diagnosis

- Bacteriology – culture swabs from joints, meninges, suppurative foci;

tissue pieces of valvular lesions, lung, spleen, synovial membrane (CULT)
- Histology – formalin-fixed samples of a variety of organs, including brain, lung, spleen, liver (LM).

DIFFERENTIAL DIAGNOSIS

Omphalophlebitis and suppurative arthritis in foals may be due to infection with *Escherichia coli*, *Actinobacillus equuli* or *Salmonella abortivoequina*, but these infections tend to take the form of a fatal septicemia within a few days of birth whereas streptococcal infections are delayed in their onset and usually produce a polyarthritis. In pigs there may be sporadic cases of arthritis due to staphylococci but the streptococcal infection is the common one. Arthritis due to *Mycoplasma hyorhinis* is less suppurative but may require cultural differentiation. Glasser's disease occurs usually in older pigs and is accompanied by pleurisy, pericarditis, and peritonitis. Erysipelas in very young pigs is usually manifested by septicemia. Nervous disease of piglets may resemble arthritis on cursory examination but there is an absence of joint enlargement and lameness. However, the meningitic form of the streptococcal infection can easily be confused with viral encephalitides. Meningitis in young calves may also be associated with *Pasteurella multocida*. Polyarthritis in calves, lambs, and piglets may also be associated with infection with *Arcanobacterium pyogenes* and *Fusobacterium necrophorum*. *S. suis* type 2 can also be the cause of meningitis in older pigs at 10–14 weeks of age.

The response of streptococcal infections to treatment with penicillin may be of value in the differentiation of the arthritides, and the microscopic and histological findings at necropsy enable exact differentiation to be made. In lambs suppurative arthritis occurs soon after birth and after docking. The other common arthritis in the newborn lamb is that associated with *Erysipelothrix rhuriophiae* but this usually occurs later and is manifested by lameness without pronounced joint enlargement. Calves may also develop erysipelatous arthritis.

TREATMENT

Penicillin is successful as treatment in all forms of the disease provided irreparable structural damage has not occurred. In newborn animals the dosage rate should be high (20 000 IU/kg body weight (BW)) and should be repeated at least once daily for 3 days. If suppuration is already present, a longer course of antibiotics will be necessary, preferably for 7–10 days. Piglets treated early in the course of the disease will survive but may runt. Because of the common litter incidence in piglets and the occurrence of subclinical bacteremia it is wise to also treat all littermates of affected piglets. Benzathine or benethamine penicillins can be used in conjunction with shorter-acting penicillins. General aspects of treatment of the newborn are dealt with in Chapter 3.

CONTROL

The principles of control of infectious diseases of the newborn are described in Chapter 3. Because the most frequent source of infection in foals is the genital tract of the dam, some attempt should be made to treat the mare and limit the contamination of the environment. Mixed bacterins have been widely used to establish immunity in mares and foals against this infection but no proof has been presented that they are effective. On heavily infected premises the administration of long-acting penicillin at birth may be advisable. A major factor in the control of navel- and joint-ill in lambs is the use of clean fields or pens for lambing, as umbilical infection originating from the environment seems to be more important than infection from the dam in this species. Docking should also be done in clean surroundings and, if necessary, temporary yards should be erected. Instruments should be chemically sterilized between lambs. Regardless of species and where practicable, all parturition stalls and pens should be kept clean and disinfected and the navels of all newborn animals should be disinfected at birth. Where screwworms are prevalent, the unhealed navels should be treated with a reliable repellent.

STREPTOCOCCUS SUIS INFECTION OF YOUNG PIGS

Synopsis

Etiology *Streptococcus suis*. At least 34 capsular types (35 if you include 1/2) have been recognized. Type 2 is most common
Epidemiology Occurs in piglets under 12 weeks of age
Signs Septicemia, arthritis, meningitis, pericarditis, endocarditis, polyserositis, and pneumonia
Clinical pathology Culture organism
Lesions Fibrinous polyserositis, fibrinous or hemorrhagic pneumonia, purulent meningitis, myocarditis, vegetative endocarditis, fibrinous arthritis
Diagnostic confirmation Culture organism from body tissues and blood
Differential diagnosis Arthritis due to:

- *Mycoplasma hyorhinis*
- Erysipelas
- Glasser's disease

Meningitis due to:

- *Escherichia coli*
- *Arcanobacterium pyogenes*
- *Pasteurella multocida*

Treatment Antimicrobials based on culture and sensitivity
Control Provision of optimum environment (temperature and relative humidity). Avoid overcrowding in nursery pens. Age spread of pigs in pens should not exceed 2 weeks. Use all-in, all-out pig flow. Control of other common infectious diseases. Avoid nutritional deficiencies. Consider mass medication of feed with antimicrobials

ETIOLOGY

There are three organisms that infect the neonatal pig quite commonly – *Haemophilus parasuis*, *S. suis*, and *Actinobacillus suis*, which have been dubbed the 'suis-cides'.[1] *S. suis* is therefore one of the early colonizers of the pig and by the end of the nursery period most pigs are infected.[2] These authors suggested that virulence may be an attribute of strains that colonize the young pig poorly but infect older animals more easily in the absence of maternal antibody.

S. suis type 1 and *S. suis* type 2 were the original capsular types of the organism, which appeared to account for most epidemics of the disease. *S. suis* types are subgroups of Lancefield's group D.[3] There are now at least 34 known *S. suis* capsular types.[4] Even now, new species of streptococcus, such as *S. ferus*, are being isolated from pigs.[5]

EPIDEMIOLOGY

The epidemiology of *S. suis* is very complex.[6] There is a great genetic heterogeneity of *S. suis*. The isolation of different strains within the same herd and the predominance of particular strains within some herds are evidence that infection by *S. suis* is a dynamic process and reinforces the idea that the epidemiology is complex.

Occurrence

Diseases associated with *S. suis* occur worldwide, affecting pigs less than 2 weeks of age and up to 22 weeks of age. Most cases occur within a few weeks after weaning which is associated with stressors such as moving, mixing, overcrowding, and inadequate ventilation. *S. suis* type 2 causes outbreaks of meningitis in young pigs 10–14 days after weaning. The disease occurs most commonly in recently weaned

pigs raised in intensive systems of high population density, such as flat-deck rooms and finishing pens. In the USA, most pigs infected with *S. suis* are under 12 weeks of age;[7] sporadic cases occur in older pigs including adults. In Canada, pigs may be affected from 3–24 weeks of age, with most cases occurring between 6 and 12 weeks of age.

The organism has also been isolated from cattle,[8] sheep, and goats,[4,9] a horse with meningitis,[10] fallow deer,[11] and cats.[12]

Prevalence of infection

S. suis type 2 is the most prevalent serotype. Types 3, 4, 7, 8, and 14 have been isolated from affected pigs in the UK.[13–15] In a survey of pigs at slaughter in Australia, *S. suis* type 2 was detected in 58% of the palatine tonsils, in 66% of the pneumonic lungs and in 28% of the healthy lungs.[16] Overall, the carrier rate in piggeries was 60%. The organism was also present in the blood of 3% of apparently normal pigs at slaughter. It could also be cultured from many other tissues, including those of the reproductive tract of females but not from males. The organism can be cultured from the vagina of sows, and it is possible that piglets are infected during birth. Specific-pathogen-free herds are free of the organism and hysterectomy-derived piglets are born free from infection. The rate of infection of the environment of the pigs can also be very high.[17]

Since 1996, at least 34 serotypes of the organism have been identified.[4] Recently it has been suggested that serotypes 32 and 34 are *Streptococcus orisratti*.[18] In Canada, all 34 serotypes have been isolated, with type 2 being most prevalent of all isolates.[4] The other capsular types in decreasing order were 3, 7, 1/2, 8, 23, and 4. Over a period of several years, more than 60% of isolates belong to capsular types 2, 1/2, 3, 4, 7, and 8.[19] In a survey of clinically healthy piglets 4–8 weeks of age in Quebec, the organism could be isolated from 94% of piglets and 98% of farms.[20] The typable isolates of the organism are more frequently recovered from pigs between 5 and 10 weeks of age, while untypable isolates are most frequently found in animals more than 24 weeks old. In the USA, serotype 3 was most prevalent (26.1%), followed by serotypes 8 (17.4%), 2, 4, and 7 (all 15.2%) with no significant differences in the epidemiological features, clinical signs or lesions in pigs infected with multiple serotypes compared with a single serotype of *S. suis*.[7,21] Only Scandinavian countries reported a higher incidence of type 7 over type 2.[22] In Denmark, serotypes 2 accounted for 29% of the isolates, serotype 7 for 17% and 3, 4 and 8 for a further 9–10%.[23] Serotype 7 was isolated more frequently than reported in other countries, causing septicemia, arthritis, and meningitis. In Finland, the most common types isolated from dead pigs were 7, 3, and 2 respectively, and they were most frequently isolated from cases of pneumonia.[24] In the Netherlands, type 2 was most frequently isolated from pigs with meningitis. *S. suis* type 9 and *S. suis* type 2 have been isolated as the cause of septicemia and meningitis in weaned pigs in Australia.[25] The organism has been isolated from a wild sow affected with pneumonia[26] and from a young wild boar.[27]

Morbidity and case fatality

The incidence of clinical disease ranges from 0–15%. In a 3-year survey of a breeding herd, the combined morbidity and mortality rates due to meningitis from *S. suis* type 2 were 3%, 8%, and 9.1%, respectively, in each of the 3 years.

Methods of transmission

The organism is carried in the tonsils and occasionally in the nose of healthy pigs, and transmission to uninfected pigs can occur within 5 days of mixing. The introduction of breeding gilts from infected herds results in disease appearing subsequently in weanlings and growing pigs in the recipient herds. The detectable carrier rates in different groups of pigs can vary from 0–80% and are highest in weaned pigs aged 4–10 weeks. Over 80% of the sows in an individual herd may be subclinical carriers. They do not normally carry the organism in the nasal cavity but in the vagina.[28] Based on the results of sampling of sows and piglets at parturition, and being able to culture multiple serotypes of the organism from the sow's vaginal secretions and oropharyngeal samples of piglets, it is highly probable that the newborn piglet is infected during birth by the organism, which is transferred from the sow's vagina to the dorsal surface and oral cavity of the piglet.[29] However, even though most pigs are colonized by weaning age, colonization by the virulent strains of *S. suis* type 2 takes longer and usually does not occur before 15 days of age.[30] This could constitute a risk factor for developing disease later when maternal immunity has waned.

Weaned carrier pigs transmit the infection to previously uninfected pigs after mixing following weaning. The organism can persist in the tonsils of carrier pigs for more than 1 year, and in the presence of circulating opsonic and binding antibodies, and in pigs receiving penicillin-medicated feed. Thus the organism can be endemic in some herds without causing recognizable clinical disease. House flies can carry the organism for at least 5 days and can contaminate feed for at least 4 days.

The carrier rate in some surveys of slaughtered pigs ranges from 32–50% of pigs 4–6 months of age, which may be associated with the high incidence of *S. suis* type 2 meningitis in humans in the Netherlands. The organism is a potential hazard for abattoir workers, particularly eviscerators who remove the larynx and lungs from carcasses, who have a significantly higher risk of exposure to *S. suis* than other workers.

S. suis type 2 has also been isolated from pigs affected with bronchopneumonia, usually secondary to enzootic pneumonia, from cases of pleuropneumonia, arthritis, vaginitis and aborted fetuses, and in neonatal piglets 1–2 days of age affected with fatal septicemia. It appears that the organism is found in the lungs of pigs affected with pneumonia more frequently in North America than in other countries. Although airborne infection of type 2 has been described it is said that indirect transmission is a much better way to infect piglets.[31]

The organism is easily transmitted via fomites. It can survive in feces for 104 days at 0°C and for 10 days at 9°C, and in dust for 54 days at 0°C and 25 days at 9°C. Experimentally, pure cultures of the organism placed on rubber and plastic surfaces, especially when protected by swine manure, are viable at up to 55°C and can survive if kept frozen for up to 10 days. The organism is readily destroyed by disinfectants. It can be spread by contaminated pig nose snares and needles used for blood sampling.[32]

Risk factors

Animal risk factors

The host factors that render pigs susceptible to clinical disease are uncertain. Over 30 different Gram-positive bacterial organisms may occur in the nasal cavities and tonsils of unweaned pigs of between 2 weeks and 6 weeks of age.[33] It is suggested that strains of *S. suis* type 2 vary in pathogenicity, and that the occurrence of disease is dependent on both exposure to a pathogenic strain and undetermined secondary factors. The peak incidence of the disease from 5–10 weeks of age suggests that the stressors of weaning may render pigs susceptible to clinical disease. The presence of other infectious diseases such as porcine reproductive and respiratory syndrome (PRRS) and *Actinobacillus pleuropneumoniae* may be associated with a higher than average prevalence of infection with *S. suis*.[34] PRRS certainly increases susceptibility to *S. suis* infection experimentally.[35,36] In utero infection with PRRS makes pigs more susceptible to subsequent neonatal *S. suis* infections.[36] Infection of specific-pathogen-free pigs with PRRS virus may be a risk factor for infection and disease associated with *S. suis*.[37] Similarly, the pseudorabies virus may

enhance clinical disease associated with *S. suis*.[38]

Environmental and management factors

The incidence of clinical disease appears to depend on environmental factors such as inadequate ventilation, high population density, and other stressors. Several environmental and managemental risk factors have been associated with a high prevalence of pigs harboring *S. suis* in swine herds.[34] Excessive environmental temperature fluctuation in the nursery pig facilities was the most common factor. Nursery pig environmental temperatures should not fluctuate more than 1.1–1.7°C over a 24-hour period to prevent chilling of pigs. Fluctuations in temperature are caused by drafts, inadequate heaters, or poorly insulated buildings. Excessive relative humidity was also a factor; the recommended range for nursery pigs is 55–70%. The third and fourth most common factors were age spread of more than 2 weeks for pigs in the same room, and crowding. The fifth most common factor was the use of continuous flow facilities, which allows for build-up of dust and manure and increased infection pressure. An unusual case where *S. suis* was isolated from the lumen of the small intestine occurred when a feed was formulated with no salt and 58.5 kg instead of 3.5 kg of vitamin premix. Once the ration was corrected the problem disappeared.[39]

Pathogen risk factors

There are now at least 34 serotypes of *S. suis*.[4] The organism is divided into serotypes by the antigenic specificity of its capsular polysaccharide.[40] The capsule, certainly for *S. suis* type 2, plays an important role in pathogenesis.[41] As described under Methods of transmission, colonization of piglets occurs very early in life, most pigs being colonized by weaning age; virulent strains of *S. suis* type 2 may not colonize until later.[30] Early colonization reduces the subsequent clinical signs.[30] Despite the association of bacteria with disease, they may also be recovered from the nasal cavities and tonsils of healthy pigs. High numbers of organisms were isolated from the cerebrospinal fluid of clinically normal pigs.[42] A study also showed that a persistent epidemic strain of *S. suis* was consistently isolated from the brains of pigs over a 2-year period, all with a similar genetic pattern.[43]

There are differences in pathogenicity between serotypes and between strains of the same serotype. In the UK there are differences in pathogenicity between types 1 and 2, type 1 causing less severe disease in piglets while type 2 causes a more severe and acute disease in older and growing pigs. Highly virulent and completely avirulent type 2 strains exist.[44] Different strains of *S. suis* type 2 vary in their ability to cause meningitis. Streptococci require manganese but not iron as a growth factor, which affects the activity of superoxide dismutase in cell cultures.[45]

The virulence markers of the organism include the structural proteins muramidase-released protein (MRP) and extracellular factor (EF).[46-48] It has also been said that they are not essential for virulence.[48] *S. suis* produces four proteases.[49] Fibrinogen-binding protein played a role in the colonization of specific organisms involved in a *S. suis* infection.[50] A secreted nuclease has also been described.[51] An IgG binding protein in the 60 kDa range has been shown to bind IgG in a nonimmune way.[52] Recently, 36 environmentally regulated genes have been identified.[53] There are virulence differences between strains of the same serotype based on the presence or absence of muramidase-released proteins. Strains of *S. suis* type 2 from Europe are genotypically different from those of North America. Most Canadian field isolates of *S. suis* type 2 do not produce these virulence-related proteins.[54] An extracellular protein with hemolytic properties, called suilysin, has been described.[55] Most type 2 field strains from four different European countries produce this hemolysin.[56] Between 58 and 90% of strains from the Netherlands, Denmark, France, England, and Italy produce the suilysin but only 1% of Canadian strains do.[54] A total of 164 field isolates from diseased pigs in four countries were serotyped and tested for suilysin. *S. suis* type 2 was the most prevalent type isolated from all four countries. After type 2, type 9 was most prevalent in the Netherlands and France and type 7 in Denmark. All the English isolates were type 2. No nonvirulent suilysin-producing *S. suis* type 2 strains have been reported.[57]

The hemolysin gene was found in over 80% of the strains that were associated with meningitis, septicemia, and arthritis but with only 44% of pneumonia isolates.[58]

The organism bears fimbriae and the capsular materials from different serotypes have distinct morphologies.[59] Certain strains possess hemagglutinating properties.[60] The type 2 isolates possess a factor that allows them to adhere to porcine lung.[61] Restriction endonuclease techniques are being used to examine the genomic structure of the organism, which could be useful for epidemiological monitoring of outbreaks of the disease.[62]

A 44 kDa protein has been isolated as a virulence marker of *S. suis* type 2, and the presence of antibodies against this protein appears to be necessary to obtain complete protection against the disease.[63] Australian isolates of *S. suis* are genetically very diverse, which suggests that serotyping is not a reliable technique for identifying specific strains and not a good predictor of the genetic background of a given isolate.[64]

Some isolates of *S. suis* have developed resistance to penicillin and tetracycline, which may reflect the usage of these antimicrobials in treatment and control programs.[34]

S. suis type 2 can survive in feces for 104 days at 0°C (32°F), up to 10 days at 9°C (48°F) and up to 8 days at 22–25°C (71–77°F).[65] It can survive in dust for up to 25 days at 9°C (48°F) but could not be isolated from dust stored at room temperature for 24 hours. The organism is rapidly inactivated by disinfectants commonly used on farms. Liquid soap inactivates *S. suis* type 2 in less than 1 minute at a dilution in water of 1 in 500. The organism can survive in pig carcasses at 40°C (104°F) for 6 weeks, which may be an important source of the organisms for infection in humans.

Zoonotic implications

Splenectomized humans are particularly at risk from certain infections, including streptococci.

Infections with *S. suis* type 2 are the most common infections in humans and occur most commonly in people having contact with pigs or raw pork. It is possible that many human cases are misdiagnosed, such as were described in south-east Asia,[66] where five of eight cases of *S. suis* were described as *S. viridans*. A truck driver has recently been described with septic shock.[67] In the UK the highest incidence of meningitis due to *S. suis* type 2 is in butchers and abattoir workers; transmission is thought to be mainly via minor skin abrasions. The clinical manifestations include meningitis and septicemia, which may be accompanied by arthritis, endophthalmitis, and disseminated intravascular coagulation. Endocarditis[68] and acute gastroenteritis have also been reported.[69] In a series of 35 human cases of *S. suis* type 2 meningitis in the UK from 1975–1990, deafness occurred in 50% of patients, vertigo and ataxia in 30% and arthritis in 53%.[62] There was a case fatality rate of 13%. The organism invades the cerebrospinal fluid within monocytes, an example of the 'Trojan horse' mechanism of entry. Deafness may follow in 50–60% of cases and is due to cochlear sepsis following invasion of the organism from the subarachnoid space into the perilymph of the inner ear. Subclinical infection in pigs sent to slaughter represents a potential source of infection for abattoir workers; eviscerators who remove the larynx and lungs have a significantly higher risk of exposure to the organism than other abattoir workers. Within infected herds in New Zealand, up

to 100% of pigs are carriers and *S. suis* type 2 infection may be one of the most infectious potentially zoonotic pathogens present in New Zealand, although very rarely resulting in clinical disease.[70] The annual incidence of subclinical infection and seroconversion in pig farmers in New Zealand is close to 28%.

PATHOGENESIS

Streptococci exist in extremely different phenotypes with regard to adhesion, invasion and cytotoxicity. These features depend on the state of encapsulation and environmental growth conditions.[71]

The tonsils are a site of persistence, multiplication and portal of entry of a variety of pathogens including *S. suis*.[72]

The organism resides in the crypts of the palatine tonsils. Invasive disease occurs in a minority of infected pigs, following entry of organisms into the systemic circulation as a bacteremia and then septicemia, leading to a meningitis.[73] Most bacteria remain extracellular, with fewer than 2% of monocytes containing bacteria. There is a high level of adhesion of bacteria to phagocytic cells. *S. suis* adheres to brain microvascular endothelial cells and suilysin can damage these.[74] It has been shown that *S. suis* capsular strains stimulate tumor necrosis factor alpha (TNF)- and interleukin (IL)-6 but that the suilysin and the extracellular protein do not do so on their own.[75] A terminal acute fatal septicemia is the common outcome in young animals, but in older animals localization can occur in synovial cavities, endocardium, eyes, and meninges. A persistent bacteremia is an important phase in the pathogenesis of *S. suis* type 2 meningitis. Virulent isolates of *S. suis* type 2 possess capsules and are relatively resistant to phagocytosis.[76] Isogenic mutants defective in capsule production were not virulent.[77] *S. suis* is able to adhere to but not to invade epithelial cells and the adhesins are partially blocked by the capsule and are part of the cell wall.[78] The highly virulent isolates possessed the suilysin, muraminidase releasing protein and extracellular protein factor phenotype.[79] *S. suis* are able to survive and replicate within macrophages, and the bacteria enter the cerebrospinal fluid space in association with migrating monocytes, which move through choroid plexuses.[80] They therefore enter the cerebrospinal fluid by a 'Trojan horse' mechanism similar to that used by some viral pathogens of the central nervous system.[80] The predominant lesions are suppurative or fibrinopurulent inflammation in brain, heart, lungs, and serosae.[81] *S. suis* type 9 may produce a different distribution of lesions compared to type 2.[82] The disease has been reproduced experimentally in pigs and laboratory animals by intravenous, intranasal, and subarachnoid routes.[83] Certain strains of *S. suis* can cause vascular lesions, with the development of fibrinohemorrhagic pneumonia and septal necrosis.[84] Of importance in the pathogenesis of *S. suis* infections is the predisposing role of PRRS. This effect of PRRS has still only been experimentally demonstrated with *S. suis*.[85]

CLINICAL FINDINGS

Multiple *Streptococcus* spp. are implicated in lameness and central nervous system signs in piglets and sows.[86] There is significant variation of carrier states and clinical signs with the individual serotypes.[87]

Arthritis and meningitis may occur alone or together and are most common in the 2–6-week age group. More commonly several piglets within a litter are affected. Meningitis is associated with serotypes 1, 2, 1/2, 3, 4, 8, 9, 14, and 16; septicemia with 2; arthritis with 7 and 14; abscesses with 2; bronchopneumonia with 2, 3, 7, 10, 15, and 27; reproductive damage with 2, 13, and 22; 14 can be associated with any clinical condition.[88]

The **arthritis** is characterized by enlarged and distended joint capsules, lameness and pain on palpation of the affected joints. Fever, depression, reluctance to move, and inactivity are common.

Meningitis is characterized by a fever, anorexia, and depression. The gait is stiff, the piglets standing on their toes, and there is swaying of the hindquarters. The ears are often retracted against the head. Blindness and gross muscular tremor develop followed by inability to maintain balance, lateral recumbency, violent paddling, and death. In many cases there is little clinical evidence of omphalophlebitis.

In **epidemics of meningitis** due to *S. suis* type 2, sudden death in one or more pigs may be the first sign. Affected pigs found alive are incoordinated and rapidly become recumbent. There is opisthotonos, paddling and convulsions and death in less than 4 hours. A fever of up to 41°C (105°F) is common. In the UK, meningitis of recently weaned pigs is the most striking feature of *S. suis* type 2 infection.

Otitis interna is a common sequel to many cases of *S. suis* meningitis.[89]

Arthritis is common in younger pigs.

In **endocarditis** and **septicemia** the piglets are usually found comatose or dead without premonitory signs having been observed.

Valvular endocarditis due to *S. suis* type 2 has also been reported in a 13-week-old fattening pig in a breeding herd that had a long history of streptococcal meningitis.[69]

CLINICAL PATHOLOGY

Culture or detection of organism

The organism can be cultured from joint fluid, cerebrospinal fluid, blood, brain, and lungs of pigs at necropsy. The tonsils of live pigs may be swabbed and cultured for the organism. Improved and selective media are available for the isolation and serotyping of the organism.[90] An indirect fluorescent antibody test can be used to identify the organism on tonsillar swabs of live pigs. Because of multiple antimicrobial resistance among strains of the organism, drug sensitivity testing on a routine basis is recommended.[91] Highly virulent strains of *S. suis* types 2 and 1 were detected in tonsillar specimens using PCR.[92] Rapid serotype-specific PCR assays have been developed.[93]

Serology

The specific serotype of *S. suis* should be determined. A simplified laboratory method is available for the identification of *S. suis* strains associated with different animal hosts or located in different body regions.[94] An enzyme-linked immunosorbent assay (ELISA) using monoclonal antibodies directed against virulence markers of *S. suis* can distinguish between virulent and avirulent strains of the organism.[47] A rapid and specific double-sandwich ELISA is available for the detection and capsular typing of the organism with a specificity of 97.6% and sensitivity of 62.5%.[95] However, many laboratories are not readily equipped to identify the numerous serotypes of the organism. The biochemical characteristics and serotyping techniques have been described.[40]

NECROPSY FINDINGS

In pigs dying from *S. suis* type 2 infection, the gross and microscopic findings include one or more of fibrinopurulent polyserositis, fibrinous polyarthritis, fibrinous or hemorrhagic bronchopneumonia, suppurative meningitis, hemorrhagic necrotizing myocarditis, and vegetative valvular endocarditis.[60] Gross myocardial lesions cannot be distinguished from those of mulberry heart disease. In cases with meningitis, there is turbidity of the cerebrospinal fluid, congestion of meningeal vessels, and variable amounts of white exudate in the subarachnoid space. This suppuration is usually most evident along the ventral aspect of the brain. The typical histological picture is one of acute inflammation – neutrophils and fibrin dominate the response. Other changes that may be observed in *S. suis* infections of the central nervous system include internal hydrocephalus, foci of liquefaction necrosis, subacute (mononuclear cell-rich) meningoencephalitis or meningoencephalomyelitis with bilateral subacute optic perineuritis and Gasserian ganglioneuritis.[60] In the tonsils, *S. suis* organisms can be seen in the subepithelial lymphoid tissue and in the crypt lumen and crypt epithelium.[96] *S. suis* type 9 is more prone to cause

bronchopneumonia than the spectrum of lesions typical of type 2.[82]

Samples for confirmation of diagnosis

- Bacteriology – lung, spleen; culture swabs from serosal surfaces, joints, meninges. Cerebrospinal fluid is the material for the best diagnosis (CULT). Bacterial culture is difficult if the animals have been treated and this is so even when they receive growth-promoting antibiotics.[97] Immunomagnetic isolation of types 2 and 1/2 from swine tonsils has been described and it is better than the standard procedure[98]
- Histology – formalin-fixed samples of a variety of organs, including lung, brain, heart, liver (LM). Immunohistochemistry and in situ hybridization have been described for use on formalin-fixed tissue and are able to detect single cells.[99]

(Note the zoonotic potential of this organism when handling carcass and submitting specimens.)

DIFFERENTIAL DIAGNOSIS

In pigs there may be sporadic cases of arthritis due to staphylococci but the streptococcal infection is the common one. Arthritis due to *M. hyorhinis* is less suppurative but may require cultural differentiation. Glasser's disease occurs usually in older pigs and is accompanied by pleurisy, pericarditis, and peritonitis. Erysipelas in very young pigs is usually manifested by septicemia. Nervous disease of piglets may resemble arthritis on cursory examination but there is an absence of joint enlargement and lameness. However, the meningitic form of the streptococcal infection can easily be confused with viral encephalitides. Meningitis in young pigs may also be associated with *P. multocida* and *E. coli*. Polyarthritis in calves, lambs, and piglets may also be associated with infection with *A. pyogenes* and *F. necrophorum*. *S. suis* type 2 can also be the cause of meningitis in older pigs of 10–14 weeks of age.

TREATMENT

Antimicrobials

In Denmark over the last 15 years there has been an increase in resistance of *S. suis* isolates to the two most commonly used antibiotics, tylosin and tetracyclines.[100] The strains show a varying pattern of resistance dependent on which of 21 ribotype profiles they belong to.[101] For example, strains causing meningitis were more resistant to sulfamethoxazole but those causing pneumonia were more resistant to tetracyclines. Tilmicosin has been used successfully to remove clinical signs of streptococcal meningitis from a herd.[102]

Penicillin has been the treatment of choice but penicillin-resistant isolates have emerged. Penicillin sensitivity can no longer be assumed for all strains of *S. suis* and the routine use of penicillin must be re-evaluated.[103] In one study, more than 50% of isolates of *S. suis* were not susceptible to penicillin.[91] Penicillin did not eliminate the organism from the tonsils of carrier pigs treated daily for several days.[104] In some surveys, the antimicrobial sensitivity of *S. suis* indicates a high degree of sensitivity to ampicillin, cephalothin, and trimethoprim–sulfamethoxazole, and resistance to the aminoglycosides gentamicin and streptomycin.[91] It is recommended that trimethoprim–sulfamethoxazole be used for the treatment of affected pigs and be given daily for 3 days. An occasional strain may be resistant to trimethoprim– sulfamethoxazole.

None of the resistant strains produced beta-lactamase. Conjugation of antibiotic resistance in *S. suis* has been reported, which may explain the multiple antimicrobial resistance.[105] The genes responsible for resistance appear to be homologous to genes found in many other species of bacteria.[106] Treatment of pigs affected with meningitis due to *S. suis* type 2 with either trimethoprim–sulfadiazine or penicillin reduced the case fatality rate from 55% to 21%. Cefquinone has been shown to improve cure rates (67%) compared to ampicillin (55%) and to reduce mortality from 35% with ampicillin to 24% with cefquinone.[107]

Passive immunization against *S. suis* type 2 has been described.[108]

CONTROL

At the present time there are no known specific methods for the prevention of the disease complex associated with *S. suis* type 2. The recommendations are based on empirical field observations.

It has been suggested that ceftiofur administered by injection for three consecutive days following *S. suis* challenge was the most effective regimen for minimizing disease associated with PRRS virus and *S. suis* infection.[109]

Environment and management

Good management and hygiene techniques should be emphasized. Based on observations of the effects of management practices on *S. suis* carrier rate in nursery pigs, excessive temperature fluctuations, high relative humidity, crowding, and an age spread exceeding 2 weeks of pigs in the same room were associated with a higher-than-average percentage of carrier pigs.

Nursery pig environmental temperature should not fluctuate more than 1.1–1.7°C over a 24-hour period.[34]

Excessive relative humidity must be avoided; the recommended range of relative humidity for nursery pigs is 55–70%.

The age spread between pigs in the same room should not exceed 2 weeks. Young, potentially naive piglets raised in the same air space as older animals may be exposed to high concentrations of the organism.

Adequate space to avoid crowding is also necessary. Crowding occurs when less than 0.18 m^2 is provided for each 22.7 kg of pig.[34] The use of an all-in, all-out production system is recommended, compared to a continuous flow system, which allows for a buildup of pathogens. The control of the most commonly encountered infectious diseases is also important. A well-fortified nutritional program may also aid in the control of *S. suis* infection and the carrier state in a swine herd.

Segregated early weaning programs have been used in an attempt to control the disease but appear to be unsuccessful in reducing the carrier state.[110] Pigs are weaned at an early age and moved to a separate site in an effort to separate the piglets from the sows, which are the primary source of the organism. Carrier pigs readily transmit the infection to uninfected pigs and the main method of spread between herds is the movement of infected breeding stock or weaner pigs. In herds that are free of the infection, it is necessary to avoid the importation of infected pigs. Eradication of *S. suis* type 2 infection can be attempted by depopulation of suspected carrier sows and replacement with noninfected breeding stock.

Mass medication of feed

Mass medication of individual pigs or medication of the feed during periods of high risk may control the incidence of clinical disease. Outbreaks in sucking piglets have been controlled by a single injection of benethamine penicillin to all piglets given 5 days before the average age of onset of clinical signs. The feeding of oxytetracycline (400 g/tonne) for 14 days immediately prior to the usual onset may control the occurrence of the disease at a low level in weaned pigs. The use of a medicated feed containing trimethoprim–sulfadiazine (1:5) at a rate of 500 g/tonne for the first 6 weeks after weaning did not significantly reduce the incidence of disease. Oral prophylactic medication with either procaine penicillin G or a mixture of chlortetracycline, sulfadimidine and procaine penicillin G reduced the incidence of meningitis. Phenoxymethyl penicillin administered orally provided higher plasma concentrations of drug. The inclusion of phenoxymethyl penicillin potassium (10%) at a rate of 2 kg/tonne of feed significantly reduced the incidence of streptococcal meningitis when fed to the pigs for a total of 6 weeks from 4–10 weeks of age.[111]

Tiamulin in the drinking water at 180 mg/L of water for 5 days significantly reduced the effects of experimentally induced *S. suis* type infections.[112]

Vaccination

Studies are being conducted on the use of vaccines containing the immunogenic polysaccharide from *S. suis* type 2. Whole-cell vaccines seem to induce significant protection in pigs against a homologous challenge.[113] A commercial vaccine reduced mortality from 17% to 2.6%.[114] However, the protection provided by whole-cell vaccines is probably type-specific, which suggests that such vaccines should contain many serotypes if broad protection is desired. A trial minimizing variation in weaning age to achieve a uniform size with a combination of an autogenous vaccine and ceftiofur sodium has been reported.[115] The protective levels of antibody did not prevent the survival of the organism in either tonsils or joints. An ELISA can be used to evaluate the antibody response in pigs vaccinated with *S. suis* type 2.[116] Different components of the organism are being examined to identify possible fractions for the preparation of a subunit vaccine. A subunit vaccine containing both MRP and EF, formulated with an oil/water adjuvant, protected pigs against challenge with a virulent *S. suis* type 2.[117] Vaccination of sows with 2 mL of bacterin prevented neurological signs but not lameness, bacteriuria, or mortality in their progeny from challenge at 13–21 days of age.[118] Immunization of experimental mice with a live avirulent strain of *S. suis* type 2 provided protection, which may be extrapolated for consideration in pigs.[119] A vaccine containing purified suilysin protected mice against a lethal homologous challenge and induced protection against clinical signs in pigs after homologous challenge.[120] Pigs vaccinated with a vaccine containing purified suilysin were protected from challenge with the homologous strain of the organism, whereas pigs vaccinated with a vaccine containing most of the extracellular antigens, and the placebo pigs, developed clinical disease.[117] Suilysin is produced by most of the field strains tested and could be an important cross-protection factor.[56]

STREPTOCOCCAL LYMPHADENITIS OF PIGS (JOWL ABSCESSES, CERVICAL ABSCESSES)

Cervical or 'jowl' abscess of pigs is observed mainly at slaughter. Clinically there is obvious enlargement of the lymph nodes of the throat region, particularly the mandibular nodes. It is of considerable

importance because of the losses due to rejection of infected carcasses at meat inspection.

The condemnation rate of pig heads at slaughter may be as high as 78–94% in some herds. However, based on annual reports from the Federal Meat and Poultry Inspection Service in the USA, the incidence of jowl abscesses in pigs declined steadily to a level in 1981 less than one-third of the peak incidence 20 years earlier.[1] This may be due to changes in management of pig herds and the use of antibiotic feeding.

Most jowl abscesses in swine are associated with beta-hemolytic streptococci of Lancefield's group E type IV,[1,2] although *P. multocida*, *E. coli*, and *A. pyogenes* may also be present. Some additional serotypes have been isolated.[3] The disease occurs primarily in postweaning and fattening swine. Piglets under 28 days of age are relatively resistant and even colostrum-deprived piglets are resistant to clinical disease following experimental infection.[4]

The disease has been produced by feeding or the intranasal or intrapharyngeal instillation of streptococci[5] and they are thought to be the cause, infection occurring through the pharyngeal mucosa from contaminated food and water.[6] In herds where cervical abscess is a problem, streptococci can commonly be isolated from the vaginas of pregnant sows and the pharynges of normal young pigs.[7] The persistence of the infection in herds is thought to depend on the presence of carrier animals.[8] Transmission occurs via feed and drinking water. After infection has occurred a bacteremia develops and abscesses are initiated in the cervical lymph nodes in a high proportion of pigs.[9] Infrequently, abscesses occur in atypical sites other than the head and neck. Pigs that have recovered from the natural disease are immune to experimental challenge.[10] A microtitration agglutination test is available to detect infections associated with type IV streptococci.[11]

Vaccination of pregnant sows with an autogenous or commercial bacterin containing streptococci and staphylococci is thought to be of value in protecting the litters of the vaccinated sows.[12] Vaccination of young pigs with a whole-culture bacterin has provided some protection. but the use of an oral vaccine prepared from an avirulent strain of group E streptococci and sprayed into the oropharynx is highly effective as a preventive measure.[13] A number of prophylactic regimens based on the feeding of antibiotics have been proposed and generally give good results. Chlortetracycline fed to young pigs at the rate of 220 g/tonne for 1 month is an example.[14] Treatment of breeding pigs at the same time is likely to have a beneficial effect in reducing the severity of exposure of the young pigs to infection. A similar advantage can be gained by keeping the treated groups isolated from untreated groups of older pigs. Because piglets under 28 days of age are relatively resistant to clinical disease, the weaning and isolation from older pigs is a successful control program.

Diseases associated with *Staphylococcus* species

Mastitis associated with *Staphylococcus aureus* is dealt with in Chapter 15, udder impetigo of cattle in the section on miscellaneous abnormalities of the udder, and staphylococcal pyoderma of horses under the heading of dermatitis. Other miscellaneous infections include:

- Tick pyemia of lambs (see below)
- Exudative epidermitis of pigs (see below)
- Staphylococcal septicemia of the newborn, especially lambs. This is a relatively common disease and may have a significant mortality rate, partly due to a high incidence of myocardial lesions. In most cases the navel appears to be the portal of infection but infection may also occur through marking wounds
- **Periorbital eczema.** A severe suppurative ulceration of the skin around the eyes, ears, nasal and maxillary area and the base of the horns occurs in adult sheep.[1,2] Lesions may be unilateral or bilateral and manifest with hair loss and erythematous swelling, initially covered by a serosanguinous exudate and eventually by a red-brown scab. The disease is associated with *S. aureus* and may be predisposed by trauma from aggression where there is inadequate trough feeding space, or by grazing over corn stalks or other abrasive pastures. Lesions persist for 4–5 weeks but a shorter course is seen with local and parenteral antibiotic therapy
- A benign folliculitis of the face of sucking lambs.[3,4] A more severe facial dermatitis is reported in 6-month-old lambs associated with a combined infection with *S. aureus* and contagious pustular dermatitis,[5] which responded well to treatment with procaine penicillin
- Dermatitis of the legs of sheep with most lesions close to the coronet[6]
- An outbreak of skin abscessation associated with *S. aureus* infection following shearing[7]
- *Staphylococcus hyicus*, the causative organism of exudative epidermitis of pigs, is also an occasional cause of a **scabby dermatitis**, accompanied by itching and alopecia, on the skin of the neck and back of donkeys and horses[8]
- Impetigo with a superficial pustular dermatitis at the base of the teats, on the udder, in the intramammary sulcus and in the perineal area occurs in goats associated with either *Staphylococcus intermedius*, *S. aureus*, or *Staphylococcus chromogens*.[9] Good response to a single dose of tilimicosin (10 mg/kg BW administered subcutaneously) is reported[10]
- A generalized dermatitis in young lambs with clinical similarities to exudative epidermitis in pigs but associated with *Staphylococcus xylosus*.[11]

TICK PYEMIA OF LAMBS (ENZOOTIC STAPHYLOCOCCOSIS OF LAMBS)

Synopsis

Etiology Infection with *Staphylococcus aureus* predisposed by infection with *Anaplasma* (formerly *Ehrlichia*) *phagocytophila*
Epidemiology Disease of young lambs that occurs in areas that are habitats for *Ixodes ricinus*
Clinical and necropsy findings Septicemia and subsequent abscessation in internal organs
Diagnostic confirmation Isolation of organism
Treatment Long-acting antimicrobials
Control Tick control

ETIOLOGY
The disease has a complex causality and results from a septicemia produced by *S. aureus* predisposed by infection with *Ehrlichia (Cytoecetes) phagocytophila*, which is transmitted by *Ixodes ricinus*.[1]

EPIDEMIOLOGY
Enzootic disease has been recorded only in the UK and occurs only in the hill areas that are habitats for the tick *I. ricinus*. The disease occurs in the spring and early summer. The annual incidence varies with the year and between farms. On average, 5% of lambs at risk are affected but on some farms the incidence may be as high as 29% in certain years.[2]

In enzootic areas the disease has considerable economic importance and has been stated to affect as many as 300 000 lambs every year, the majority of which die or fail to be profitable.[2]

PATHOGENESIS
Experimental and epidemiological studies have established a clear relationship between infection with *E. phagocytophila*, the agent of tick-borne fever, and susceptibility to infection with *S. aureus*.[1] The role of the tick is in the transmission of *E. phagocytophila*.[1]

Infection with *E. phagocytophila* produces a significant lymphocytopenia that develops 6 days after infection and affects all subsets of T and B lymphocytes, and also a prolonged neutropenia lasting for 2–3 weeks combined with a thrombocytopenia. Up to 70% of the neutrophils are parasitized from the onset of the parasitemia and have impaired function, and lambs with tick-borne fever have a much higher susceptibility to experimental infection with *S. aureus* than do non-infected lambs.[2] The ticks are not thought to necessarily provide portals of entry for, nor to be the primary carriers of, the infection with *S. aureus*, although they are important in this respect.[3] *S. aureus* can gain entry through a variety of sources and in affected flocks there is a high incidence of lambs carrying the same infection on their nasal mucosa.[4]

CLINICAL AND NECROPSY FINDINGS
Lambs aged 2–10 weeks are affected. They may die quickly of septicemia or show signs of localization of infection. Clinically this is most evident by infections that localize in joints or the meninges to manifest as arthritis or meningitis but on postmortem examination abscesses can be found in any organ, including the skin, muscles, tendon sheaths, joints, viscera, and brain.

TREATMENT AND CONTROL
Treatment of the established disease has limited value and efforts should be directed at prevention or mitigation of early infection during the bacteremic phase.

The strategic use of **long-acting antibiotics** has shown success in this respect. On farms with enzootic disease, benzathine penicillin administered at 3 weeks of life has been shown to result in a marked decrease in the incidence of subsequent clinical disease.[5] The use of long-acting tetracyclines has the additional advantage of protecting against infection with the agent of tick-borne fever as well as *S. aureus* infection; two treatments of lambs, the first between 1 and 3 weeks of age and the second between 5 and 7 weeks, has been shown to result in a significant reduction in morbidity and mortality.[1] In addition, the treatment has been accompanied by increased weight gain.

Tick control by dipping lambs in an organophosphatic insecticide every 3 weeks significantly reduces the incidence of clinical disease and increases weight gain of clinically normal lambs. Separation of the lambs for dipping has not been associated with problems of mis-mothering.[1]

Pour-on preparations on the lambs are also successful.[2] A combination of antibiotic and acaricide treatment may be the most effective and in one trial reduced losses from 10.3% to 0.6%.[2] Dipping the whole flock in an acaricide in spring, whereas it will not completely eradicate tick infestation, will reduce the incidence of tick pyemia.

Pyemic infection with *S. aureus* is also recorded in association with tick infestation in camels in Saudi Arabia.[6]

EXUDATIVE EPIDERMITIS (GREASY PIG DISEASE)

Synopsis

Etiology *Staphylococcus hyicus*
Epidemiology Affects suckling and weanling piglets under 6 weeks of age; peak incidence under 1 week of age. Morbidity 20–100%; case fatality 50–75%. Organism carried by sow
Signs Marked cutaneous erythema and pain, dehydration, extensive greasy exudate; peracute cases die; less severe cases may survive
Clinical pathology Bacterial culture of skin
Necropsy findings Exudative epidermitis; degenerative changes in kidney
Diagnostic confirmation Culture of organism
Differential diagnosis See Table 16.3
Treatment Penicillin parenterally
Control Sanitation and hygiene of pens. In outbreaks, isolate affected piglets and sows

ETIOLOGY
The condition of exudative dermatitis is similar to staphylococcal scalded skin syndrome in humans associated with *S. aureus*.[1]

Staphylococcus hyicus is the cause of exudative epidermitis in suckling and weaned piglets.[2] It also causes several other diseases sporadically in different animal species; bacteriuria in pigs, polyarthritis in pigs,[3] abortion in pigs, flank biting and necrotic ear lesions,[4] and pneumonia.[5]

In other species it has been associated with skin infections in horses, donkeys, and cattle, subclinical mastitis in cows and osteomyelitis in heifers.[2]

A second species, *Staphylococcus chromogenes*, is part of the normal skin flora of pigs,[6,7] cattle, and poultry. It had been considered nonpathogenic until exudative epidermitis was associated with it in 2005.[8] These strains also produced exfoliative toxin type B (ExLB), which was identified by PCR.

EPIDEMIOLOGY
Occurrence
Most cases of exudative epidermitis occur in suckling and weaned piglets under 6 weeks of age, with a peak incidence in piglets under 1 week. Occasionally groups of pigs up to 3 months of age may be affected. Within litters the incidence is high, often all piglets being affected. The morbidity will vary from 20–100% and the case fatality rate from 50–75%. The organism has been isolated from the joint fluid of lame pigs affected with arthritis.[3] In 28% and 26% of studies of cases of exudative epidermitis[9,10] no cases of toxigenic *S. hyicus* could be detected. In a recent study of 314 cases in Denmark it was shown that 20% had exfoliatum toxin A, 33% had B, 18% had C, and 22% had D in 60% of cases of exudative epidermitis investigated.

Method of transmission
The source of the organism is unknown but the gilt or sow is probably an inapparent carrier. It can be isolated from the skin of healthy in-contact piglets and healthy sows.[11] It can be frequently isolated from the vagina of prepubertal gilts and the majority of the litters from the same gilts may be colonized by the organism within 24 hours after farrowing.[12] The maternal strains of *S. hyicus* persisted on the skin of the offspring piglets for the first 3 weeks of the piglets' life – the critical period for outbreaks of exudative epidermitis.[12] The organism has also been isolated from the atmosphere of buildings housing affected pigs. Bacteriophage

Table 16.3 Differential diagnosis of diseases of swine with skin lesions

Disease	Epidemiology	Clinical and laboratory findings	Response to treatment
Swine pox	Mainly suckling piglets. High morbidity but low mortality except in very young piglets. Usually associated with swine louse infestation	Papules, vesicles, and circular red-brown scabs on ventral belly wall and over the sides and back. Pox characteristics	None required except for insect and louse control. Spontaneous recovery in 3 weeks
Skin necrosis	Suckling piglets. High morbidity with abrasive flooring	Abrasion and necrosis starting shortly after birth and reaching maximum severity at about 1 week. Anterior aspect of carpus more common site but also fetlock, hock, elbow, and coronet. Bilateral. Necrosis and erosion of anterior two or three pairs of teats	Usually none required. Recovery 3–5 weeks. Protect area with tape if severe, plus topical antiseptics. Teat necrosis will render animal unsuitable for selection and breeding. Correction of flooring
Exudative epidermitis (greasy pig disease)	Entire litters of sucklings pigs, most severe under 1 week of age, occurs up to 10 weeks, high case fatality in younger pigs	Marked cutaneous erythema with seborrhea, severe dehydration, and death in piglets under 10 days. Older piglets covered with greasy exudate and recover. *Staph. hyicus* on culture	Piglets under 10 days of age die in spite of therapy. Older pigs may survive with penicillin treatment topically and parenterally
Dermatosis vegetans	Inherited and congenital, high morbidity. High case fatality by 8 weeks	Erythema and edema of coronets, uneven brittle hooves, dry brown crusts on belly wall, giant cell pneumonia. Club foot	None indicated. Genetic control
Ptyriasis rosea	One or more piglets in litter after weaning. High morbidity, nil mortality	Lesions begin as small red flat plaques which enlarge from 1 to 2 cm diameter with a prominent ring of erythematous skin covered in center by thin, dry, brown, loose scales. Lesions usually coalesce forming a mosaic pattern, especially on belly. Scraping negative. No growth depression	None required. Emollient to soothe the lesion. Recovery occurs in 4–8 weeks
Parakeratosis (zinc deficiency)	Weaners and feeder pigs on diet low in zinc and high in calcium. Herd problem, high morbidity, no mortality	Erythematous areas on ventral abdomen and symmetrically over back and legs develop into thick crusts and fissures. No pruritus. Skin scrapings negative. Growth rate depression	Add zinc to diet 100 ppm. Adjust calcium. Recovery in 2–6 weeks
Ringworm	Feeder and mature pigs. Usually several pigs within pen or shed. High morbidity with *M. nanum* in sows	Centrifugally progressing ring of inflammation surrounding an area with scabs, crusts, and brown or black exudate. May reach large size. Bristles usually intact. No pruritus. Positive skin scrapings and hair. No ground depression	Fungicides. In growers spontaneous recovery in 8–10 weeks if well nourished. *M. nanum* in sows is persistent and responds poorly
Facial dermatitis	Suckling piglets. High incidence in litters associated with fighting. Low mortality	Lesions on cheeks – usually bilateral abrasions which become infected. Scabs hard and brown and difficult to remove. Overlie a raw shallow bleeding ulcer. Occasional extension to other areas	Usually none indicated. Topical antibacterials. Clip teeth at birth
Ulcerative granuloma	Young pigs but all ages. Sporadic Infection following abrasion. Poor hygiene	Large swollen tumorous mass with several discharging sinuses. Central slough and ulcer	Fair, depending on site. Surgical removal and/or sulfadimidine and streptomycin
Sarcoptic mange	All ages of pigs. Herd problem. Reservoir of infection in sows. High morbidity. Nil mortality	Intense pruritus. Mites on scraping. Erythematous spots with scale and minor brown exudation. Especially evident in thin skin areas. Secondary trauma to skin and bristles from rubbing. If severe, intense erythema. Chronic infections, thickening and wrinkling of skin. Depression of weight pain	Good response to vigorous therapy with ascaricides. Treat on herd basis
Allergic dermatoses to *Tyroglyphus* spp. (harvest mites)	Weaner and feeder pigs few weeks after eating dry ground feed from autonomic feeders	Pinpoint erythematous spots and fragile scales. Intense pruritus. Skin scraping positive for mites	Spontaneous recovery common. Insecticide effective
Eysipelas	Feeder and adult pigs, occasionally weaners. Variable morbidity. Low mortality if treated early	Small red spots developing to characteristic rhomboidal lesion raised and red in color. Lesions may become joined and lose their characteristic shape. Progress to necrosis and desquamation. Fever and other signs of septicemia	Penicillin

typing of *S. hyicus* subsp. *hyicus* isolated from pigs with or without exudative epidermitis revealed two or more phage patterns in the isolates from each pig with the disease and a single-phage pattern in isolates from healthy pigs.[13,14]

Risk factors

Animal risk factors

Field evidence suggests that environmental stress of various kinds, including agalactia in the sow and intercurrent infection, predisposes to the disease. Lesions commonly develop first over the head, apparently in association with bite wounds, which occur when the needle teeth have not been cut or have been cut badly. Other factors include fighting following mixing of litters, excessive humidity over 70%, and following sarcoptic mange. The presence of the disease in a swine herd can account for a 35% reduction in the margin of output over feed and veterinary costs over a 2-month period.

Pathogen risk factors

Strains of *S. hyicus* can be divided into virulent and avirulent strains with regard to ability to produce exudative epidermitis in experimental piglets; both types of strain can be isolated simultaneously from diseased piglets.[4] It has been shown that different types of *S. hyicus* expressing different types of toxin may be present in the same diseased pig.[10]

S. hyicus produces an exfoliative toxin that can be used to reproduce the disease.[15,16] There are several toxins, including ExLA, ExLB, ExLC, ExLD, SHETa, and SHETb.[17] The exfoliative toxins from isolates from different countries have recently been described.[18] Strains of the organism isolated from a large number of Danish pig herds indicated different electrophoretic motility and plasma-mediated antibiotic resistance patterns.[19] The antibiotic and plasmid profiles of strains isolated from pig herds may be a reflection of the use of antibiotics in those herds.[20] Different types of toxin are produced.[21–23]

Recently the genes encoding for the exfoliative toxins SHETb, ExLA, ExLB, ExLC, and ExLD have been identified[24] and sequenced.

The condition has been seen more frequently in cases of PRRS and PCV2 infections.[25,26]

The organism has been found as a frequent inhabitant of the skin of cattle and has been isolated from cattle with skin lesions.[27,28] Naturally occurring lesions of dermatitis of the lower limbs of horses[29] and similar lesions over the neck and back of donkeys[30] have been recorded. Experimentally, the organism can cause lesions in horses similar to those of exudative epidermitis. A concurrent infection with *Dermatophilus congolensis* has also been reported.[31]

PATHOGENESIS

S. hyicus has cytotoxic activity for porcine keratinocyte cells in culture, which may indicate one of its virulence factors.[31]

The exfoliative toxins are actually epidermolysins[32] that are active against desmoglein-1, which is a desmosomal cadherin-like molecule[33] involved in cell-to-cell adhesion.[34] The ExLs can cause blister formation in the porcine skin by digesting porcine desmoglein-1 in a similar way to exfoliative toxins of *S. aureus*.

The earliest lesion is a subcorneal pustular dermatitis involving the interfollicular epidermis. Exfoliation follows with sebaceous exudation and formation of a crust. In the well-developed case there is a thick surface crust composed of orthokeratotic and parakeratotic hyperkeratosis and neutrophilic microabscesses with numerous colonies of Gram-positive cocci.[35]

Although the principal lesion is an inflammatory–exudative reaction in the corium and upper layers of the epidermis, the disease is probably a systemic rather than a local one. Experimental infection of gnotobiotic pigs leads to dermatitis of the snout and ears, then the medial aspect of the thighs, the abdominal wall and the coronets. The lesions can be produced experimentally by using crude extracellular products and a partially purified exfoliative toxin.[36]

CLINICAL FINDINGS

The morbidity varies from 10–100% and the mortality from 5–90%, with an average of 25%.[35]

In the peracute form, which occurs most commonly in piglets only a few days of age, there is a sudden onset of marked cutaneous erythema, with severe pain on palpation, evidenced by squealing. Anorexia, severe dehydration, and weakness are present and death occurs in 24–48 hours. The entire skin coat appears wrinkled and reddened and is covered with a greasy, gray-brown exudate that accumulates in thick clumps around the eyes, behind the ears, and over the abdominal wall. In the less acute form, seen in older pigs 3–10 weeks of age, the greasy exudate becomes thickened and brown and peels off in scabs, leaving a deep-pink-colored to normal skin surface. There is no irritation or pruritus. In the subacute form, the exudate dries into brown scales that are most prominent on the face, around the eyes, and behind the ears. In a small percentage of pigs the chronic form occurs and the course is much longer; there is thickening with wrinkling of the skin and thick scabs that crack along flexion lines, forming deep fissures. Most peracute cases die, while piglets with the less severe forms will survive if treated. Some pigs are affected with ulcerative glossitis and stomatitis.

Abortion in a sow has been attributed to the organism.[37]

CLINICAL PATHOLOGY

Bacterial examination of skin swabs may reveal the presence of *S. hyicus*. A phage typing system can be used to determine the presence of virulent strains and to distinguish them from less virulent strains.[14]

NECROPSY FINDINGS

Necropsy of these dehydrated, unthrifty piglets often reveals a white precipitate in the renal papillae and pelvis. Occasionally this cellular debris causes ureteral blockage. Some piglets also have a mild ulcerative glossitis and stomatitis. Microscopically, there is separation of the cells of the epidermis in the upper stratum spinosum, exfoliation of the skin, erythema, and serous exudation. The crusting dermatitis features a superficial folliculitis and a hyperkeratotic perivascular dermatitis with intracorneal pustules and prominent bacterial colonies. Degenerative changes are visible in the renal tubular epithelium.

Samples for confirmation of diagnosis

- Bacteriology – samples of acute skin lesions (CULT). The organism forms 3–4 mm white, nonhemolytic colonies on blood agar. It is catalase- and mannitol-negative but hyaluronidase-positive
- Histology – formalin-fixed skin (multiple sites), kidney (LM).

A PCR is available but requires a pure culture and large numbers of organisms to be successful.

DIFFERENTIAL DIAGNOSIS

Exudative epidermitis may resemble several skin diseases of pigs of all age groups (Table 16.3). However, in exudative epidermitis there is no pruritus or fever. Careful gross examination of the lesions, particularly their distribution, the state of the hair shaft, the character of the exudate and the presence or absence of pruritus must be considered, along with skin scrapings and biopsies.

TREATMENT

Experimentally infected piglets respond favorably to a topical application of cloxacillin 10 000 IU/g of lanolin base and 1% hydrocortisone combined with parenteral cloxacillin. Treatment must be administered as soon as the lesions are visible. Procaine benzylpenicillin at a dose of 20 000 IU/kg BW intramuscularly daily for 3 days is also recommended. The antimicrobial sensi-

tivities determined in one field investigation revealed that all isolates were sensitive to novobiocin, neomycin, and cloxacillin. Novobiocin may be the antimicrobial of choice since staphylococci are universally sensitive to this antibiotic.[38] However, there is no available information on the efficacy of antimicrobials for naturally occurring cases of exudative epidermitis. A study has suggested that erythromycin, sulfathiazole, and trimethoprim may be the most useful drugs, whereas penicillin and tetracyclines may not be very useful.[39] Naturally occurring cases in piglets under 10 days of age respond poorly, while older pigs recover with a skin wash using a suitable disinfectant soap. The most successful treatment is antibiotics and skin washing for a period of at least 5–7 days. It is also essential to make sure that there is sufficient dietary provision of zinc, biotin, fat, selenium, and vitamin E in the diet.

CONTROL

The infected accommodation should be cleaned, disinfected and left vacant before another farrowing sow is placed in the pen. Strict isolation of the affected piglets and their dam is necessary to prevent spread throughout the herd. Dead piglets should be removed promptly from the premises and in-contact sows should be washed with a suitable disinfectant soap. Maternal antibodies will protect piglets in the first few weeks of life.

Autogenous **vaccines** have been used with varying degrees of success. It is important to use a strain that produces the exfoliative toxin, so the recent development of PCRs that identify the genes for toxin development will ensure that the right isolate is used for the autogenous vaccine. It will also facilitate the development of a commercial vaccine.

A novel approach to the control is **bacterial interference**. Experimentally, the precolonization of the skin of gnotobiotic piglets with an avirulent strain of *S. hyicus* will prevent the experimental reproduction of the disease with the virulent strain of the organism.

Diseases associated with *Corynebacterium, Actinobaculum,* and *Arcanobacterium* species

Arcanobacterium pyogenes

Arcanobacterium (formerly *Corynebacterium* or *Actinomyces*) *pyogenes* is an ubiquitous organism and is the primary cause of, or a secondary invader in, a wide variety of pyogenic infections in ruminants, pigs and, occasionally, horses.[1] It is present in the environment, in the intestinal tract, and may be carried in the tonsils of healthy cattle.[2]

The organism gains access to the body through contaminated abrasions, wounds, or insect bites and the infection may remain localized in the form of a **subcutaneous abscess** with inflammation of the draining lymph node or it may proceed to a **bacteremia** with internal localization. Internal abscessation is frequently clinically silent but is important in food quality. The organism is a cause of **endocarditis** and commonly present in necrotizing pneumonias. It is a common isolate in omphalophlebitis and is also a cause of septic arthritis in calves.

A. pyogenes is a common isolate from iatrogenic syndromes such as frontal sinusitis following dehorning, injection site abscess, and surgical wound infections. Extensive subcutaneous abscessation and suppurative cellulitis occurs in **buller feedlot cattle** as a result of multiple skin abrasions.

A. pyogenes is a common isolate from **intracranial and spinal abscesses**, which may result from hematogenous spread, in association with parasitic migration or from invasion from surrounding structures. Outbreaks of spinal abscessation can occur in conjunction with **tail-biting** in pigs and ear abscessation as a result of ear-biting. A seasonal occurrence of intracranial abscessation occurs in male deer during the period following velvet shedding to the time of antler casting and is associated with wounds and fractures of the antler pedicle.[3] *A. pyogenes* is one of the more common organisms isolated from osteomyelitis in cattle and is also the common isolate from pituitary abscesses.

A syndrome of chronic rhinitis and sinusitis with unilateral or bilateral foul-smelling nasal discharge is reported affecting dairy cattle in three herds in the UK. Contamination of feed by the discharge resulted in food refusal. There was no evidence of predisposing common respiratory viral or other bacterial infection.[4]

The organism is sensitive to penicillin but infections with *A. pyogenes* are **poorly responsive** to antimicrobial therapy despite in vitro sensitivity and usually require surgical drainage in combination with antibiotic therapy. Resistance to tetracyclines and tylosin is more prevalent in isolates from animals in which these antimicrobials are used for growth promotion and disease prophylaxis.[5]

Vaccines against the organism are commercially available in most countries but there is little evidence that they induce protective immunity against infection or the pyogenic process.[6]

The role of *A. pyogenes* in the production of **mastitis** in cattle is described in Chapter 15, as a secondary invader in calf and sheep **pneumonia** in the descriptions of the viral pneumonias of calves and sheep, and in **foot abscess** of sheep under that heading.

Corynebacterium pseudotuberculosis

Corynebacterium pseudotuberculosis is a soil-borne organism and causes caseous lymphadenitis in sheep and goats, ulcerative lymphangitis in cattle and horses, and also external and internal abscesses in horses. The organism possesses a cytotoxic surface lipid coat that appears to facilitate intracellular survival and abscess formation and produces a phospholipase exotoxin that increases vascular permeability, has an inhibitory effect on phagocytes, and may facilitate spread of infection in the host. There are two biotypes, with the ovine and caprine isolates a different biotype from equine and cattle isolates.

The important specific diseases associated with *Arcanobacterium, Corynebacte-*

rium, and *Actinobaculum* spp. are described later in this section. Other minor diseases include the following.

METRITIS AND ABORTION

A. pyogenes is an important cause of **postpartum metritis** and infertility in cattle and sheep.[7–10]

Cows are infected soon after calving and infection is frequently accompanied by infection with the Gram-negative anaerobes *Fusobacterium necrophorum* and *Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*), which act synergistically, enhancing the growth and pathogenicity of each other.[11] However, the inoculation of pure cultures of *A. pyogenes* into the nonpregnant uterus is followed by the development of endometritis with a persistent corpus luteum.[12] With natural cases, infections are more common after the retention of fetal membranes. Isolation of *A. pyogenes* from the uterus during the postpartum period is significantly associated with endometritis, pyometritis and purulent discharge, resulting in an increase in time to first service, more services to conception, an increase in days open and an increase in cows culled because of infertility.[7,9,10,13] Oxytetracycline is commonly used in therapy but minimum inhibitory concentrations (MICs) of various antibiotics for isolates from the uterus of cattle suggest that cephalosporins would be more effective.[14]

The organism is also a cause of **abortion**.[9,15] The fetus is autolyzed but the organism can be isolated from all internal organs and the placenta. Abortion can occur at any stage of pregnancy and has been reproduced experimentally in early pregnancy and in mid-gestation.[16] The prevalence of abortion associated with this organism is low and it accounts for fewer than 5% of abortions in cattle.[9,15,16] The examination of a placentome in addition to the aborted fetus improves the accuracy of diagnosis.[17] An unidentified *Corynebacterium*-like organism tentatively identified as *Arcanobaculum pluranimalium* has been isolated from the placenta and stomach contents of lambs in cases of sporadic abortion in sheep.[18,19]

PERINATAL DISEASE

A. pyogenes and *Actinobaculum suis* are occasional causes of perinatal septicemia and polyarthritis in calves, lambs, and foals.[20,21]

ARTHRITIS AND BURSITIS

Corynebacterium pseudotuberculosis has been determined to cause a nonsuppurative arthritis and bursitis in lambs. The joints are only slightly enlarged and many animals show only mild clinical signs. Recovery occurs if the lambs are fed and confined.

PERIODONTAL DISEASE: CARA INCHADA

A. pyogenes and *P. melaninogenica* have been isolated from periodontal lesions occurring in young cattle grazing new pastures sown in recently cleared forest areas in Brazil. The cause of the disease is uncertain and multifactorial but enzymes and toxins from these organisms are stated as being capable of causing primary destruction of periodontal tissue.[22] Cattle are affected at an age when premolar and molar teeth erupt. Trace element deficiencies have been suspected of predisposing to the disease but are not proven to do so. One theory is that there is a large increase in *Actinomycetes* in soil following the clearance of the forest, that these produce antibiotics, mainly streptomycin, and that the ingestion of subinhibitory concentrations of these predisposes to adherence of bacteria to the gingival epithelium. The disease has markedly decreased in incidence in recent years as forest clearing and the occupation of virgin land for cattle raising has almost ceased.[23] Cara inchada is manifest with a purulent periodontitis, halitosis, progressive loss of premolar teeth, mainly of the upper jaw, and emaciation. In risk areas attack rates and case fatality rates are high. The disease can be suppressed by including spiramycin or virginiamycin in the mineral mix fed to the cattle.

CHRONIC PECTORAL AND VENTRAL MIDLINE ABSCESS IN HORSES (PIGEON FEVER)

In California,[24,25] Texas,[26] and Colorado,[27] *C. pseudotuberculosis* has been associated with a high regional prevalence of chronic abscessation in horses. There is no apparent breed or sex predisposition and cases occur in horses of all ages, but the majority are adult horses and there are few cases under 1 year of age. Usually, only a single horse on a farm is affected. A small proportion of farms have endemic infection, with a prevalence of disease of 5–10% and recurrent infections each year. In some years spread to naive horses results in epidemic disease. Cases can occur in all months of the year but are most common in dry months in autumn, with a peak prevalence in September, October, and November.[17] There is a variation in the prevalence from year to year and, in both Texas and California, years with high prevalence of the disease have been preceded by seasons with higher than normal rainfall and conditions that promote high insect populations. Insects, such as horn flies (*Habronema irritans*), that produce a ventral midline dermatitis during feeding may predispose to infection, and the organism has been detected by PCR populations of *H. irritans*, *Stomoxys calcitrans*, and *Musca domestica*.[28] Patterns of spatial and temporal clustering indicate that disease is transmitted directly or indirectly from horse to horse with an incubation period of 3–4 weeks.[25] The disease occurs in a region where caseous lymphadenitis is also common in sheep. Stable hygiene, insect control and isolation of infected horses may aid in control.[25]

External abscesses

These occur in a variety of areas on the body but in the majority of cases they are in the pectoral, axillary, inguinal, or ventral midline regions.[24] The abscesses may reach a diameter of 10–20 cm, with a surrounding area of edema, before they rupture 1–4 weeks later. Clinical signs include local swelling, lameness, pain on palpation, ventral edema, reluctance to move, midline dermatitis, fever and depression in the early stage, and eventually rupture of the abscesses.

Treatment of external abscesses is by hot packs to encourage opening and by surgical drainage and lavage. Ultrasound can aid in the detection of deeper abscesses. NSAIDs can be used to control swelling and pain. Recovery rates are excellent and are not improved by antimicrobial therapy.[24]

Internal abscesses

These occur at a variety of sites but predominantly in the liver and can occur in horses with no external abscessation. The diagnosis should be suspected in horses, in the region and the season, with a clinical history of external abscess, fever, anemia and colic, and laboratory evidence of leukocytosis with neutrophilia, anemia, hyperglobulinemia and hyperfibrinogenemia, and elevated activity of hepatic-associated enzymes. Abdominocentesis in most cases shows an elevated protein and nucleated cell count, and the organism can be cultured.[24] Treatment is with antimicrobial therapy but the case fatality rate is high.

The value of a synergistic hemolysis inhibition serological test in diagnosis has been examined.[24] In horses with external abscesses a range of titers was found but high titers were found in horses with internal abscessation.[24]

An autogenous vaccine has given protection against experimental challenge but, in field trials, there has been no difference in the incidence of infection between vaccinated and control horses.[29]

C. pseudotuberculosis is also recorded as a cause of pericarditis and pleuritis in a

horse[30] and in association with suppurative facial dermatitis following trauma.[31]

CONTAGIOUS BOVINE PYELONEPHRITIS

Synopsis

Etiology *Corynebacterium renale*
Epidemiology Organism is present in the vagina of carrier animals. Infection spread, and disease initiated, by trauma such as breeding or catheterization
Clinical findings Periodic episodes of hematuria, pyuria, colic, straining to urinate, fever, loss of condition. Palpable abnormality on rectal examination. Cystitis determined by endoscopic examination, pyelonephritis by renal biopsy and ultrasound examination
Clinical pathology Urine pH alkaline. Pyuria on microscopic examination. Elevated blood creatinine and urea concentrations
Necropsy findings Cystitis and pyelonephritis
Diagnostic confirmation Gross changes in urine, together with palpable abnormalities in the urinary tract and the presence of bacteria including *C. renale* in the urine
Treatment Prolonged course of penicillin. Nephrectomy
Control Avoidance of urinary catheterization. Artificial insemination

ETIOLOGY

Corynebacterium renale, the specific etiological agent, has three serotypes of which types I and III appear to be the most pathogenic. Piliated forms occur and may be important in attachment to the epithelium in the reproductive and urinary tract.[1,2] *Corynebacterium pilosum* and *Corynebacterium cystitidis* are commonly isolated in conjunction with *C. renale* but are considered part of the normal flora of the vulva.

Corynebacterium pseudotuberculosis, *Arcanobacterium pyogenes*, *Actinobacillus equuli*, *Escherichia coli*, and *Staphylococcus aureus* are sometimes found in the urinary tract of cattle and pigs affected with pyelonephritis, either alone or associated with *C. renale*. Of these organisms, *E. coli* in particular is considered a separate cause of pyelonephritis in the cow.[3]

C. renale has little apparent resistance to physical or chemical agents and can survive in soil for at least 56 days.[3]

Infection with *C. renale* may stimulate production of antibody that gives cross-reactions with the complement-fixing test for Johne's disease.

EPIDEMIOLOGY

Occurrence

The disease is widespread in Europe, North America, Australia, Africa, Japan, and Israel and probably occurs in all countries, although it seldom constitutes an important problem in any herd or area. As a rule, clinical cases are **sporadic**, even in herds found to harbor a significant number of carriers. Differences in disease prevalence probably reflect differences in management. One study in seven herds found an annual incidence that varied from 0.5–1.5% and in one herd was 16%.[4] Subclinical infection may be more frequent than commonly recognized. Chronic cystitis and pyelonephritis (etiology unstated) have been found in 5.3% and 0.2% of cattle at slaughter.[4,5]

Although pyelonephritis is considered to be essentially a bovine disease, sheep are occasionally affected.

Source of infection and transmission

C. renale can be isolated from the urine of affected or **carrier** animals and in Japan has been isolated from the vagina or vaginal vestibule of approximately 6% of **healthy** cows.[6] The incidence of cows excreting *C. renale* in their urine is higher in herds where the disease occurs than in herds where the disease is unknown. *C. renale* is present in the urinary tract of other animals, including rodents, and can be isolated from dust and the environment of infected animals.[7]

In cattle, infection can be **transmitted** by direct contact, by the use of contaminated brushes or by the careless use of **catheters**. A change in the policy of catheterizing cows with suspect ketosis for the collection of urine can be associated with a fall in the incidence of the disease.

There is a strong inference that in some circumstances the disease, or the infection, can be spread **venereally**. This is suggested by the occasional occurrence of a series of cases in a herd, usually related to the use of a particular bull,[8] and the cessation of cases when artificial insemination is used. The organism can often be isolated from the prepuce, urethra, and semen of bulls that have no detectable lesions in the prepuce. *C. renale* can be a cause of balanoposthitis in bulls.

Risk factors

Cattle are seldom affected before maturity and cows appear to be much more susceptible than bulls. In cows, clinical cases are more common in early lactation. **Mature cows** of all ages are susceptible but in one study there was a significantly higher risk for disease in cows in their second lactation.[4] An increase in clinical cases is usually found in the colder seasons of the year and heavily fed, high-producing dairy herds appear to show an increased susceptibility.

A significant decreased risk for pyelonephritis has been found for cows that have postparturient uterine disease, which may be associated with the treatment of these cows with antibiotics.

Bulls can be predisposed to pyelonephritis by obstructive urinary abnormalities.[9]

In Israel, the ingestion of rock rose (*Cistus salvifolius*) is reported to produce urinary retention and predisposes to pyelonephritis.[10]

Experimental production

The disease can be reproduced by inoculation of the organism into the urethra.[11,12] It can also be reproduced by intravenous challenge, although the vulva is believed to be the natural portal of entry. Although not intentionally produced, the disease occurred in 10% of a group of cattle used to teach veterinary students the technique of urinary catheterization.

Economic importance

Unless appropriate treatment is instituted early, the disease is highly fatal and economic loss is due mainly to the deaths of affected animals.

PATHOGENESIS

Pyelonephritis usually develops as an **ascending infection** involving successively the bladder, ureters, and kidneys. Trauma to the urethra, or urine stasis, may facilitate ascending infection. The destruction of renal tissue and obstruction of urinary outflow ultimately result in uremia and the death of the animal.

Piliated and nonpiliated forms of *C. renale* are present in infected animals but

their relative importance to the pathogenesis of the disease is uncertain. Piliated forms of *C. renale* have a greater ability to attach to urinary tract epithelium, are more resistant to phagocytosis and are probably important to carriage of the organism and to the initial ascending infection.[11] However, in the course of an infection there is a shift from piliated to nonpiliated forms, which may reflect a response to the development of antipilus antibody.[13]

CLINICAL FINDINGS

Early signs vary considerably from case to case.[14] The first sign observed may be the passage of **bloodstained urine** in an otherwise normal cow. In other cases, the first sign may be an attack of acute **colic**, manifest by swishing of the tail, treading of the feet and kicking at the abdomen, and straining to urinate, the attack passing off in a few hours. Such attacks are caused by obstruction of a ureter or renal calyx by pus or tissue debris and may be confused with acute intestinal obstruction. More often the onset is gradual with a **fluctuating temperature** (about 39.5°C, 103°F), **capricious appetite**, loss of condition and **fall in milk yield** over a period of weeks. Other than this, there is little systemic reaction and the diagnostic signs are associated with the urinary tract.

The most **obvious sign** is the presence of **blood, pus, mucus, and tissue debris in the urine**, particularly in the last portion voided. Urination is frequent, may occur in a dribble rather than a stream, and may be painful. Periods during which the urine is abnormal may be followed by apparent recovery with later remissions.

In the early stages, **rectal examination** may be negative but later there is usually detectable thickening and contraction of the bladder wall and enlargement of one or both ureters. These are not normally palpable but in chronic cases may be felt in their course from the renal pelvis of the left kidney to the bladder. The terminal portion of the ureters may also be palpated through the floor of the vagina over the neck of the bladder. The palpable left kidney may show enlargement, absence of lobulation and pain on palpation, and the right kidney may be palpable if it is significantly enlarged.[14] In many cases there are no distinct clinical signs referable to the urinary tract and the history and clinical signs may be of weight loss and suspected gastrointestinal disease. In these cases examination of the urine is essential to diagnosis.

Endoscopic examination of the urethra and bladder can be diagnostic. Ultrasound examination shows a reduction in renal pelvis diameter, a reduction in renal parenchyma and the bladder wall is hyperechoic.

The course is usually several weeks or even months and the terminal signs are those of uremia.

CLINICAL PATHOLOGY

There is proteinuria and hematuria. Urine pH is greater than 8.5 and the specific gravity has been recorded between 1.008 and 1.021.[14] **Microscopic examination** will show pyuria. The presence of *C. renale* in suspected urine can be confirmed by **culture**, specific immunofluorescence[7] or direct microscopic examination.

There may be hypoalbuminemia and hypergammaglobulinemia. Neutrophilia may be present but is not constant in all cases. There is an elevation of serum creatinine and urea, and concentrations above 1.5 mg/dL and 100 mg/dL, respectively, carry a grave prognosis.[4]

Renal biopsy[15] and **ultrasound**[16] can aid in diagnosis. Ultrasound may demonstrate a dilated renal collecting system containing echogenic material and can be an aid in the determination of the severity of the disease.

NECROPSY FINDINGS

The kidneys are usually enlarged and the lobulation less evident than normal. The renal calyces and grossly enlarged ureters contain blood, pus, and mucus. Light-colored necrotic areas may be observed on the kidney surface. Changes visible on the cut surface include excavation of papillae, abscessation and wedge-shaped areas of necrosis that extend from the distal medulla into the cortex. The bladder and urethra are thick-walled and their mucous membranes are hemorrhagic, edematous and eroded. Histologically, the renal lesions are a confusing mixture of acute suppurative changes and various degrees of fibrosis with mononuclear cell infiltration.

Samples for confirmation of diagnosis

- Bacteriology – kidney; culture swab from ureter (CULT)
- Histology – formalin-fixed kidney, ureter, bladder (LM)
- Clinical pathology – 1 mL aqueous fluid from eye (BUN).

TREATMENT

Although several antibiotics appear to inhibit *C. renale*, penicillin remains the antibiotic of choice for treatment of pyelonephritis. Large doses (15 000 IU/kg BW of procaine penicillin G) are recommended daily for at least 3 weeks.[3] In early cases where little structural damage has occurred, permanent recovery can be expected following such a course of treatment.[14] In general, a good prognosis is suggested by an improvement in condition, appetite and milk yield and clearing of the urine. However, in well-established cases, relapse is not uncommon and, where tissue destruction has been extensive, relief through antibiotic therapy is only temporary. In valuable animals, where ultrasound has established the diagnosis, unilateral nephrectomy may be an alternative and the surgical technique has been described.[16]

DIFFERENTIAL DIAGNOSIS

Cases characterized by acute colic can be differentiated from acute intestinal obstruction by the absence of a palpable obstruction and the disappearance of abdominal pain within a few hours. Chronic cases may be confused with traumatic reticulitis but may be differentiated by the urine changes present in pyelonephritis.

Sporadic cases of nonspecific cystitis can only be differentiated by culture of the urine.

Polypoid cystitis is a nonspecific result of bladder inflammation and may be a cause of dysuria and obstructive uropathy.[17,18] The differential diagnosis is best made by endoscopic examination, which reveals multiple frond-like fungiform polyps and papillae on the bladder wall.

CONTROL

No specific control measures are usually practiced but isolation of affected animals and destruction of infected litter and bedding should reduce the population of the organism in the local environment and minimize the opportunity for transmission. Procedures such as urinary catheterization should be avoided and routine vaginal examinations should be conducted with proper hygienic precautions. Where natural breeding is practiced, some reduction in occurrence may be achieved by the introduction of artificial insemination.

CYSTITIS AND PYELONEPHRITIS OF SOWS

Synopsis

Etiology *Actinobaculum suis* (*Eubacterium suis*, *Corynebacterium suis*) is the specific cause but a range of other bacteria (principally *Escherichia coli*) may also cause the condition
Epidemiology Infection of male pigs causes the disease in sows. Organism is in the prepuce and environment. Transmission is venereal and through dirty farrowing houses. Trauma to the urogenital tract of females predisposes to disease
Clinical findings Unexpected death in acute cases. Pain on urination, bloodstained, turbid urine accompanied by vaginal discharge. Cystitis on endoscopic examination
Clinical pathology Hematuria, pyuria, proteinuria, bacteremia. Urine pH >8.5. Demonstration of organism by culture or immunofluorescence. Azotemia, increased concentrations of urea and creatinine, hyperkalemia and hyponatremia
Necropsy findings Purulent cystitis and pyelonephritis
Diagnostic confirmation Urinalysis, endoscopic examination and demonstration of *A. suis*
Treatment Unrewarding unless early in the course of the disease – antimicrobials and supportive therapy. Humane destruction of cases
Control Antimicrobials by injection, in water or in feed. Insure adequate water supply for lactating sows to aid urination and improve postfarrowing hygiene

ETIOLOGY

The disease is associated with a variety of agents. A variety of syndromes associated with different bacteria can be distinguished. Urinary tract infections in sows can be associated with *E. coli* and other bacteria (*Pseudomonas aeruginosa*, staphylococci, streptococci, *Proteus* spp., *Klebsiella* spp., enterococci, and *A. pyogenes*) and infections with most of these organisms result in catarrhal/purulent cystitis.

The specific disease is most commonly associated with *Actinobaculum suis*. This was formerly known as *Eubacterium suis* and before that as *Corynebacterium suis*. This organism is a Gram-positive rod that is difficult and slow to grow and requires special culture media.

All these organisms causing this problem are believed to produce the condition as a result of ascending infection. The disease is a particular problem when sows are in stalls or tethered. The condition may not be so serious when associated with all the species other than *A. suis* and in these cases may be seen as frequent urination, the presence of blood or pus in the urine and a progressive loss of condition.

EPIDEMIOLOGY

The disease occurs in postpubertal sows that have bred.

Occurrence

The infection may be common but the disease is better viewed as sporadic.

The disease is probably worldwide and has been reported from Great Britain, Europe, North America, Asia, and Australia. It occurs both in outdoor and indoor units. There are no measures of prevalence, although it has been described as the most important cause of sow deaths, with up to 25% associated with urinary tract infection.[1] It probably occurs more frequently than is recognized as there is a considerable subclinical infection rate. In a recent study in the USA, *A. suis* was isolated from 4.7% of the bladders of sows collected at random at a slaughterhouse.[2]

In small herds, the disease tends to occur in small outbreaks when a small number of sows become infected after being mated to a single boar. Often, the clinical outbreak may be 2–3 weeks after the use of the suspected boar. More serious outbreaks can occur in large intensive piggeries. The disease can also occur sporadically and be a normal feature of sow mortality.[3]

In a recent study of 1745 pregnant sows 28.3% were found to have urinary infections and *A. suis* was found in 20.6% of these.[4] *A. suis* was less prevalent (13.7%) in the sows with urinary infections than in those without (23.1%). In an abattoir survey in the Netherlands the prevalence of cystitis in slaughtered sows was 11%, with a variation depending on group from 0–35%.[5] In this study of 114 bladders, *A. suis* was not isolated but *E. coli* was the most commonly isolated together with *S. dysgalactiae*, *A. pyogenes*, *Aerococcus viridans*, and *S. suis*.

Source of infection and transmission

A. suis is a normal inhabitant of the porcine prepuce and can be isolated from the preputial diverticulum of boars of various ages.[3,6,7] The prevalence of the infection in adult males may be as high as 90%[3] and the organism can be isolated from the floor of the pens containing infected boars.

Infection and **colonization** of the preputial diverticulum may occur in pigs as early as 5 weeks of age if they are housed with older pigs. Frequently, this infection may occur from pen floor contamination because of poor hygiene. Piglets can also become infected, at an early age, from sows that have chronic cystitis and pyelonephritis, and the infection can spread rapidly to other male pigs when they are grouped at weaning.[8] Although infection is common in the male pig, cystitis and pyelonephritis is extremely uncommon in males. *A. suis* is rarely isolated from the urogenital tract of the healthy female pig.

Clinical disease is almost entirely restricted to the female pig that has bred. **Venereal transmission** is believed to be the primary if not the sole method of infection of the sow.[8,9]

Trauma to the vagina may be an important predisposing factor allowing infection to establish and trauma at parturition with infection from the environment may also be important.

There is no doubt that, where the conditions in stall houses are bad with fecal contamination and poor drainage from the rear half of the stall, perineal and vulval contamination is much greater.

Risk factors

Clinical signs may occur at any age but are common at 3–4 weeks post-service. The disease is more common in sows kept in intensive **confinement** conditions than in those that are kept in open lots, pens, or pasture[10] but it does occur in these systems if the hygiene is poor. Differences in feeding patterns and exercise that occur in the different management systems can influence the **frequency and volume of water intake.** This in turn has an important effect on the frequency of urination and the residual volume of urine in the bladder following micturition, which is one of the factors that may predispose to the establishment of urinary tract infection. Since many lactating sows will only stand when they are fed, usually twice a day, they will also only urinate and drink twice a day. If they cannot take in enough water from either a trough or a tap during this period at the correct flow rate, they may be suffering from an inadequate water intake.[11,12] It has also been shown that crystalluria may well damage the mucosa and aid the formation of cystitis and that the crystals also support infection of the bladder, particularly where there is an insufficient water supply.[13]

Economic importance

In one of the best studies of sow mortality in the UK it was reported that the principal cause of death in up to 25% of the sows was urinary tract infection.[1] If the sow mortality is below 5% then cystitis/pyelonephritis is unlikely to be an important problem in the herd.

Cystitis and pyelonephritis is of great importance as it is a major cause of death (annual death rate may be in excess of 5%)[11] in sows in both Britain[8] and the USA[10] and even more importantly a cause of serious culling as the recommendation is to cull affected sows as they will always be a source of infection. Considerable prevention, treatment and hygiene costs will also ensue.

PATHOGENESIS

In healthy sows *A. suis* can be isolated from the vagina, but not from the bladder, for a short period after an infected service.[8] The factors that allow it to establish in the urogenital tract are unknown but trauma to the vagina and urethral opening and service into the bladder are supposed factors.[6,8] It has been suggested that the other organisms mentioned above may also act synergistically to damage the mucosa and facilitate colonization by *A. suis*.[10] This may be true, as *A. suis* possesses pili by which it attaches to damaged bladder epithelium. Cystitis results in damage to the ureterovesicular junction and there is an ascending infection from the bladder to the kidneys.[14,15] In infected sows, tortuosity of the ureters and blockage of the ureters is fairly common.[8] This and the changes in the kidney may lead to chronic renal failure and even acute renal failure if the blockage is complete and bilateral.

CLINICAL FINDINGS

It is worth remembering that many mildly affected sows may only show transient inappetence, and other animals are recognized because they are uremic. In the more severely affected groups the presentation is either as an acute case, usually post-service, or as a chronic one, which can occur at any time.

Most commonly sows present as **acute renal failure** as they cannot retain sodium and this leads to rises in plasma potassium and sudden death. Sows are suddenly severely ill, unwilling to rise, show profound depression and circulatory collapse and die within 12 hours. In one series of cases, 40% of the affected sows presented as **unexpected deaths** and in the remainder the mean interval between presenting signs and death was 1.6 days with the longest interval 5 days.[8] In a recent study in Ireland[16] the authors reported the condition mainly in fourth parity sows and above.

Where the surveillance is good the sows are observed to be depressed, anorectic, mildly febrile (normal to 39.5°C, 103°F) and sometimes show arching of the back, twitching of the tail and **painful urination**. There is frequent passage of **bloodstained, turbid urine** accompanied by vaginal discharge. Examination with a **vaginal speculum** will confirm the bladder as the source of the bloody discharge.

The case fatality rate is high. Sows that survive the acute disease develop chronic renal failure with weight loss and polydipsia and polyuria.[9] They are usually culled for poor performance.

Endoscopic examination of the bladder in acute cases may show little other than mild inflammation but in more serious cases there are ulcerative and erosive bladder lesions.[17] In sows large enough to allow **rectal examination**, in chronic cases it may be possible to feel the large and thickened bladder and dilated tortuous ureters. Boars are usually unaffected clinically but intermittent, hematuric episodes lasting several days have been recorded.

The condition can be seen as a sequel to any locomotory, particularly central brain or spinal condition in which there is an inability to stand to drink or micturate, e.g. organophosphorus poisoning.[18]

CLINICAL PATHOLOGY

Sows' urine is frequently turbid (83.1%)[4] and usually this can be associated with the presence of crystals (96.1%).[4]

Urinalysis usually shows hematuria, pyuria, proteinuria, and a pronounced bacteriuria (usually in excess of 10^5 cfu/mL of urine). A Gram stain on a smear of the urine or pus may show the organisms. The urine is **alkaline** with a pH of more than 8.5 and usually approaching 9 as a result of the urease, which cleaves urea to produce ammonia. Midstream urine contains 10^5 cfu/mL or more.[19] A number of species of bacteria may be found as suggested in the introduction but *A. suis* requires special culture media.[3,20] It is now possible to use immunofluorescence for a more rapid and specific diagnosis.[21] Examination of blood shows a pronounced **azotemia**, with increased concentrations of urea and creatinine and also hyperkalemia and hyponatremia. *N*-acetyl-B-D-glucosaminidase concentrations are elevated, indicating proximal renal tubular damage.[8]

NECROPSY FINDINGS

A very varied pathology may be visible in these cases. In some sows there may be an extensive purulent nephritis and pyelitis with similar changes in the dilated ureters and the bladder. In others there may be severely hemorrhagic kidneys and blood in the pelvises.

In acute cases the bladder wall is swollen, edematous, and hyperemic and may be covered by a gritty, mucinous material.[2] In others the bladder wall may just be thickened, inflamed and covered by an extensive thick mucus. In some of these cases the ureterovesicular valves may have been completely destroyed by necrosis.[14,15] There may be minimal gross changes in the kidneys in acute cases but there may be microscopic changes of a diffuse tubular and interstitial nephritis. In the chronic case there are ulcerative and erosive lesions in the bladder wall and there may be pus in the bladder, thick-walled ureters and an obvious pyelonephritis.

Samples for the confirmation of diagnosis

- Bacteriology – kidney, bladder, and ureter for aerobic and anaerobic culture and special media for *A. suis*. A special urea-enriched medium[21] in which dry colonies of *A. suis*, about 2–3 mm in diameter, grow after 2 days incubation
- Histology – formalin-fixed bladder, ureter, and kidney
- Clinical pathology – from the eye (BUN).

DIAGNOSIS

Diagnosis is based on high mortality, clinical findings, history of service, clinical pathology, particularly bacteriology, immunofluorescence for specific bacteria, or isolation by culture.

DIFFERENTIAL DIAGNOSIS

- Other causes of sudden and unexpected deaths
- Hematuria
- *Stephanurus dentatus* (where it occurs)
- The separation of the condition associated with *A. suis* from those associated with other bacteria can only be achieved by bacterial culture and other laboratory techniques.

TREATMENT

Early treatment with **antibiotics** is recommended, but if there is acute renal failure then the case fatality rate is high. Penicillin given at 15 000 IU/kg daily for 3–5 days has been successful. The intramuscular injection of streptomycin at 10 mg/kg has also been used successfully.[8] The isolation of other organisms may indicate the need for other broad-spectrum antibiotics. A recent outbreak of cystitis and endometritis[16] associated with a falling conception rate from 88% to 75% and believed to be due to *E. coli* (together with staphylococci and streptococci) was successfully treated with an ammonium chloride urinary acidifier whereas the amoxicillin used previously was without effect. Enrofloxacin at the rate of 10 mg/kg BW in the feed for a period of 10 days has also proved effective, as has 2.5 mg/kg in the food for at least 20 days.

The response can be monitored by the reduction in the urine pH. Treated sows should be loose housed with access to plenty of water. The treatment should be continued for at least 2–3 weeks after the outbreak has appeared to finish clinically. Oral **electrolyte therapy** is also beneficial. In chronic cases the lesions are well advanced and the organisms may be contained in the calculi and then therapy is not successful and relapses may well occur. In many cases **humane destruction**

is the best option especially as it is not possible except in very early cases to eliminate the organism. Preputial washing on a regular basis may prevent the carriage of organisms by boars especially as it has been shown that semen may be frequently contaminated by *A. suis*, and it is said that up to 50% of boars in some studs may be affected.

CONTROL

Routine **prophylactic administration of antibiotics** has proved of little value in the long-term control of the disease. A **temporary solution** has been the use of sow treatment with oxytetracycline followed by in-feed medication with 400 g/ton for 21 days.[11] It is not possible to eradicate the infection from the prepuce of a boar, although daily infusions may help to reduce the infection.[7] Artificial insemination with the semen treated with antibiotics is a further option.

Trauma to the vagina at mating should be reduced by boar management and the supervision of mating. There should be nonslip floors in the service areas. Animals showing distress, pain, or bleeding after mating should be treated.

The service areas should have very good hygiene with regular cleaning and disinfection after every use. The perineal region of each sow should be cleaned before mating. Farrowing accommodation and crates should also be properly **cleaned and disinfected** and allowed to dry before sows are introduced. The major organism (*A. suis*) will persist in bad floors but is susceptible to phenolic, quaternary ammonium and formalin-based products.[9]

Other control procedures involve the provision of an **adequate water intake**. This should preferably be from the mains without impurities or toxins or bacterial contamination. Loose housing and twice-a-day feeding will encourage the consumption of water. The provision of adequate numbers of drinkers for the stage of the breeding cycle, providing the necessary flow rate for each age of pig is essential (at least 1.5 L/min for gestating sows and 2.2 L/min for lactating sows). A simple check on water supply can be to check appetite: if the sows are not consuming 10 kg of food on day 18 of lactation then there is probably something wrong with water provision. Similarly, troughs must contain at least a reasonable supply of water. In the welfare codes all animals have to be provided with a fresh supply of high quality water.

ENZOOTIC POSTHITIS (PIZZLE ROT, SHEATH ROT, BALANOPOSTHITIS); VULVOVAGINITIS (SCABBY ULCER)

Synopsis

Etiology Multifactorial. Organisms that produce urease, usually *Corynebacterium renale*, produce lesions only in certain circumstances of management and urinary composition
Epidemiology Disease of wether sheep and occasional disease of bulls and goats. May occur as enzootic disease in sheep on high-protein diets and following good rains
Clinical findings Pustules and scabs at preputial orifice. Extension to involve internal prepuce in severe disease with signs of urinary obstruction. Ulcers and scabs at mucocutaneous junction of vulva in ewes. Urine staining of wool predisposes to fly strike
Diagnostic confirmation Clinical
Treatment Dietary restriction, topical disinfectants, surgical opening of ventral prepuce
Control Reduction of protein intake, testosterone, hemicastrate or cryptorchid castration

ETIOLOGY

The etiology is **multifactorial**. High urea concentrations in urine, associated with high protein in pasture, result in cytotoxic levels of ammonia when the urea is split by urease-producing organisms present in the prepuce and vagina. Estrogens in pasture, causing swelling and congestion of the prepuce, may predispose to disease. Most commonly the organism is *C. renale* but an outbreak of posthitis in sheep associated with *Rhodococcus equi* and *Corynebacterium hofmannii*, both of which produce urease, and not associated with *C. renale*, is described.[1]

Mycoplasma mycoides LC has also been incriminated as a cause of posthitis and vulvovaginitis in sheep.[2]

EPIDEMIOLOGY

The disease is reported primarily from Australia, South Africa, and South America but occurs in all countries with large pastoral sheep industries.

Host occurrence

Sheep

In Australia, enzootic posthitis occurs most commonly in Merino sheep, particularly **wethers** over 3 years of age and young rams, but in a severe outbreak young wethers and old rams may also be affected. An ulcerative **vulvitis** often occurs in ewes in the same flocks in which posthitis occurs in wethers and is thought to be a venereal extension of that disease. The disease also occurs in **goats**.[3]

Cattle

Posthitis is uncommon in bulls but is reported to occur at high rates and to be economically important in South America.[4] There appears to be no counterpart to ovine vulvitis in cows.

Source of infection and transmission

The causative organism can be recovered from lesions and from the clinically normal prepuce of most sheep. It is also present in the lesions of vulvitis in ewes and posthitis in bulls and Angora goat wethers.

Flies are considered to be probable **mechanical vectors**, and contact with infected soil and herbage is a likely method of spread. Infection at dipping or shearing seems not to be important. Transmission to ewes appears to occur **venereally** from infected rams. Although the natural disease in cattle is usually benign they may act as reservoirs of infection for sheep on the same farm.

Host and environmental risk factors

Diet and season are the major risk factors. Enzootic posthitis occurs most extensively on lush, **improved pasture** with a high **legume** content and reaches its highest incidence in the autumn in summer rainfall areas and in the spring where the major rainfall is in winter. In these circumstances it can occur in epizootic proportions in wethers. The incidence in affected flocks may be as high as 40% and in some areas

the disease is so common that it is not possible to maintain bands of wethers.

Factors of lesser importance are continued wetness of the area around the prepuce due to removal of preputial hairs at shearing, a high-calcium, low-phosphorus diet and the ingestion of large quantities of alkaline water.

The high incidence in castrates and young rams is probably related to the close adherence of the preputial and penile skins, which separate in mature entire animals, and to a lesser understood influence of **testosterone**.

Experimental reproduction

Implantation of the organism on a scarified prepuce in the presence of urine is capable of causing the external ulceration that is characteristic of the disease.

Economic importance

Many deaths occur because of uremia and secondary bacterial infections and all affected sheep show a severe setback in growth rate and wool production. Young rams that are affected are incapable of mating.

PATHOGENESIS

The organism is capable of hydrolyzing urea with the production of ammonia. It is believed the initial lesion in the wether (the external lesion) is caused by the **cytotoxic effect of ammonia**, produced from urea in the urine by the causative bacteria.[5] This lesion may remain in a static condition for a long period but, when there is a high urea content of the urine associated with a high-protein diet, and continued wetting of the wool around the prepuce, the lesion proceeds to invade the interior of the prepuce, producing the 'internal lesion'. A similar pathogenesis is postulated for vulvar lesions.

CLINICAL FINDINGS

The primary lesion starts as a pustule, which breaks and forms a soft scab. Small scabs are found on the skin dorsal to the preputial orifice (**external lesion**) and around the external orifice on the non-haired part of the prepuce. These may persist for long periods without the appearance of any clinical signs. The scab is adherent and tenacious. When extension to the interior of the prepuce occurs (**internal lesion**) there is extensive ulceration and scabbing of the preputial opening and a hard core can be palpated extending 1–2 inches into the prepuce. With pressure, a semisolid core of purulent material can be extruded from the preputial orifice. Affected sheep may show restlessness, kicking at the belly and dribbling urine as in urethral obstruction. The area is often infested by blowfly maggots. In rams, the development of pus and fibrous tissue adhesions may interfere with urination and protrusion of the penis, and cause permanent impairment of function.

Some deaths occur due to obstructive uremia, toxemia, and septicemia. During an outbreak many sheep may be affected without showing clinical signs and are detected only when they are subjected to a physical examination. Others recover spontaneously when feed conditions deteriorate.

In ewes the lesions are confined to the lips of the vulva and consist of pustules, ulcers, and scabs. These extend minimally into the vagina. Their presence may distort the vulva and the ewe may urinate onto the wool with a consequent increased susceptibility to fly strike.

In bulls, lesions are similar to the external lesions which occur in wethers but rarely there may be invasion of the interior of the prepuce. The external lesions occur at any point around the urethral orifice and may encircle it. Their severity varies from local excoriation to marked ulceration with exudation and edema. There is a tendency for the lesions to persist for several months without treatment and with highly alkaline urine.

CLINICAL PATHOLOGY

Isolation of the causative diphtheroid bacterium may be necessary if there is doubt as to the identity of the disease.

NECROPSY AND DIAGNOSTIC CONFIRMATION

Necropsy is not required and the diagnosis is clinical.

DIFFERENTIAL DIAGNOSIS

- Ulcerative dermatosis in sheep
- Herpes balanoposthitis in bulls

Obstructive urolithiasis in wethers may superficially resemble posthitis but there is no preputial lesion.

TREATMENT

The principal measures are restriction of the diet to reduce the urea content of the urine, removal of the wool around the prepuce or vulva to reduce the risk of fly strike, segregation of affected sheep and disinfection of the preputial area, and surgical treatment of severe cases.

Sheep can be removed on to dry pasture and their feed intake restricted to that required for subsistence only. They should be inspected at regular intervals, the wool should be shorn from around the prepuce, and affected animals should be treated individually. Weekly application of a 10% copper sulfate ointment is recommended for external lesions; when the interior of the prepuce is involved, it should be irrigated twice weekly with a 5% solution of copper sulfate. Cetrimide (20% in alcohol or water with or without 0.25% acid fuchsin) or alcohol alone (90%) are about as effective as copper sulfate preparations.

Penicillin topically or parenterally may effect a temporary response. Thiabendazole by mouth appears to have a beneficial effect on the lesions but does not eliminate them.

In severe cases the only satisfactory treatment is surgical, and surgical treatment is necessary if the prepuce is obstructed. The recommended procedure is to open the ventral sheath by inserting one blade of a pair of scissors into the external preputial orifice and cutting the prepuce back as far as the end of the urethral process; extension beyond this leads to trauma of the penis. Badly affected rams should be disposed of as they are unlikely to be of value for breeding.

CONTROL

Subcutaneous implantation with testosterone propionate is highly effective as a preventive but is no longer used for sheep that will be used for human food. A single implantation of 60–90 mg is effective for 3 months; although the treatments can be repeated four times a year, it is more economical to time them to coincide with periods of maximum incidence, which will vary from district to district. Three implantations in fall, winter, and spring provide an effective control program in most areas. The tablets are implanted subcutaneously, preferably at the base of the ear, using preloaded tubes to avoid undue contact to the operator.

Alternative control procedures are under investigation, in part because of public resistance to meat products exposed to synthetic hormones. One alternative is to run male lambs as cryptorchids, so-called **short scrotum** lambs. The testes are pushed into the inguinal canal and a rubber ring is applied to remove the scrotum. Another is to run male lambs as hemicastrates.[6] The prevalence of posthitis is significantly reduced in Merino short scrotum lambs and hemicastrates.[6,7] There is an increase in live weight, with no increase in fleece weight, but there are obvious masculine characteristics such as horn growth.[6–8]

CASEOUS LYMPHADENITIS OF SHEEP AND GOATS

Etiology *Corynebacterium pseudotuberculosis*
Epidemiology Disease of sheep and goats. Source of infection is discharge from pulmonary or skin abscesses. Infection is through intact skin or skin wounds. Transmission in sheep occurs at shearing and dipping in sheep and in goats and sheep by direct contact
Clinical findings Abscesses in superficial lymph nodes. Respiratory or wasting disease associated with internal abscesses
Clinical pathology ELISA tests can be used to determine flock status but sensitivity and specificity is inadequate to provide reliable identification of infected individuals
Necropsy findings Abscesses in lymph nodes and internal organs
Diagnostic confirmation The clinical and necropsy features are typical. Confirmation is by bacterial culture
Treatment Surgical for superficial abscesses
Control Culling of abscessed sheep or based on serological testing, hygiene at shearing, avoidance of management risk factors, vaccination

ETIOLOGY

Corynebacterium pseudotuberculosis is the specific cause of the disease. There are two proposed biotypes, ovine/caprine and equine/bovine.[1] Both biotypes produce an exotoxin, phospholipidase D, which functions as a sphingomyelinase and is an immunodominant antigen.[2] Variation in toxin production between strains may be related to differences in pathogenicity.[3] The toxic lipid cell wall mediates resistance to killing by phagocytes and is also a virulence factor.

C. pseudotuberculosis is also the cause of ulcerative lymphangitis of cattle and horses, and contagious acne of horses, but these have been dealt with as separate diseases because they appear to have a separate pathogenesis and do not occur in association with caseous lymphadenitis.

EPIDEMIOLOGY

Geographical occurrence

Caseous lymphadenitis occurs in the major sheep-producing countries in the world including Australia, New Zealand, South Africa, the Middle East, North and South America, the UK, and most of northern and southern Europe. The disease did not occur in the UK and the Netherlands until the importation of infected goats in the late 1980s[4,5] but subsequently spread to be an important disease in both countries.

Host occurrence

Caseous lymphadenitis occurs in sheep and goats.

Sheep

Caseous lymphadenitis increases in prevalence with age[6] and reaches a peak incidence in adults. In one Australian population of unvaccinated sheep the frequency of infection at abattoir inspection was 3.4% for lambs and 54% for adult ewes[7] and similar levels of prevalence are recorded in North[8] and South America.[9] In another large study of mature age slaughter sheep in Australia the overall prevalence of lesions was 26%, with carcass lesions in 20.4% of sheep and offal lesions in 9.5%.[10] The prevalence of lesioned sheep from individual farms can be higher. The prevalence of infection in ewes culled for age in Western Australia has fallen from over 50% in the 1980s to approximately 25% in the early 2000s, which is suggested to be in part the result of the cessation of compulsory dipping for lice during this period.[11] Following the introduction to British flocks in the late 1980s, outbreaks increased to reach a peak in 1998 and have decreased in occurrence since.[12] An examination, by pulse field gel electrophoresis, of isolates through this period suggests that all are related to the initial introduction.[13] A recent serological survey of 745 flocks showed an overall prevalence of seropositive animals of approximately 10%, with 18% of the flocks sampled having one or more positive animals.[12]

Goats

Prevalence rates in goats may be lower than in sheep. In **domesticated** goats an overall prevalence rate of 8% is recorded in the USA[14] and a similar prevalence is recorded in **feral** goats in Australia.[15] As with sheep the prevalence increases with age – the prevalence at 4 years of age is as high as 22%. The assessment of prevalence in goats based on the presence of abscess is complicated by the fact that a significant proportion of abscesses in goats may be produced by *Arcanobacterium pyogenes.*[16]

Source of infection

The primary habitat of *C. pseudotuberculosis* is in infected animals. Sources of infection are the **discharges** from ruptured abscessed **superficial lymph nodes** and the **nasal and oral secretions** from animals with **pulmonary abscesses** draining into the bronchial tree.[17]

The organism can survive in pus-infected **soil** for up to 8 months, in infected **shearing sheds** for approximately 4 months, and on straw, hay and other fomites for up to 2 months,[18] but it is not easily isolated from the soil of infected premises.[3] Low temperatures and moist conditions prolong survival time.[18] Infectivity persists in sheep dips for at least 24 hours.

Transmission

Infection of an animal is facilitated by the presence of **skin wounds** but the organism can invade through **intact skin**.[2] Transmission is by **direct** contact with infective discharges or **mediated** by contaminated shearing equipment, contaminated shearing shed boards or holding pens, contaminated dipping or shower fluids, or dust from contaminated shearing sheds and yards.

Risk factors

Sheep

Most studies on risk factors have been conducted in Australia and observed risk factors may not always apply to management systems in other countries.

Age and sex

There is a higher prevalence in older sheep, which probably reflects greater exposure to risk factors such as shearing. In the UK a disproportionate number of rams are infected and there is a significant prevalence of infection in terminal sire breeds, which are an important vector to otherwise closed flocks.[12] The prevalence in rams may be related to the high stocking rate at which rams are kept for most of the year and fighting behavior with transmission through head wounds.

Breed

All breeds are susceptible but, in New Zealand, which has a mix of fine wool and meat sheep breeds, the prevalence of disease is higher in Merino and Merino-cross breeds. This may relate to greater susceptibility to skin damage at shearing because of their finer skin and the presence of neck wrinkles.[19] In the UK, infection is more prevalent in terminal sire breeds.[12,20]

Shearing

Shearing is a major risk factor in sheep and, in general, infection rates increase with the number of times sheep have been shorn. The risk for spread varies with shearings. When spread occurs, it occurs mostly within groups of sheep shorn together.[21,22] Sheep may be infected by transfer of pus from abscesses discharging or cut at shearing, via shearing combs, but spread from sheep with discharging pulmonary abscesses to sheep with skin cuts is considered more important.[22]

Close contact of recently shorn sheep in any circumstance may facilitate transmission of the disease through the contact of **infected respiratory secretions** with susceptible skin. Sheep are commonly in close contact in collecting pens immediately following shearing and infected nasal and oral secretions can be deposited

directly on to shearing cuts. Keeping sheep under cover for more than an hour after shearing increases the odds for spread.[21]

Poor hygiene in the shearing shed, allowing contamination of shearing boards and holding pens, may allow infection of sheep. Movement of infection between flocks can occur through contamination of shearing equipment, of mobile shearing sheds and infection on the clothing of shearers. Contract shearing has been shown to be a risk factor in the UK.[23]

Dust

Dust from contaminated yards may transmit infection to recently shorn sheep, although epidemiological studies suggest that environmental contamination is not a major risk factor for disease in Australia.[21]

Housing

Close contact associated with high stocking rates at pasture or in-door housing for much of the year may lead to high rates of infection. The difference in lesion distribution between sheep in the UK and Australia is believed to be due to close contact at shared feed troughs under conditions of intensive husbandry in the UK.[23]

Dips

The organism can persist in reused (plunge dip) or recycled (shower dip) fluids used for ectoparasite control. As few as 25 organisms/mL in the dip can produce infection.[24] Sheep dipped in infected dipping fluid within a few days of having been shorn are especially susceptible to infection because of the ease of contact between the bacteria and the skin[3] but spread can also occur through dips in sheep shorn 6 months previously.[19,24] An experimental study, where infection-free sheep were shorn and exposed to artificially contaminated dips at 0, 2, 4, 8, and 24 weeks after shearing, showed that a larger percentage of the sheep dipped immediately after shearing seroconverted and had lymph node lesions at slaughter. However, lesions also were present at slaughter in sheep dipped 2 or more weeks after shearing and there was no significant difference in their prevalence in the groups dipped at 2–24 weeks after shearing. This supports the observation that infection can occur through intact skin, possibly in the case of dip-associated infections, influenced by loss of wool grease because of wetting agents in the dip.[24] Shower dipping sheep immediately after shearing also significantly increases the odds of a high incidence of caseous lymphadenitis.[19]

Whereas shearing and dipping are important risk factors, disease can also be transmitted from sheep with pulmonary abscesses to nonshorn sheep by contact.[17]

Goats

Shearing is not a risk factor, other than with Angoras. The difference in abscess distribution in goats compared to sheep, with a predominance in the head, neck and sternum in goats, suggests that contact, fomites and trauma are important vector mechanisms. Social contact, head butting, trauma from browse and the use of common neck collars and feed troughs are probable risk factors. Pulmonary abscesses are not as prevalent in goats[15] as in sheep and may be of lesser importance as a source of infection.

With both sheep and goats, **contamination of soil** on bedding grounds, in yards, or in shelters may result in persistence of the organism in the environment for periods significant to the transmission of the disease and can result in infection of wounds created by docking and castration and infection in the region of the sternum.

Experimental reproduction

The disease can be readily produced experimentally in sheep and goats by parenteral or intradermal injection, and in both species abscesses form in regional draining lymph nodes and in internal organs.[7,25,26] The disease can also be produced experimentally in sheep by exposure to contaminated dips.[24] The incubation period for the development and rupture of abscesses in regional lymph nodes varies from 3 weeks to 6 months, and shedding of *C. pseudotuberculosis* from open abscesses averages 20 days.[7,26]

Economic importance

In the majority of young infected animals there is no overt clinical disease or impairment of health other than visible abscessation but the disease is of considerable economic importance to the sheep and goat industries. In sheep, infection has been associated with a 6.6% reduction in clean **fleece weight** in the first year of infection and a reduction in growth rate.[25,27] Infection is a significant cause of **condemnation of carcass** for human consumption with condemnation rates as high as 3–5% for mutton carcasses and 0.02–0.03% for lamb carcasses.[28] Condemnation rates and economic loss varies depending on country – differences in the number of abscessed lymph nodes dictating condemnation rather than carcass trimming.

In goats the **hide** can represent a significant proportion of the value of the carcass and blemishes produced by infection markedly reduce its value.

Clinical disease occurs in animals with the disseminated visceral form which is a cause of reproductive inefficiency, a major cause of the **thin ewe syndrome**, and of death and culling in older sheep in infected flocks.

Zoonotic implications

Human infection is rare, produces a lymphadenitis with a long and recurrent course[29] and is an occupational disease of shearers and abattoir workers with infection occurring through cuts. *C. pseudotuberculosis* may be present in the milk of goats from udders where the mammary lymph node is affected.[30]

PATHOGENESIS

Multiple microscopic abscesses develop in the draining lymph node by 1 day after experimental infection in the skin, and between 3 and 10 days of infection these coalesce to form typical pyogranulomas.[31] The sphingomyelin-specific phospholipidase D exotoxin produced by the organism is believed to facilitate spread of infection by promoting leakage of plasma from small blood vessels at the site of infection with flooding of lymphatic spaces. Abscesses develop in 60–80% of infected sheep.[25,27] The high lipid content of the bacterial cell wall gives resistance to the digestive enzymes of the phagocyte and the organism persists as a facultative intracellular parasite.[3]

The reduction of **wool growth** in the first year of infection probably results from the catabolic effects of cytokine and toxic metabolites released during the acute inflammatory and immune response to initial infection.[27]

Hematogenous spread of the organism results in abscess formation in many organs and these may occur in the absence of peripheral lesions. Up to 25% of affected sheep at abattoirs are recorded as having lesions only in thoracic viscera.[3] This tendency for a high incidence of lesions in the lung appears to be general, but prevalence varies considerably between geographical areas. The abdominal visceral and somatic tissues are also commonly affected. Less commonly, hematogenous infection occurs in **young lambs** to produce septicemic disease.

CLINICAL FINDINGS

There is palpable enlargement of one or more of the superficial lymph nodes. Those most commonly affected are the submaxillary, prescapular, prefemoral, supramammary and popliteal nodes. The abscesses commonly rupture and creamy to caseated pus, with no odor, is discharged. Goats have a much greater proportion of lesions in the lymph nodes draining the head, related possibly to superficial injury during browsing.[15] Abscesses may subsequently develop in other lymph nodes. In the UK, clinical signs of infection in sheep are most commonly associated with the superficial lymph nodes of the head and neck.[20] Both sheep and goats may also show abscess in

the skin, particularly of the face, with loss of overlying hair.

In cases in which systemic involvement occurs, chronic pneumonia, pyelonephritis, ataxia, and paraplegia may be present depending on the site of infection. The debilitating disease of adult ewes commonly referred to as '**thin ewe syndrome**' is often associated with the occurrence of internal abscesses (81% of ewes), many of which contain *C. pseudotuberculosis* (86%). Other bacteria, especially *Moraxella* spp., are also commonly present. In ewes, local spread from the supramammary lymph node to the mammary tissue is common. The resulting fall in milk yields leads to poor growth and even death of lambs and this may be a serious economic feature in badly affected flocks. Intrascrotal lesions are common in rams but do not involve the testicles or semen.

CLINICAL PATHOLOGY

There is an increase in blood lymphocytes and neutrophils.[32]

C. pseudotuberculosis can be cultured from pus obtained by needle biopsy or by transtracheal wash.

Serological tests that have been used in serodiagnosis include indirect hemagglutination, hemolysis inhibition, synergic hemolysis inhibition, immunodiffusion and ELISA tests to detect antibody to cell wall antigens or to the phospholipase exoenzyme. Many of these tests have good specificity but few have high **specificity and sensitivity**. Some have been used to determine flock infection and have been used in eradication schemes.[5] As yet, none is sufficiently reliable to confidently detect infection in individual sheep. The sensitivity of equivalent tests in goats is generally higher and they are used for official control schemes in goats in some countries. An indirect double antibody sandwich ELISA with high specificity and sensitivity at the herd level in goats and sheep is being used in herd eradication of caseous lymphadenitis in the Netherlands.[33]

Recently, an interferon-gamma assay that assesses cell-mediated immunity rather than humoral immunity has been developed and showed high reliability in detecting both infected and noninfected sheep and goats in a limited number of experimental animals.[34,35]

NECROPSY FINDINGS

Caseous abscesses filled with greenish-yellow pus occur chiefly in lymph nodes and to a lesser extent in internal organs. In the early stages the pus is soft and pasty but in the later stages it is firm and dry and has a characteristic lamellated appearance. Locally extensive bronchopneumonia, with more fluid pus of a similar color, may also be present. Microscopically, nodal architecture is effaced by the abscess. As the lesion expands, the limiting fibrous wall keeps reforming, creating the 'onion-skin' layering noted grossly.

Samples for confirmation of diagnosis

- Bacteriology – lymph node, lung, culture swab from outer portion of abscess (CULT)
- Histology – formalin-fixed lymph node (LM).

DIFFERENTIAL DIAGNOSIS

- Melioidosis
- Tularemia
- Other causes of pneumonia in small ruminants
- Lymphosarcoma (rare)

Suppurative lymphadenitis in lambs has also been found to be associated with infection with *Pasteurella multocida*, and a disease characterized by the presence of yellow-green pus in abscesses situated in close proximity to the lymph nodes of sheep is associated with a Gram-positive micrococcus. The latter disease occurs in France and Kenya and is referred to as **Morel's disease**.

TREATMENT

The organism is susceptible to antibiotics other than the aminoglycoside group but treatment is not usually attempted because the abscess is encapsulated, the organism is intracellular and response is poor. Subcutaneous abscesses can be treated with surgical drainage or extirpation.

CONTROL

Culling

A measure of control can be achieved by culling all animals with enlarged lymph nodes. Although this is a logical procedure it is worth noting that it is not capable of detecting early lesions, nor of detecting those animals with internal abscess but no external abscesses. Ideally, control would be by the identification and culling of infected animals using serological testing. Culling on the basis of serological tests has been used[5,33,36] but the sensitivity and specificity of current tests does not make this a perfect selection method.

Control of spread

All docking implements, ear taggers, and shears used for the Mules operation should be dipped in strong disinfectant before each use. Similar attention should be given to the combs and cutters at shearing time. There should be good hygiene and disinfection in the shearing shed, especially of the shearing board and holding pens. Mobile shearing trailers should be cleaned and disinfected between farms. The importance of personal hygiene should be impressed on shearers and farm-specific overclothing should be provided if possible. Younger age groups should be shorn first, rams second to last and any sheep with palpable lesions last. Pus spilled on the shearing floor should be cleaned up and the area disinfected. All shearing cuts should be disinfected. There can still be a high abscess rate in flocks that practice these control procedures.[16]

Close contact of sheep following shearing should be avoided. All efforts must also be directed to avoid contaminating dipping fluid; one discharging abscess is capable of contaminating an entire tank of fluid. Dipping after shearing may be undesirable in badly affected flocks. The addition of an efficient bactericidal agent to the dipping fluid is worthy of consideration.

Goat housing should be free of wire or other causes of skin trauma, and communal use of equipment such as neck collars should be avoided. External parasites must be controlled. Goat herds that are free of the disease should avoid the purchase of animals from herds with a history of abscessation.

Vaccination

Vaccines formulated from concentrated, formalin-inactivated *C. pseudotuberculosis* culture supernatants containing phospholipase D have considerable efficacy and are available in many countries. Attenuated mutant vaccines also show promise.[32] Vaccination does not provide complete protection against the development of abscesses but controlled field trials show a significant reduction in the number of sheep that develop abscesses and a reduction in the number of abscesses in infected sheep.[8,22,25,28,37,38] Vaccinated sheep have fewer lung abscesses than unvaccinated sheep, in one study 96% fewer,[22] and are less likely to spread infection from this source. Compliance with the recommended full course of the vaccine has an important influence on the efficacy of vaccination. An Australian study showed that flocks that followed the recommended protocol of two priming doses to lambs with yearly boosters to adult sheep throughout their life had an average slaughter prevalence of infection in sheep of 3%, whereas the average prevalence of lesioned sheep at slaughter from flocks that only partially followed this protocol, by administering a single dose to lambs or not giving yearly boosters to adult sheep, varied from 22–33%.[39]

Immunity to caseous lymphadenitis is believed to be associated with antitoxin activity[10] and primarily cell-mediated,[40] but colostral immunity will protect against experimental challenge at 6 weeks of life. **Colostral immunity** will also affect the development of immunity from

vaccination and lambs in flocks with a high prevalence of caseous lymphadenitis should not be vaccinated at less than 10 weeks of age.[41]

Vaccination appears less successful in **goats** and, although it protects against experimental challenge and spread of the organism from the site of infection,[42,43] there has been little protection from natural infection in field trials.[38,42]

PREVENTION

All potential introductions to a flock should be examined clinically for evidence of disease. While this is not a particularly sensitive method of detection of infection, obvious clinical cases will be detected. Determining the infection status of the source flock is a safer procedure and purchase should be direct and not through markets. The ultimate method of prevention will include serological testing of individual animal introductions when adequate tests become available.

ERADICATION

Eradication is reported in endemically infected flocks by initial culling of all sheep with clinical signs and subsequent serological testing and culling of reactors. Seropositive ewes were allowed to lamb before culling but lambs were removed at birth, isolated from the infected dams and fed cow's colostrum and milk replacer. These procedures were coupled with rigorous disinfection of facilities, removal of bedding and topsoil from barns and pens, isolation of seronegative sheep for 6 months from previously used pastures and tracks, and hygiene at skin-damaging management procedures. Serologically positive sheep were not detected after the second screening.[5]

Total herd or flock eradication and replacement with infection-free animals is also possible.

BOLO DISEASE

This disease of the fleece of sheep appears confined to the Eastern Cape province of South Africa and gets its name from the region where it was first described. An unclassified *Corynebacterium* sp. closely resembling *Corynebacterium pseudodiphtheriticum* and *Corynebacterium urealyticum* can be isolated from the skin of affected sheep.[1] This organism is rarely isolated from the skin of sheep with normal fleeces.[2] The disease can be experimentally reproduced by the topical application of the organism on to the intact skin of newly shorn sheep and sheep in 5 months wool, and the organism persists in the produced lesions for at least 169 days.[3]

Bolo disease is a disease of medium- and medium–strong-wool **Merino** sheep with dense fleeces containing a high yolk content. It occurs in sheep on natural grazing. There is no sex predilection but older sheep and poor-conditioned sheep are more severely affected. It can occur in semi-arid climates and there is no apparent seasonal or climatic influence or influence of external parasites.[3] The attack rate in a flock can be as high as 90% and the disease has considerable economic impact, as the wool is of inferior quality and low economic value.

Lesions occur most commonly on the sides of **neck** and the **shoulders**, and are more easily seen in unshorn sheep as well defined, dark gray to black **patches** and bands that vary in number and in size (20 mm to 30 cm in diameter) and are sunk below the surface of the tips of the surrounding staple. The underlying **skin** is red-purple in color, tender to the touch and breaks easily. There is a yellow sticky exudate on the surface of the skin and in between the wool fibers, resulting in a spiky staple. On freshly shorn sheep the affected areas are chalky white.

Histologically there is acanthosis, superficial and follicular hyperkeratosis and hyperpigmentation, and sebaceous gland hypertrophy.

Treatment regimes are not defined but high-dose parenteral penicillin as used in mycotic dermatitis might be effective.

Bolo disease can be differentiated from fleece rot and mycotic dermatitis by its clinical presentation and the epidemiological circumstances in which it occurs.

ULCERATIVE LYMPHANGITIS OF HORSES AND CATTLE

Synopsis

Etiology *Corynebacterium pseudotuberculosis* biotype 2
Epidemiology Ulcerative lymphangitis in horses is now an uncommon disease but is associated with poor stable hygiene. Disease in cattle is common in North Africa and Israel. Infection of cattle with this organism can result in subcutaneous abscesses, occurring most commonly in the summer months, and an ulcerative dermatitis of the heel of the foot, occurring most commonly in the winter months. Flies are vectors of infection
Clinical findings Pyogranulomatous abscessation at the site of infection with lymphadenitis and abscessation along drainage lymphatic tracts
Lesions Pyogranulomatous abscessation
Diagnostic confirmation Culture of *C. pseudotuberculosis*
Treatment Drainage of abscesses and local treatment. Antibiotics of limited value
Control Housing hygiene. Herd security

ETIOLOGY

Corynebacterium pseudotuberculosis causes the classical disease. It is a soil-borne organism that gains access to tissue through wounds or insect bites. *C. pseudotuberculosis* possesses a cytotoxic surface lipid coat that appears to facilitate intracellular survival and abscess formation. It also produces a phospholipase exotoxin that increases vascular permeability, has an inhibitory effect on phagocytes and may facilitate spread of infection in the host. Biotypes associated with ulcerative lymphangitis in cattle

and horses are different from the biotype associated with caseous lymphadenitis in sheep and goats.

EPIDEMIOLOGY

Horses

The disease was of considerable importance and widely distributed during the workhorse era but is now uncommon. The mortality rate was negligible but among the affected horses there was interference with their ability to perform. Infection occurs through abrasions on the lower limbs and is more likely when horses are crowded together in dirty, unhygienic quarters. Contact and inanimate transmission is the means of spread but passive transmission by flies is probable.[1,2] As a rule only sporadic cases occur in a stable.

Cattle

Occurrence

Infection with *C. pseudotuberculosis* is uncommon in most countries but has importance in North Africa and Israel.[1,3–6] It is one of the most commonly diagnosed infectious diseases in cattle in Israel.

The disease may present as ulcerative lymphangitis affecting the limbs, a cutaneous form with pyogranulomatous abscess formation in areas of the body, which may also be accompanied by mastitis or internal abscessation, or a necrotic and ulcerative dermatitis on the heel of the foot accompanied by edematous swelling and lameness.[5,7]

In a study recording the disease in 45 herds over a 13-year period the average morbidity rate was observed to be 6.4%. The disease occurred sporadically in 26 dairy herds, with morbidity rates of up to 5%, and in an epidemic form in 19 herds, in which the morbidity rate ranged from 5–35%. Outbreaks in herds have a course of approximately 5 months. Culling and mortality rates can approach 16%.[4] The disease tends not to recur in a herd following an outbreak suggesting the development of herd immunity.

Methods of transmission

Infection may spread within the herd by direct contact between infected and uninfected animals, and by mechanical transmission by houseflies or other diptera.[2] Spread between herds is by introduction of infected animals.

Animal risk factors

In Israel ulcerative lymphangitis and skin abscessation is more common in mature animals but necrotic and ulcerative dermatitis on the heel of the foot occurs in heifers.[4]

Environmental risk factors

Both outbreaks and sporadic cases of the cutaneous form occur most commonly during the summer months (March to October) in Israel, which may be related to large populations of houseflies during these months.[4] In contrast the peak incidence of necrotic and ulcerative dermatitis on the heel occurs during the winter months possibly due to conditions underfoot during this season. The organism can survive for prolonged periods in contaminated environments under favorable conditions.[4]

Economic importance

In cattle, the economic losses are associated with high culling rates, a decrease in average monthly milk production and an increase in the bulk tank milk somatic cell count.[5]

Zoonotic implications

The infection can be zoonotic and human infection can occur as a result of continued close contact with infected animals. Consumption of infected nonpasteurized milk can also be a risk for human infection.

PATHOGENESIS

Infection of skin wounds is followed by invasion of lymphatic vessels and the development of abscesses along their course. Generalized lymph node involvement is unusual. The organism possesses a cytotoxic surface lipid coat that appears to facilitate intracellular survival and abscess formation and produces a phospholipase exotoxin that increases vascular permeability and has an inhibitory effect on phagocytes.

CLINICAL FINDINGS

Horses

Ulcerative lymphangitis: In horses the initial wound infection is followed by swelling and pain of the pastern, often sufficient to cause severe lameness. Nodules develop in the subcutaneous tissue, particularly around the fetlock. This is followed by infection of lymphatic vessels and the development of abscesses along their course. Spread to other subcutaneous sites on all parts of the body can occur.[7] These may enlarge to 5–7 cm in diameter and rupture to discharge a creamy green pus. The resulting ulcer has ragged edges and a necrotic base. Lymphatics draining the area become enlarged and hard and secondary ulcers may develop along them. Lesions heal in 1–2 weeks but fresh crops may occur and cause persistence of the disease for up to 12 months.

Cattle

Ulcerative lymphangitis: The lesions in cattle are similar to those in horses except that there may be draining lymph node enlargement and the ulcers discharge a gelatinous clear exudate.[3]

Cutaneous form. Single or multiple painful abscesses occur in the skin and subcutaneous tissue on the head, flanks, shoulders, neck, and hind legs above the stifle joint. Abscesses can reach a diameter of 15–20 cm and have a firm, fibrous tissue capsule. Abscesses ulcerate and develop draining tracts. Ruptured abscesses discharge serosanguinous exudates or blood-stained yellowish pus. The regional draining lymph nodes are enlarged but generalized lymphangitis does not occur. Recurrence occurs in a small percentage of animals following initial recovery.

Necrotic and ulcerative dermatitis on the heel of the foot. Lameness is apparent and there is edematous swelling on the distal part of the legs associated with a necrotic-ulcerative dermatitis on the heel of the foot.

CLINICAL PATHOLOGY

The isolation of *C. pseudotuberculosis* from discharging lesions is necessary to confirm the diagnosis. There are no serological tests validated for infection in cattle or horses but serological tests used for serological diagnosis of caseous lymphadenitis in sheep are used for diagnosis of *C. pseudotuberculosis* in horses in some laboratories.

DIFFERENTIAL DIAGNOSIS

Horses

- Epizootic lymphangitis
- Glanders
- Sporotrichosis
- *Rhodococcus equi*

Similar lesions can be associated with infection with other pyogenic organisms including streptococci, staphylococci, and *Pseudomonas aeruginosa*.

Differentiation of ulcerative lymphangitis from the other diseases causing similar lesions is important because of the serious nature of such diseases as glanders and epizootic lymphangitis in horses.

Restriction of the lesion to the lower limbs and absence of lymph node involvement are important features although these are shared by sporotrichosis.

Cattle

- Digital dermatitis
- *Dermatophilus congolensis*

TREATMENT

C. pseudotuberculosis is sensitive to all common antimicrobial drugs with the exception of the aminoglycoside group, but systemic treatment of infected animals does not affect the recovery period.[4] Local treatment of ulcers is the usual and most effective procedure but parenteral injections of penicillin or tetracycline may be necessary in severe cases. In the early stages an autogenous bacterin may have value as treatment.

CONTROL

Good hygiene in stables and under-foot, careful disinfection of injuries to the lower limbs usually afford adequate protection against ulcerative lymphangitis. With all

manifestations, isolation of the affected animals and local treatment with antiseptics act to prevent the disease from spreading to other animals in the herd. Infected animals should not be introduced to a naive herd and there should be adequate fly control.

CONTAGIOUS ACNE OF HORSES (CANADIAN HORSE POX, CONTAGIOUS PUSTULAR DERMATITIS)

Contagious acne of horses is characterized by the development of pustules, particularly where the skin comes in contact with harness.

ETIOLOGY

Corynebacterium pseudotuberculosis is the specific cause of this disease.

EPIDEMIOLOGY

The disease is spread from animal to animal by means of contaminated grooming utensils or harness. An existing seborrhea or folliculitis due to blockage of sebaceous gland ducts by pressure from harness probably predisposes to infection. Inefficient grooming may also be a contributing cause.

Contagious acne is of limited occurrence and causes temporary inconvenience when affected horses are unable to work.

PATHOGENESIS

Infection of the hair follicle leads to local suppuration and the formation of pustules which rupture and contaminate surrounding skin areas. Occasional lesions penetrate deeply and develop into indolent ulcers.

CLINICAL FINDINGS

The skin lesions usually develop in groups in areas which come into contact with harness. The lesions take the form of papules which develop into pustules varying in diameter from 1–2.5 cm. There is no pruritus but the lesions may be painful to touch. Rupture of the pustules leads to crust formation over an accumulation of greenish-tinged pus. Healing of lesions occurs in about 1 week but the disease may persist for 4 or more weeks if successive crops of lesions develop.

CLINICAL PATHOLOGY

Swabs of the lesions can be taken to determine the presence of *C. pseudotuberculosis*.

DIFFERENTIAL DIAGNOSIS

- Ringworm
- Staphylococcal pyoderma
- Nodular necrobiosis

Diagnostic confirmation
Isolation of *C. pseudotuberculosis* from lesions.

TREATMENT

Affected animals should be rested until all lesions are healed. Frequent washing with a mild skin disinfectant solution followed by the application of antibacterial ointments to the lesions should facilitate healing and prevent the development of further lesions. Parenteral administration of antibiotics may be advisable in severe cases.

CONTROL

Infected horses should be rigidly isolated and all grooming equipment, harness and blankets must be disinfected. Grooming tools must be disinfected before each use. Vaccination is not likely to be effective because of the poor antigenicity of the organism.

RHODOCOCCUS EQUI PNEUMONIA OF FOALS

Synopsis

Etiology Virulent strains of *Rhodococcus equi*
Epidemiology Sporadic disease of 1–5-month-old foals that is endemic on some farms. Foals are infected by ingestion or inhalation during first weeks of life
Clinical signs Pneumonia, fever, respiratory distress, cough, lack of nasal discharge, failure to thrive, multiple distended joints and uveitis. Occasionally diarrhea or septic osteomyelitis
Clinical pathology Leukocytosis, hyperfibrinogenemia, inflammatory cells in tracheal aspirate
Necropsy lesions Pulmonary consolidation and abscessation. Nonseptic polyarthritis
Diagnostic confirmation Culture of *R. equi* from tracheal aspirate
Treatment Erythromycin estolate or microencapsulated base 25 mg/kg every 8 hours orally, in combination with rifampin 5 mg/kg every 12 hours orally. Clarithromycin (7.5 mg/kg every 12 h orally) may be substituted for erythromycin
Control Insure adequate transfer of passive immunity. Decrease stocking density. Decrease environmental contamination by virulent strains of *R. equi*

ETIOLOGY

Rhodococcus equi is a Gram-positive, pleomorphic rod. The most important manifestation of *R. equi* infection is pneumonia in foals. It also causes pleuropneumonia, pneumonia, osteomyelitis, and abortion in immunocompromised and normal adult horses, abscesses that must be differentiated from tuberculosis in pigs and ruminants, and pneumonia in immunosuppressed humans.[1–5] The organism is a natural inhabitant of soil, grows well at temperatures ranging from 10–40°C, and is readily isolated from the feces of herbivores and their environment. However, isolates of *R. equi* vary in virulence, with many isolates obtained from feces or soil not being pathogenic.[6]

There are a large number of virulent strains of *R. equi*, based on pulsed-field gel electrophoresis of chromosomal DNA.[7,8] While there is evidence of clustering of strains on farms and on most farms 1 or 2 strains predominate, there is little evidence of marked regional variations in prevalence of strains of virulent *R. equi*.[7,8] Only rarely will it be possible to link infections to a given site or region on the basis of analysis of chromosomal DNA.[7]

Virulence of *R. equi* is dependent upon the ability of the organism to enter, survive in and replicate in macrophages. Virulence is associated with the presence of highly immunogenic **virulence associated proteins** (Vap A, C, D, E, G, H), of which Vap A is apparently the most important, although the role of the other Vap proteins has not been determined.[9,10] Vap A is a surface-expressed, lipid-modified protein that elicits an intense humoral response by foals.[10] Expression of Vap A, C, D, and E is upregulated by incubation at 37°C, consistent with their role as virulence factors. Other genes probably involved in virulence are also upregulated by conditions that mimic those in vivo.[11] The presence of the virulence proteins is associated with enhanced ability of virulent *R. equi* to survive and replicate within macrophages, whereas avirulent strains replicate poorly or not at all.[12] However, the exact virulence mechanisms of *R. equi* are not known.[13]

The genes for Vaps A and C–H are present in a pathogenicity island in an 80–85 kb plasmid that is present in 98% of isolates of *R. equi* from foals with pneumonia.[14] Most isolates from the environment, feces, pigs, cattle, and human patients with *R. equi* infection do not contain either of the two identified virulence plasmids.[4,15,16] Virulence is associated with the presence of the plasmid, and loss of the plasmid by a strain of *R. equi* results in loss of virulence. There is geographical variation both within and between countries in the prevalence of each of the virulence plasmids in isolates from foals with pneumonia.[15,17,18]

EPIDEMIOLOGY

Occurrence

R. equi pneumonia in foals has a worldwide distribution. Clinical disease is often

sporadic but on farms where the disease is endemic annual **morbidity** can be as high and can vary widely from year to year.[19] The median percentage of foals that developed *R. equi* at farms on which the disease was endemic was 6.6%, with 38% of farms having more than 10% of foals affected.[20] Case fatality rates for foals on farms, as opposed to those treated at veterinary teaching hospitals, is reported as 29–42% (for 113 and 19 affected foals, respectively).[20,21] The median case fatality rate for 32 farms in Texas was 25% and the case fatality rate was more than 50% for 22% of farms. The case fatality rate among foals treated at veterinary teaching hospitals is approximately 28%.[22] The detection of *R. equi* pneumonia in one foal on a farm should prompt an examination of all other foals on that farm.

Current evidence supports the hypothesis that foals are exposed and infected within the first several days of life.[23] The **age at onset** of clinical signs of disease associated with *R. equi* varies between 2 weeks and 6 months but the peak prevalence for pneumonic disease is between 1 and 3 months.[24] The disease is rare in adult horses. Risk factors in foals for development of *R. equi* pneumonia have not been determined although a large number of factors have been examined.[25] The month in which the foal was born, gestational age, dam's parity, antimicrobial administration during the first week of life, exposure to pasture at less than 2 weeks of age, need for treatment to correct inadequate transfer of passive immunity, and size of mare/foal groups were not associated with risk of disease on farms in Texas.[26]

The prevalence of virulent *R. equi* in isolates from the environment does not appear to be greater on farms where the disease is endemic.[18,27] Morbidity varies widely among geographical areas and individual farms, probably because of environmental factors that affect the number of virulent *R. equi* and the ease of infection. Because aerosol infection by virulent *R. equi* in dust is thought to be the most important route of infection of foals, factors that favor the accumulation and persistence of *R. equi* in soil and its ability to become aerosolized most probably increase the risk of infection. Such factors might include:[24]

- Hot and dry weather, favoring formation of dust
- Soil pH and moisture
- Crowding of pastures with young horses
- Poor pasture hygiene, allowing accumulation of feces
- Dusty pastures.

However, empirical demonstration of the importance of these risk factors has not been reported, with several exceptions. **Soil** pH, salinity and concentrations of various elements including iron, zinc, and copper are not associated with the risk of foals developing *R. equi* pneumonia on farms in Texas.[28] These soil-associated risk factors were examined because *R. equi* is a normal inhabitant of the soil and of the intestine of ruminants, horses, and pigs. It is not highly resistant but it has been found to survive in moist soil for periods of longer than 12 months. The infection is considered to be soil associated and to be maintained through a soil–horse cycle.[29] The number of organisms in the soil and stable areas on horse farms increases with the time that the farms have housed horses, although there is not a strong correlation between *R. equi* concentration in soil and prevalence of pneumonia in foals.[18,30]

Farms of larger size, with more resident mares, greater numbers of foals (≥15), and greater foal density per acre, and the presence of mares brought on to the farm for breeding, are all associated with greater risk of foals developing *R. equi* pneumonia.[20,31] *R. equi* pneumonia does not appear to be associated with poor farm management or lack of preventative health practices such as vaccination, deworming, or administration of hyperimmune plasma.[25] The practice of testing for failure of transfer of passive immunity is associated with an increased likelihood of the disease on a farm.[32] However, this association probably reflects the facts that the disease is more likely on larger farms, which are more likely to perform this test, and that farms that have had the disease are more likely to institute preventive care procedures.

Transmission

Most foals are exposed to infection, as demonstrated by seroconversion, but only a few develop disease. The organism colonizes the intestine of the normal foal during the first 2 months of life and has been detected in the feces as early as 5 days.[33] Inhalation of the organism in dust is probably the most important route of transmission for pneumonic disease.[34,35] Intestinal disease, which may be clinically inapparent, usually occurs with pulmonary disease but the source of the infection is unclear, although it may be ingestion of contaminated material or swallowing of infected respiratory secretions. Foals over 5 weeks of age have generally been resistant to experimental challenge.

Zoonotic implications

R. equi is an occasional pathogen of humans. Infection is more common in immunocompromised people but is only infrequently associated with strains of *R. equi* that are virulent in foals.[15,34]

PATHOGENESIS

Exposure of foals to *R. equi* is common, based on rate of seroconversion, yet the development of respiratory infection and clinical disease is much less common. The reason for this is not fully understood, although development of the disease probably depends on exposure to an infectious dose of organism and the susceptibility of the foal. Recent epidemiology studies suggest that exposure occurs within the first few days of life, before waning of maternally derived passive immunity, and that affected foals have lower $CD4^+$:$CD8^+$ ratios before development of the clinically apparent disease than foals that do not subsequently develop the disease.[36] The differences between groups of foals was largest during the first 2 weeks of life, suggesting that foals that subsequently develop disease associated with *R. equi* may have impaired immune function during early life.[36] In adult horses, in which the disease is rare, protective immunity is associated with both cellular and humoral immune responses characterized by enhanced immunoproliferative responses of $CD4^+$ and $CD8^+$ cells and presence of IgGa and IgGb antibodies to Vap A.[37] Opsonizing antibody to *R. equi* is an important defense mechanism in experimentally infected foals and administration of *R. equi* hyperimmune plasma or plasma rich in anti-Vap A and C antibodies protects experimentally infected foals from developing pneumonia.[38] Overall, these results suggest that foals that develop *R. equi* pneumonia have a T helper cell (Th)2-like response to infection, rather than a Th1-like response. Th1-like responses, which are associated with enhanced $CD4^+$ and $CD8^+$ responses, are believed to be important in resistance to the disease.[13] Whether the switch to a Th2-like response to infection is a function of virulent *R. equi* or an attribute of susceptible foals has not been determined.

Experimental and clinical studies indicate that the foal is infected several weeks or months before clinical signs are observed. **Virulent strains** of *R. equi* are facultative intracellular parasites of macrophages, which they ultimately destroy. Neutrophils are bactericidal for *R. equi* but the organism can survive by inclusion in macrophages. Opsonization of *R. equi* by specific antibodies results in enhanced lysosome–phagosome fusion and greater killing of *R. equi* by equine macrophages and monocytes,[13] whereas entry of *R. equi* into macrophages by nonimmune phagocytosis is not associated with enhanced killing. Its survival in the macrophage is associated with absence of phagosome–lysosome fusion.[39] Nonvirulent strains do not proliferate in macrophages and monocytes. The combined action of humoral

and cellular immune systems is important in preventing development of the disease after inhalation of bacteria. Without opsonization, the capacity of the pulmonary macrophage of foals to kill *R. equi* is impaired and the organism has been shown to be able to persist in the pulmonary macrophage of infected foals. The inability of the pulmonary macrophages to destroy *R. equi* leads to persistent infection in the lung and a chronic bronchopneumonia with extensive abscessation and an associated suppurative lymphadenitis.

Intestinal infection is common in foals with *R. equi* pneumonia,[40] although clinical manifestations of the intestinal infection, such as diarrhea, are uncommon. Gastrointestinal tract infection is characterized by ulcerative lesions of the mucosa of the large intestine and cecum. In rare cases bacteremia and subsequent **suppurative foci** may develop in many organs, including bones and joints, liver, kidneys, and subcutis.

CLINICAL FINDINGS

***R. equi* pneumonia** of foals may present as an acute onset of inappetence, fever, depression and tachypnea or as a more chronic disease characterized by cough and failure to thrive. The former presentation is more common and usually occurs in foals less than 3–4 months of age, with younger foals being more severely affected. It is important to realize that the acute onset of the disease is preceded by a **long incubation period** during which clinical signs are minimal and that the development of clinical signs is associated with severe and extensive lung lesions. The foal is often in respiratory distress and is reluctant to move and to suckle. Cyanosis may be present in severe cases. **Auscultation** of the chest may reveal crackles and wheezes, but abnormal lung sounds are often much less apparent than the severity of the respiratory disease suggests they should be. Foals with *R. equi* **abscesses** may not have abnormal lung sounds. There is usually minimal nasal discharge.

Subcutaneous abscesses, osteomyelitis and septic arthritis may be present or develop.[41] Many foals (20%) have an **aseptic polyarthritis**, evident as nonpainful distension of joints, at the time they develop signs of respiratory disease. Immune-mediated **uveitis** occurs in approximately 10% of severely affected foals.[42]

In older foals the disease assumes a characteristic clinical syndrome marked by development of severe lesions without clinical signs in the foal. A subacute pneumonia develops slowly with coughing, an increase in the depth of respiration with respiratory distress developing in the late stages, and characteristic loud, moist crackles or 'rattles' on auscultation. The foal continues to suck and the temperature is sometimes normal but the foal becomes emaciated. Severe diarrhea may follow or accompany the respiratory signs. Nasal discharge and lymph node enlargement in the throat regions are absent. Severely affected animals die in 1–2 weeks. **Thoracic auscultation** may not reveal any abnormalities during the preclinical stage of the disease, although careful auscultation when tidal volume of the foal is increased by exertion or use of a rebreathing bag can reveal localized wheezes and crackles or changes in the intensity of normal breath sounds (indicative of areas of lung consolidation).

Radiographic examination is a valuable aid in diagnosis and in monitoring progress in hospitalized foals.[43] Affected animals show evidence of consolidation of lung tissue, lymphadenopathy, and cavitating lesions in the lungs.

Ultrasonographic examination of the chest may reveal the presence of pulmonary consolidation before clinical signs are apparent and is useful means of detecting subclinical disease.

When lesions are confined to the intestinal wall the predominant clinical sign will be diarrhea, which may be acute or chronic and intermittent.

Intra-abdominal abscesses are associated with ill-thrift, weight loss, variable abdominal distension, fever, depression and in some cases colic. Ultrasonographic examination can reveal the abscess provided that it is within the field of the ultrasound probe.

PROGNOSIS

R. equi infection in Thoroughbred and Standardbred foals is associated with a reduced chance of racing as an adult compared with the overall population of foals, but affected foals that survive have a similar racing performance as adults to horses that did not have *R. equi* pneumonia.[22,44] The morbidity and case fatality rates are provide above under Epidemiology.

CLINICAL PATHOLOGY

Hematological evaluation usually reveals leukocytosis with neutrophilia and monocytosis, and elevation in the concentrations of acute phase proteins including plasma fibrinogen and serum amyloid A – changes characteristic, but not diagnostic, of *R. equi* infection.[45] Monitoring of blood white cell concentration and plasma fibrinogen concentration are useful in foals from farms on which the disease is endemic. **White blood cell concentrations** above 13.0×10^9/L (13 000 cells/μL) have a sensitivity and specificity of 95% and 61% respectively for *R. equi* pneumonia.[46] The high sensitivity means that few foals with the disease will be missed, while the moderate specificity means that a number of foals will be incorrectly suspected as having the disease. Because a high white cell count can be caused by a number of diseases other than *R. equi* pneumonia, foals with high white cell counts from farms on which the disease is endemic should be further examined for evidence of disease, including detailed clinical examination possibly including ultrasonographic examination, culture or PCR of tracheal aspirates, or thoracic radiography. Measurement of **plasma fibrinogen concentration** is less useful for detecting foals with *R. equi* pneumonia. Plasma fibrinogen concentrations of 400 mg/dL (0.4 g/L) have sensitivity and specificity of 91% and 51%, respectively, whereas concentrations of 600 mg/dL (0.6 g/L) have sensitivity and specificity of 38% and 96%, respectively.[46] The positive and negative predictive values of the tests depends on the prevalence of the disease among the group of foals examined, being low for farms on which the disease is rare and increasing as the prevalence of the disease increases. Serial measurement of **serum amyloid A** concentrations is not useful for detecting foals with clinically inapparent *R. equi* pneumonia, nor do foals with pneumonia reliably have higher serum amyloid A concentrations than normal foals.[47]

Transtracheal aspirates from affected foals reveal a neutrophilic leukocytosis. Intracellular, Gram-positive pleomorphic rods characteristic of *R. equi* may be present in tracheal aspirates but the sensitivity of this observation has not been determined and all tracheal aspirates should be cultured.

Although numerous **serological tests** have been developed, including agar gel immunodiffusion, synergistic hemolysis inhibition, radial immunodiffusion and various ELISAs, none has demonstrated value in the diagnosis of the disease in individual animals. Currently available serological tests, either as single or paired samples, are not reliable in confirming or excluding the presence of *R. equi* pneumonia in foals.[28]

Culture of tracheal aspirates is the gold standard for antemortem diagnosis of the disease, although sensitivity of culture is less than that of PCR examination of tracheal aspirates. Culture of tracheal aspirates has a sensitivity of approximately 86%, based on diagnosis of *R. equi* pneumonia at necropsy.[46] However, *R. equi* can be cultured from 35% of clinical normal foals in populations in which the disease is endemic.[48] A **PCR** test for the rapid detection of *R. equi* in tracheal aspirates has a sensitivity of 100% and a specificity of 91% in foals with a clinical diagnosis of *R. equi* pneumonia.[49] PCR examination of nasal swabs for presence of *R. equi* has a

sensitivity of 15%, which is too low to be clinically useful.[50] More recent quantitative real-time PCR assays permit the rapid detection and quantification of virulent (*VapA*-gene-positive) strains of *R. equi* in tracheobronchial aspirates.[51] This assay detects *R. equi* at concentrations as low as 20 cfu/mL of tracheobronchial fluid, providing a specific and highly sensitive test for the presence of this organism. A **multiplex PCR** test simultaneously detects *R. equi* and the presence of virulence factors, thereby permitting rapid differentiation of pathogenic from nonpathogenic strains of *R. equi* in biological samples.[52]

NECROPSY FINDINGS

The predominant lesions are a **pyogranulomatous pneumonia** plus **lymphadenitis** of the bronchial lymph nodes.[12] Grossly, the firm, raised lung nodules may reach several centimeters in diameter and be located anywhere in the lung field, especially in the cranioventral quadrant. If several nodules coalesce, the lesion may be misinterpreted as a suppurative bronchopneumonia. Histologically, organisms are easily demonstrated within the macrophages and giant cells comprising these lesions. Many cases also have ulcerative enterocolitis, with abscessation of mesenteric or cecocolic lymph nodes. Although necropsy may reveal widespread infection, many cases are subclinical.

Samples for postmortem confirmation of diagnosis

- Bacteriology – chilled lung, affected lymph nodes and swabs from atypical sites (CULT)
- Histology – formalin-fixed lung, lymph node, and colonic lesions.

DIAGNOSTIC CONFIRMATION

Antemortem diagnosis is by culture of *R. equi* from aspirates of tracheal fluid. Currently available serological tests do not provide confirmation of disease in individual animals.

DIFFERENTIAL DIAGNOSIS

The pneumonic form of the disease may be confused with other causes of pneumonia in foals (Table 16.4). Other causes of diarrhea in this age group include parasitism due to cyathostomes, infection by *Salmonella* sp. and antibiotic-induced diarrhea.

The aseptic synovitis and joint effusion that frequently accompanies *R. equi* pneumonia should be differentiated from septic arthritis due to *S. zooepidemicus*, *Salmonella* spp., *R. equi* or other bacteria.

TREATMENT

The principles of treatment are cure of *R. equi* infection, relief of respiratory distress and correction of associated immune-mediated diseases.

Elimination of infection requires the administration of antimicrobial agents that are both effective against the organism and able to penetrate infected macrophages to gain access to the organism. **In**

Table 16.4 Differential diagnosis of respiratory diseases of older (not newborn) foals

Disease	Epidemiology	Clinical findings	Clinical pathology	Necropsy findings	Treatment and response
Rhodococcus equi infection	Enzootic to a farm. Foals up to 6 months. Infection by inhalation. Case fatality rate ≈30%	Pneumonia in 1–6-month-olds. Occasional diarrhea. Aseptic synovitis and uveitis in affected foal. Septic osteomyelitis	Inflammatory cells in tracheal aspirate. Culture or PCR detection of *R. equi* from tracheal fluid. Serum tests not useful in individual animals	Suppurative bronchopneumonia. May be mesenteric and other lymph node abscess. Rarely septicemia	Erythromycin estolate, or clarithromycin, plus rifampicin. Advanced cases may be refractory
Interstitial pneumonia	Sporadic occurrence in foals to 6 months of age. Cause not identified	Respiratory distress with minimal cough, slight nasal discharge and low grade to non-existent fever. Lungs sounds not remarkable	None diagnostic. Rule out other diseases. Radiography useful	Interstitial pneumonia	Corticosteroids. Broad-spectrum antibiotics (e.g. penicillin and gentamicin). Supportive care
Viral respiratory disease (see Table 16.1)	Foals usually over 2 months. Rhinitis virus, herpesvirus and influenza virus infection	Fever, cough, nasal discharge	Viral isolation. Serology	Usually survive although fatal influenza infection reported	Supportive. Antibiotics for secondary bacterial (*Streptococcus zooepidemicus*) infection
Combined immunodeficiency of Arabian foals	Inherited as autosomal recessive trait. Affected animals are homozygous	Poor condition, tire easily, cough, ocular and nasal discharge, diarrhea in some	Severe lymphopenia. Hypogammaglobulinemic as passive immunity declines	Lymphocytes absent from lymphoid tissue. Adenoviral pneumonia	Nil
Respiratory tract infection with *S. zooepidemicus*	Outbreaks in foals up to weaning. Likely secondary to viral infection	Fever, nasal discharge, cough, inappetence. Minimal lymphadenopathy	*S. zooepidemicus* in tracheal aspirates	Usually survive	Penicillin. Good recovery rate
Parasitic pneumonia	Migrating stages of *Parascaris equorum*. Foals > 6 weeks old	Cough, slight nasal discharge. Rarely fever	Eosinophils in tracheal aspirate	Death rare	Anthelmintics, e.g. fenbendazole
Pneumocystis jirovici (formerly *carinii*) pneumonia	Immunodeficient foals or foals administered corticosteroids	Cough, mucopurulent nasal discharge, fever, lethargy, tachypnea	Neutrophils and macrophages and *P. jirovici* cysts in tracheal aspirate or bronchoalveolar avage fluid	Pneumonia, diffuse with neutrophilic or lymphocytic/plasmacytic infiltration and alveolar edema. *P. jirovici* evident in silver-stained lung sections	Sulfonamide/ trimethoprim 30 mg/kg q 12 h recommended but often not effective

vitro antibiotic sensitivity testing has not been demonstrated to be useful in predicting the clinical efficacy of treatment. *R. equi* isolates from ill foals are frequently sensitive in vitro to a variety of antibiotics, including the aminoglycosides gentamicin and neomycin, tetracycline, sulfonamides and chloramphenicol, while most are resistant to cephalosporins and penicillin.[53–55] However, treatment with antibiotics other than erythromycin and rifampin is associated with a lower recovery rate. Treatment with **penicillin**, with or without **gentamicin**, chloramphenicol or tetracycline, is not effective.[53] **Trimethoprim–sulfadiazine** combinations might be effective in some foals but are not the preferred treatment.[53] Neomycin has been recommended for treatment of *R. equi* pneumonia[56] but the risk of nephrotoxicosis, need for parenteral administration and lack of demonstration of clinical efficacy do not support its use at this time.

The **treatment of *R. equi* pneumonia** in foals is achieved by administration of macrolide antibiotics in combination with rifampin. Conventional treatment is administration of the combination of an acid-stable **erythromycin** (preferably estolate) at a dose of 25 mg/kg orally every 12 hours and **rifampin** at a dose of either 5 mg/kg every 12 hours or 10 mg/kg every 24 hours. Other esters or preparations of erythromycin are less well absorbed or have shorter elimination half-lives than the estolate ester and must be administered more frequently.[32] Erythromycin ethylsuccinate does not provide optimal therapy for *R. equi* pneumonia in foals because of poor absorption after oral administration.[55,57] The macrolide antibiotics **azithromycin** and **clarithromycin** have also been used to treat foals with *R. equi* pneumonia. Treatment of foals with a combination of clarithromycin (7.5 mg/kg orally every 12 h) and rifampin results in improved survival over foals treated with azithromycin (10 mg/kg orally every 24 h) and rifampin or erythromycin and rifampin in a veterinary teaching hospital.[58]

Therapy should be continued until the foal is clinically normal **and** has a normal plasma fibrinogen concentration and white blood cell count, which can require treatment for at least 1 month and often longer. Radiographic or ultrasonographic demonstration of resolution of the pulmonary consolidation and abscessation is useful in the decision to stop therapy. The case fatality rate is approximately 30% (see Epidemiology, above) even with appropriate treatment.

Side-effects of erythromycin–rifampin therapy include the development of **diarrhea** in some foals and their dams.[59] Administration of erythromycin to foals is associated with an eightfold increase in the risk of diarrhea.[50] Antibiotic therapy should be temporarily discontinued in foals that develop diarrhea.

During hot weather, some foals treated with erythromycin become **hyperthermic** (40–41°C, 104–105.5°F) and **tachypneic** and occasional deaths result from this syndrome.[50,60] The basis for this hyperthermic event, which may occur in healthy foals administered erythromycin, is unknown. Affected foals should be treated urgently with antipyretics, cold water bathing and housing in a cooler environment.

The emergence of *R. equi* isolates **resistant to rifampin** during therapy of foals with *R. equi* pneumonia has been reported.[61] However, one case had an atypical clinical course, in that the foal was 10 months of age at presentation and may have been immunosuppressed, and in the other instance the foal was treated with only rifampin. The development of resistance during monotherapy with rifampin is a recognized contraindication to the use of this drug alone.

Ancillary therapy with NSAIDs, bronchodilators, and mucolytics might be of value.[53] Foals in severe respiratory distress require intranasal or intratracheal administration of oxygen.

CONTROL

Control measures are designed to maximize the resistance of the foal to infection and to reduce the infection pressure on the foal by decreasing contamination of the foal's environment with virulent *R. equi*. Insuring adequate transfer of **colostral immunoglobulins** in all foals through routine monitoring of serum immunoglobulin concentrations in 1-day-old foals is an essential part of any control program. To **decrease environmental contamination** with virulent *R. equi*, efforts should be made to reduce fecal contamination of pastures and to reduce or eliminate dusty or sandy areas.[24,62] These efforts should include grassing or paving of bare areas, removal and composting of fecal material on a regular basis, reduction of stocking density and reduction in the size of mare/foal bands.[24]

On farms with endemic disease, regular physical examination, including auscultation of foals and once-daily monitoring of rectal temperature, can permit early identification and treatment of affected foals.[63] Measurement of blood white cell count, as detailed above, can be useful in early identification of affected foals. Identification of one foal affected with *R. equi* pneumonia on a farm should prompt an examination of all other foals on the farm.

Ultrasonographic examination of the thorax of foals may permit identification of foals with clinically inapparent pulmonary abscesses.

The administration to foals of a hyperimmune serum, obtained from mares vaccinated with an autogenous vaccine, limits the severity of disease produced by experimental challenge but has not been consistently useful in preventing or decreasing the prevalence of naturally occurring disease.[19,34,64,65] There are no vaccines effective in prevention of *R. equi* pneumonia in foals.

Diseases associated with *Listeria* species

There are currently six species classified within the genus *Listeria*[1] but only *Listeria monocytogenes* and *Listeria ivanovii* (previously classified as *L. monocytogenes* serotype 5) are pathogenic for domestic animals. *L. ivanovii* is only mildly pathogenic and is an occasional cause of abortion in sheep and cattle.[2–4] Aborted fetuses have suppurative bronchopneumonia and lack the multifocal hepatocellular necrosis commonly seen in abortions associated with *L. monocytogenes*.[3] *Listeria innocua* is occasionally associated with encephalitis in ruminants that is clinically and pathologically similar to that associated with *L. monocytogenes*.[5] Most, but not all, reports of both infections record that the animals were being fed silage.

LISTERIOSIS

Synopsis

Etiology *Listeria monocytogenes*. Ubiquitous in farm environment
Epidemiology Ruminants, particularly sheep. Prime occurrence is seasonal associated with feeding silage with high listerial growth. Also following management-induced stress. Commonly manifest with multiple cases in a group
Clinical findings Most commonly encephalitis with brainstem and cranial nerve dysfunction or abortion in last third of pregnancy. Less commonly septicemia in periparturient and neonatal sheep and goats, enteritis in weaned sheep, spinal myelitis, ophthalmitis and occasionally mastitis
Clinical pathology Culture. Pleocytosis and elevated protein in cerebrospinal fluid with encephalitis
Lesions Microabscesses in brainstem in listerial encephalitis, spinal cord in spinal myelitis, intestine in enteritis. Visceral lesions in septicemia
Diagnostic confirmation Culture and histopathology
Treatment Chlortetracycline or penicillin. Must be given early in clinical disease
Control Control of listerial growth in feeds. Vaccination

ETIOLOGY

L. monocytogenes is widespread in nature and has characteristics that allow its survival and growth in a wide variety of environments. There is a highly diverse range of strains some of which have the capability of causing disease in animals and humans.

Optimal growth temperatures are between 30°C and 37°C but the organism can grow and reproduce at temperatures between –0.4°C and 45°C. It can grow between pH 4.5 and 9.6 although growth at low pH is minimal at low temperatures.[1] The organism is susceptible to common disinfectants.

L. monocytogenes can be divided into 16 serovars on the basis of somatic and flagellar antigens and there is considerable genetic diversity between serovars. Serovars 4b, 1/2a and 1/2b and 3 are most commonly isolated from diseased animals but there are geographical differences.[1–3] Virulent strains can multiply in macrophages and monocytes and produce a hemolysin, listeriolysin O, which is believed to be a major virulence factor.[3]

EPIDEMIOLOGY

Occurrence

Geographical

Although the organism is widespread in nature, clinical disease in animals occurs mainly in the northern and southern latitudes and is much less common in tropical and subtropical than in temperate climates. The disease is important in North America, Europe, the UK, New Zealand, and Australia.

Seasonal

In the northern hemispheres listeriosis has a distinct seasonal occurrence, probably associated with seasonal feeding of silage, with the highest prevalence in the months of December through May[4] but seasonal occurrence is not a feature in Australia.[5]

Host

Listeriosis is primarily a disease of ruminants, particularly sheep, and the major diseases associated with *L. monocytogenes* are encephalitis and abortion. In ruminants it also produces syndromes of septicemia, spinal myelitis, uveitis, gastroenteritis, and mastitis. Occasional septicemic disease occurs in horses and pigs.

- **Encephalitis** usually occurs sporadically, affecting a single animal in a herd or flock or a few individuals over several weeks. The mean attack rate in 50 affected flocks in Britain was 2.5% with a range of 0.1–13.3%.[6] More serious outbreaks can occur with attack rates as high as 35% and cases occurring over a 2-month period. The disease occurs in sheep older than 6 weeks but may be more prevalent in lambs between 6 and 12 weeks of age and ewes over 2 years of age. The case fatality is high, especially in sheep, because the short clinical course often precludes treatment
- **Abortion** may also occur sporadically, which is usually true in cattle, but in sheep and goats it more commonly occurs as an outbreak with an attack rate that frequently approaches 10%
- **Spinal myelitis** is an uncommon manifestation but is recorded as occurring in 0.8–2.5% of sheep in affected flocks and in all ages of sheep[4] 4 weeks following spray dipping. Spinal myelitis also occurs sporadically in cattle 12–18 months of age[5]
- **Septicemic disease** is also a less common manifestation of infection with *L. monocytogenes* but can occur as an outbreak with a high case fatality in newborn lambs and kids and also in periparturient ewes and does
- **Ophthalmitis/uveitis** occurs in both sheep and cattle, and can occur as an outbreak. Many, but not all, outbreaks have been associated with round-bale 'self-feed' silage in the winter period[7] and eye infection is directly from the silage as the animals burrow their head into the silage to eat. *L. monocytogenes* is also associated with outbreaks of catarrhal **conjunctivitis** of cattle

- **Gastroenteritis** has been reported primarily by veterinary diagnostic labs in Great Britain and New Zealand as a sporadic disease affecting all ages of sheep after weaning. It occurs during the winter months most commonly in sheep fed baleage or silage. Cases occur 2 days or more after the onset of feeding.[8,9] Less commonly, cases occur in sheep on root crops or on pasture where the quality of the pasture is poor and they are at high stocking densities
- **Mastitis** is uncommon but can occur in cattle, sheep, and goats. It results in contamination of milk with *L. monocytogenes*. The more common source of *L. monocytogenes* in raw milk is fecal contamination. In a Danish study of quarter milk samples from over 1 000 000 cows in 36 199 herds, 0.4% of cows had listerial mastitis and 1.2% of herds had infected cows.[10]

Source of infection

The organism is common in the environment and infection is not limited to agricultural animals. *L. monocytogenes* has been isolated from 42 species of mammals, 22 species of birds as well as fish, crustaceans, and insects. It is truly **ubiquitous in the environment** and can be commonly isolated from animal feces, human feces, farm slurry, sewerage sludge, soil, farm water troughs, surface water, plants, animal feeds and the walls, floors, drains, etc. of farms and other environments.[1,11,12] The ability to form biofilms may assist in its survival in the environment[13] and may assist in perpetuating its presence in water troughs on infected farms.

Most feed hays, grains and formulated feeds have the potential to contain *L. monocytogenes* but, with most, low levels of available water restrict its multiplication.

In ruminants *L. monocytogenes* can be isolated from the feces and nasal secretions of healthy animals and has been isolated from the feces of cattle in 46% of 249 herds examined[14] and from 82% of samples of feedstuffs.[15] In temperate climates the prevalence of *L. monocytogenes* in the feces of ruminants appears to vary with the season, being higher in the winter period. It is also increased during periods of environmental stress and in association with the stress of lambing and transport.[16–18] The presence in feces and secretions can also be influenced by the numbers of the organism in feeds fed to the animals.[15,18,19] In herds where there is a high proportion of cattle excreting in feces, the organism can be isolated from dried fecal dust on walls and most farm surfaces.

L. monocytogenes is not isolated from the feces or environment in all farms and its presence in isolable numbers is largely a reflection of its presence in feed, or the presence of animals with intestinal carriage. It is apparent that in some healthy herds and flocks there may be a multitude of different strains in the silage and feed, water troughs, feces and environment in a single herd.[19,20]

The presence of *L. monocytogenes* in bulk tank milk or milk filters is used as a measure of farm infection prevalence.[21] Obviously this measure is influenced by the management and environmental conditions on farms that might result in fecal contamination of the teats. Although bulk tank and milk filter infection rates provide information of possible value to measures of environmental contamination and risk for human exposure there is no evidence that this measure has any relation to risk for animal disease on the farm being studied.

Silage

L. monocytogenes is commonly present in silage, but it does not multiply to any significant extent in effectively preserved silage which is characterized by anaerobic storage, high density, a high concentration of organic acids, and a pH below 4.5. *Listeria* can multiply in silage above pH 5.0–5.5, the critical pH depending upon the dry matter content.[10,22,23] *L. monocytogenes* may be present in silage which is **poorly fermented** but it can also occur in pockets of **aerobic deterioration** in otherwise good silage[24] and this is the common occurrence. These areas are often indicated by mold growth and occur at the edges of the clamp and in the top few inches of the surface in plastic-covered clamps where air has circulated under the plastic. Thus the growth of *L. monocytogenes* is a surface problem in silage – except those that are poorly fermented – and occurs in small areas sporadically over the surface of a silage.

The risk for contamination of silage with *Listeria* is higher when it contains soil. **Soil** may be incorporated from mole-hills present in the field and it may also be incorporated in the front of the clamp during final packing. An **ash content** of greater than 70 mg/kg dry matter indicates soil contamination.

Big bale silage may have a higher risk for listerial infection than conventional silage because of its lower density, poorer fermentation, the greater surface area relative to clamp silage and the greater risk for mechanical damage to the plastic covering.[10]

Moist preserved feeds other than grass silage are at risk for listerial growth; listeriosis is recorded, for example, in association with the feeding of moist brewers' grains, wet spoiled hay bales and silage made from commodity by-products such as orange and artichoke waste. A relatively rapid method for the quantitative assessment of the occurrence and distribution of *Listeria* in suspect silage is available.[24]

Infective material also derives from infected animals in the feces, urine, aborted fetuses and uterine discharge, and in the milk. Although immediate spread among animals in a group has been demonstrated, field observations suggest that mediate contagion by means of inanimate objects also occurs. **Woody browse** may be a risk factor for goats.[25]

Transmission

With septicemic disease and abortion the organism is transmitted by ingestion of contaminated material. Lambs which develop septicemic disease may acquire infection from contamination on the ewe's teat, from the ingestion of milk containing the organism from ewes or does with subclinical bacteremia, through the navel from the environment, and also as a congenital infection. The encephalitic form of the disease results from infection of the terminals of the trigeminal nerve consequent to abrasions of the buccal mucosa from feed or browse or from infection of tooth cavities. Spinal myelitis is believed to result from growth up spinal nerves subsequent to body area infections.

Outbreaks of encephalitis which occur in sheep after introduction to silage usually commence about 3–4 weeks later, although there is wide variation and one study of a large number of outbreaks found the median time of this period to be 44 days.[6] This delay reflects the time for ascending infection.

Commonly, the serotype that is isolated from the brain of an affected animal is also present in the silage being fed. However, the recent development of methods for genetic analyses of *L. monocytogenes* has demonstrated that serotyping is a relatively crude tool for epidemiological studies and in many instances, although the isolate from brain may be the same serotype as that from silage, there is no relationship on genetic analysis.[20,26] Possibly this reflects differences in strains at different sites in silage and the difference between the time of sampling of the silage and the time when the affected cow ate it.

Septicemic disease in sheep and goats usually occurs within 2 days of introduction to silage and abortions 6–13 days later.[17,27]

Risk factors

Despite the ubiquity of *L. monocytogenes*, only a small proportion of animals develop clinical disease. A number of predisposing factors have been observed, or proposed, as risk factors for disease. These include factors that cause a lowering of the host animal's resistance and factors that increase

the infection pressure of the organism. In farm animals the latter appear the most important.

Host management risk factors

Observed risk factors include:

- Poor nutritional state
- Sudden changes of weather to very cold and wet
- The stress of late pregnancy and parturition
- Transport
- Long periods of flooding with resulting poor access to pasture.

Area outbreaks affecting several flocks can occur in sheep on poorly drained and muddy pastures following floods, but outbreaks are also described in droughts.[28] Overcrowding and insanitary conditions with poor access to feed supplies may predispose housed sheep.

Breed difference in susceptibility (Angora goats and Rambouillet sheep) has been observed in some studies[21,29] but not in others.[4]

Pathogen risk factors

Factors that increase the infection pressure largely involve a massive multiplication of *L. monocytogenes* in the feed or environment. The feeding of grass or corn silage as a major risk factor for the occurrence of listeriosis has been recognized for many decades. The increase in use of silage for feed in ruminants may be the reason for the apparent increase in the prevalence of the disease in recent years. Silage may also exert its effect by increasing the susceptibility of the host to listerial infection, although this has been disputed.[30]

Introduction of **virulent strains** to the flock may also occur via a carrier animal, and birds, such as seagulls that scavenge on sewerage areas, may carry a heavy population of the bacteria and can contaminate feed or pastures for silage. The organism persists for as long as 3 months in sheep feces and has been shown to survive for up to 11.5 months in damp soil, up to 16.5 months in cattle feces, up to 207 days on dry straw and for more than 2 years in dry soil and feces. It is resistant to temperatures of –20°C (–6°F) for 2 years and is still viable after repeated freezing and thawing.

Experimental reproduction

Oral or parenteral challenge of nonpregnant sheep and goats will produce a bacteremia with minor clinical signs of pyrexia and depression in animals with no preexisting antibody. Clinical disease is more severe in young animals and the infection clears with the development of an immune response.[31–33] The challenge of animals with pre-existing antibody is not associated with clinical disease although there may be a bacteremia. Lactating animals secrete the organism in milk during the bacteremic period. Prior challenge of goats with *L. ivanovii* or *Listeria innocua* does not protect against subsequent challenge with *L. monocytogenes*.[33]

Several studies have shown that oral, conjunctival, and parenteral challenge of **pregnant animals** results in more severe signs of septicemia and can be followed by **abortion**, although this is not an invariable sequel.[34] Encephalitis has not been reproduced experimentally by intravenous challenge, although meningoencephalitis may occur following this route of challenge in young lambs. **Encephalitis** has been reproduced experimentally by the injection of organisms into the buccal mucosa or the tooth pulp cavity, the organism traveling centripetally via the trigeminal nerve to reach the brain stem.[35]

Zoonotic implications

In humans, listeriosis may occur as a sporadic disease or as a food-borne outbreak to produce septicemic disease, meningoencephalitis, abortion and infection in other organs. **Sporadic disease** may involve healthy humans of any age but the disease usually occurs in the very young or unborn, the very old and people who are otherwise immunocompromised. The case fatality is high, and overall approximately 25% of reported cases die. Active surveillance for sporadic cases indicates that approximately 2000 cases and 450 deaths occur each year in the USA to give an annual incidence of 0.8 per 100 000 population.[16] The incidence is increasing, possibly because of an increase in susceptible populations.

The similarity of the disease spectrum in humans and animals and the occurrence of food-borne outbreaks has led to concerns that the disease could be a zoonosis. Whereas there is a potential for zoonotic transmission it would appear that the majority of human exposures to the organism, and the risk for disease, result from contamination of foods during processing and from the particular ability of the organism to grow at refrigerator temperature.

Milk products

Milk products have been incriminated in some outbreaks of disease. Numerous studies have shown that *L. monocytogenes* is commonly present in low numbers (usually less than 1/mL) in raw milk from some herds. In the vast majority of herds this is the result of fecal contamination during the milking process or other environmental contamination. Rarely, its presence in raw milk is from an animal with subclinical mastitis and in this case its numbers in bulk tank milk are much higher (2000–5000/mL), even when there is a single cow or goat with *L. monocytogenes* mastitis.[36,37] In goats and sheep the presence in raw milk may also be the result of a subclinical bacteremia.

There have been concerns that the organism might survive pasteurization, especially if present in phagocytes. D-values for *Listeria* in milk have been determined to be in the range of 0.9 seconds at 71.1°C. The legal limit for high-temperature/short-time pasteurization in the US is 71.7°C for 15 seconds and this temperature is sufficient to inactivate numbers far beyond those present in raw milk.[38] There is no evidence that the organism will survive correct pasteurization procedures.[1]

Bulk tank infection rates are higher in winter and spring and cross-sectional and case-control studies have shown that the risk for detecting *L. monocytogenes* in bulk milk is higher in those herds that used a bucket milking system rather than a pipeline system. It is also higher in herds fed component feeds, fed leftover feed, fed from plastic feed bunks and with a low frequency of feed bunk cleaning.[39,40] It is lower in herds that practice premilking teat disinfection.[40]

Farmers or others who consume **raw milk** need to be aware of the risk of infection, especially if they fall within at-risk categories. There may be a particular risk with milk from goats and sheep fed silage. People associated with agriculture are also more liable to direct zoonotic transmission of listerial disease. **Dermatitis** with a papular and pustular rash occurs on the arms of **veterinarians** following the handling of infected dystocial cases and aborted fetuses. **Conjunctivitis** is also recorded in agricultural workers handling infected livestock.

Although *L. monocytogenes* rarely causes disease in **pigs** it is present in the tonsils and feces of some pigs at slaughter and this presence is a potential source of contamination of the carcass and the slaughterhouse environment. There is a significantly higher prevalence in the tonsils of fattening pigs than in those of sows.[41] The organism can be isolated from the floors, walls, and feed in pig units. Wet feeding, poor hygiene, and a short spelling period between batches of pigs in the finishing house have been found to be risk factors for infection in pigs. Paradoxically, disinfecting the pipeline used for wet feeding was associated with a higher risk of fecal contamination than no disinfection at all.[42,43]

A further concern for indirect zoonotic risk of *L. monocytogenes* is the presence of the organism in the feces on infected farms and the potential for fecal or windborne dust spread to adjacent fields that may contain crops for human consumption.

PATHOGENESIS

In most animals, ingestion of the organism, with penetration of the mucosa of the intestine, leads to an inapparent infection with prolonged fecal excretion of the organism and to a subclinical bacteremia, which clears with the development of immunity. The bacteremic infection is frequently subclinical and may be accompanied by excretion of the organism in milk. Septicemic listeriosis, with or without meningitis, occurs most commonly in neonatal ruminants and in adult sheep and goats, particularly if they are pregnant and when the infection challenge is large.

The organism is a facultative intracellular pathogen that can infect cells, including intestinal cells, by directed endocytosis. It can survive and grow in macrophages and monocytes.[3] Bacterial superoxide dismutase protects against the bactericidal activity of the respiratory burst of the phagocyte and listeriolysin O disrupts lysosomal membranes, allowing the organism to grow in the cytoplasm.[1,3] The experimental mouse model indicates that cell-mediated immunity is important in protection against listerial infection but studies in goats suggest that the clearance of bacteremic infection and resistance to infection are also strongly associated with humoral antibody.[44]

In **pregnant animals** invasion of the placenta and fetus may occur within 24 hours of the onset of bacteremia. Edema and necrosis of the placenta leads to **abortion**, usually 5–10 days postinfection. Infection late in pregnancy results in **stillbirths** or the delivery of young that rapidly develop a fatal septicemia. Maternal **metritis** is constant and if the fetus is retained a fatal listerial septicemia may follow. Infection of the uterus causing abortion and intrauterine infection occurs in all mammals.

Encephalitis

Encephalitis in ruminants occurs as an acute inflammation of the brainstem and is usually unilateral. The portal of entry is by ascending infection of the trigeminal or other cranial nerves following loss of the integrity of the buccal mucosa resulting from trauma, the shedding of deciduous or permanent teeth or from periodontitis.[35] Clinical signs are characterized most strongly by an **asymmetric** disorder of cranial nerve function, and in particular the trigeminal, facial, vestibular, and glossopharyngeal nerves, but there is some variation in the involvement of individual cranial nerves depending upon the distribution of lesions in the brainstem. Lesions in the sensory portion of the trigeminal nucleus and the facial nucleus are common and lead to ipsilateral facial hypalgesia and paralysis; involvement of the vestibular nucleus is also common and leads to ataxia with circling and a head tilt to the affected side.[45] The additional signs of dullness, head-pressing, and delirium are referable to the more general effects of inflammation of the brain developing in the agonal stages. Spread of the infection along the optic nerve may result in endophthalmitis in sheep and cattle.

Spinal myelitis

Spinal myelitis possibly results from ascending infection in the sensory nerves of the skin following dermatitis from prolonged wetting of the fleece.[4]

Mastitis

L. monocytogenes is rarely found to be a cause of **mastitis** in cattle, despite the fact that it can be common in the dairy environment of herds that have milking practices that could be conducive to the introduction of environmental pathogens into the udder. This suggests that it is not a particularly invasive or perpetuating organism for the udder.[36]

CLINICAL FINDINGS

When disease occurs it is usual to have an outbreak of either encephalitis or abortion. Encephalitis is the most prevalent manifestation in sheep. Septicemia in lambs may occur in conjunction with abortion but it is rare to have all three syndromes on the same farm, at least in the same temporal period. There are always exceptions to such generalities, and the occurrence of septicemia, abortion, and encephalitis in a flock of sheep is possible.[27]

Listerial encephalitis

Sheep

In sheep, early signs are separation from the flock, and depression with a hunched stance. Sheep approached during this early stage show a frenetic desire to escape but are uncoordinated as they run and fall easily. The syndrome progresses rapidly with more severe depression to the point of somnolence and the development of signs of cranial nerve dysfunction. Fever – usually 40°C (104°F) but occasionally as high as 42°C (107°F) – is usual in the early stages of the disease but the temperature is usually normal when overt clinical signs are present.

Signs vary between individual sheep but incoordination, head deviation sometimes with head tilt, walking in circles, unilateral facial hypalgesia and facial paralysis are usually present. Facial hypalgesia can be detected with pressure from a hemostat and the facial paralysis is manifest with drooping of the ear, paralysis of the lips and ptosis on the same side of the face as the hypalgesia. This may be accompanied by exposure keratitis, often severe enough to cause corneal ulceration. Strabismus and nystagmus occur in some. Panophthalmitis, with pus evident in the anterior chamber of one or both eyes, is not uncommon in cattle that have been affected for a number of days. Also there is paresis of the muscles of the jaw, with poor tone or a dropped jaw, in which case prehension and mastication are slow and the animal may stand for long periods drooling saliva and with food hanging from its mouth.

The position of the head varies. In many cases there is deviation of the head to one side with the poll–nose relationship undisturbed (i.e. there is no rotation) but in others there is also head tilt. The head may be retroflexed or ventroflexed depending on the localization of the lesions and in some cases may be in a normal position. The deviation of the head cannot be corrected actively by the animal and if it is corrected passively the head returns to its previous position as soon as it is released. Progression is usually in a circle in the direction of the deviation and the circle is of small diameter. There is ataxia, often with consistent falling to one side, and an affected sheep may lean against the examiner or a fence. The affected animal becomes recumbent and is unable to rise, although often still able to move its legs. Death is due to respiratory failure.

Cattle

In cattle, the clinical signs are essentially the same but the clinical course is longer.[46] In adult cattle the course of the disease is usually 1–2 weeks but in sheep and calves the disease is more acute, death occurring in 2–4 days.

Goats

In goats the disease is similar to that in the other species, but in the young goat the onset is very sudden and the course short, with death occurring in 2–3 days.

Listerial abortion

Outbreaks of abortion are recorded in cattle but occur more commonly in sheep and in goats. Abortion due to this organism is rare in pigs.

Cattle

In cattle, abortion or stillbirth occurs sporadically and usually in the last third of pregnancy; retention of the afterbirth occurs commonly, in which case there is clinical illness and fever of up to 40.5°C (105°F). Abortion has been observed soon after the commencement of silage feeding but does not always have this association.

Sheep and goats

In sheep and goats abortions occur from the 12th week of pregnancy onwards, the afterbirth is usually retained, and there is a bloodstained vaginal discharge for several days. There may be some deaths of ewes from septicemia if the fetus is retained. In both species the rates of abortion in a group

are low but may reach as high as 15%. On some farms, abortions recur each year.

Abortion due to *Listeria ivanovii*

This occurs as a sporadic disease in cattle and has no distinguishing clinical features from that associated with *L. monocytogenes*.[46,47] Outbreaks in sheep are manifest with abortion and stillbirth but particularly with the birth of live infected lambs, which seldom survive long enough to walk or suck.

Septicemic listeriosis

Acute septicemia due to *L. monocytogenes* is not common in adult ruminants but does occur in monogastric animals, and in newborn lambs and calves. There are no signs suggestive of nervous system involvement, the syndrome being a general one comprising depression, weakness, emaciation, pyrexia, and diarrhea in some cases, with hepatic necrosis and gastroenteritis at necropsy. The same syndrome is also seen in ewes and goats after abortion if the fetus is retained. A rather better defined but less common syndrome has been described in calves 3–7 days old. Corneal opacity is accompanied by dyspnea, nystagmus, and mild opisthotonos. Death follows in about 12 hours. At necropsy there is ophthalmitis and serofibrinous meningitis. Septicemic listeriosis is recorded in a foal.[48]

Mastitis

Infection in the udder may involve a single quarter or both quarters; it is chronic and poorly responsive to treatment. There is a high somatic cell count in milk from the affected quarter, but the milk appears normal.

Spinal myelitis

There is fever, ataxia with initial knuckling of the hindlimbs progressing to hindlimb weakness and paralysis. In some cases, both in sheep and cattle, there is also paresis and paralysis of the front limbs. There is no evidence of cranial nerve involvement and affected animals are initially mentally alert, bright and continue to eat. However, there is rapid deterioration and affected animals are commonly humanely destroyed.

Ophthalmitis, iritis

There is swelling of the iris and constriction of the pupil; white focal lesions are evident on the internal surface of the cornea with floccular material in the anterior chamber. Advanced cases have pannus and corneal opacity. One or both eyes are affected.

Enteritis in weaner sheep

Initially, sheep are found dead. Others in the group show lethargy, anorexia and pass loose, green-colored feces. Pregnant ewes may abort.

CLINICAL PATHOLOGY

The organism can be cultivated from vaginal secretions for up to 2 weeks after abortion and a proportion of aborting animals also have *L. monocytogenes* in the milk and feces.

The cerebrospinal fluid in cases of encephalitis has increased protein and an increased number of leukocytes, most of which are mononuclear cells or lymphocytes.[45,49] *L. monocytogenes* is not detectable by culture or PCR.[50] Electrodiagnostic examinations are reported.[51]

Serological tests (agglutination and complement fixation tests) have been used but lack the predictive value required for diagnostic use. Ruminants commonly have antibody to *Listeria* and high titers are commonly encountered in normal animals in flocks and herds where there have been clinical cases. Nucleic-acid-based techniques can be used to determine the source of a strain of *L. monocytogenes* in an outbreak.[13]

NECROPSY FINDINGS

Typically there are no distinctive gross changes associated with listerial **encephalitis**. Histological examination of central nervous system tissue is necessary to demonstrate the microabscesses that are characteristic of the disease. These are present in the brainstem in listerial encephalitis and in the cervical and/or lumbar spinal cord in outbreaks of spinal myelitis. Sampling of the forebrain will typically result in a false-negative diagnosis. Cold enrichment techniques are advisable when attempting to isolate the organism. Gram staining of paraffin-embedded tissue may permit confirmation of the diagnosis in cases for which suitable culture material is unavailable. Alternative test methods such as fluorescent antibody or immunoperoxidase tests are available in some laboratories. In one retrospective study comparing diagnostic methods, immunoperoxidase staining was superior to bacterial culture when correlated with histopathological changes.[52]

Visceral lesions occur as multiple foci of necrosis in the liver, spleen, and myocardium in the **septicemic form** and in **aborted fetuses**. Aborted fetuses are usually edematous and autolyzed, with very large numbers of bacteria visible microscopically in a variety of tissues. In aborting dams, there is placentitis and endometritis in addition to the lesions in the fetus.[30]

Sheep with **enteritis** show ulcerative abomasitis and some also have typhlocolitis at necropsy; histologically there are microabscesses throughout the intestine and a characteristic infiltration of degenerating neutrophils in the mucosa lamina muscularis of the abomasum.[8]

Samples for confirmation of diagnosis

Central nervous system listeriosis

- Bacteriology – half of midsagittally sectioned brain, **including brainstem**, chilled or frozen (CULT, FAT)
- Histology – formalin-fixed half of midsagittally sectioned brain, **including brainstem**; appropriate segment of spinal cord if spinal myelitis suspected (LM, IHC).

Septicemia and abortion

- Bacteriology – chilled liver, spleen, lung, placenta, fetal stomach content (CULT, FAT)
- Histology – formalin-fixed liver, spleen, lung, brain, placenta, fetal intestine (LM, IHC).

DIFFERENTIAL DIAGNOSIS

Encephalitis
- Pregnancy toxemia in sheep
- Nervous ketosis in cattle
- Rabies
- Gid
- Polioencephalomalacia
- Middle ear disease
- Scrapie

Abortion
- Sheep (Table 18.4)
- Cattle (Table 18.5).

Gastroenteritis
- Salmonellosis

Uveitis
- Contagious ophthalmia

TREATMENT

The intravenous injection of chlortetracycline (10 mg/kg BW per day for 5 d) is reasonably effective in meningoencephalitis of cattle but less so in sheep. Penicillin at a dosage of 44 000 IU/kg BW given intramuscularly daily for 7 days, and in many cases for 10–14 days, can also be used. The recovery rate depends largely on the time that treatment is started after the onset of clinical signs. If severe clinical signs are already evident, death usually follows in spite of treatment. Usually the course of events in an outbreak is that the first case dies but subsequent cases are detected sufficiently early for treatment. Dehydration, acid–base imbalances and electrolyte disturbances must also be corrected. Cases of spinal myelitis are poorly responsive to treatment.

Treatment of listerial iritis is with systemic antibiotics in the early stages coupled with subpalpebral corticosteroid and atropine to dilate the pupil.

In vitro resistance to the tetracycline group of antimicrobials is reported.[53]

CONTROL

Control is difficult because of the ubiquitous occurrence of the organism, the lack

of a simple method of determining when it is present in high numbers in the environment and a poor understanding of the risk factors other than silage. Where the risk factor is silage there may be some merit in the recommendation that a change of diet to include heavy feeding of silage should be made slowly, particularly if the silage is spoiled or if listeriosis has occurred on the premises previously. Tetracyclines can be fed in the ration of animals at risk in a feedlot. When possible, the obviously spoiled areas of silage should be separated and not fed.

Other recommendations on the feeding of silage include: avoiding making silage from fields where molehills may have contaminated the grass; avoiding soil contamination when filling the clamp; the use of additives to improve fermentation and the avoidance of silage that is obviously decayed, or with a pH of greater than 5 or an ash content of more than 70 mg/kg of dry matter.

Silage removed from the clamp should be fed as soon as possible.

Where uveitis is a problem, feeding systems that avoid eye contact with silage should be used.

A live attenuated **vaccine** has been shown to induce protection against intravenous challenge[54] and a live attenuated vaccine in use in Norway for several years is reported to reduce the annual incidence of the disease in sheep from 4% to 1.5%.[55] An economic model is available for determining whether vaccination should be practiced.[56] Commercial killed vaccines are available for the control of the disease in some countries and some companies will also produce autogenous vaccines on request. The efficacy of vaccination still requires further determination; however; when economics or food availability on the farm dictate that contaminated silage must be fed, consideration might be given to vaccination as a means of providing some protection.

Diseases associated with *Erysipelothrix rhusiopathiae* (*insidiosa*)

ERYSIPELAS OF SWINE

Erysipelas of pigs is the major disease of animals associated with this bacterium but there are several other minor conditions that require mention. In pigs the condition is seen as sudden death, possibly with diamond-shaped skin lesions and also arthritis and endocarditis.

Synopsis

Etiology *Erysipelothrix rhusiopathiae* (*Erysipelothrix tonsillarum* is nonpathogenic)
Epidemiology Pigs worldwide. Common in unvaccinated pigs raised outdoors. High case fatality rate if not treated. Organism in environment and transmitted by carrier pigs. Important zoonosis
Clinical signs Sudden onset of acute disease, fever, anorexia, typical diamond-shaped skin lesions. Arthritis, endocarditis in chronic form
Clinical pathology Organism in blood. Hemogram and serology
Necropsy findings Skin lesions, widespread ecchymotic hemorrhages (kidney, pleura, peritoneum), venous infarction of stomach. Nonsuppurative proliferative arthritis. Vegetative endocarditis
Diagnosis Culture and isolate organism from blood in acute case and then tissues
Differential diagnosis *Other septicemias of pigs:*

- Septicemic salmonellosis
- Hog cholera (African Swine Fever)
- Streptococcal septicemia and arthritis
- Streptococcal endocarditis

Other arthritides of pigs:

- Glasser's disease
- *Mycoplasma* arthritis
- Rickets and chronic zinc poisoning
- Foot rot of pigs
- Leg weakness

Treatment Penicillin
Control Vaccination, with at most 6 month intervals until new vaccines appear

ETIOLOGY

Erysipelothrix rhusiopathiae (*insidiosa*) is the causative bacterium and the disease can be produced in acute and subacute septicemic and chronic forms by the injection of cultures of the organism. A number of different serotypes[1] have been identified, usually types 1 and 2 in pigs. Many of the serotypes have been regrouped and called *Erysipelothrix tonsillarum*. This is a nonpathogenic type found in the tonsil that is morphologically and biochemically similar to *E. rhusiopathiae* but has a very distinctive genetic profile. In many minimal-disease herds they have tended not to vaccinate and then the epizootics have occurred as a result of an increasing lack of immunity.[2]

EPIDEMIOLOGY

Occurrence

Erysipelas in pigs occurs worldwide and in most countries has reached a level of

incidence sufficient to cause serious economic loss due to deaths of pigs and devaluation of pig carcasses because of arthritis. An epidemic occurred in the USA in 1989/90.[3] However, since total indoor confinement of swine herds and the lack of contact with contaminated soil has increased, the occurrence of the disease has decreased markedly. The exception to this would be outdoor units where no vaccination is practiced. Historically, the disease occurred most commonly in unvaccinated growing pigs over 3 months of age and adults. This is primarily because the maternal antibody is believed to last up to 3 months. The infection, usually with serotypes 1a or 2, has also been demonstrated in wild boars, so these should not be forgotten as a reservoir.[4] Perhaps more importantly, these were resistant to oxytetracycline and/or dihydrostreptomycin.

Prevalence of infection

The prevalence of infection with *E. rhusiopathiae* in carrier pigs ranges from 3–98%, with most surveys indicating that 20–40% of pigs are carriers.[5] Carriers occur among vaccinated as well as unvaccinated pigs. The organism has been isolated from 10% of apparently healthy slaughter pigs.[5] This explains why the usual source is other pigs.

Morbidity and case fatality

Morbidity and case fatality rates in pigs vary considerably from area to area, largely because of variations in virulence of the particular strain of the organism involved. On individual farms or in particular areas the disease may occur as a chronic arthritis in finishing pigs, or as extensive outbreaks of the acute septicemia, or both forms may occur together. In unvaccinated pigs, the morbidity in the acute form will vary from 10–30%; the case fatality rate may be as high as 75%.

Methods of transmission

Soil contamination occurs through the feces of affected or carrier pigs.[6] Other sources of infection include infected animals of other species, and birds. The clinically normal carrier pig is the most important source of infection, the tonsils being the predilection site for the organism. Young pigs in contact with carrier sows rapidly acquire the status of carriers and shedders. Since the organism can pass through the stomach without loss of viability, carrier animals may re-infect the soil continuously and this, rather than survival of the organism, appears to be the main cause of environmental contamination. The organism can survive in feces for several months. All effluent contains species of *Erysipelothrix* but there is no need to assume that it is *E. rhusiopathiae*.[7] However, its persistence in soil is variable and may be governed by many factors including temperature, pH and the presence of other bacteria. It can survive for 60 months in frozen or refrigerated media, 4 months in flesh and 90 days in highly alkaline soil.

The organism can be isolated from the effluent of commercial piggeries and from the soil and pasture of effluent disposal sites for up to 2 weeks after application of the effluent containing the organism. In a survey of the occurrence of potential pathogens in slurry, the organism was found in samples from 49% of 84 cattle herds, 44% of 32 pig herds and 39% of 67 cattle and pig herds.[8] Although the environment is considered to be secondary to animals as a reservoir of infection, the survival of the organism in the environment could create an infection hazard. Flies are known to transmit the disease and a lowered prevalence has been attributed to the use of insecticides.

Under natural conditions, skin abrasions and the alimentary tract mucosa are considered to be the probable portals of entry and transmission is by ingestion of contaminated feed. Occasional outbreaks occur after the use of virulent and incomplete avirulent culture as vaccines. Abortion storms in late pregnant sows with septicemic death in sucklers may be the first indication of the disease in specific-pathogen-free herds.

Spread of the infection can also occur to most other species. The organism has been recovered from sylvatic mammals in north-western Canada.[9] It has been isolated from a horse affected with vegetative endocarditis.[10] It has, at times, been found in fish meal but this is now used much less often in pig diets. It is possible that other species, such as cattle,[11] may harbor strains that are pathogenic for swine.

Risk factors

There is considerable variation in the ease with which the disease can be reproduced, and in its severity. Many factors such as age, health and intercurrent disease, exposure to erysipelas and heredity govern the ease of both natural and artificial transmission. Although those factors that come under the description of stress may predispose to the condition, virulence of the strain is probably the most important factor. Smooth strains can be used successfully to produce the disease experimentally but rough strains appear to be nonpathogenic. This variation in virulence between strains of the organism has been utilized in the production of living, avirulent vaccines.

Animal risk factors

Pigs of all ages are susceptible, although adult pigs are most likely to be affected if the local strain is of relatively low virulence. Recently farrowed sows seem to be particularly susceptible. This suggests that fatigue may be a factor. Sudden diet changes have also predisposed, as have heat and cold stress. When the strain is virulent, pigs of all ages, even sucklers a few weeks old, develop the disease. Almost entire litters under 2 weeks of age may be affected.[12] Piglets from an immune sow may get sufficient antibodies in the colostrum to give them immunity for some weeks. It is likely that the animals are immune to the strains that are normally found in their particular environment. It is possible that it is the arrival of new serotypes through new pig arrivals or the turning over of previously contaminated land together with an increase in stress that are the main factors. It is thought that between 20–50% of pigs may carry the organism in the tonsil by slaughter. It is known that *E. rhusiopathiae* from bovine tonsils is pathogenic for mice and pigs and possibly pathogenic for other animals and humans.[13]

Pathogen risk factors

At least 32 serotypes are known to exist[5] and many strains;[14] however, 15 probably commonly affect pigs.[15] Serotypes 1 and 2 are the most common types isolated from swine affected with clinical erysipelas and are generally believed to be the only serotypes that cause the acute disease. The other serotypes are relatively uncommon and none of them has yet been a cause of acute epidemics, but some have been isolated from lesions of chronic erysipelas. Serotypes 1a, 3, 5, 6, 8, 11, 21, and type N have been isolated from pigs with chronic erysipelas, mainly arthritis and lymphadenitis.[16] In the USA, 19 of the 22 serotypes have been found and the most frequent are serotypes 1, 2, 5, 6, and 21.[17]

Not all serotypes isolated from pigs are virulent. In a survey in Japan, the organism was found in 10% of the tonsils of healthy slaughter pigs: 54% were serotype 7, 32% serotype 2, 9.5% serotype 6 and 1.6% each of serotypes 11, 12, and 16.[5] All serotype 2 isolates were highly virulent for pigs while the other serotypes were only weakly virulent. Members of the other nonvirulent or weakly virulent group, mainly serotype 7 strains, are considered to be resident in porcine tonsils. Serotypes 1 (subtypes 1a and 1b), 2, 5, 6, and 4 have been found in Puerto Rico.[13] Serotypes 1a or 2 were found most commonly in pigs in Australia, less commonly in sheep and infrequently in other animals.[18] Serotypes 1a and 1b accounted for 79% of the isolates from diseased pigs.[18] A cluster of avirulent strains of serotype 7 from the tonsils of pigs has been identified as *E. tonsillarum*.[19] The genetic diversity of Australian field isolates of *E. rhusiopathiae* and *E. tonsillarum* indicates widespread diversity. Those recovered from sheep or

birds were more diverse than those isolated from pigs, and isolates of serovar 1 were more diverse than those of serovar 2. The diversity indicated that serotyping of *E. rhusiopathiae* is unreliable as an epidemiological tool.[20]

The relatedness of the isolates tested by DNA fingerprinting suggests that *E. tonsillarum* contains the former serotypes 3, 7, 10, 14, 20, 22, and 23, with serotypes 13 and 18 intermediate between this species and *E. rhusiopathiae*. *E. rhusiopathiae represents serotypes* 1, 2, 4, 5, 6, 8, 9, 11, 12, 15, 16, 17, 19, 21, and N. Some serotypes shown to be *E. tonsillarum* on serological grounds have been found to be *E. rhusiopathiae* on enzyme analysis. The serotype antigens of *E. rhusiopathiae (insidiosa)* are immunologically distinct, and commercial bacterins prepared from the common serotypes will not provide protection against other pathogenic serotypes. This may be an explanation for the epidemics that may occur in vaccinated pigs. The 64–66 kDa protein appears to be most immunogenic.[21] Also, a variety of serotypes may be recovered from pigs affected with the septicemic and arthritic forms of the disease.

The organism is resistant to most environmental influences, and to heat (15 min at 60°C) and can survive in animal tissues at 40° C and frozen tissues and is not readily destroyed by chemical disinfection, including 0.2% phenol and by drying agents.

Zoonotic implications

Because of humans' susceptibility, swine erysipelas has some public health significance.[22] Veterinarians in particular are exposed to infection when vaccinating with virulent culture. It commonly contaminates pig products[23] and therefore is quite a common infection in abattoir workers or butchers, or those employed in similar trades. It usually produces a swollen finger and is known as erysipeloid. In this context, there have been recent advances in slide agglutination and latex agglutination tests for rapid diagnosis,[24] which have good correlation with each other and subsequent culture. Now a PCR identifying four species has been described, principally for use in the abattoir.[25] Recently, a case of endocarditis and presumptive osteomyelitis has been described, so care is needed.[26]

PATHOGENESIS

The invasion of the susceptible pig by *E. rhusiopathiae* can occur under particular circumstances, i.e. if weather conditions are hot and humid or in particular fields or buildings. Experimentally, it is often easier to infect the pig through scarified wounds than through intravenous infusions.

No specific virulence factors have been found but there is the presence in the pathogenic serotypes of an ability to produce a capsule that resists phagocytosis.[27] Some others may produce a neuraminidase, which may cleave the mucopolysaccharides in cell walls and cause vascular damage leading to hemorrhage and thrombosis. Invasion of the bloodstream occurs in all infected animals in the first instance. Septicemia results within 1–7 days. The subsequent development of either an acute septicemia or a bacteremia with localization in organs and joints is dependent on undetermined factors. Virulence of the particular strain may be important and this may depend upon the number of recent pig passages experienced. Coagulase activity is a possible virulence factor.[28] Concurrent viral infection, especially hog cholera, may increase susceptibility of the host.

Localization in the chronic form is commonly in the skin and joints, and on other heart valves, with probable subsequent bacteremic episodes, and it may start from as early as 4 days after initial infection, although the cartilage lesions may be delayed until about 8 months and they can then continue to progress for at least 2 years. Selective adherence of some strains of *E. rhusiopathiae (insidiosa)* to heart valves may be a factor in the pathogenesis of endocarditis.[29] In joints, the initial lesion is an increase in synovial fluid and hyperemia of the synovial membrane, followed in several weeks by the proliferation of synovial villi (really a synovitis), thickening of the joint capsule and enlargement of the local lymph nodes. Diskospondylitis also occurs in association with chronic polyarthritis due to erysipelas.[30] Amyloidosis may occur in pigs with chronic erysipelas polyarthritis.[31] The heart lesions may begin with early inflammatory changes associated with emboli.

There has been some controversy over whether the arthrodial lesions result from primary infection or whether they result from hypersensitivity to the *Erysipelothrix* or other antigen. Current opinion suggests that the former is the case but that the lesions are enhanced by immunological mechanisms to persistent antigen at the site. There are increased levels of immunoglobulins IgG and IgM in the synovial fluids of pigs with polyarthritis due to *E. rhusiopathiae (insidiosa)*[32] and the levels are considered only partly due to serum and increased permeability.

Experimentally the disease can be produced by oral dosing, by intradermal, intravenous, and intra-articular injection, and by application to scarified skin, conjunctiva, and nasal mucosa. The arthritic form of the disease can be reproduced by multiple intravenous inoculations of *E. rhusiopathiae*.[1]

The microscopic lesions include vasculitis in capillaries and venules in many sites, including glomeruli, pulmonary capillaries, and the skin. Sometimes, it is possible to see emboli of bacteria without specific stains to demonstrate bacteria.

CLINICAL FINDINGS

Hyperacute form

Quite often the disease is seen for the first time in pigs approaching market weight.

The animal is found dead or is dull, depressed and with a temperature of 42°C (106–109°F), usually in finishing pigs – it is uncommon in sows.

Acute form

After an incubation period of 1–7 days there is a sudden onset of high fever (up to 42°C (108°F)), which is followed some time later by severe prostration, complete anorexia, thirst and occasional vomiting. Initially, affected pigs may be quite active and continue to eat even though their temperatures are high. However, generally in an outbreak one is initially presented with one or two dead or severely affected pigs showing marked red to purple discoloration of the skin of the jowl and ventral surface (may even be whole-body cyanosis), with others in the group showing high fever, reluctance to rise and some incoordination while walking. Dyspnea is a common feature. A conjunctivitis with ocular discharge may be present. Acute nonfatal erysipelas in sows was described recently in the USA.[33] In this outbreak the sows were pyrexic, lethargic, lame, and had multiple erythematous plaques.

Skin lesions are almost pathognomonic but may not always be apparent. These may take the form of the classical diamond-shaped, red, urticarial plaques about 2.5–5 cm square or a more diffuse edematous eruption with the same appearance. In the early stages the lesions are often palpable before they are visible. The lesions are most common on the belly, inside the thighs and on the throat, neck, and ears, and usually appear about 24 hours after the initial signs of illness. Sometimes they can be felt rather than seen. After a course of 2–4 days the pig recovers or dies, with diarrhea, dyspnea, and cyanosis evident terminally. The mortality rate may reach 75% but wide variation occurs. Pregnant animals may abort and it is thought that this is due to the fever but it may be that there is a direct fetal action, as congenital infections and isolations of the organism from the fetus have occurred.

The so-called **'skin' form** is usually the acute form with more prominent skin localization but less severe signs of septicemia and with a low mortality. The skin lesions disappear in about 10 days without residual effects. In the more serious cases the plaques spread and coalesce, often over the back, to form a

continuous, deep purple area extending over a greater part of the skin surface. The affected skin becomes black and hard, and the edges curl up and separate from an underlying, raw surface. The dry skin may hang on for a considerable time and rattle while the pig walks, or it may slough off.

Chronic form

Signs are vague and indistinct except for the joint lesions characteristic of this form of the disease. There may be alopecia, sloughing of the tail and tips of the ears, and a dermatitis in the form of hyperkeratosis of the skin of the back, shoulders, and legs; growth may be retarded. Joint lesions are commonest in the elbow, hip, hock, stifle, and knee joints and cause lameness and stiffness. The joints are obviously enlarged and are usually hot and painful at first but in 2–3 weeks are quite firm and without heat. This is especially the case when the arthritis has been present for some time, allowing healing and ankylosis to develop. Paraplegia may occur when intervertebral joints are involved or when there is gross distortion of limb joints.

A subclinical form of synovitis may occur which affects feed intake and results in a reduced rate of growth.[1]

Endocarditis also occurs as a chronic form of the disease with or without arthritis. Suggestive clinical signs are often absent, the animals dying suddenly without previous illness, especially at times of exertion such as mating, or movement between pens. In others there is progressive emaciation and inability to perform exercise. With forced exercise dyspnea, cyanosis and even sudden death may occur. The cardiac impulse is usually markedly increased, the heart rate is faster, and a loud murmur is audible on auscultation if the valves are badly damaged.

In Switzerland, they suspect[34] chronic swine erysipelas in herds where there is vegetative endocarditis, arthritis and the culture of *E. rhusiopathiae* from vulval discharges. These signs are also accompanied by poor fertility and increased prevalence of abortions, stillbirths and small litter size. The same authors describe the use of vaccine to control an outbreak of purulent periparturient vulval discharge[34] in which *E. rhusiopathiae* was the only organism isolated. In one of their studies anterior vaginal samples from 64 sows all yielded *E. rhusiopathiae*.[35]

CLINICAL FINDINGS

Detection of organism

In the acute form, examination of blood smears may reveal the presence of the bacteria, particularly in the leukocytes, but blood culture is likely to be more successful as a method of diagnosis. Repeated examinations in the chronic forms of the disease may by chance give a positive result during a bacteremic phase. final identification of the organism necessitates mouse or pigeon inoculation tests, and protection tests in these animals using anti-erysipelas serum.

Hematology

In the early stages of the acute form there is first a leukocytosis followed by a leukopenia and a monocytosis. The leukopenia is of moderate degree (40% reduction in total leukocyte count at most) compared with that occurring in hog cholera. The monocytosis is quite marked, varying from a fivefold to a tenfold increase (2.5–4.5% normal levels rise to 25%).

Serology

The efficiency of agglutination tests for *E. rhusiopathiae (insidiosa)* is not clear. They appear to be satisfactory for herd diagnosis but not sufficiently accurate for identification of individual affected pigs, particularly clinically normal carrier animals. A more accurate complement fixation test is available but an enzyme immunoassay test is much quicker, easier and more economical to perform.[36] An ELISA test has been used to measure the serological response of experimentally induced erysipelas arthritis in pigs[1] and 65 kDa antigen from the organism is being evaluated as an antigen agent.[37] Complement fixation tests may be more reliable.

NECROPSY FINDINGS

Acute form

In the hyperacute cases all that may be seen is a congested carcass with discoloration of the skin. The degree of skin discoloration may provide a clue to prognosis, in that it is said that if the skin lesions are pink to light purple then resolution will often occur within 4–7 days but the dark angry black/purple lesions have a grave prognosis.

Classic 'diamond skin' lesions may be present. However, the diffuse, purplish discoloration of the belly and cyanosis of the extremities common to other septicemic diseases of pigs is a more reliable finding. Internally, petechial and ecchymotic hemorrhage occurs, mainly on the pleura and peritoneum and beneath the renal capsule but also on the heart, liver, and spleen. Venous infarction of the stomach is accompanied by swollen, hemorrhagic mesenteric lymph nodes and there is congestion of the lungs and liver. Infarcts may be present in the spleen and kidney and the former much enlarged. Histological changes in all tissues are those of toxemia and thrombosis. Large numbers of intravascular organisms are often visible. There are no specific histological changes.

Chronic form

A nonsuppurative proliferative arthritis involving limb and intervertebral joints is characteristic. A synovitis, with a serous or serofibrinous amber-colored intra-articular effusion occurs first and degenerative changes in the subendochondral bone, cartilage and ligaments follow. When the synovial changes predominate, the joint capsule and villi are thickened. There are enlarged, dark red pedunculations or patches of vascular granulation tissue, which spread as a pannus on to the articular surface. When bony changes predominate, the articular cartilage is detached from the underlying bone, causing abnormal mobility of the joint. Ulceration of the articular cartilage may also be present. Local lymph node enlargement is usual. With time, the joint lesions often repair by fibrosis and ankylosis sufficiently to permit use of the limb.

Endocardial lesions, when present, are large, friable vegetations on the valves, often of sufficient size to block the valvular orifice. Occasionally, endocarditis may be the only lesion seen but this is a rare occurrence. Erysipelas is often said to rank below *S. suis* as a cause of endocarditis in growing pigs but *E. rhusiopathiae (insidiosa)* was the most frequent isolate from cases of endocarditis seen in slaughtered pigs.[31] Infarcts occur in the kidney and these may also yield pure cultures of the organism. Chronic joint lesions are often sterile but bacteriological culture should nevertheless be attempted. The probability of positive isolation increases with the number of joints sampled, and isolations are more frequent from the smaller, distal joints.

Enrichment techniques and the use of selective media will also increase the frequency of isolation of *E. rhusiopathiae (insidiosa)*.[1,38]

Samples for confirmation of diagnosis

From acute cases includes:

- Bacteriology – culture swabs from joints; synovial membranes in culture media, heart valve masses, spleen, kidney, and bone marrow, particularly from a long bone. Smears of heart blood are particularly useful in the first 1–2 days of the acute diseases. The organism is a slender, facultatively anaerobic, Gram-positive rod that produces a 1 mm gray colony after 24 hours incubation on blood agar. It may be observed singly, in short chains or as a palisade. Different morphological types (rough and smooth colonies) exist and the rough are considered less virulent. Bacteriological examination of subacute cases is less successful and chronic cases not successful. Florescent techniques have been developed to show antigen in joints.

New PCR techniques have also been used[39]
- Histology – formalin-fixed synovial membranes, heart valve masses, spleen, kidney, skin lesions (LM).

Note: the zoonotic potential of this organism when handling carcass and submitting specimens.

DIAGNOSIS

Clinical signs, isolation of the agent from multiple sites including blood in the acute stages; but diagnosis from joints in chronic stages is more difficult.

DIFFERENTIAL DIAGNOSIS

Erysipelas in pigs is not ordinarily difficult to diagnose because of the characteristic clinical and necropsy findings. In the occasional situation where anthrax may have occurred in the past it is worth testing a smear of edema fluid taken by a needle from the jowl or ear region for this pathogen. The acute disease may be confused with the other septicemias affecting pigs, but pigs with erysipelas usually show the characteristic skin lesions and are less depressed than pigs with hog cholera or salmonellosis.

Other septicemias of pigs

- **Septicemic salmonellosis** is characterized by gross blue-purplish discoloration of the skin, especially the ears, some evidence of enteritis, and polypnea and dyspnea
- **Hog cholera** is characterized by large numbers of pigs affected quickly, weakness, fever, muscle tremors, skin discoloration and rapid death; convulsions are also common
- **Streptococcal septicemia** and arthritis are almost entirely confined to suckling pigs in the first few weeks of life as is septicemia associated with *Actinobacillus suis*
- **Streptococcal endocarditis** has a similar age distribution to erysipelas endocarditis and bacteriological examination is necessary to differentiate them.

Other arthritides of pigs

The chronic disease characterized by joint disease occurs in pigs of all ages but less commonly in adults and must be differentiated from the following conditions:

- **Glasser's disease** in pigs is accompanied by a severe painful dyspnea. At necropsy there is serositis and meningitis
- ***Mycoplasma* arthritis** generally affects pigs less than 10 weeks of age and produces a polyserositis as well as polyarthritis. However, *Mycoplasma hyosynoviae* can produce simple polyarthritis in growing pigs. In general the periarticular, synovial, and cartilaginous changes are less severe in these infections when compared to erysipelas; however, cultural differentiation is frequently necessary
- **Rickets** and **chronic zinc poisoning** produce lameness in pigs but they occur under special circumstances, are not associated with fever, and rickets is accompanied by abnormalities of posture and gait that are not seen in erysipelas
- **Foot rot of pigs** is easily differentiated by the swelling of the hoof and the development of discharging sinuses at the coronet
- **Leg weakness**. In recent years there has been a marked increase in chronic osteoarthritis and various forms of 'leg weakness' in growing swine, probably related to the increased growth rate resulting from modern feeding and management practices.

TREATMENT

Antimicrobial therapy

Penicillin and anti-erysipelas serum comprise the standard treatment, often administered together by dissolving the penicillin in the serum. Penicillin alone is usually adequate when the strain has only mild virulence. Standard dose rates give a good response in the field but experimental studies suggest that 50 000 IU/kg BW of procaine penicillin intramuscularly for 3 days are required for complete chemotherapeutic effect. Most animals are significantly improved within 2 days. Oxytetracycline is also useful.[40] Chronic cases do not respond well to either treatment because of the structural damage that occurs to the joints and the inaccessibility of the organism in the endocardial lesions. Most strains are resistant to apramycin, neomycin, streptomycin, and spectinomycin and also sulfonamides and polymyxins.

CONTROL

Successful control depends on good hygiene, biosecurity (other pigs and other species), reduction of stress, an effective 6-monthly vaccination policy, preferably two doses, for all animals including boars over 3 months of age, as well as rapid diagnosis, quarantine, and treatment.

Eradication

Eradication is virtually impossible because of the ubiquitous nature of the organism and its resistance to adverse environmental conditions. Complete removal of all pigs and leaving the pens unstocked is seldom satisfactory. Eradication by slaughter of reactors to the agglutination test is not recommended because of the uncertain status of the test.

General hygienic precautions should be adopted. Clinically affected animals should be disposed of quickly and all introductions should be isolated and examined for signs of arthritis and endocarditis. This procedure will not prevent the introduction of clinically normal carrier animals. All animals dying of the disease should be properly incinerated to avoid contamination of the environment. Although thorough cleaning of the premises and the use of very strong disinfectant solutions is advisable, these measures are unlikely to be completely effective. The organism is susceptible to all the usual disinfectants, particularly caustic soda and hypochlorites. Whenever practicable, contaminated feedlots or paddocks should be cultivated.

Specific-pathogen-free piggeries established on virgin soil may remain clinically free of erysipelas for several years. However, because of the high risk of introduction of the organism, it is advisable to vaccinate routinely.

Immunization

Because of the difficulty of eradication, biological prophylactic methods are in common use. Immunizing agents available include hyperimmune serum and vaccines.

Anti-erysipelas serum

The parenteral administration of 5–20 mL of serum, the amount depending on age, will protect in-contact pigs for a minimum of 1–2 weeks, possibly up to 6 weeks, during an outbreak. Suckling pigs in herds where the disease is endemic should receive 10 mL during the first week of life and at monthly intervals until they are actively vaccinated, which can be done as early as 6 weeks provided the sows have not been vaccinated. Repeated administration of the serum may cause anaphylaxis because of its equine origin. For this reason, it has been withdrawn from sale in many countries.

Vaccination

There is no fully satisfactory vaccine available for erysipelas because of the strain variation[41] and short duration of immunity but the vaccines have reduced the occurrence of clinical disease.[42] Regular administration at 6-monthly intervals overcomes this to some extent but there is always the possibility of a new strain appearing. Vaccines containing serotypes 2 and 10 protect against both *Erysipelothrix* species.[43] Serum-simultaneous vaccination has been largely replaced by the use of bacterins, for which lysate and absorbate preparations are available, or by the use of attenuated or avirulent live-culture vaccines, which are administered orally or by injection. The use of live-culture vaccines is prohibited in many countries because of the risk of variation in virulence of the strains used and the possibility of spreading infection.

None of these vaccines gives lifelong protection from a single vaccination, and the actual duration of protection achieved following vaccination varies considerably. You should not assume that protection lasts longer than 6 months. The recent

identification of the region responsible for protective immunity[44] should improve these vaccines in future. Most of the commercially available vaccines are formalin-treated whole cultures with an adjuvant.

There is considerable difficulty in the experimental evaluation of the efficacy of erysipelas vaccines. Strain differences in immunogenicity and variation in host response to vaccination due to innate and acquired factors influence this evaluation, as does variation in virulence of the challenge strain and the method of challenge. A recent experiment has shown that an antigen of serotype 1a will elicit a protective response to a challenge with serotypes 1a and 2b.[45,46] Similar factors are involved in the variations seen in field response to the use of these vaccines. Cross-protection of mice and pigs given a live-organism vaccine against 10 serovars of *E. rhusiopathiae (insidiosa)* has been demonstrated.[47] The use of culture filtrate from a broth culture of an attenuated strain of the organism has been evaluated to produce cross-protective antibody.[48]

Vaccination will reduce the incidence of polyarthritis due to erysipelas, but not mild cases of arthritis. Passively acquired maternal immunity may significantly affect the immune response to vaccination in the young piglet. Also, the immunity engendered by standard vaccines is not uniformly effective against all strains. Under certain conditions, some unusual serotypes have the potential for causing disease in animals vaccinated with vaccines containing the common serotypes. This possibility cannot be ignored and must be considered when vaccination failures occur. Nevertheless, these vaccines are valuable immunizing agents in field situations.

Vaccination program

Following a single vaccination at 6–10 weeks of age, significant protection is provided to market age. However, a second 'booster' vaccination given 2–4 weeks later is advisable. In herds where sows are routinely vaccinated prior to farrowing, a persisting maternal passive immunity may require that piglet vaccination be delayed until 10–12 weeks of age for effective active immunity.

Replacement gilts and adults should also be vaccinated. Bacterins are effective, and field evidence suggests that vaccination provides immunity for approximately 6 months. Sows should be vaccinated twice yearly, preferably 3–6 weeks before farrowing, as this will also provide significant protection against the septicemic form in young sucklers. If possible, a closed herd should be maintained. Abortion may occur sporadically following the use of live vaccines.[49]

Vaccination is subcutaneous in the skin behind the ear, or the axilla and the flank. Reactions at the site of injection are not uncommon. Swelling with subsequent nodule formation and occasional abscessation may occur following the injection of bacterins, and modified live vaccines may produce hemorrhage in the skin at the injection site. Granulomatous lesions may occur following the use of oil-based vaccines. There is little evidence that vaccination increases the incidence of arthritis. It has been suggested by a very limited study[50] that maternal antibody does not appear to interfere with the vaccination. These vaccines were also used in pigs with PRRS and found to be safe and effective. [51] In those cases where the vaccine has not worked it may be that the correct serotype was not in the vaccine or the administration and storage instructions were not followed.[52]

Diseases associated with *Bacillus* species

ANTHRAX

Etiology *Bacillus anthracis*
Epidemiology Global occurrence and often occurs as outbreaks. Spores survive in soil for many years and disease is enzootic in certain areas. Pastoral outbreaks associated with periods of climatic extremes. Outbreaks also associated with infected feedstuffs
Clinical findings Ruminants and horses – peracute disease characterized by fever, septicemia and sudden death. This may be accompanied by subcutaneous edematous swellings in horses. More prolonged disease with cellulitis of the neck and throat occurs in swine
Clinical pathology Because of risk, hematology and blood chemistry are not performed. Demonstration of organism in blood or subcutaneous fluid
Necropsy findings Carcass not opened if anthrax suspected; the diagnosis is made from the examination of aspirated carcass blood. Exudation of tarry blood from the body orifices of the cadaver, failure of the blood to clot, absence of rigor mortis and the presence of splenomegaly
Diagnostic confirmation Identification of organism in blood or tissues by polychrome methylene blue stain of smear or by monoclonal antibody-fluorescent conjugates. Culture, Ascoli test
Treatment Antibiotics, antiserum
Control Prevention of further spread. Vaccination

ETIOLOGY

Bacillus anthracis is the specific cause of the disease, and pathogenic strains have plasmid-encoded virulent factors: a poly-D-glutamic capsule, which aids in resistance to phagocytosis and is encoded by virulence plasmid pX02, and a tripartite toxin comprised of edema (factor I) lethal (factor II) and protective antigen (factor III) encoded by plasmid pX01.[1,2] Both plasmids are required for full virulence and avirulent strains occur.[3] There is little diversity among isolates of *B. anthracis* but genotyping can be used for epidemiological studies.[4] The organism forms spores that persist in the environment for decades.

EPIDEMIOLOGY

Occurrence

The disease probably originated in sub-Saharan Africa[4,5] and has spread to have a worldwide distribution, although the area prevalence varies with the soil, the climate and the efforts put into suppressing its occurrence. It is often restricted to particular areas, the so-called '**anthrax belts**', where it is enzootic.

Currently, the characteristic epidemiology of anthrax in developed countries is the occurrence of multicentric foci of infection. Many sudden deaths occur without observed illness, in areas that have recently had appropriate climatic conditions and in which the disease has occurred as long ago as 30 years previously.

In **tropical and subtropical climates** with high annual rainfalls, the infection persists in the soil, so that frequent, serious outbreaks of anthrax are commonly encountered. In some African countries the disease occurs every summer and reaches a devastating occurrence rate in years with a heavy rainfall. Wild fauna – including hippos, cape buffalo, and elephants – die in large numbers. It is probable that predators act as inert carriers of the infection.[5,6]

In **temperate, cool climates** only sporadic outbreaks derive from the soil-borne infection. Accidental ingestion of contaminated bone meal or pasture contaminated by tannery effluent are more common sources. In this circumstance outbreaks are few and the number of animals affected is small. The development of an effective livestock vaccine coupled with the use of penicillin and the implementation of quarantine regulations has caused a marked decline in the occurrence of anthrax in most countries compared to its historical incidence.[5]

Source of the infection

B. anthracis can infect animals directly from the soil or from fodder grown on infected soil, from contaminated bone meal or protein concentrates, or from infected excreta, blood, or other discharges from infected animals. The initial source is often from old anthrax graves where the soil has been disturbed.[5,7]

Spread of the organism within an area may be accomplished by streams, insects, dogs, feral pigs, and other carnivores, and by fecal contamination from infected animals and birds. Avian scavengers such as gulls, vultures, and ravens can carry spores over considerable distances and the feces of carrion-eating birds can contaminate waterholes. Infected wildlife are also a source for domestic animals on common grazing land.[5]

Introduction of infection into a new area is usually through contaminated animal products such as bone meal, fertilizers, hides, hair and wool, or by contaminated concentrates or forage. In recent times as many as 50% of consignments of bone meal imported into the UK have been shown to be contaminated with the anthrax bacillus. Outbreaks in pigs can usually be traced to the ingestion of infected bone meal or carcasses. Water can be contaminated by the effluent from tanneries, from infected carcasses and by flooding and the deposition of anthrax-infected soil.

An outbreak of anthrax has been recorded following the injection of infected blood for the purpose of immunization against anaplasmosis. There have been a number of reports of the occurrence of anthrax after vaccination, probably as a result of inadequately attenuated spores. Wound infection occurs occasionally.

Transmission of the infection

Infection gains entrance to the body by ingestion, inhalation, or through the skin. While the exact mode of infection is often in doubt, it is generally considered that most animals are infected by the ingestion of contaminated food or water. It is true that experimental transmission by this means has not always been successful. Injury to the mucous membrane of the digestive tract will facilitate infection but there is little doubt that infection can take place without such injury. The increased incidence of the disease on sparse pasture is probably due both to the ingestion of contaminated soil and to injury to the oral mucosa facilitating invasion by the organism.

Inhalation infection is thought to be of minor importance in animals, although the possibility of infection through contaminated dust must always be considered. 'Woolsorter's disease' in humans is due to the inhalation of anthrax spores by workers in the wool and hair industries, but even in these industries cutaneous anthrax is much more common.

Biting flies, mosquitoes, ticks, and other insects have often been found to harbor anthrax organisms and the ability of some to transmit the infection has been demonstrated experimentally.[5,8,9] However, there is little evidence that they are important in the spread of naturally occurring disease, with the exception of tabanid flies.[5] The transmission is mechanical only[8,9] and a local inflammatory reaction is evident at the site of the bite. The tendency, in infected districts, for the heaviest incidence to occur in the late summer and autumn may be due to the increase in the fly population at that time but an effect of higher temperature on vegetative proliferation of *B. anthracis* in the soil is more likely.

Risk factors

Host risk factors

The disease occurs in all vertebrates but is most common in cattle and sheep and less frequent in goats and horses. Humans occupy an intermediate position between this group and the relatively resistant pigs, dogs, and cats. In farm animals, the disease is almost invariably fatal, except in pigs, and even in this species the case fatality rate is high.

Algerian sheep are said to be resistant and, within all species, certain individuals seem to possess sufficient immunity to resist natural exposure. Whether or not this immunity has a genetic basis has not been determined. The most interesting example of natural resistance is the dwarf pig, in which it is impossible to establish the disease. Spores remain in tissues ungerminated and there is complete clearance from all organs by 48 hours. The ability to prevent spore germination appears to be inherited in this species.

Environment risk factors

Outbreaks originating from a soil-borne infection always occur after a major climate change, for example heavy rain after a prolonged drought, or dry summer months after prolonged rain, and always in warm weather when the environmental temperature is over 15°C (60°F). The hypothesis that these climatic conditions lead to sporulation and vegetative proliferation with the production of **incubator areas** for anthrax in the soil appears improbable, but spores have a high buoyant density and in wet soils could become concentrated and remain suspended in standing water with further concentration on the soil surface as the water evaporates.[10] This relationship to climate has made it possible to predict 'anthrax years'.

Other risk factors in the environment include close grazing of tough, scratchy feed in dry times, which results in abrasions of the oral mucosa, and confined grazing on heavily contaminated areas around water holes. Some genotypes appear to persist better in calcium-rich soils and organic soils and poorly drained soils have risk in endemic areas.[1,5,7,11]

Pathogen risk factors

When material containing anthrax bacilli is exposed to the air, spores are formed that protract the infectivity of the environment for very long periods. The spores are resistant to most external influences including the salting of hides, normal environmental temperatures and standard disinfectants. Anthrax bacilli have remained viable in soil stored for 60 years in a rubber-stoppered bottle, and field observations indicate a similar duration of viability in exposed soil, particularly in the presence of organic matter, in an undrained alkaline soil and in a warm climate. Acid soils reduce the survival of *B. anthracis*.

Economic importance

In most developed countries vaccination of susceptible animals in enzootic areas has reduced the prevalence of the disease to negligible proportions on a national basis, but heavy losses may still occur in individual herds. Loss occurs due to mortality but also from withholding of milk in infected dairy herds and for a period following vaccination.

Zoonotic potential

Anthrax has been an important cause of fatal human illness in most parts of the world, but in developed countries it is no longer a significant cause of human or livestock wastage because of appropriate control measures. However, it still holds an important position because of its potential as a zoonosis and it is still an important zoonosis in developing countries. It is a major concern as an agent of bioterrorism and is listed as a category A agent by the US Centers for Disease Control and Prevention.[12]

An account of an outbreak in a piggery in the UK should be compulsory reading for veterinary students as an example of the responsibilities of veterinarians in a modern public-health-conscious and litigation-minded community.[13,14] In developing countries anthrax can still be a major cause of livestock losses and a serious cause of mortality amongst humans who eat meat from infected animals and develop the alimentary form of this disease, or who handle infected carcasses.[15]

Cutaneous anthrax has occurred in veterinarians following postmortem examination of anthrax carcasses. The areas at particular risk for infection are the forearm above the glove line and the neck. Infection begins as a pruritic papule or vesicle that enlarges and erodes in 1–2 days leaving a necrotic ulcer with subsequent formation of a central black eschar.

PATHOGENESIS

Upon ingestion of the spores, infection may occur through the intact mucous membrane, through defects in the epithelium around erupting teeth, or through scratches from tough, fibrous food materials. The organisms are resistant to phagocytosis, in part due to the presence of the poly-D-glutamic acid capsule, and proliferate in regional draining lymph nodes, subsequently passing via the lymphatic vessels into the bloodstream; septicemia, with massive invasion of all body tissues, follows. *B. anthracis* produces a lethal toxin that causes edema and tissue damage, death resulting from shock and acute renal failure and terminal anoxia.

In pigs, localization occurs in the lymph nodes of the throat after invasion through the upper part of the digestive tract. Local lesions usually eventually lead to a fatal septicemia.

CLINICAL FINDINGS

The incubation period after field infection is not easy to determine but is probably 1–2 weeks.

Cattle and sheep

Only two forms of the disease occur in these species, the peracute and the acute.

The **peracute** form of the disease is most common at the beginning of an outbreak. The animals are usually found dead without premonitory signs, the course being probably only 1–2 hours, but fever, muscle tremor, dyspnea, and congestion of the mucosae may be observed. The animal soon collapses, and dies after terminal convulsions. After death, discharges of blood from the nostrils, mouth, anus, and vulva are common.

The **acute** form runs a course of about 48 hours. Severe depression and listlessness are usually observed first, although they are sometimes preceded by a short period of excitement. The body temperature is high, up to 42°C (107°F), the respiration rapid and deep, the mucosae congested and hemorrhagic, and the heart rate much increased. No food is taken and ruminal stasis is evident. Pregnant cows may abort. In milking cows the yield is very much reduced and the milk may be bloodstained or deep yellow in color. Alimentary tract involvement is usual and is characterized by diarrhea and dysentery. Local edema of the tongue and edematous lesions in the region of the throat, sternum, perineum, and flanks may occur.

Pigs

In pigs anthrax may be acute or subacute. There is fever, with dullness and anorexia, and a characteristic inflammatory edema of the throat and face. The swellings are hot but not painful and may cause obstruction to swallowing and respiration. Bloodstained froth may be present at the mouth when pharyngeal involvement occurs. Petechial hemorrhages are present in the skin, and when localization occurs in the intestinal wall there is dysentery, often without edema of the throat. A pulmonary form of the disease has been observed in baby pigs that inhaled infected dust. Lobar pneumonia and exudative pleurisy were characteristic. Death usually occurs after a course of 12–36 hours, although individual cases may linger for several days.

Horses

Anthrax in the horse is always acute but varies in its manifestations with the mode of infection. When infection is by ingestion there is septicemia with enteritis and colic. When infection is by insect transmission, hot, painful, edematous, subcutaneous swellings appear about the throat, lower neck, floor of the thorax and abdomen, prepuce, and mammary gland. There is high fever and severe depression and there may be dyspnea due to swelling of the throat or colic due to intestinal irritation. The course is usually 48–96 hours.

CLINICAL PATHOLOGY

Hematology and blood chemistry examinations are not conducted because of the risk for human exposure. In the living animal the organism may be detected in a stained smear of peripheral blood. The **reference standard** for diagnosis is the detection, by microscopic examination, of a clearly defined metachromatic capsule on square-ended bacilli (often in chains) in a blood smear stained with aged polychrome methylene blue. The blood should be carefully collected in a syringe to avoid contamination of the environment. When local edema is evident smears may be made from aspirated edema fluid or from lymph nodes that drain that area. For a more certain diagnosis, especially in the early stages when bacilli may not be present in the bloodstream in great numbers, blood culture or the injection of syringe-collected blood into guinea-pigs is satisfactory.

Fluorescent antibody techniques are available for use on blood smears and tissue sections. Monoclonal antibodies are also used to provide specific identification of anthrax organisms.[16]

As the carcass decomposes and the vegetative forms of *B. anthracis* die, diagnosis by smear is more difficult and an immunochromatographic test for protective antigen has been developed that has high specificity and does not give positive results in recently vaccinated cattle.[17] In cases where antibiotic therapy has been used, the identification from blood smears or culture may be difficult and animal passage may be necessary. Isolation of anthrax bacilli from infected soil is difficult, but a real-time quantitative PCR with reported high sensitivity has been described.[18]

NECROPSY FINDINGS

There is a striking absence of rigor mortis and the carcass undergoes gaseous decomposition, quickly assuming the characteristic 'sawhorse' posture. All natural orifices usually exude dark, tarry blood that does not clot. **If there is a good reason to suspect the existence of anthrax the carcass should not be opened**. If a necropsy is carried out, the failure of the blood to clot, widespread ecchymoses, bloodstained serous fluid in the body cavities, severe enteritis and splenomegaly are strong indications of the presence of anthrax. The enlarged spleen is soft, with a consistency likened to 'blackberry jam'. Subcutaneous swellings containing gelatinous material, and enlargement of the local lymph nodes are features of the disease in horses and pigs. Lesions are most frequently seen in the **soft tissues of the neck and pharynx** in these species.

To confirm the diagnosis on an **unopened carcass**, peripheral blood or local edema fluid should be collected by needle puncture. Since the blood clots poorly, jugular venipuncture may permit sample collection. Smears prepared from these fluids should be stained with polychrome methylene blue and examined (see Clinical pathology, above). These fluid samples can also be used for bacteriological culture if smear results are equivocal. The smears should be prepared and interpreted by an experienced and qualified microbiologist.

If decomposition of a carcass is advanced, a small quantity of blood may be collected from the fresh surface of an amputated tail or ear. A portion of spleen is the specimen of choice for bacteriological culture if the carcass has been opened. An immunofluorescence test is available but cross-reactivity with other *Bacillus* spp. makes its use impractical. An immunochromatographic test that has high specificity for protective antigen has been developed for use in decomposed carcasses.[17]

The Ascoli test can be used to demonstrate antigen in severely decayed tissue samples and a nested PCR technique has been used to demonstrate antigen in environmental samples;[19] PCR methods can also be used to confirm the identity of bacterial isolates. If other detection methods fail, experimental animal inoculation can be attempted. Immunohistochemical detection of the bacilli in skin biopsies of cutaneous anthrax in humans has been described.[20] This technique may be useful in retrospective analyses of suspect cases if suitable fresh tissue samples were not collected.

Anthrax is a **reportable disease** in many countries, requiring the involvement of government regulatory agencies when the disease is suspected or when the diagnosis is confirmed. Representatives of these agencies can often facilitate sample collection and transportation to an appropriate laboratory. **If anthrax is suspected, then shipping diagnostic samples via the mail or courier systems is strongly discouraged.** Instead, samples should be appropriately packed, labeled and transported directly to the laboratory by one of the staff members of the veterinary clinic. In some countries it may be illegal to send material such as anthrax through the mail system.

Samples for confirmation of diagnosis

- Bacteriology – unopened carcass: blood or edema fluid in sealed, leakproof container; opened carcass: above samples plus spleen (local lymph nodes in horses, pigs) in sealed, leakproof containers (direct smear, CULT, bioassay)
- Histology – formalin-fixed spleen/local lymph nodes if carcass has been opened (LM).

Note the zoonotic potential of this organism when handling carcass and submitting specimens.

DIFFERENTIAL DIAGNOSIS

There are many causes of sudden death in farm animals and differentiation is often difficult. Diseases where there can be multiple deaths suggestive of anthrax include:

- Lightning strike
- Peracute blackleg
- Malignant edema
- Bacillary hemoglobinuria
- Hypomagnesemic tetany

TREATMENT

Severely ill animals are unlikely to recover but in the early stages, particularly when fever is detected before other signs are evident, recovery can be anticipated if the correct treatment is provided. Penicillin (20 000 IU/kg BW twice daily) has had considerable vogue, but streptomycin (8–10g/d in two doses intramuscularly for cattle) is much more effective. Oxytetracycline (5 mg/kg BW per day) parenterally has also proved superior to penicillin in the treatment of clinical cases after vaccination in cattle and sheep. Antiserum, if available, should also be administered for at least 5 days in doses of 100–250 mL daily but it is expensive.

In vitro studies show all isolates to be susceptible to ampicillin, streptomycin, erythromycin, tetracycline, methicillin, and netilmicin.[21] It is desirable to prolong treatment to at least 5 days to avoid a recrudescence of the disease.

CONTROL

The control of meat- and milk-producing animals in infected herds in such a way as to avoid any risk to the human population is a special aspect of the control of anthrax. It is necessary at the same time to avoid unnecessary waste and the imposition of unnecessarily harsh prohibitions on the farmer. When an outbreak occurs, the placing of the farm in quarantine, the destruction of discharges and cadavers, and the vaccination of survivors, are part of the animal disease control program and indirectly reduce human exposure. Prohibition of movement of milk and meat from the farm during the quarantine period should prevent entry of the infection into the human food chain. Vaccination of animals, although the vaccine is a live one, does not present a hazard to humans, although there is a withholding period for meat and milk after its use.

Disposal of infected material is most important and hygiene is the biggest single factor in the prevention of spread of the disease. Infected carcasses should not be opened but immediately burned in situ or buried, together with bedding and soil contaminated by discharges. If this can not be done immediately, a liberal application of 5% formaldehyde on the carcass and its immediate surroundings will discourage scavengers. Burning is the preferred method of disposal. Approximately one cord of wood is required to effectively incinerate the carcass of a mature cow. Bags of charcoal briquettes have also been used.[5]

Burial should be at least 2 m deep with an ample supply of quicklime added. All suspected cases and in-contact animals must be segregated until cases cease and for 2 weeks thereafter the affected farm must be kept in quarantine to prevent the movement of livestock. The administration of hyperimmune serum to in-contact animals may prevent further losses during the quarantine period, but prophylactic administration of a single dose of long-acting tetracycline or penicillin is a much commoner tactic.

Disinfection of premises, hides, bone meal, fertilizer, wool, and hair requires special care. When disinfection can be carried out immediately, before spore formation can occur, ordinary disinfectants or heat (60°C (140°F) for a few minutes) are sufficient to kill vegetative forms. This is satisfactory when the necropsy room or abattoir floor is contaminated. When spore formation occurs (i.e. within a few hours of exposure to the air), disinfection is almost impossible by ordinary means. Strong disinfectants such as 5% Lysol require to be in contact with spores for at least 2 days. Strong solutions of formalin or sodium hydroxide (5–10%) are probably most effective. Peracetic acid (3% solution) is an

effective sporicide and, if applied to the soil in appropriate amounts (8 L/m^2), is an effective sterilant. Infected clothing should be sterilized by soaking in 10% formaldehyde. Shoes may present a difficulty and sterilization is most efficiently achieved by placing them in a plastic bag and introducing ethylene oxide. Contaminated materials should be damp and left in contact with the gas for 18 hours. Hides, wool, and mohair are sterilized commercially by gamma-irradiation, usually from a radioactive cobalt source. Special care must be taken to avoid human contact with infected material and, if such contact does occur, the contaminated skin must be thoroughly disinfected. The source of the infection must be traced and steps taken to prevent further spread of the disease. Control of the disease in a feral animal population presents major problems.

Immunization

Immunization of animals as a control measure is extensively used and many types of vaccine are available. Those vaccines that consist of living attenuated strains of the organism with low virulence but capable of forming spores have been most successful. The sporulation character has the advantage of keeping the living vaccine viable over long periods. These vaccines have the disadvantage that the various animal species show varying susceptibility to the vaccine, and anthrax may result in some cases from vaccination. This has been largely overcome by preparing vaccines of differing degrees of virulence for use in different species and in varying circumstances. Another method of overcoming the virulence is the use of saponin or saturated saline solution in the vehicle to delay absorption. This is the basis of the carbozoo vaccine.[22]

The **Stern avirulent spore vaccine** has overcome the risk of causing anthrax by vaccination and produces a strong immunity that lasts for at least 26 months in sheep and 1 year in cattle. It is the vaccine used in most countries. Although only one dose was originally thought to be necessary, with cases ceasing about 8 days after vaccination, it now appears that two vaccinations are necessary in some situations.[7,23]

A febrile reaction does occur after vaccination; the milk yield of dairy cows will be depressed and pregnant sows will probably abort. The injection of penicillin, and probably other antibiotics, at this time should be avoided as it may interfere with the development of immunity.

When the disease occurs for the first time in a previously clean area, all in-contact animals should either be treated with hyperimmune serum or be vaccinated. The measures used to control outbreaks and the choice of a vaccine depend largely on local legislation and experience. Ring vaccination has been used to contain outbreaks of the disease[7,24] and in enzootic areas annual revaccination of all stock is necessary. Surface contamination of a pasture (as opposed to deep soil contamination) can persist for 3 years and cattle grazing these pastures should be revaccinated annually for this period.[5] In endemic areas cattle are routinely vaccinated yearly.

Milk from vaccinated cows is usually discarded for 72 hours after the injection in case the organisms in the vaccine should be excreted in the milk. Ordinarily the organisms of the Stern vaccine do not appear in the milk nor can they be isolated from the blood for 10 and 7 days respectively after vaccination. Vaccinated animals are usually withheld from slaughter for 45 days.

Deaths due to anthrax have occurred in 3-month-old llamas after vaccination with a Stern vaccine[25] and may occur in goats. Older crias and adults were unaffected. It was assumed that the dose of vaccine was excessive for such young animals. In these species two vaccinations 1 month apart with the first dose one-quarter of the standard dose can be used.[5]

Diseases associated with bacteria – II

17

Diseases associated with *Clostridium* species

The clostridia are of major importance in farm animals as primary causes of disease. They rarely act as secondary invaders except where gangrene is already present. They are all potent producers of exotoxins, upon which their pathogenicity depends. The **toxins** of the different organisms vary in their effects and in the manner in which they gain entry to the circulation; they may be:

- Ingested preformed in the feed, as in botulism
- Absorbed from the gut after abnormal proliferation of the causative organism in the alimentary tract, as in enterotoxemia
- Elaborated in a more proper infection of the tissues, such as blackleg.

Other clostridial infections develop as local infections with elaboration of toxins in minor lesions, as in tetanus, black disease, braxy and bacillary hemoglobinuria.

Pathogenic clostridia are commonly present in **soils rich in humus** and may multiply in soil in warm weather following heavy rain.[1] They are also found in the intestinal contents of normal animals and cause disease only in special circumstances. The ubiquitous character of these organisms makes eradication of the clostridial diseases virtually impossible and necessitates control by prophylactic measures. Fortunately, diseases of this group are virtually unique among bacterial diseases in that they can be effectively prevented in almost all instances by vaccination with killed culture vaccines.

Because of the common occurrence of a number of clostridial infections in an area, it has become a common practice in recent years to use **multivalent bacterin-toxoids** containing *Clostridium chauvoei*, *Clostridium septicum*, *Clostridium novyi*, *Clostridium sordellii*, and *Clostridium perfringens* types C and D. The vaccines appear to be highly effective and, in situations where the extra expense can be justified, worthy of recommendation. In high-risk situations such as feedlots they appear to be cost-effective.[2] In the USA more than 60% of producers vaccinate calves before weaning for some form of clostridial disease, as do 91% of the larger feedlots.[3]

Prepartum vaccination of the dam, to provide colostral immunity to the young calf or lamb, and subsequent **active immunization** of the growing animal is recommended for most of the clostridial vaccines. However, because of management constraints, particularly in range beef cattle, clostridial vaccines are not always administered at the age and time recommended by the manufacturers. This may result in suboptimal protection. Clostridial vaccines are usually given to nursing beef calves at the time when they are first handled for castration and branding, at 1–4 months of age. With most clostridial vaccines a booster vaccination is recommended 2–6 weeks following the primary vaccination, but this may not be given until weaning in range cattle.

Clostridial vaccines administered intramuscularly can cause **injection site lesions** and severe damage to muscle that can persist for 7–12 months after vaccination;[4] in the USA approximately 10% of top sirloin cuts have lesions at slaughter.[5] These must be trimmed from the carcass at slaughter and, if not detected at that time can result in unfavorable experiences by beef consumers and a loss in confidence in the quality of beef products. Multivalent vaccines cause more damage and there is variation in the degree of damage with different vaccines.[3] The prevention of injection site lesions in muscle is a focus of **beef quality assurance programs** in several countries, and subcutaneous administration of vaccines in the neck area is recommended. Subcutaneous administration will result in subcutaneous injection site lesions and the dichotomy is that cattle that develop injection site lesions have a better antibody response to the vaccine than non-lesioned cattle.[6]

There appears to be a difference between **sheep and goats** with respect to their response to clostridial infections. Goats in general suffer more severe forms of these diseases than do sheep, and the protection afforded to goats by multivalent vaccines is less than that afforded to sheep.

As well as the specific disease entities set out below there are some less well-known occurrences of pathogenic clostridia.

Clostridium sordellii abomasitis

C. sordellii appears to be an emerging pathogen for sheep in Great Britain and possibly Europe in association with a syndrome of **abomasitis and sudden death** in young lambs and adult sheep. Death is reported in 6 hours in sheep previously observed to be normal. Lambs between 3 and 10 weeks of age are particularly at risk and losses vary from sporadic to up to 8%.[7]

Commonly the lambs are from well-managed flocks and from good milking ewes. Many of the affected lambs have had ad libitum access to creep pellets from an early age, and this may be a risk factor.[8] The characteristic finding at necropsy is a severe abomasitis with areas of congestion and erosion on the abomasal folds, gastrorrhagia and **subserosal emphysema** and edema. Sudden death with abomasitis also occurs in weaned and adult sheep but subserosal emphysema and edema are not present. *C. sordellii* is also recorded as a cause of sudden death in periparturient sheep.[9] Carcasses show

rapid decomposition but the salient finding is metritis with a uterine wall that is greatly thickened and emphysematous.

C. sordellii has also been associated with fatal hepatitis in newborn lambs, enteritis with hemorrhagic diarrhea in calves and in mature cattle can be an agent in blackleg or malignant edema.

Sudden death syndrome

Clostridial infection has been considered a cause of a **sudden death syndrome in feedlot cattle**, which occurs following the acclimatization phase of feeding and presents as death without premonitory signs of illness or agonal struggling and with rapid autolysis of the carcass and no evidence, on postmortem examination, of the common diseases that cause rapid death in feedlot cattle. However, a large controlled trial found no effect on mortality rates from sudden death syndrome from booster vaccination of feedlot cattle with a multivalent bacterin-toxoid (*C. chauvoei*, *C. septicum*, *C. novyi*, *C. sordellii*, and *C. perfringens* types C and D).[10]

Enteritis associated with clostridia

The enteric diseases associated with *C. perfringens* and *Clostridium difficile* are described under those headings. *Clostridium tertium* has been isolated from the intestine of cattle with diarrhea and a mild enteritis has been reproduced by experimental challenge with this organism.[11] *C. sordellii* and *Clostridium cadaveris* have been isolated from cases of enterocolitis in horses.

TETANUS

Synopsis

Etiology Muscle spasm from action of the exotoxin tetanospasmin produced by the vegetative stage of *Clostridium tetani*
Epidemiology All species susceptible. Usually a history of a wound or other tissue trauma. Occurs as isolated cases but also as outbreaks in young ruminants following castration and docking
Clinical findings Generalized muscular rigidity and spasms, hyperesthesia, prolapse of third eyelid, trismus, convulsions, respiratory arrest, and death. High case fatality
Necropsy findings None. May demonstrate the organism in necrotic tissue in some cases
Diagnostic confirmation No definitive antemortem test or postmortem lesion. Diagnosis is based on characteristic clinical signs and wound history
Treatment Neutralize residual toxin, control muscle spasms until the toxin is eliminated or destroyed, maintain hydration and nutrition, provide supportive treatment
Control Antitoxin if recent injury but risk of serum hepatitis in horses. Vaccination

ETIOLOGY

An exotoxin, tetanospasmin, is produced by *Clostridium tetani* growing under anaerobic conditions. The organism forms spores that can persist in soil for many years. The spores are resistant to many standard disinfection procedures, including steam heat at 100°C (212°F) for 20 minutes but can be destroyed by heating at 115°C (239°F) for 20 minutes.

EPIDEMIOLOGY

Occurrence

Tetanus occurs in all parts of the world and is most common in closely settled areas under intensive cultivation. It occurs in all farm animals, mainly as individual, sporadic cases, although outbreaks are occasionally observed in young cattle, young pigs, and lambs following wounding management procedures.

Case fatality rate

In young ruminants the case fatality rate is over 80%, but the recovery rate is high in adult cattle. In horses it varies widely between areas. In some areas almost all animals die acutely, in others the mortality rate is consistently about 50%.

Source of infection

C. tetani organisms are commonly present in the feces of animals, especially horses, and in the soil contaminated by these feces. Surveys in different areas of the world show it is present in 30–42% of soil samples.[1] The survival period of the organism in soil varies very widely from soil to soil.

Transmission

The **portal of entry** is usually through deep puncture wounds but the spores may lie dormant in the tissues for some time and produce clinical illness only when tissue conditions favor their proliferation. For this reason the portal of entry is often difficult to determine. Puncture wounds of the hooves are common sites of entry in horses. Introduction to the genital tract at the time of parturition is the usual portal of entry in cattle. A high incidence of tetanus may occur in young pigs following castration and in lambs following castration, shearing, docking, vaccinations, or injections of pharmaceuticals, especially anthelmintics. Docking by the use of elastic band ligatures is reputed to be especially hazardous. **Neonatal tetanus** occurs when there is infection in the umbilical cord associated with insanitary conditions at parturition.

Outbreaks of '**idiopathic tetanus**' occur occasionally in young cattle without a wound being apparent, usually in association with the grazing of rough, fibrous feed, and it is probable that toxin is produced in wounds in the mouth or gastrointestinal tract or is ingested preformed in the feed. Proliferation in the rumen may also result in toxin production.

Animal risk factors

The neurotoxin of *C. tetani* is exceedingly potent but there is considerable variation in susceptibility between animal species, horses being the most susceptible and cattle the least. The variation in prevalence of the disease in the different species is partly due to this variation in susceptibility but is also because exposure and wounding management practices are more likely to occur in some species than in others.

Importance

Tetanus is important because of its high case fatality and the very long convalescence in the survivors.

PATHOGENESIS

The tetanus bacilli remain **localized** at their site of introduction and do not invade surrounding tissues. They proliferate and produce tetanolysin and tetanospasmin only if certain environmental conditions are attained, particularly a lowering of the local tissue oxygen tension. Tetanolysin promotes local tissue necrosis. Toxin production may occur immediately after introduction if the accompanying trauma has been sufficiently severe, or if foreign material has also been introduced to the wound, or may be delayed for several months until subsequent trauma to the site causes tissue damage. The original injury may be inapparent by then.

Tetanospasmin diffuses to the systemic circulation, is bound to motor end-plates and travels up peripheral nerve trunks via retrograde intra-axonal transport. The exact mechanisms by which the toxin exerts its effects on nervous tissue are not known[2] but it blocks the spontaneous and nerve-impulse-evoked release of neurotransmitter, resulting in the disinhibition of gamma motor neurones. No structural lesions are produced but there is central potentiation of normal sensory stimuli so

that a state of constant muscular spasticity is produced and normally innocuous stimuli cause exaggerated responses. Death occurs by asphyxiation due to fixation of the muscles of respiration.

CLINICAL FINDINGS

The **incubation period** varies between 3 days and 4 weeks, with occasional cases occurring as long as several months after the infection is introduced. In sheep and lambs cases appear 3–10 days after shearing or docking.

Clinical findings are similar in all animal species. Initially, there is an increase in **muscle stiffness**, accompanied by muscle tremor. There is **trismus** with restriction of jaw movements, **prolapse of the third eyelid**, stiffness of the hind limbs causing an unsteady, straddling gait, and the tail is held out stiffly, especially when backing or turning. Retraction of the eye and prolapse of the third eyelid – a rapid movement of the third eyelid across the cornea followed by a slow retraction – is one of the earliest and consistent signs (with the exception of sheep) and can be exaggerated by sharp lifting of the muzzle or tapping the face below the eye. Additional signs include an anxious and alert expression contributed to by an erect carriage of the ears, retraction of the eyelids and dilation of the nostrils, and hyperesthesia with exaggerated responses to normal stimuli.

The animal may continue to eat and drink in the early stages but mastication is soon prevented by tetany of the masseter muscles, and saliva may drool from the mouth. If food or water are taken, attempts at swallowing are followed by regurgitation from the nose. Constipation is usual and the urine is retained, partly as a result of inability to assume the normal position for urination. The rectal temperature and pulse rate are within the normal range in the early stages but may rise later when muscular tone and activity are further increased. In cattle, particularly young animals, bloat is an early sign but is not usually severe and is accompanied by strong, frequent rumen contractions.

As the disease progresses, muscular tetany increases and the animal adopts a **'sawhorse' posture**. Uneven muscular contractions may cause the development of a curve in the spine and deviation of the tail to one side. There is great difficulty in walking and the animal is inclined to fall, especially when startled. Falling occurs with the limbs still in a state of **tetany** and the animal can cause itself severe injury. Once down it is almost impossible to get a large animal to its feet again. Tetanic convulsions begin in which the tetany is still further exaggerated. Opisthotonos is marked, the hind limbs are stuck out stiffly behind and the forelegs forward. Sweating may be profuse and the temperature rises, often to 42°C (107°F). The convulsions are at first only stimulated by sound or touch but soon occur spontaneously. In fatal cases there is often a transient period of improvement for several hours before a final, severe tetanic spasm during which respiration is arrested.

The **course of the disease** and the **prognosis** vary both between and within species. The **duration** of a fatal illness in horses and cattle is usually 5–10 days but sheep usually die on about the third or fourth day. A long incubation period is usually associated with a mild syndrome, a long course and a favorable prognosis. **Mild cases** that recover usually do so slowly, the stiffness disappearing gradually over a period of weeks or even months. The prognosis is poor when signs rapidly progress. Animals vaccinated in the past year have a better prognosis, as do horses that have received parenteral penicillin and tetanus antitoxin and in which the wound was aggressively cleaned when fresh.[3]

CLINICAL PATHOLOGY

There are no specific abnormalities in blood or cerebrospinal fluid[3] and no antemortem test of value in confirming the diagnosis. Blood levels of tetanus toxin are usually too low to be detected.

NECROPSY FINDINGS

There are no gross or histological findings by which a diagnosis can be confirmed, although a search should be made for the site of infection. Culture of the organism is difficult but should be attempted. If minimal autolysis has occurred by the time of necropsy, the identification of large Gram-positive rods with terminal spores ('tennis-racket morphology') in smears prepared from the wound site or spleen is supportive of a diagnosis of tetanus.

Samples for confirmation of diagnosis

- Bacteriology – air-dried impression smears from spleen, wound site (cyto – Gram stain), culture swab from wound site in anaerobic transport media; spleen in sterile, leakproof container (anaerobic CULT, bioassay).

TREATMENT

The main principles in the treatment of tetanus are to:

- Eliminate the causative bacteria
- Neutralize residual toxin
- Control muscle spasms until the toxin is eliminated or destroyed
- Maintain hydration and nutrition
- Provide supportive treatment.

There are no structural changes in the nervous system, and the management of cases of tetanus depends largely on keeping the animal alive through the critical stages.

Elimination of the organism is usually attempted by the parenteral administration of penicillin in large doses, preferably by intravenous administration. If the infection site is found, the wound should be aggressively cleaned and debrided but only after antitoxin has been administered, because debridement, irrigation with hydrogen peroxide, and the local application of penicillin may facilitate the absorption of the toxin.

Tetanus antitoxin is administered but is of little value once signs have appeared. After the experimental administration of toxin, antitoxin is of limited value at 10 hours and ineffective by 48 hours. The recommended dose is controversial but for optimal results horses should receive 300 000 IU 12-hourly for three injections. Local injection of some of the antitoxin around the wound is advised. There have been a number of attempts to justify the treatment of early cases of equine tetanus by the intrathecal injection of antitoxin but there is limited evidence of therapeutic value and the procedure carries risk.[3,4]

Relaxation of the muscle tetany can be attempted with various drugs. Chlorpromazine (0.4–0.8 mg/kg body weight (BW) intravenously, 1.0 mg/kg BW intramuscularly, three or four times daily) and acetyl promazine (0.05 mg/kg BW twice daily) administered until severe signs subside, are widely used.[3,5] A combination of diazepam (0.01–0.4 mg/kg) and xylazine (0.5–1.0 mg/kg, intravenously or intramuscularly) may be effective in horses refractory to phenothiazine tranquilizers.[3]

DIFFERENTIAL DIAGNOSIS

Fully developed tetanus is so distinctive clinically that it is seldom confused with other diseases. The muscular spasms, the prolapse of the third eyelid and a recent history of accidental injury or surgery are characteristic findings. However, in its early stages, tetanus may be confused with other diseases.

All species
- Strychnine poisoning
- Meningitis (

Horses
- Hypocalcemic tetany (eclampsia)
- Acute laminitis
- Hyperkalemic periodic paralysis
- Myositis, particularly after injection in the cervical region

Ruminants
- Hypomagnesemia – cows, sheep and calves
- White muscle disease
- Polioencephalomalacia
- Enterotoxemia

Hydration can be maintained by intravenous or stomach-tube feeding during the critical stages when the animal cannot eat or drink. The use of an indwelling tube should be considered because of the disturbance caused each time the stomach tube is passed. Feed and water containers should be elevated and the feed should be soft and moist.

Additional supportive treatment includes slinging of horses during the recovery period when hyperesthesia is diminishing. Affected animals should be kept as quiet as possible and provided with dark, well-bedded quarters with nonslip flooring and plenty of room to avoid injury if convulsions occur. Administration of enemas and catheterization may relieve the animal's discomfort. This level of nursing, plus penicillin, ataractic drug and antitoxin for an average of 14 days, can deliver something like a 50% recovery by an average of 27 days, but the cost is high.

Horses that fall frequently sustain bone fractures and may need to be destroyed.

CONTROL

Many cases of tetanus could be avoided by proper skin and instrument disinfection at castrating, docking, and shearing time. These operations should be carried out in clean surroundings; in the case of lambs docked in the field, temporary pens are to be preferred to permanent yards for catching and penning.

Passive immunity

Short-term prophylaxis can be achieved by the injection of 1500 IU of tetanus antitoxin. The immunity is transient, persisting for only 10–14 days.

Tetanus antitoxin

Tetanus antitoxin should be given to any horse with a penetrating wound or deep laceration, and the wound should also be cleaned aggressively. Tetanus toxoid can be administered at the same time as tetanus antitoxin, provided they are injected at different sites and using different syringes. Animals that suffer injury are usually given an injection of antitoxin and one of toxoid to insure complete protection.

Tetanus antitoxin is often routinely given to **mares** following foaling and to newborn foals. In some areas the risk for tetanus in young foals is high and repeated doses of antitoxin at weekly intervals may be required for protection.

On farms where the incidence of tetanus in **lambs** is high, antitoxin is usually given at the time of docking or castration; 200 IU has been shown to be effective. The risk for tetanus in calves is lower than in lambs and tetanus antitoxin is not commonly given at the time of castration.

There is a risk for **serum hepatitis** in horses that have been given tetanus antitoxin[6,7] and, while this risk is small,[7] a policy of routine active immunization of the mare to provide the mare with active immunity and the foal with passive colostral immunity is preferred to one that relies on antitoxin. Provided foals get an adequate supply of colostrum they are protected during the first 10 weeks of life by active vaccination of the mare during the last weeks of pregnancy. Prevention of tetanus in newborn lambs is also best effected by vaccination of the ewe in late pregnancy.

Active immunity

Available vaccines are formalin-inactivated adjuvanated toxoids; they induce long-lasting immunity. Primary vaccination requires two doses 3–6 weeks apart. Protective titers are obtained within 14 days of the second injection and last for at least a year and up to 5 years.

Traditionally **foals** have received primary vaccination at 3–4 months of age, however there is evidence that maternal antibodies acquired by foals born to mares vaccinated shortly before parturition significantly inhibit the antibody response of the foal to primary vaccination until it is 6 months of age and that primary vaccination should be delayed until that age.[8]

Although immunity lasts longer than 1 year, it is common to revaccinate horses yearly with a single booster injection. Pregnant mares should receive a booster injection 4–6 weeks before foaling to provide adequate colostral immunity to the foal.

Ewes are immunized with a similar schedule except that the primary doses are usually given at a managementally convenient time when the flock is yarded. A prelambing booster vaccination is given yearly. Commonly, commercial vaccines for sheep also contain antigens for other clostridial diseases for which sheep are at high risk.

Vaccination of **cattle** is usually not considered unless an outbreak of the disease has occurred in the immediate past and further cases may be anticipated.

BOTULISM

Synopsis

Etiology Neurotoxin produced by *Clostridium botulinum* during vegetative growth. *C. botulinum* types B, C, and D are associated with disease in animals but the type prevalence varies geographically
Epidemiology Ingestion of preformed toxin where feed preparation or storage allows multiplication of the organism in the feed with toxin production. Contamination of feed with carrion containing toxin. Consumption of carrion on pasture by phosphorus-deficient animals. Risk factors often result in multiple cases. Rare cases occur from toxin production from organisms in the intestine or wounds
Clinical findings Early muscle tremor, progressive symmetrical weakness, and motor paralysis leading to recumbency. Mydriasis, ptosis, weak tongue retraction; sensation and consciousness retained until death
Necropsy findings None specific
Diagnostic confirmation Demonstration of toxin in serum or feed. Demonstration of organisms in feed, intestinal contents or wounds
Treatment Type-specific antiserum and supportive treatment
Control Avoidance of exposure by feed management. Vaccination

ETIOLOGY

The causative organism *Clostridium botulinum*, a spore-forming anaerobe, produces neurotoxins during vegetative growth. Spores can **survive in the environment** for over 30 years. Under favorable conditions of warmth and moisture the spores germinate and vegetative cells multiply rapidly, elaborating a stable and highly lethal toxin which, when ingested, or absorbed from tissues, causes the disease. The toxin is also capable of surviving for long periods, particularly in bones or if protected from leaching. Seven antigenically distinct **toxin types** (A–G), some with subtypes, have been identified. Farm animal disease is produced primarily by types B, C, and D.

The **geographical distribution** of these types varies considerably. In a study in the USA,[1] type A was found in neutral or alkaline soils in the west, while types B and E were in damp or wet soil all over, except that B was not found in the south. Type C was found in acid soils in the Gulf coast, and type D in alkaline soils in the west. Microorganisms capable of inhibiting *C. botulinum* were present, with or without the clostridia, in many soils. Type B is also common in soils in the UK and in Europe. Types C and D are more common in warm climates.[1,2]

The organism is present in the **alimentary tract** of animals that have recently

ingested contaminated material and may be introduced into new areas in this way, or by birds and blowflies.

EPIDEMIOLOGY

Occurrence

Botulism has **no geographical limitations**, isolated cases and sporadic outbreaks occurring in most countries. The source of exposure to toxin and the risk for disease differ between regions because of differences in food storage, feeding, and management practices. **Outbreaks** associated with ingestion of toxin in conserved feeds are more common in the northern states of the USA and in Europe whereas outbreaks in animals on pasture are reported primarily from South Africa, Australia, and the Gulf coast area of the USA. The disease usually occurs in a number of animals at one time and has a high case fatality rate.

Source of infection

Most incidents of botulism are associated with the ingestion of preformed toxin (**forage botulism**). Toxin in feeds may result from the primary growth of *C. botulinum* in the feed or from the contamination of the feed with toxin-containing carrion (**carrion-associated botulism**). Less common sources are growth with toxin production in wounds (**wound botulism**) or growth and toxin production in the alimentary tract (**toxicoinfectious botulism**).

Forage botulism

Forage botulism occurs when pH, moisture, and anaerobic conditions in the feedstuff allow the vegetative growth of *C. botulinum* and the production of toxin. This can occur in a number of spoiled stored forages. Cereal silages carry a risk in the USA. Silage and hay may spoil to a stage suitable for the growth of *C. botulinum*. This is most likely if the forage is very succulent or is wet by rain when it is made.[3,4]

Big bale silage is a particular risk. The type of forage ensiled in big bales often has insufficient water-soluble carbohydrate for adequate lactic acid fermentation to achieve a stable low pH, and the higher dry matter content can also lead to a higher pH.[3] Clostridial multiplication is inhibited below pH 4.5. Most non-carrion-associated botulism is due to type B strains, and horses appear to be especially susceptible.[5]

Proliferation of the organism can occur in **decaying vegetable material**. The disease has also occurred in horses fed on spoiled vegetables and potatoes contaminated by *C. botulinum*, and on alfalfa haylage packed in airtight aluminum foil envelopes. Grass clippings allowed to accumulate and decay in a pile have poisoned horses, as has round bale hay that spoiled after rain.[6] Decaying grass at the base of old tussocks and in trampled stubble are known to be suitable sites for growth of *C. botulinum*. Cases have occurred with brewer's grains, and high-moisture grain has the potential for toxicity.

Carrion-associated botulism

This is almost always the cause of botulism in animals on pasture, and carrion is also a common cause of botulism in animals on conserved feeds. Carrion includes domestic and wild animals and birds. In endemic botulism areas, the carcass of dead animals is invaded by *C. botulinum* and high concentrations of toxin are produced such that very small amounts of flesh or bone have lethal concentrations. Most outbreaks of carrion-associated botulism are associated with **type C and D strains**, these strains producing much higher concentrations of toxin in carrion than type A and B strains.[7] Toxin can persist in carrion for at least 1 year. Where the carcasses of rodents, cats, and birds contaminate hay or silage, toxin can leach out and contaminate surrounding hay or other feeds to cause multiple cases of botulism. In one instance a single mouse carcass is believed to have contaminated 200 000 tons of alfalfa cubes.[5] A common source in Australia is hay made at the time of a mouse plague. At such times even good, fresh hay can contain a great deal of carrion. In another recorded incident 427 of 444 dairy cattle died after ingesting feed contaminated with botulinum type C toxin from a cat carcass.[8]

Poultry manure and ensiled **poultry litter** have caused outbreaks of botulism when used as cattle feed, as has poultry litter used for bedding cattle. Outbreaks of botulism have occurred in cattle and sheep grazing pastures that have been fertilized with poultry manure or poultry litter. Cattle and sheep may eat poultry litter piled on a pasture prior to disposal. It is probable that the source of toxin in poultry litter is from poultry carcasses. Disease is usually due to *C. botulinum* type C.[9]

Direct carrion ingestion can occur where **cattle** subsist on a **phosphorus-deficient diet** and manifest osteophagia, with subsequent ingestion of carrion. The disease is likely to occur in outbreak form. In **sheep**, pica is more usually associated with a dietary **deficiency of protein** or net energy. Occasional outbreaks occur that are due to drinking of **water** contaminated by carcasses of dead animals. A not uncommon occurrence is in livestock drinking lake water contaminated by the carcasses of ducks and other waterfowl that have died of botulism. Wetlands where outbreaks of avian botulism have occurred are likely to have repeated occurrences because of soil contamination.

Wound botulism

Wound botulism is rare but is recorded in horses following castration, with omphalophlebitis, umbilical hernias treated with clamps, with an infected wound and in association with an injection abscess.[10]

Toxicoinfectious botulism

This results when toxin is produced by *C. botulinum* present in the intestine. The disease is also called the '**shaker foal syndrome**'. It is a disease of young foals up to 8 months of age with the highest prevalence in foals 3–8 weeks of age.[11]

The disease occurs sporadically in the USA, Australia, and the UK but may occur repeatedly on some farms. *C. botulinum* type B has been isolated from the feces of naturally occurring cases of the disease and the condition has been produced experimentally by the intravenous injection of *C. botulinum* toxin.

Toxicoinfectious botulism is also postulated[12,13] as the possible cause of equine grass sickness (equine dysautonomia) which is described elsewhere in this text.

Experimental reproduction

Cows challenged with type C botulinum toxin intravenously showed initial signs of constipation and straining at defecation 48 hours after injection and weakness, decreased tail tone, decreased tongue tone and muscle fasciculation of large-muscle groups between 76 and 92 hours. Weakness progressed to total posterior paresis between 80 and 140 hours in these cattle. On a weight-for-weight basis, cattle were considered to be 13 times more sensitive than mice to type C botulinum toxin.[14]

Risk factors

Animal risk factors

Botulism is most common in birds, particularly the domestic chicken and wild waterfowl. Cattle, sheep, and horses are susceptible but pigs, dogs, and cats appear to be resistant. The horse appears to be particularly susceptible to type B toxin. Cattle and sheep are usually affected by types C and D.

Environment risk factors

Botulism in range animals has a seasonal distribution. Outbreaks are most likely to occur during drought periods when feed is sparse, phosphorus intake is low and carrion is plentiful. Silage-associated botulism is also seasonal with the feeding of silage. The variation that occurs in the geographical distribution of the various types, and in carrion versus non-carrion-associated botulism is an important factor when considering prophylactic vaccination programs.

Importance

Severe outbreaks with high case fatality rates can occur when contaminated feed is fed to large numbers of animals. Under extensive grazing conditions massive outbreaks of carrion-associated botulism also occur unless the animals are vaccinated.

Zoonotic implications

Botulinum toxin is identified as a possible agent for bioterrorism.

The meat and milk from cattle that have botulism should not be used for human consumption.

PATHOGENESIS

The toxins of *C. botulinum* are neurotoxins and produce functional paralysis without the development of histological lesions. Botulinum toxins are absorbed from the intestinal tract or the wound and carried via the bloodstream to peripheral cholinergic nerve terminals including neuromuscular junctions, postganglionic parasympathetic nerve endings, and peripheral ganglia. The heavy chain of the toxin is responsible for binding to the receptors and translocation into the cell and the light chain of the toxin for resultant blockade of the release of acetylcholine at the neuromuscular junction.[5,15,16] Flaccid paralysis develops and the animal dies of respiratory paralysis.

CLINICAL FINDINGS

Cattle and horses

Signs usually appear 3–17 days after the animals gain access to the toxic material, but occasionally as soon as 1 day,[5,10,17] the incubation period being shorter as the amount of toxin available is increased. **Peracute cases** die without prior signs of illness, although a few fail to take water or food for a day beforehand. The disease is not accompanied by fever and the characteristic clinical picture is one of progressive symmetric muscular paralysis affecting particularly the limb muscles and the muscles of the jaw, tongue, and throat. Muscle weakness and paralysis commence in the hindquarters and progress to the forequarters, head, and neck. The onset is marked by very obvious muscle tremor and fasciculation, often sufficient to make the whole limb tremble. Colic may be an initial sign in horses.

In most cases the disease is **subacute**. Restlessness, incoordination, stumbling, knuckling, and ataxia are followed by inability to rise or to lift the head. Mydriasis and ptosis occur early in the clinical course; mydriasis can be prominent in type C botulism in the horse.[18] Skin sensation is retained. Affected animals lie in sternal recumbency with the head on the ground or turned into the flank, not unlike the posture of a cow with parturient paresis. Tongue tone is reduced, as is the strength of tongue retraction. In some cases the tongue becomes paralyzed and hangs from the mouth, the animal is unable to chew or swallow and it drools saliva. In others there is no impairment of swallowing or mastication and the animal continues to eat until the end.[19] This variation in signs is often a characteristic of an outbreak, all the cases having tongue paralysis or all of them not having it. Ruminal movements are depressed. Defecation and urination are usually unaffected, although cattle may be constipated. Paralysis of the chest muscles results in a terminal abdominal-type respiration. Sensation and consciousness are retained until the end, which usually occurs quietly, and with the animal in lateral recumbency, 1–4 days after the commencement of illness.

Occasional field cases and some experimental cases in cattle show **mild signs** and recover after an illness of 3–4 weeks. These chronic cases show restlessness and respiratory distress followed by knuckling, stumbling, and disinclination to rise. Anorexia and adipsia are important early signs but are often not observed in pastured animals. In some there is a pronounced roaring sound with each respiration. The roaring persists for up to 3 months. During the major part of the illness the animals spend most of their time in sternal recumbency. In some animals there is difficulty in prehending hay but concentrate and ensilage may be taken. This disability may persist for 3 weeks.

A syndrome ascribed to toxicosis with type B botulinum toxin and manifest with anorexia, decline in milk production, dysphagia, a fetid diarrhea, vomiting, profuse salivation but without myesthesia, paresis and recumbency is reported in cattle in Holland and Israel.[20] In these cases death occurred as a result of aspiration pneumonia.

With **toxicoinfectious botulism** in foals muscle tremor is often a prominent early sign. If the foal can walk, the gait is stiff and stilted and the toes are dragged. If the foal sucks, milk drools from the mouth; if it attempts to eat hay some of the material is regurgitated through the nostrils. Constipation occurs consistently. There is a rapid progression to severe muscular weakness and prostration, with the foal going down and being unable to rise. If it is held up there is a gross muscle tremor, which is not evident when the foal is lying down. Prostrate foals are bright and alert, have normal mentation and pain perception, and have dilatation of the pupils with a sluggish pupillary light reflex. During the latter period of the illness there is a complete cessation of peristalsis. The temperature varies from being slightly elevated to slightly depressed. Death occurs about 72 hours after the onset of signs and is due to respiratory failure.

Sheep

Sheep do not show the typical flaccid paralysis of other species until the final stages of the disease. There is stiffness while walking, and incoordination and some excitability in the early stages. The head may be held on one side or bobbed up and down while walking (**limber neck**). Lateral switching of the tail, salivation, and serous nasal discharge are also common. In the terminal stages there is abdominal respiration, limb paralysis, and rapid death.

Pigs

Authentic reports in this species are rare. Clinical signs include staggering followed by recumbency, vomiting, and pupillary dilatation. The muscular paralysis is flaccid and affected animals do not eat or drink.

CLINICAL PATHOLOGY

There are no changes in hematological values or serum biochemistry that are specific to botulism.[11]

Hypophosphatemia may be present where this is a risk factor. Muscle enzyme activities may be moderately elevated.

In foals, arterial blood analysis shows acidemia, hypercapnia, hypoxemia, and desaturation of hemoglobin, and repeated arterial blood gas analyses should be conducted during the first 48 hours of treatment as a significant proportion of foals will require some form of ventilatory support.[11]

Laboratory diagnosis of botulism in the live or dead animal is difficult because of the lack of sensitive confirmatory laboratory tests. Laboratory confirmation[5] is attempted by:

- Detection of preformed toxin in serum, intestinal tract contents, or feed
- Demonstration of spores of *C. botulinum* in the feed or gastrointestinal contents
- Detection of antibody in recovering or clinically normal at-risk animals.

Detection of toxin using bioassay in mice coupled with toxin neutralization with polyvalent antitoxin is used but the sensitivity is low in both ruminants and horses as they are substantially more sensitive than mice to botulinum toxin.[14]

In outbreaks of botulism it is not uncommon to have only a proportion of clinically affected animals, or none, test positive. Protection with monovalent antitoxin allows type identification. Toxin detection by an enzyme-linked immunosorbent assay (ELISA) test appears less

sensitive than mouse bioassay.[21] Toxin production or carrion contamination can potentially occur in a number of feeds; however the majority of outbreaks are associated with contamination in hay or silage[5] and suspect feeds should be tested in mice for toxin. To get around the problem of lack of sensitivity with the mouse test, suspect feed has been fed to experimental cattle. Alternatively one can make an infusion of the feed sample and use this as the sole drinking water supply for experimental animals. The problem with all feeding experiments is that the botulinum toxin is likely to be very patchy in its distribution in the feed.

Failure to produce the disease in animals vaccinated against botulism, when deaths are occurring in the unvaccinated controls, has also been used as a diagnostic procedure.

Demonstration of spores of *C. botulinum* in the feed being fed or the feces of affected animals supports a diagnosis of botulism as botulism spores are rarely detected in the feces of normal foals and adult horses.[5]

The detection of antibody in chronically affected animals and at-risk herd mates by an ELISA test has been used to support a diagnosis in outbreaks of type C and type D botulism.[22,23] It has been used in range cattle where acutely affected clinical cases or fresh animals for postmortem toxin testing were not available. Cattle exposed to sublethal and subclinical amounts of toxin with sufficient immunogenicity develop a specific antibody response.[23] An increased antibody prevalence over time or an increased antibody prevalence in an affected group compared with a similar group nearby suggests exposure to the toxin.

NECROPSY FINDINGS

There are no specific changes detectable at necropsy, although the presence of suspicious feedstuffs in the forestomachs or stomach may be suggestive. There may be nonspecific subendocardial and subepicardial hemorrhages and congestion of the intestines. Microscopic changes in the brain are also nonspecific, consisting mainly of perivascular hemorrhages in the corpus striatum, cerebellum, and cerebrum. Nonetheless, unless classic flaccid paralysis was observed clinically, the brain should be examined histologically to eliminate other causes of neurological disease. The presence of *C. botulinum* in the alimentary tract is a further test. The presence of toxin in the gut contents is confirmatory if found but is often misleading, because the toxin may have already been absorbed. The presence of the toxin in the liver at postmortem examination is taken as evidence that the disease has occurred. In addition to traditional bioassays such as the mouse protection test, newer methods for toxin detection include ELISA techniques, and a recently described immuno-polymerase chain reaction (PCR) assay.[24]

Samples for confirmation of diagnosis

- Bacteriology – suspected contaminated feed material, liver, rumen contents, plus serum from clinically affected herdmates (bioassay, anaerobic CULT, ELISA)
- Histology – formalin-fixed brain.

DIFFERENTIAL DIAGNOSIS

A presumptive diagnosis is made on the clinical signs and history, occurrence in unvaccinated animals and the ruling out of other diseases with a similar clinical presentation. The symmetric motor paralysis of botulism with muscle paralysis that progresses to recumbency in 1–4 days is a major differential for botulism from other causes of neurological dysfunction in large animals.

Ruminants

Clinically and at necropsy the disease resembles parturient paresis in cattle and hypocalcemia in sheep but the conditions under which the diseases occur are quite different.

- Tick paralysis
- Paralytic rabies
- Poisoning by *Phalaris aquatica*
- Organophosphate/carbamate poisoning
- Louping ill in sheep

Horses

- Equine protozoal myelitis
- Equine encephalomyelitis
- Hepatic encephalopathy
- Paralytic rabies
- Ionophore toxicity

TREATMENT

Recent studies report a survival rate in foals of 96% which was achieved by the early administration of antitoxin (before complete recumbency) coupled with a high quality of intensive care fluid therapy, enteral or parenteral feeding, nasal insufflation with oxygen and mechanical ventilation if required. Duration of hospitalization approximated 2 weeks.[11] Antitoxin was considered essential to the high success rate in this report and this would limit the success of treatment geographically as antitoxin to the various botulinum toxin types is not available universally. Specific or **polyvalent antiserum** is available in some countries and, if administered early in the course at a dose of 30 000 IU for a foal and 70 000 IU for adult horses, can improve the likelihood of survival.[5] A single dose is sufficient but it is expensive.[25]

Animals should be confined to a stall with **supportive fluid therapy** and enteral feeding. Muzzling may be required to prevent aspiration pneumonia and frequent turning to prevent muscle necrosis and decubital ulcers. Bladder catheterization may be required in horses that do not urinate and mechanical ventilation may be necessary for recumbent horses. Mineral oil is used to prevent constipation and antimicrobial drugs are used to treat secondary complications such as aspiration pneumonia. Therapy should avoid the use of drugs that deplete the neuromuscular junction of acetylcholine, such as neostigmine, and those, such as procaine penicillin, tetracyclines, and aminoglycosides, that potentiate neuromuscular weakness.

A rapid progression of signs suggests a poor prognosis and, in general, treatment should only be undertaken in subacute cases in which signs develop slowly and which have some chance of recovery. The prognosis in recumbent horses is grave.

Where groups of animals have had the same exposure factor the remainder of the animals in the group should be vaccinated immediately.

CONTROL

In range animals, **correction of dietary deficiencies** by supplementation with phosphorus or protein should be implemented if conditions permit. Hygienic **disposal of carcasses** is advisable to prevent further pasture contamination but may not be practicable under range conditions. **Vaccination** with type-specific or combined (bivalent C and D) toxoid is practiced in enzootic areas in Australia and southern Africa. Type B and C vaccines would be more appropriate for prevention of disease in North America and Europe. The immunity engendered by vaccination is type-specific. The number and interval of vaccinations required varies with the vaccine, and the manufacturer's directions should be followed. In horses, the disease is usually sporadic and due to accidental contamination of feed or water; vaccination is seldom practiced in this species. Some local reactions are encountered after vaccination in horses but they are seldom serious. Vaccination of the mare may not prevent the occurrence of botulism in foals.[11]

A common problem that arises when the disease appears to have resulted from feeding contaminated silage, hay, or other feed is what to do with the residue of the feed; there may be a large quantity of it. In these circumstances the stock should be vigorously vaccinated with a toxoid on three occasions at 2-week intervals and then feeding of the same material can be recommenced.

BLACKLEG

Synopsis

Etiology Infectious myositis associated with *Clostridium chauvoei*. True blackleg is common only in cattle but infection with this organism initiated by trauma occurs occasionally in other animals

Epidemiology Cattle 6 months to 2 years of age that are rapidly growing and on a high plane of nutrition. Seasonal occurrence in warm wet months. There are often multiple cases in at-risk animals. Sheep of all ages – occurs as outbreaks predisposed by wounds from shearing, docking, castration, dystocia

Clinical findings Lameness and pronounced swelling of upper limb in many. Myonecrosis of skeletal or cardiac muscles, severe toxemia and a high case fatality rate. May be found dead

Clinical pathology Culture from needle biopsy. No diagnostic change in hematology or serum biochemistry. Fluorescent antibody

Necropsy findings Myositis; dark, rancid odor, metallic sheen on the cut surface

Diagnostic confirmation Fluorescent antibody identification of *C. chauvoei* in lesion

Treatment High doses of penicillin in early stages. Surgical debridement

Control Vaccination

ETIOLOGY

True blackleg, the clostridial myositis of skeletal muscles, is associated with *Clostridium (feseri) chauvoei*, a Gram-positive, spore-forming, rod-shaped bacterium. The spores are highly resistant to environmental changes and disinfectants and persist in soil for many years.

EPIDEMIOLOGY

Occurrence

When the disease occurs it is usual for a number of animals to be affected within the space of a few days. The disease is enzootic in particular areas, especially when they are subject to flooding; such an area may vary in size from a group of farms to an individual field.

The **case fatality rate** in blackleg approaches 100%.

Source of infection

Blackleg is a **soil-borne** infection but the portal by which the organism enters the body is still in dispute. It is presumed that the portal of entry is through the alimentary mucosa after ingestion of contaminated feed or associated with erupting teeth. The bacteria may be found in the spleen, liver, and alimentary tract of normal animals, and contamination of the soil and pasture may occur from infected feces or decomposition of carcasses of animals dying of the disease. True blackleg develops when spores that are not lodged in normal tissues are caused to proliferate by mechanisms such as trauma or anoxia.

Transmission

In cattle the disease usually occurs without a history of trauma but in sheep is almost always a wound infection. Infection of skin wounds at **shearing** and **docking** and of the **navel** at birth may cause the development of local lesions. Infections of the vulva and vagina of the ewe at **lambing** may cause serious outbreaks and the disease has occurred in groups of young ewes and rams up to a year old, usually as a result of infection of skin wounds caused by **fighting**. Occasional outbreaks have occurred in sheep **after vaccination** against enterotoxemia. Presumably the formalinized vaccine causes sufficient tissue damage to permit latent spores of the organism to proliferate.

A special occurrence is in **fetal lambs**. Ewes exposed to infection at shearing develop typical lesions but ewes treated with penicillin are unaffected except that the pregnant ewes in the latter group show distended abdomens, weakness and recumbency due to edema and gas formation in the fetus, from which *C. chauvoei* can be isolated.

Risk factors

Environment risk factors

Typical blackleg of cattle has a **seasonal incidence**, with most cases occurring in the warm months of the year. The highest incidence may vary from spring to autumn, depending probably on when calves reach the susceptible age group. In some areas there is an increased prevalence in years of high rainfall. Outbreaks of blackleg in cattle have occurred following excavation of soil, which suggests that disturbance of the soil may expose and activate latent spores.

Animal risk factors

True blackleg is usually thought of as a disease of cattle and occasionally sheep but outbreaks of the disease have been recorded in deer and it is reported in a horse.[1] In cattle the disease is largely confined to young stock between the ages of 6 months and 2 years, although disease occurs occasionally in younger animals and cattle up to 3 years. In the field, **risk factors** include rapidly growing cattle and a high plane of nutrition. Elevation of the nutritional status of sheep by increased protein feeding increases their susceptibility to blackleg. In sheep there is no restriction to age group.

In pigs, blackleg is not common, although a gas gangrene type of lesion may be associated with *C. chauvoei* or *C. septicum* infection.

Economic importance

Blackleg is a cause of severe financial loss to cattle raisers in many parts of the world. For the most part major outbreaks are prevented by vaccination, although outbreaks still occur occasionally in vaccinated herds or cattle incompletely vaccinated.

PATHOGENESIS

In true blackleg the stimulus that results in growth of the latent bacterial spores is unknown. There is usually no history of trauma, although trauma while passing through an alley is reported as the likely inciting factor in one outbreak.[2] Toxin formed by the organism produces a severe necrotizing myositis locally in skeletal muscles, and a systemic toxemia that is usually fatal. In cattle and sheep atypical outbreaks of sudden death occur in which the lethal lesion is a clostridial cardiac myositis.[3,4]

CLINICAL FINDINGS

Cattle

If the animal is observed before death there is severe lameness, usually with pronounced swelling of the upper part of the affected leg. On closer examination the animal will be found to be very depressed and have complete anorexia and ruminal stasis, and a high temperature (41°C, 106°F) and pulse rate (100–120/min). Pyrexia is not present in all cases.[2] In the early stages the swelling is hot and painful to the touch but soon becomes cold and painless, and edema and emphysema can be felt. The skin is discolored and soon becomes dry and cracked.

Although the lesions are usually confined to the upper part of one limb, occasional cases are seen where the lesions are present in other locations such as the base of the tongue, the heart muscle, the diaphragm and psoas muscles, the brisket, and the udder. Lesions are sometimes present in more than one of these locations in one animal. The condition develops rapidly and the animal dies quietly 12–36 hours after the appearance of signs. Many animals die without signs having been observed.

Sheep

When blackleg lesions occur in the limb musculature in sheep, there is a stiff gait and the sheep is disinclined to move because of severe lameness in one limb or, more commonly, in several limbs. The lameness may be severe enough to prevent walking in some animals but be only moderate in others. Subcutaneous edema is not common and gaseous crepitation cannot be felt before death. Discoloration of the skin may be evident but skin necrosis and gangrene do not occur.

In those cases where infection occurs through **wounds** of the skin, vulva, or vagina there is an extensive local lesion. Lesions of the head may be accompanied by severe local swelling due to edema and there may be bleeding from the nose. In all instances there is high fever, anorexia, and depression, and death occurs very quickly. Sheep and cattle with cardiac myositis associated with *C. chauvoei* are usually found dead.[3,4]

Horses

The clinical syndrome in horses is not well defined. Pectoral edema, stiff gait, and incoordination are recorded.[1]

CLINICAL PATHOLOGY

The disease is usually so acute that necropsy material is readily available but, failing this, it may be possible to obtain material suitable for cultural examination by needle puncture or swabs from wounds. There are no constant changes in hematological parameters or serum biochemistry.[2]

NECROPSY FINDINGS

Cattle found dead of blackleg are often in a characteristic position; lying on the side with the affected hindlimb stuck out stiffly. Bloating and putrefaction occur quickly and bloodstained froth exudes from the nostrils and anus. Clotting of the blood occurs rapidly. Incision of the affected muscle mass reveals dark red to black, swollen tissue with a rancid odor and thin, sanguineous fluid containing bubbles of gas. Freshly cut surfaces are often dry and may have a metallic sheen. The heart and all skeletal muscles, including those of the tongue, diaphragm, and lumbar region, must be checked, as the lesion may be small and escape cursory examination. The thoracic cavity and the pericardial sac may contain excess bloodstained fluid with variable amounts of fibrin. This serositis is often overlooked, or is misinterpreted as a component of pleuropneumonia. The lungs are usually congested and may be atelectatic as a result of abdominal tympany.

In **sheep** the muscle lesions are more localized and deeper and the **subcutaneous edema is not so marked, except around the head**. Gas is present in the affected muscles but not in such large amounts as in cattle. When the disease has resulted from infection of skin wounds, the lesions are more obvious superficially, with subcutaneous edema and swelling and involvement of the underlying musculature. When invasion of the genital tract occurs, typical lesions are found in the perineal tissues and in the walls of the vagina and occasionally the uterus. In the special case of pregnant ewes, typical lesions may involve the entire fetus and cause abdominal distension in the ewe.

Histologically, blackleg cases feature myonecrosis, edema, emphysema, and an unimpressive neutrophilic cellulitis. Organisms may be few in number but can usually be seen in tissue sections. Smears from the affected tissue should be made and material collected for bacteriological examination. The isolation and identification of *C. chauvoei* and *C. novyi* is difficult because of the fastidiousness of these species in culture and rapid postmortem contamination of the tissues by clostridial species from the gastrointestinal tract. Thus it is essential that tissues be examined as soon after death as possible.[5] Most laboratories use fluorescent antibody tests performed on tissue smears to complement (or substitute) anaerobic culture.

'False blackleg' may be associated with *C. septicum* and *C. novyi* but this disease is more accurately classified as malignant edema. Mixed infections with *C. chauvoei* and *C. septicum* are not uncommon but the significance of *C. septicum* as a cause of the disease is debated. However, in a study of 176 cases of clostridial myositis in cattle, *C. chauvoei* either alone or with *C. septicum* was demonstrated in 56%. In 36%, *C. novyi* was found alone or with *C. septicum*.[5] This indicates that maximum protection to cattle can be provided only by a multivalent vaccine that contains the antigens of *C. chauvoei*, *C. novyi*, and *C. septicum*. A mutiplex PCR based on the flagellin gene sequence has been used to identify pathogenic clostridia in clinical specimens.[6]

Samples for confirmation of diagnosis

- Bacteriology – muscle, placed in air-tight container; four air-dried impression smears of surface of freshly cut lesion (anaerobic CULT, FAT)
- Histology – fixed samples of suspected muscle lesion

DIFFERENTIAL DIAGNOSIS

In establishing a diagnosis when a number of animals are found dead in a group not kept under close observation and postmortem decomposition is so advanced that little information can be obtained, one must depend on one's knowledge of local disease incidence, season of the year, age group affected and pasture conditions, and on a close inspection of the environment in which the animals have been maintained. More frequent observation should be established so that sick animals or fresh cadavers will be available for examination.

- **Malignant edema**. In typical cases of blackleg in cattle a definite diagnosis can be made on the clinical signs and the necropsy findings. Definitive identification of *C. chauvoei* is by fluorescent antibody staining. Diagnosis on gross postmortem findings from other causes of clostridial myositides is hazardous and may result in improper recommendations for control
- **Anthrax**
- **Lightning strike**
- **Bacillary hemoglobinuria**
- Other causes of sudden unexpected death.

TREATMENT

Treatment of affected animals with **penicillin and surgical debridement** of the lesion, including fasciotomy, is indicated if the animal is not moribund. Recovery rates are low because of the extensive nature of the lesions. Large doses (40 000 IU/kg BW) should be administered, commencing with crystalline penicillin intravenously and followed by longer-acting preparations. Blackleg **antiserum** is unlikely to be of much value in treatment unless very large doses are given.

CONTROL

Cattle

On farms where the disease is enzootic, annual vaccination of all cattle between 3 and 6 months with two vaccinations given 4 weeks apart followed by an annual booster vaccination is recommended. This should be done just prior to the anticipated danger period, usually spring and summer. Maternal immunity persists for at least 3 months and will interfere with active immunity in calves vaccinated before this age.

In an **outbreak** all unaffected cattle should be vaccinated immediately and injected with penicillin at a dose of 10 000 IU/kg BW intramuscularly or a combination of penicillin and benzathine penicillin. Movement of the cattle from the affected pasture is advisable. If antibiotics are not given, new cases of blackleg may occur for up to 14 days until immunity develops, and constant surveillance and the early treatment of cases will be necessary.

Sheep

With sheep in areas where the disease is enzootic, the **maiden ewes** should be vaccinated twice, the last vaccination given about 1 month before lambing and a subsequent yearly booster given at the same time before lambing. This will prevent infection of the ewes at lambing and will also protect lambs against umbilical infection at birth and infection of the tail wound at docking, provided the tail is docked at a young age. If an **outbreak** commences in a flock of ewes at lambing time, prophylactic injections of penicillin and antiserum to ewes requiring assistance are recommended.

A single vaccination of **wethers** can also be carried out 2–3 weeks before **shearing** if infection is anticipated. Because of the common occurrences of the disease in young sheep, vaccination before they go on to pasture and are exposed to infection of skin wounds from fighting is recommended in danger areas. The duration of the immunity in these young vaccinated animals is relatively short and ewes in particular must be revaccinated before they lamb for the first time. Clostridial vaccines have **poorer antigenicity** in sheep and goats than in cattle.

In both sheep and cattle it is advisable to use a **combined vaccine** containing at least *C. chauvoei*, *C. septicum*, and *C. novyi*, where these organisms occur in the area and cause clostridial myositis.

There is limited information on which to base the recommendations above as there is limited information on the **efficacy** of available individual manufacturers' vaccines. There is variability in the immune response and its duration with different vaccines.[7] **Vaccine failure** has been associated with an inadequate spectrum of the antigens in the vaccine, and in these circumstances a bacterin prepared from a local strain of *C. chauvoei* is preferred.[8] Vaccines combined with anthelmintics or with trace elements are used in some areas to minimize the number of injections required when processing sheep.[9]

It is important that **carcasses** of animals dying of blackleg are destroyed by burning or deep burial to limit soil contamination.

MALIGNANT EDEMA, CLOSTRIDIAL MYONECROSIS (GAS GANGRENE)

Synopsis

Etiology Malignant edema is an acute wound infection associated with organisms of the genus *Clostridium*
Epidemiology All ages and species of animals are susceptible. Sporadic disease affecting individual animals following injections but outbreaks following contamination of wounds produced by management procedures
Clinical findings Acute onset with fever and toxemia. Inflammation and swelling at site of a wound with heat, edema, pain on palpation, and usually subcutaneous emphysema
Clinical pathology No diagnostic change in hematology or serum biochemistry. Fluorescent antibody staining
Necropsy findings Gangrene of the skin with edema of the subcutaneous and intermuscular connective tissue around the site of infection
Diagnostic confirmation Demonstration of the causal organisms by fluorescent antibody staining
Treatment Antibiotics, surgical debridement
Control Vaccination. Prophylactic antibiotics

ETIOLOGY

Clostridium septicum, *C. chauvoei*, *C. perfringens*, *C. sordellii*, and *C. novyi* have all been isolated from lesions typical of malignant edema of animals. In some cases there can be mixed infections. The occurrence of malignant edema due to *C. chauvoei* has been discussed in the section on blackleg.

C. sordellii has been associated chiefly with malignant edema of cattle but it has been found to be a cause of malignant edema and swelled head in sheep. However, swelled head of rams, in which the lesions of malignant edema are restricted to the head, is most commonly associated with *C. novyi* infection.

In a retrospective study of 37 horses with clostridial myonecrosis, *C. perfringens* was isolated from 68%, *C. septicum* from 16% and mixed infections with these two species or infection with other clostridia in the remainder.[1]

EPIDEMIOLOGY

All ages and species of animals are affected. The clostridia that cause malignant edema are **common inhabitants** of the animal environment and intestinal tract and, although some of the causative species have a restricted distribution, the disease is general in most parts of the world. The disease occurs sporadically, affecting individual animals except in circumstances where a management procedure to a group of animals results in an outbreak.

Source of infection

The infection is usually **soil-borne**, and the resistance of spores of the causative clostridia to environmental influence leads to **persistence** of the infection for long periods in a local area. A dirty environment that permits contamination of wounds with soil is the common predisposing cause.

Transmission

In most cases a wound is the **portal of entry**. Deep puncture wounds accompanied by severe trauma provide the most favorable conditions for growth of anaerobes, and malignant edema occurs most frequently under such conditions. Infection may occur through surgical or accidental wounds following vaccination, intramuscular injection of drugs, venipuncture, or through the umbilical cord in the

newborn. It is assumed that infection is introduced through the wound but cases of malignant edema can occur following intramuscular injection of drugs despite careful attention to aseptic technique. Dormant spores of *C. perfringens* and other clostridial species can be found in the normal muscle of horses and it is possible in some cases that these may be activated by anaerobic conditions produced by the injected material.[2]

Animal and management risk factors

In horses intramuscular injection of drugs, commonly in association with the treatment of colic, is the common precipitating factor. Certain drugs may have a greater propensity to initiate muscle necrosis and disease but these drugs are also commonly used in the treatment of colic. Perivascular leaking of drugs is also a precipitating cause in horses.[1,3,4] In all species there is risk with the intramuscular injection of drugs such as anthelmintics and nutritional supplements, some of which can cause significant tissue damage at the site, particularly if proper asepsis is not practiced.[5–7]

Outbreaks can occur in sheep after management practices such as shearing, and docking, or following lambing. Outbreaks have also been observed in cattle following **parturition**, sometimes associated with lacerations of the vulva. An unusual method of infection occurs when crows that have eaten infected carrion carry the infection to live, weak sheep and to lambs when they attack their eyes. Castration wounds in pigs and cattle may also become infected. Unless treatment is instituted in the early stages the death rate is extremely high.

The practice of **dipping** sheep immediately they are shorn may cause a high incidence of malignant edema if the dip is heavily contaminated. The disease '**swelled head**', a form of malignant edema, occurs in young rams 6 months to 2 years old when they are run in bands and fight among themselves.

Importance

Outbreaks of malignant edema are probably less common as a result of education of farmers and the availability of vaccines. In the wrong circumstances with improper hygiene severe disease can still occur.[8]

PATHOGENESIS

Potent necrotoxins are produced in the local lesion and cause death when absorbed into the bloodstream. Locally the exotoxins cause extensive edema and necrosis followed by gangrene.

CLINICAL FINDINGS

Clinical signs appear within 6–48 hours of infection. There is always a local lesion at the **site of infection** consisting of a soft, doughy swelling with marked local erythema accompanied by severe pain on palpation. At a later stage the swelling becomes tense and the skin dark and taut. Emphysema may or may not be present, depending on the type of infection, and may be so marked as to cause extensive frothy exudation from the wound. With *C. novyi* infections there is no emphysema. A high fever (41–42°C, 106–107°F) is always present; affected animals are depressed, weak and show muscle tremor and usually stiffness or lameness. The mucosae are dry and congested and have very poor capillary refill. The illness is of short duration and affected animals die within 24–48 hours of the first appearance of signs. New cases continue to appear for 3–4 days after shearing or other precipitating cause.

When infection occurs at **parturition**, swelling of the vulva accompanied by the discharge of a reddish-brown fluid occurs within 2–3 days. The swelling extends to involve the pelvic tissues and perineal region. The local lesions are accompanied by a profound toxemia and death occurs within 1–2 days.

In '**swelled head**' of rams the edema is restricted initially to the head. It occurs first under the eyes and spreads to the subcutaneous tissues of the head and down the neck.

In **pigs** the lesions are usually restricted to the axilla, limbs, and throat and are edematous, with very little evidence of emphysema. Local skin lesions consisting of raised, dull red plaques distended with clear serous fluid containing *C. septicum* and causing no systemic illness may be encountered in pigs at abattoirs.

In horses, emphysema, detected by palpation or ultrasound, is an early sign.[1,3,4]

CLINICAL PATHOLOGY

Antemortem laboratory examination of affected farm animals is not usually undertaken, usually because there are carcasses for postmortem examination.

Examination of a Gram-stained smear of aspirated fluid from edematous swellings or swabs from wounds will give an early diagnosis, allowing therapy early in the course of the disease. A PCR has been developed to allow the rapid identification and differentiation of the clostridia associated with malignant edema in livestock.[9]

Hematological examination in horses may show evidence of an immune-mediated hemolytic anemia.[1,10]

NECROPSY FINDINGS

Tissue changes occur rapidly after death, particularly in warm weather, and this must be kept in mind when evaluating postmortem findings. There is usually gangrene of the skin with edema of the subcutaneous and intermuscular connective tissue around the site of infection. There may be some involvement of underlying muscle but this is not marked. The edema fluid varies from thin serum to a gelatinous deposit. It is usually blood-stained and contains bubbles of gas except in *C. novyi* infections when the deposit is gelatinous, clear and contains no gas. A foul, putrid odor is often present in infections with *C. perfringens* and *C. sordellii*.

Subserous hemorrhages and accumulations of serosanguineous fluid in body cavities are usual. In 'swelled head' of rams the edema of the head and neck may extend into the pleural cavity and also involve the lungs.

The **histological** picture of malignant edema consists of abundant edema fluid, emphysema, and neutrophils within the connective tissues. Muscle is not spared but the damage is focused along fascial planes.

Samples for confirmation of diagnosis

- Bacteriology – fascial tissue, placed in an airtight container; four air-dried smears of fluid from lesion (anaerobic CULT, FAT)
- Histology – fixed sample of lesion.

DIFFERENTIAL DIAGNOSIS

The association of profound toxemia and local inflammation and emphysema at the site of a wound is characteristic.

- **Blackleg**. The disease is differentiated from blackleg by the absence of typical muscle involvement and the presence of wounds
- **Anthrax** in pigs and horses
- **Photosensitivity** in white-faced sheep with swelled head

TREATMENT

Affected animals should be treated as emergency cases because of the acute nature of the disease. Specific treatment requires the administration of penicillin (high doses of crystalline penicillin intravenously, repeated at 4–6-hour intervals) or a broad-spectrum antibiotic. Antitoxin aids in controlling the toxemia but is expensive and must be given very early in the course of the disease. A nonsteroidal anti-inflammatory drug (NSAID) and supportive therapy are recommended. Injection of penicillin directly into and around the periphery of the lesions may be of value in some cases. Local treatment consists of surgical incision to provide drainage, and irrigation with hydrogen peroxide. In horses, early and aggressive treatment with myotomy and fasciotomy, repeated if indicated, coupled with intravenous potassium penicillin is reported to

allow recovery rates approaching 70%. The success rate in treating horses with infections with *C. perfringens* was higher than that with *C. septicum*.[1]

CONTROL

Hygiene at lambing, shearing, castration and docking is essential to the control of the infection in sheep. Vaccination with a specific or multivalent clostridial bacterin-toxoid will prevent the occurrence of the disease in enzootic areas. Penicillin can be given prophylactically to animals at risk for the disease.

BRAXY (BRADSOT)

Braxy is an acute infectious disease of sheep in Britain characterized by inflammation of the abomasal wall, toxemia, and a high mortality rate. The disease was common in the early 20th century but now is extremely rare, as reflected in reports by the British Veterinary Laboratories Agency (Veterinary Investigation Centres).

Synopsis

Etiology *Clostridium septicum* and ingestion of frosted feedstuffs
Epidemiology Weaners and yearling sheep in winter
Clinical findings Rapid death
Clinical pathology Death too rapid
Necropsy findings Pathognomonic lesion in abomasum
Diagnostic confirmation Typical abomasal lesion and positive fluorescent antibody staining of organism in lesion
Treatment None
Control Annual vaccination preceding the period of risk

ETIOLOGY

Clostridium septicum, the common cause of malignant edema in animals, is generally regarded as the causative bacterium.

EPIDEMIOLOGY

The disease occurs only in midwinter when there are heavy frosts and snow, and usually only in weaner and yearling sheep. It has occurred in experimental sheep receiving infusions of acetic acid into the abomasum. These were thought to cause abomasitis.[1] Adult animals in an enzootic area appear to have acquired immunity.

C. septicum is a soil-borne organism and in many areas can be considered as a normal inhabitant of the ovine intestinal tract.

The disease occurs in the UK and various parts of Europe and has been reported in the southern part of Australia[1] but appears to be rare in North America. It is now not of major importance because of its low incidence, although at one time it was sufficiently common to be an important cause of loss in some countries. In affected sheep the case fatality rate is usually about 50% and in enzootic areas an annual loss of 8% has been reported.

PATHOGENESIS

Presumably a primary abomasitis, associated with the ingestion of frozen grass or other feed, permits invasion by *C. septicum*, resulting in a fatal toxemia.

CLINICAL FINDINGS

There is a sudden onset of illness with segregation from the group, complete anorexia, depression, and high fever (42°C (107°F) or more). The abdomen may be distended with gas and there may be signs of abdominal pain. The sheep becomes recumbent, comatose and dies within a few hours of first becoming ill.

CLINICAL PATHOLOGY

Antemortem laboratory examinations are of little value in establishing a diagnosis.

NECROPSY FINDINGS

There are localized areas of edema, congestion, necrosis, and ulceration of the abomasal wall. Congestion of the mucosa of the small intestine may also be present and there may be a few subepicardial petechiae. *C. septicum* can be isolated by smear from the cut surface of the abomasal wall or by culture from the heart, blood, and other organs of fresh carcasses. Bacteriological examinations of tissues must be carried out within an hour of death if the diagnosis is to be confirmed.

Mortality in **calves** with braxy-like lesions in the abomasum is recorded.[2,3]

Samples for confirmation of diagnosis

- Bacteriology – frozen abomasum, in air-tight container; four air-dried impression smears from freshly cut surface of abomasal mucosa (anaerobic CULT, FAT)
- Histology – fixed abomasum.

DIFFERENTIAL DIAGNOSIS

Clinically the diagnosis of braxy is most difficult. At necropsy the lesions of abomasitis are characteristic, especially if the disease occurs under conditions of severe cold. Overeating on grain may cause local patches of rumenitis and reticulitis but there are no lesions in the abomasum. Braxy may resemble infectious necrotic hepatitis but there are no liver lesions in braxy. The final diagnosis depends on isolation of *C. septicum* from typical alimentary tract lesions.

TREATMENT

No treatment has been found to be of value.

CONTROL

Management of the flock is important. The sheep should be yarded at night, and fed hay before being let out to the frosted pasture each morning. Vaccination with a formalin-killed whole culture of *C. septicum*, preferably 2 injections 2 weeks apart, is also an effective preventive.

INFECTIOUS NECROTIC HEPATITIS (BLACK DISEASE)

Synopsis

Etiology An acute toxemia of sheep, cattle and sometimes pigs and horses caused by the toxin of *Clostridium novyi* elaborated in damaged liver tissue. Outbreaks usually associated with fascioliasis
Epidemiology Adult sheep in good condition. Seasonal prevalence related to the migration of immature liver fluke in the liver
Clinical findings Sheep – rapid clinical course and usually found dead. Short clinical course in cattle and horses with profound depression and toxemia, abdominal pain and peritonitis
Clinical pathology None described
Necropsy findings Rapid autolysis, engorgement of subcutaneous vessels with edema. Liver has small areas of yellow-colored necrosis surrounded by a zone of hyperemia
Diagnostic confirmation Finding of *C. novyi* in the typical liver lesion. Fluorescent antibody staining identifies *C. novyi* but not the type
Treatment Parenteral penicillin but high case fatality
Control Vaccination

ETIOLOGY

The disease occurs in sheep and cattle and rarely in pigs and in horses[1–4] *Clostridium novyi*, type B, is the cause of

the disease; it is resident in soil and may be present in the liver of normal animals. The intervention of a necrotic process in the liver, which causes the organism to proliferate and produce lethal amounts of toxin, is commonly stated to be the precipitating cause. *C. novyi* types A and C are also resident in soil and may invade a carcass postmortem, but do not cause infectious necrotic hepatitis. Type C is nontoxigenic.

The disease has been produced experimentally in sheep by the administration of spores of *C. novyi* after prior infection with fluke metacercaria.[5] Although field outbreaks of the disease are usually precipitated by invasion of the liver by immature liver fluke it is possible that other causes of local hepatic injury, e.g. invasion by cysts of *Cysticercus tenuicollis*, and trauma from liver biopsy[6] may precipitate the disease. *Thysanosoma actinoides* is believed to be a predisposing infection in South America.[7]

Cases are reported in which no specific precipitating lesions are detected and have been advanced as an explanation of sudden deaths in feedlot cattle. *C. novyi* types A and B have been incriminated as a cause of sudden death in sows.[8,9]

EPIDEMIOLOGY

Occurrence

The disease is **worldwide** in distribution but is of particular importance in Australia and New Zealand and to a lesser extent in the UK, the US, and Europe. In sheep, the incidence rate in a given year is usually about 5% in affected flocks but may be as high as 10–30% and in rare cases up to 50%. The disease is always fatal in both sheep and cattle. Details of the incidence in cattle are scanty but the disease is becoming more common in some areas where fluke is being introduced. The disease is rare in horses.

Risk factors

Animal risk factors

Well-nourished adult sheep in the 2–4-year age group are particularly susceptible, lambs and yearlings rarely being affected.

Environmental risk factors

The epidemiological association between **liver fluke** and *C. novyi* has been supported by the observation that both are more prevalent in the soil in areas where black disease occurs than in other areas, and the survival of both the bacteria and the fluke is favored by the same type of soil environment.[10]

In temperate climates, a **seasonal occurrence** is marked because of fluctuation in the liver fluke and host snail population. Outbreaks are most common in the summer or autumn months and cease within a few weeks after frosts occur because of destruction of encysted metacercaria. Exposure to fluke infestation, as occurs when sheep graze on marshy ground during dry summers and drought, is commonly associated with outbreaks of black disease, although they can occur in winter. Sheep removed from a black disease farm may die of the disease up to 6 weeks later because of the timelag required for migration of the flukes.

Heavy irrigation of pastures creates favorable conditions for the development of flukes and may predispose disease. Outbreaks in cattle commonly occur on irrigated farms.

Source of infection

Fecal contamination of the pasture by carrier animals is the most important source of infection, although the cadavers of sheep dead of the disease may cause heavy contamination. Many normal animals in flocks in which the disease occurs carry *C. novyi* in their livers, not all strains being pathogenic.[11] The **spread of infection** from farm to farm occurs via these sheep and probably also by infected wild animals and birds and by the carriage of contaminated soil during flooding.

Other species

There is little information of the epidemiology of the disease in the horse, although prior administration of an anthelmintic may be a risk factor.[2,4] *C. novyi* can be a significant cause of **sudden death of adult pigs**.[8,9,12] In some herds the disease is more common in older sows (average parity 5.6 litters) with the highest prevalence in the spring months.[9,12]

PATHOGENESIS

Spores of *C. novyi* are ingested and carried to the liver in the lymphatic system; the organism can be isolated from the livers of normal animals.[13] Under local anaerobic conditions, such as occur in the liver when migrating flukes cause severe tissue destruction, the organisms already present in the liver proliferate, liberating alpha toxin, which is necrotoxic and causes local liver necrosis and more diffuse damage to the vascular system. The nervous signs observed may be due to this general vascular disturbance or to a specific neurotoxin.

CLINICAL FINDINGS

Sheep

Affected sheep commonly die during the night and are found dead without having exhibited any previous signs of illness. When observation is possible, clinically affected sheep are seen to segregate from the rest of the flock, lag behind and fall down if driven. There is fever (40–42°C, 105–107°F), which subsides to a premortal (subnormal) level, and some hyperesthesia; respiration is rapid and shallow; the sheep remains in sternal recumbency and often dies within a few minutes while still in this position. The course from first illness to death is never more than a few hours and death usually occurs quietly, without evidence of struggling.

Cattle

Clinical findings are the same in cattle as in sheep but the course is longer, the illness lasting for 1–2 days. Outstanding clinical findings in cattle include a sudden severe depression, reluctance to move, coldness of the skin, absence of rumen sounds, a low or normal temperature, and weakness and muffling of the heart sounds. There is abdominal pain, especially on deep palpation of the liver, and the feces are semifluid. Periorbital edema may also develop.

Horses

In the horse[2–4] the syndrome presents as a peritonitis accompanied by severe and progressive toxemia and manifests with depression, reluctance to walk, pain on palpation of the abdomen, frequent straining and recumbency. Fluid from abdominal paracentesis has a profound increase in nucleated cells and protein. Death occurs within 72 hours of onset of the disease.

CLINICAL PATHOLOGY

Antemortem laboratory examinations are not usually possible because of the peracute nature of the disease, and there is no body of information for this disease.

NECROPSY FINDINGS

Bloodstained froth may exude from the nostrils. The carcass undergoes rapid putrefaction. There is pronounced engorgement of the subcutaneous vessels and a variable degree of subcutaneous edema. The dark appearance of the inside of the skin, particularly noticeable on drying, has given rise to the name **black disease**. Gelatinous exudate may be present in moderate quantities in the fascial planes of the abdominal musculature. Bloodstained serous fluid is always present in abnormally large amounts in the pericardial, pleural, and peritoneal cavities. Subendocardial and subepicardial hemorrhages are frequent.

The **liver** is swollen, gray-brown and exhibits characteristic **areas of necrosis**. These are yellow areas 1–2 cm in diameter and are surrounded by a **zone of bright red hyperemia**. They occur mostly under the capsule of the diaphragmatic surface of the organ but may be more deeply seated and can easily be missed unless the liver is sliced carefully. In cattle they are often linear in shape and may be

difficult to find. There is usually evidence of recent invasion by liver fluke, with channels of damaged liver tissue evident on the cut surface of the liver. These may be mistaken for subcapsular hemorrhages when viewed from the surface. Mature flukes are not ordinarily observed. **Histologically**, the liver lesion consists of a central tract of eosinophilic inflammation (due to fluke migration) surrounded by a zone of coagulation necrosis and an outer rim of infiltrating neutrophils. Gram-positive bacilli can easily be demonstrated within the lesion.

A diagnosis of black disease requires the culture of *C. novyi* from the typical liver lesion and the demonstration of preformed toxin in the peritoneal fluid and/or the liver lesion from a fresh carcass. Autolysis rapidly clouds the postmortem findings and false-positive diagnoses are likely if toxin assays are performed on carcasses more than 24 hours old.[14] Another problem is the relatively common occurrence of nonpathogenic strains of *C. novyi* B. These strains are detected in livers by the fluorescent antibody technique and this may lead to a false-positive identification of black disease.

Fluorescent antibody techniques are almost as accurate and much less time-consuming than traditional anaerobic culture methods. An ELISA for beta toxin in intestinal contents has been described[8] and PCR techniques for better identification of toxin-producing strains of clostridia are available.

Unusual lesions, such as a large area of inflammation in the wall of the abomasum and congestion of the subcutaneous tissue and muscle in the shoulder and withers, have been observed in some cattle dying of the disease.

Samples for confirmation of diagnosis

- Bacteriology – liver in air-tight container; four impression smears from periphery of lesion (anaerobic CULT, FAT)
- Histology – fixed liver.

DIFFERENTIAL DIAGNOSIS

- **Acute fascioliasis** in sheep can cause heavy mortality due to massive liver destruction at the same time and under the same conditions as does black disease
- **Other clostridial disease** – blackleg, malignant edema
- **Anthrax**

TREATMENT

No effective treatment is available. In cattle and horses the longer course of the disease suggests the possibility of controlling the clostridial infection by the parenteral use of penicillin or broad-spectrum antibiotics but reported cases have high case fatality.

CONTROL

Vaccination with an alum-precipitated toxoid is highly effective and can be carried out during the course of an outbreak. The mortality begins to subside within 2 weeks. On an affected farm the initial vaccination is followed by a second vaccination 4–6 weeks later and subsequently by annual vaccinations. To provide maximum immunity at the time when the disease is most likely to occur, vaccination as a prophylactic measure should be carried out in early summer.

Control of the disease should also be attempted by **control of the liver fluke**. The host snail must be destroyed in streams and marshes by the use of a molluscicide and the flukes eliminated from the sheep by treatment with flukicides. Pasture contamination from cadavers should be minimized by burning the carcasses.

BACILLARY HEMOGLOBINURIA

Synopsis

Etiology Necrotoxic and hemolytic beta toxin produced by *Clostridium haemolyticum*, a soil-borne anaerobe, growing in a necrotic infarct in the liver
Epidemiology Cattle and sheep. Occurs in summer and autumn in endemic areas, which are usually irrigated or subirrigated fields
Clinical findings Toxemia, fever, hemoglobinuria and jaundice; high case fatality
Clinical pathology Hemoglobinuria, anemia, blood culture
Necropsy findings Single ischemic pale infarct in the liver surrounded by a zone of hyperemia. Hemoglobinuria
Diagnostic confirmation Typical liver lesion and positive fluorescent antibody staining of organism in lesion
Treatment Antibiotics, antiserum and blood transfusion
Control Annual vaccination preceding the period of risk

ETIOLOGY

Clostridium haemolyticum (*C. novyi* type D) is a **soil-borne** anaerobe. The longevity of the spores in soil is unknown but the organism has been isolated from bones a year after the death of an animal from bacillary hemoglobinuria. In infected areas the organism is often found in the livers of **healthy cattle**. Under anaerobic conditions the organism grows and produces a necrotoxic and hemolytic toxin that is responsible for the clinical disease. Damage to the liver from telangiectasis, necrobacillosis caused by *Fusobacterium necrophorum*, and fascioliasis have been suggested as precipitating causes.[1,2]

The disease has been produced experimentally by infecting calves orally and inducing liver damage by liver biopsy, or by implanting the organism in the liver.[3] Cultures of the organism produce severe muscle necrosis and hemoglobinuria when injected intramuscularly into cattle and experimental animals.

EPIDEMIOLOGY

Occurrence

Bacillary hemoglobinuria has been reported principally from the western part of the **USA**, although the disease has also been observed in the southern states, Canada, Mexico, Venezuela, Chile, Turkey, Australia, New Zealand, the UK, and Ireland. The disease is not common but on infected farms death losses, which are usually less than 5%, may reach as high as 25%.

Risk factors

Animal risk factors

Cattle are the usual species involved although occasional cases occur in sheep and rare cases in pigs. As is the case in many clostridial diseases, animals in good condition are more susceptible.

Environmental risk factors

Bacillary hemoglobinuria is a disease of the **summer and autumn** months. A primary association occurs with pastures that also are associated with the occurrence of liver fluke although other, less determined risk factors obtain. The highest

incidence of bacillary hemoglobinuria is on irrigated or poorly drained pasture, especially if the soil is alkaline in reaction.[4] Some outbreaks have occurred in **feedlots** where hay cut from infected fields was fed.

The disease is rare on dry, open **range country** but does occur in range country where cattle have access to swales with areas naturally irrigated by springs or streams. Heavy mortalities may occur when cattle from an uninfected area are brought on to an infected farm, cases beginning to occur 7–10 days later.

The disease is **spread** from infected to noninfected areas by flooding, natural drainage, contaminated hay from infected areas, or carrier animals. The carriage of bones or meat by dogs or other carnivores could also effect spread of the infection. Contamination of pasture may occur from feces or from decomposing cadavers.

PATHOGENESIS

Although attempts to produce the disease by feeding the organism have been unsuccessful it is probable that under natural conditions in endemic areas invasion occurs from the alimentary tract after ingestion of contaminated material. Migrating flukes are the primary factor leading to liver necrosis and the establishment of anaerobic conditions in the liver that will lead to the multiplication of the causative organism. Invasion of the liver by *Cysticercus tenuicollis* and other causes of liver damage can also lead to the disease.[5] As in black disease of sheep, the bacteria are carried to the liver and lodge there until damage to the parenchyma of the liver and the resulting hypoxia create conditions suitable for their proliferation. The development of an organized thrombus in a subterminal branch of the portal vein produces the large anemic infarct that is characteristic of the disease. Most of the bacteria are to be found in this infarct and, under the anaerobic conditions, the necrotoxic and hemolytic beta toxin is released systemically to result in toxemia, generalized vascular damage and intravascular hemolysis.

CLINICAL FINDINGS

Animals brought into contact with the infection in endemic areas seldom develop disease until 7–10 days later. The illness is of short duration and cattle at pasture may be **found dead** without signs having been observed. More often there is a **sudden onset**, with complete cessation of rumination, feeding, lactation, and defecation. Abdominal pain is evidenced by disinclination to move and an arched-back posture. Grunting may be evident on walking. Respiration is shallow and labored and the pulse is weak and rapid. Fever (39.5–41°C, 103–106°F) is evident in the early stages but the temperature subsides to subnormal before death. **Edema** of the brisket is a common finding. The feces are dark brown; there may be diarrhea with much mucus and some blood. The **urine** is dark red. Jaundice is present but is never very obvious. The duration of the illness varies from 12 hours in dairy cows in advanced pregnancy to 4 days in dry stock. Pregnant cows often abort. Severe dyspnea is evident just before death. The disease in sheep presents with similar signs.[6]

CLINICAL PATHOLOGY

The red color of the urine is due to the presence of hemoglobin: there are no free red cells. In the later stages there is **anemia**, the erythrocyte count being depressed to between 1 and 4 × 10^{12}/L and the hemoglobin to 3–8 g/L. Leukocyte counts vary considerably from 6700–34 800 × 10^{9}/L. Differential counts vary similarly, with a tendency to neutrophilia in severe cases. Serum calcium and phosphorus levels are normal but blood glucose levels may be elevated (100–120 mg/dL) in some cases.

Blood cultures during the acute stages of the disease may be positive. Serum **agglutinins** against *C. haemolyticum* may be detectable at low levels (1:25 or 1:50) during the clinical illness and, if the animal recovers, rise to appreciable levels (1:50 to 1:800) a week later. Titers greater than 1:400 are usual at this time. A positive agglutination test is not conclusive evidence of the presence of the disease.

NECROPSY FINDINGS

Rigor mortis develops quickly. The perineum is soiled with bloodstained urine and feces. Subcutaneous, gelatinous edema, which tends to become crepitant in a few hours, and extensive petechial or diffuse hemorrhages in subcutaneous tissue are characteristic. There is a variable degree of jaundice. Excessive amounts of fluid, varying from clear to bloodstained and turbid, are present in the pleural, pericardial, and peritoneal cavities. Generalized subserous hemorrhages are also present. Similar hemorrhages appear under the endocardium. Hemorrhagic abomasitis and enteritis are accompanied by the presence of bloodstained ingesta or free blood. The characteristic lesion of bacillary hemoglobinuria is an ischemic infarct in the liver. One or more may be present in any part of the organ and vary from 5–20 cm in diameter. The infarct is pale, surrounded by a zone of hyperemia, and has the general appearance of local necrosis. Red urine is present in the kidneys and bladder and petechiation is evident throughout the kidney.

C. haemolyticum can be isolated from the liver infarct and many other organs from a fresh carcass, but postmortem invaders quickly obscure its presence. A positive fluorescent antibody test on impression smears taken from the hyperemic zone around the liver infarct and stained with FITC-labeled rabbit anti-sheep *C. novyi* antiserum will confirm the presence of *C. novyi*-type organisms but cannot differentiate type B from type D. A PCR test to identify toxin-producing genotypes of *Clostridium* spp. may assist in the identification of isolates.

Samples for confirmation of diagnosis

- Bacteriology – tissue from edge of liver infarct, placed in an airtight container; four air-dried impression smears from lesion border (anaerobic CULT, FAT)
- Histology – fixed liver lesion, kidney.

DIFFERENTIAL DIAGNOSIS

The diagnosis of bacillary hemoglobinuria is largely a question of differentiation from other diseases in which hemoglobinuria, myoglobinuria, and hematuria are cardial signs. In an animal found dead differentiation from other clostridial diseases and anthrax may be required.

- Acute leptospirosis
- Postparturient hemoglobinuria
- Hemolytic anemia caused by cruciferous plants
- Babesiosis and anaplasmosis
- Enzootic hematuria
- Chronic copper poisoning (sheep)

TREATMENT

Specific treatment includes the immediate use of penicillin or tetracyclines at high doses and antitoxic serum if available. Prompt treatment is essential: provided that the serum is administered in the early stages of the disease, hemoglobinuria may disappear within 12 hours.

Supportive treatment – including blood transfusion, parenteral fluid, and electrolyte solutions – is of considerable importance. Care is required during treatment and examination, as undue excitement or exercise may cause sudden death. Bulls should not be used for service until at least 3 weeks after recovery because of the danger of liver rupture. Convalescence is often prolonged and animals should be protected from nutritional and climatic stress until they are fully recovered. Hemopoiesis should be facilitated by the provision of mineral supplements containing iron, copper, and cobalt.

CONTROL

A formalin-killed whole culture adsorbed on aluminum hydroxide gives good

protection for a year in cattle. Vaccination is carried out 4–6 weeks before the expected occurrence of the disease. Annual revaccination of all animals over 6 months of age is necessary in enzootic areas. In some **locations of extreme risk** a second vaccination during the grazing season is recommended. To obviate the local reaction that occurs at the site of injection the inoculum may be administered at several sites and distributed under the skin by massage. The injection must be subcutaneous, as intradermal and intramuscular injections are likely to produce severe reactions. Modern vaccines prepared so as to avoid these local reactions lack immunogenicity and require to be administered twice a year.[7] The carcasses of animals dying of the disease should be disposed of by burning or deep burial.

TYZZER'S DISEASE

This is a fatal necrotizing hepatitis associated with *Clostridium piliformis* (previously *Bacillus piliformis*).

Monoclonal antibodies for different flagellar antigens of isolates from different animals show that there are distinct antigenic types and that these may have some species specificity. At least two antigenic types infect the horse, one with a rat epitope and one with a horse epitope.[1,2]

Infection is recorded in rodents, lagomorphs, foxes, coyotes, several other wildlife species, cats, foals,[3,4] and calves.[5] In farm animals it is principally a disease of foals 1–5 weeks of age, and in them and in calves it is marked by a sudden onset, high fever (to 40.5°C (113°F)), shock, terminal coma, and a short course of a few hours to 2 days. Foals running with mares are difficult to assess in terms of preclinical disease but it is probable that foals with Tyzzer's disease have clinical signs of fever, tachycardia, and tachypnea for up to 48 hours before the observable depression appears.[6] Jaundice and severe diarrhea occur in some. Clinicopathological examination shows severe leukopenia with leukocyte counts in the range of 2000–4000/μL, hypoglycemia and severe metabolic acidosis. Serum concentrations of liver-specific enzymes are highly elevated.

At necropsy examination the liver is grossly enlarged and has miliary necrotic foci; there is also jaundice, a necrotizing colitis[7] and in some cases myocarditis. Culture of the causative organism is sufficiently difficult to encourage diagnosis by staining a smear to demonstrate the characteristic bacteria. An ELISA test using a trivalent flagellar antigen is available.[8]

Although clinical disease is rare, the prevalence of antibody in horses suggests that infection is common and the reason for the susceptibility of particular foals remains to be determined.[1] The disease appears to be increasing in prevalence in the USA, although the prevalence is still very low and the occurrence is sporadic, but certain horse farms may have multiple cases. A study in California on a horse farm with a history of Tyzzer's disease found that foals born between March 13 and April 13 were at seven times greater risk of disease than those born at other times in the foaling season and that foals of visiting mares and those of young mares were at greater risk. In examining the management factors that might influence these differences it was thought that they could reflect a difference in exposure to infection coupled with differences in the quality of transferred maternal immunity.[9]

Originally the disease probably came from wildlife, but adult horses become inapparent carriers, excreting the organism in feces, and infect newborn foals, which are normally coprophagous.[10] The disease is likely to be confused with shigellosis, septicemia associated with *Rhodococcus equi*, adenovirus pneumonia of immunodeficient Arabian foals, chronic abscess in the urachus, and idiopathic myopathy. It has been recorded concurrently with combined immune deficiency in Arabian foals.[10] The recovery of a presumptive case of Tyzzer's disease in a foal following penicillin, sulfamethiazole–trimethoprim and intensive supportive therapy is reported.[11]

ENTERIC DISEASE ASSOCIATED WITH *CLOSTRIDIUM PERFRINGENS*

Clostridium perfringens resides in the intestinal tract of domestic animals and can produce a number of toxins that result in enteric and histotoxic disease. *C. perfringens* isolates are classified into one of five types, types A–E, depending on their ability to produce the four major lethal toxins: the alpha, beta, epsilon, and iota toxins. The activities of these major lethal toxins are the basis of the pathogenesis of the classical enterotoxemias attributed to this organism and described below. More recently, it has been recognized that *C. perfringens* produces other toxins of probable importance in animal disease. These include an enterotoxin and a cytotoxic beta-2 toxin, the latter encoded by the *cbp2* gene.[1,2]

The amino acid sequence of the beta-2 toxin has little homology with that of the major beta toxin and they are only weakly related immunologically, but the biological activity of the two toxins is similar and both are cytotoxic and cause hemorrhagic necrosis of the intestinal wall.[3] The importance of enterotoxin and the beta-2 toxin to animal disease is still uncertain. Both appear important in the cause and pathogenesis of enteric disease in pigs.[1,2,4,5] The beta-2 toxin may have importance in enterocolitis in foals and adult horses as Cbp2-positive *C. perfringens* type A has been isolated from diarrheic foals and adult horses; however, the significance of these isolations to the disease is still not fully determined.[2,3,6]

ENTEROTOXEMIA ASSOCIATED WITH *CLOSTRIDIUM PERFRINGENS* TYPE A

The role of *C. perfringens* type A in the pathogenesis of diseases of animals is uncertain because the organism forms part of the bacterial flora of the alimentary tract in many normal animals. However, there are an increasing number of reports that attribute disease and mortality to this organism. The validity of these attributions remains to be fully determined but they are listed below.

Enterocolitis in horses

Enterocolitis in foals and adult horses is an etiologically poorly defined syndrome. Enterocolitis associated with *C. difficile* is one cause and is covered under that heading elsewhere in this text. In addition, enterocolitis associated with *C. perfringens* type C is covered under that heading. There remains a syndrome of enterocolitis that is manifest with enteritis, diarrhea and colic, and a high case fatality, and one that is diagnosed most often at postmortem. It appears to occur worldwide and although occurrence is sporadic, there is the perception that there is an increasing prevalence of this disease.[1] A study of risk factors in the western USA found that stock horse breeds were more at risk and that the presence of other livestock on the farm, and housing in a stall or dry lot for the first 3 days of life, was associated with increased risk.[2] Other studies have implicated barn hygiene as a factor that should be considered in preventive procedures.[1]

There have been a number of clostridial species that have historically been associated with the syndrome besides *C. perfringens* type A. In some cases this association has been by identification of type-specific toxin in the intestine of the affected horse but in others it has been made by the presence of large numbers of the incriminated organism in affected animals in comparison to occurrence and numbers in normal horses. This association has risk as the number of clostridia in the intestine can be influenced by diet, clostridia can multiply in the intestine following death, and they can exist in different forms that may be variably isolated with different cultural techniques.

Equine intestinal clostridiosis

A syndrome historically named equine intestinal clostridiosis has been attributed to intestinal infection with *C. perfringens* type A in adult horses.[3,4] The syndrome was characterized by an acute profuse watery diarrhea with high mortality in adult horses and the demonstration of large numbers of *C. perfringens* type A in the intestine at postmortem. It was described as occurring in horses with hemorrhagic cecitis and colitis similar to colitis X, in horses collapsing and dying following exercise, and in other circumstances. Diarrhea and death were reproduced with massive (biologically implausible) oral challenge with broth cultures of these organisms[4] and colic and hemorrhagic gastroenteritis were produced by intravenous injection of ponies with *C. perfringens* type A enterotoxin.[5] The evidence of an association of *C. perfringens* type A with disease in these early studies was equivocal but *C. perfringens* type A can be isolated from both foals and adults with enterocolitis.[6–9] However, isolation from this disease and causal association remain to be determined. *C. perfringens* is common in the environment of foals and one study in over 128 healthy foals found that *C. perfringens* type A could be isolated from the feces of the majority of foals at 3 days of age. *C. perfringens* with the gene for beta-2 toxin expression were found in the feces of 28 foals and with the enterotoxin gene in five foals.[1] Consequently the isolation of *C. perfringens* type A expressing the gene for beta-2 toxin does not constitute a causal diagnosis. There is, however, a suggestion that *C. perfringens* type A that expresses the gene for beta-2 toxin may be the particular subset of this isolate that is responsible for this disease.

Enteritis in piglets

C. perfringens type A is associated with diarrheic food poisoning in humans and a similar **diarrhea in pigs** may be produced by infection with this organism.[10,11] The disease is manifest with a watery yellow diarrhea occurring in piglets under 5 days of age, usually in the first 3 days of age, and a high morbidity but low case fatality.[12] At postmortem there is a mild enterocolitis and villous atrophy. It is controlled with sanitation procedures or with the type of prophylactic procedures used with enterotoxemia associated with *C. perfringens* type C.

Hemorrhagic enterotoxemia and hemolytic disease in cattle, sheep, and goats

There are reports of a highly fatal **hemolytic disease** in cattle, sheep, and lambs[13,14] (**yellow lamb disease**), of an acute **hemorrhagic enteritis** in calves and adult cattle,[11,15] and of an acute **hemolytic enterotoxemia** in foals[5,16] and goats,[11,17] associated with the presence of large numbers of *C. perfringens* type A in the intestine. These reports have some credibility because of the activity of the primary toxin of *C. perfringens* type A, alpha toxin, which possesses phospholipase C and sphingomyelinase activity and consequently hemolytic action.[11,18] Also the presence of beta-2 toxin in these strains may contribute to the pathogenicity.[19,20]

Some credibility is also engendered by reports, albeit occasional, of similar syndromes in different geographical areas and by different institutes.

In the **hemolytic disease** there is an acute onset of severe depression, collapse, mucosal pallor, jaundice, hemoglobinuria, dyspnea, and the presence of severe abdominal pain. Temperatures range from normal to 41°C (106°F). The disease is highly fatal, most affected animals dying within 12 hours of the onset of illness, although occasional animals survive for several days. Large numbers of *C. perfringens* and the presence of the specific toxin in feces is used to make a presumptive diagnosis. At **necropsy** the cardinal features are pallor, jaundice, and hemoglobinuria. The kidneys are swollen, dark brown in color, and may contain infarcts; the liver is pale and swollen and there may be hydropericardium and pulmonary edema. There is extensive necrosis of the small intestine. Clostridia dominate the bacterial population of the small intestine, as indicated by smears made from the contents, and alpha toxin is present in large quantities. The toxin is present in large quantities in the intestine, which is indicative of the existence of the disease.

The syndrome is very similar to that associated with chronic copper poisoning and leptospirosis in calves.

In the **hemorrhagic enteritis** of calves, foals, and adult cattle the syndrome observed is indistinguishable from that associated with *C. perfringens* types B and C. The disease in adult cattle occurs most commonly in the period shortly after calving. The experimental disease in lambs[21] and calves[22] produced by the intravenous injection of toxin is characterized by transitory diarrhea and hyperemia of the intestinal mucosa. Type A antiserum has been effective in prevention of the disease in calves and a formalinized vaccine has shown some immunizing capacity in sheep.[23]

Abomasal ulcer

C. perfringens type A has been suspected in the etiology of **abomasal ulcers** in suckling beef calves in western North America and less commonly elsewhere, but there is no compelling evidence for this.[24,25]

Jejunal hemorrhage syndrome in cattle

C. perfringens type A has been proposed as a cause of this disease, largely based on the isolation of this organism from the intestine of affected animals.[26,27]

This organism is present in the intestinal tract of normal animals and, while it is possible that a subset of Cbp2-positive, beta-2 toxin-producing *C. perfringens* type A organisms are responsible for this disease, there is little convincing evidence for an association with current information.

ENTEROTOXEMIA ASSOCIATED WITH *CLOSTRIDIUM PERFRINGENS* TYPES B, C, AND E

Etiology Beta toxin, a trypsin-sensitive toxin produced by *C. perfringens* types B and C, produces hemorrhagic enteritis and ulceration of the intestinal mucosa resulting in diarrhea and dysentery in young lambs, goats, calves, pigs, and foals. Beta-2 toxin also contributes to these diseases. A number of diseases associated with these clostridia occur in different parts of the world and are given specific names
Epidemiology Young animals, with the exception of struck in sheep, often occurring as outbreaks with a high case fatality rate where there is buildup of infection
Clinical findings Rapid course with hemorrhagic diarrhea, abdominal pain and toxemia
Necropsy findings Focal (type B) or extensive (type C) areas of necrosis in the small intestine
Diagnostic confirmation Clinical signs, gross and microscopic pathology from sacrificed or freshly dead animals, and direct or cultural examination for clostridia
Treatment Antibiotics, specific antitoxin, supportive therapy
Control Vaccination

ETIOLOGY

The general etiology of these diseases is given below but, because of differing circumstances of occurrence, the description of the epidemiology of these diseases is given separately according to animal species.

The causative clostridia occur commonly in soil, the animals' housing environment and the alimentary tract of healthy animals, and management factors precipitate disease. The diseases produced by these organisms occur in animals in the first few days of life, with the exception of the disease struck in sheep. Their predominance in very **young animals** may be due to the immaturity of their alimentary tracts, the beta toxin being readily inactivated by **trypsin**, and because of the ready colonization of the gut by *C. perfringens* in the absence of a mature intestinal flora.[1] It is probable that many animals become subclinically challenged but do not show clinical illness, as antitoxin has been detected in clinically normal animals.[2]

The bacteria are capable of forming **spores** that survive for long periods. In general, rapidly growing, well-nourished animals are most susceptible. The **toxins** produced are alpha, beta, and epsilon in type B, and alpha and beta in type C.

Beta-2 toxin is also produced by some of these organisms and appears important to their pathogenicity in pigs and horses. There are subtypes of these organisms with differing toxin production abilities. Alpha and iota toxin are produced by type E, which is a rare cause of enterotoxemia in calves and lambs.

The diseases that are produced by these organisms in the different animal species, and the organisms' names, are as follows:

- **Lamb dysentery** associated with *C. perfringens* type B. An enterotoxemia of young lambs is also associated with *C. perfringens* type C
- **Goat enterotoxemia** associated with *C. perfringens* type C and rarely by type B
- **Necrotic enteritis of pigs, pig enterotoxemia** associated with *C. perfringens* types C and less commonly by type B[3]
- **Foal enterotoxemia** associated with *C. perfringens* types C and B
- **Calf enterotoxemia** associated with *C. perfringens* types B and C
- **Struck**, associated with *C. perfringens* type C, affects adult sheep, particularly when feed is abundant.

EPIDEMIOLOGY

Lamb dysentery and type C enterotoxemia

Occurrence

Lamb dysentery associated with **type B** occurs in Great Britain, Europe, and South Africa and is an important disease in these countries. In contrast, this disease is rare or absent in Australia, New Zealand, North America, and Japan, where type C infections are more important. The geographical variation may be due to variation in the occurrence of the types of *C. perfringens*. Lamb dysentery does not occur in New Zealand and *C. perfringens* type B has not been found in sheep or soil samples in that country.[4]

Type C enterotoxemia in lambs and goats occurs particularly with shed lambing in North America and where there is close stocking of ewes and lambs at lambing. It is also recorded in Australasia.

Animal and environmental risk factors

In **lamb dysentery**, the incidence of clinical disease in groups of lambs may reach as high as 20–30%. In an outbreak, the disease initially affects 1–4-day-old lambs and the clinical course is very short. A characteristic of the disease is the tendency for an increase in incidence rate as lambing progresses and for the involvement of older lambs, up to 2–3 weeks of age, which survive for longer periods. The case fatality rate approaches 100%.

In Great Britain **lamb dysentery** occurs primarily in the **hill breeds** of sheep, breeds that have a small litter size but good milk production, and the appearance of the disease in a particular year appears to be related to weather conditions that allow sufficient pasture growth to produce profuse lactation in the ewes. The time of onset of the disease in a lambing season is related to the weather conditions that predispose to its occurrence.

Type C enterotoxemia in lambs and goats is prevalent in cold weather and on farms where ewes are kept closely confined in small yards or fields for lambing and kidding. Gross contamination of the surroundings with the causative bacteria is likely to occur in these circumstances. The disease can occur as an outbreak with an attack rate of 15–20% and a case fatality that approaches 100%. Type C enterotoxemia is more common in single-born lambs and is largely restricted to lambs 12 hours to 4 days of age. Sporadic disease occurs in orphan or 'bummer' lambs reared on milk replacer, which appear particularly at risk and may develop the disease at up to 2 weeks of age.

Necrotic enteritis of pigs

Occurrence

Necrotic enteritis is an important disease of piglets, particularly in intensive pig units. It occurs in most countries but has been reported most commonly from certain areas in the USA, Europe, and the UK.

Animal and environmental risk factors

The **organisms** are recoverable from the skin of sows and the feces of affected piglets, and infection probably occurs during suckling. The number of piglets affected varies between herds and between litters. The **disease** may occur sporadically in a piggery but commonly occurs as an outbreak affecting several litters within a given time period. Pigs up to 7 days of age are most commonly affected and susceptibility to disease and

its severity decreases with age. **Peracute disease** with rapid death occurs in piglets affected at 1–2 days of age, whereas piglets affected at 1–2 weeks show a more protracted clinical course. The case fatality is high and in severe outbreaks 80% of piglets at risk may die.[5] The disease tends to become **endemic** in pig units and to recur on the same premises in succeeding years.[6,7]

Insufficient cleaning and disinfection of farrowing pens, the housing of pigs on concrete, and the routine use of antibiotics to which *C. perfringens* is resistant, such as the aminoglycosides, have been proposed as **risk factors** for buildup of infection in swine units.[8]

Enterotoxemia in foals

Enterotoxemia in foals has been associated with both *C. perfringens* type B and type C. Type C predominates in reports from North America.[9–13] Reports are of a single foal on a farm being affected and the disease generally occurs in foals under 7 days of age, although enterotoxemia associated with type B has been recorded in a 4-week-old foal.[14] The factors that predispose to disease in foals are poorly defined.

Enterotoxemia in calves

Enterotoxemia due to *C. perfringens* type B or C is uncommon in calves. The disease usually occurs as outbreaks of severe dysentery with some deaths in calves 7–10 days old, although calves up to 10 weeks of age may be affected.

Struck in sheep

Struck in adult sheep on good pasture in spring is limited in its occurrence to certain localities in Britain and is rarely reported.

PATHOGENESIS

The organism is **ingested** from soil and fecal contamination on the surface of the dam's udder. It proliferates and attaches to the surface of the epithelial cells of the intestinal villus but toxin production and mucosal damage may precede attachment. The factors that allow proliferation and attachment are poorly understood. Toxigenic strains of *C. perfringens* types B and C both produce both alpha and beta toxin.

The **alpha toxin** is a lethal toxin and is produced in varying amounts by isolates of both types. It is a phospholipase, and hydrolysis of membrane phospholipids in erythrocytes, platelets, leukocytes, and endothelial cells results in cell lysis or other forms of cytotoxicity. The **beta toxin** causes increased capillary permeability and may facilitate its uptake from the intestine. Beta toxin is a necrotizing toxin and initially produces damage to the microvilli with degeneration of mitochondria, with eventual destruction and desquamation of the intestinal epithelial cells and the production of a hemorrhagic enteritis and ulceration of the intestinal mucosa.[15–17]

The **age incidence** of these diseases may be partially explained by the observation that beta toxin is highly sensitive to inactivation by trypsin, which is a component of normal pancreatic proteases. Colostrum contains a trypsin inhibitor and trypsin is decreased or absent in affected pigs. Experimentally administered soybean flour used as a protease inhibitor converts experimentally induced clostridial enteritis from a nonfatal to a fatal disease.

CLINICAL FINDINGS

Lamb dysentery can be manifest by sudden death without premonitory signs in peracute cases. In the more common **acute form**, there is loss of sucking drive and severe **abdominal pain** manifest by bleating, stretching, and looking at the abdomen. Lambs pass brown, fluid feces sometimes containing blood, and defecation is often accompanied by painful straining. Death usually occurs after a period of recumbency and coma and within 24 hours of the onset of illness. On farms where the disease has become established, cases may occur in older lambs up to 3 weeks of age and occasional cases may survive for several days. A chronic form of the disease in older lambs called '**pine**', and manifest with chronic abdominal pain and reluctance to suck but no diarrhea, is recognized and responds to treatment with specific antiserum.

Necrotic enteritis in piglets is also manifest with rapid death in young animals and more prolonged disease in slightly older piglets. Affected pigs become dull and depressed and exhibit diarrhea, dysentery, and gross reddening of the anus. The feces of piglets affected within 2–3 days of life is watery and initially yellow but in a proportion of pigs will become hemorrhagic and red-brown in color, and contain necrotic debris. The clinical course in piglets affected at this age is usually less than 24 hours; they rapidly become dehydrated, hypoglycemic, hypothermic, and comatose. Piglets affected at an older age have a fluid, yellow-colored diarrhea and blood may not be evident. Frequently the majority of litters born during an outbreak will be affected, although affected litters may include some normal pigs. Occasionally weaned pigs are affected. Acute outbreaks in herds may be followed by the occurrence of chronic necrotizing enteritis.[18]

Foals with enterotoxemia associated with *C. perfringens* type B or C show evidence of severe depression, pronounced toxemia, and marked abdominal pain. Affected foals are a few days old and have an acute attack of collapse with bloody feces, subnormal temperature, fast pulse and respiratory rate, and death within a few hours.[10] Colic may be evident and a major differential diagnosis is an acute intestinal accident. The clinical course is very short and diarrhea does not occur in many cases. There are limited descriptions of the clinical disease in foals because of its sporadic occurrence and rapid course.

In **calves** signs include diarrhea, dysentery, and acute abdominal pain accompanied by violent bellowing and aimless running. There may be additional nervous signs, including tetany and opisthotonos. In very acute cases, death occurs in a few hours, sometimes without diarrhea being evident. In less severe cases, the illness lasts for about 4 days and recovery is slow, usually requiring 10–14 days.

Struck in adult sheep is manifested only by sudden death, clinical signs not being observed beforehand. Occasionally death is preceded by abdominal pain and convulsions.

CLINICAL PATHOLOGY

The disease in all species is so acute and so highly fatal that the diagnosis is usually made on necropsy material. Antemortem laboratory examinations are not widely used in diagnosis and there is no database but the predominance of clostridia in a fecal smear may suggest a diagnosis of hemorrhagic enterotoxemia. Specific antitoxins are detectable in the sera of recovered animals. A severe hypoglycemia has been observed in baby pigs dying of the disease but this is not specific in this infection.

NECROPSY FINDINGS

The major lesion in all species is a hemorrhagic enteritis, with ulceration of the mucosa in some cases. With **type B infections** the lesions occur as localized areas of necrosis, usually most evident in the ileum. The intestinal mucosa is dark red and the ulcers are large (up to 2.5 cm in diameter) and almost transmural. Intestinal contents are bloodstained and may contain fibrin clots.

With **type C infection** the areas of necrosis are more extensive, involving entire segments of small intestine and often inducing a peritonitis. Subendocardial and subepicardial hemorrhages are common in ruminants dying of enterotoxemia. If the necropsy of adult sheep is delayed for several hours, the fascial tissues may develop the appearance of malignant edema. Carcasses of 7–10-day-old pigs may lack the severe hemorrhagic enteritis typical of the disease in newborn pigs. The less acute disease course in this older age group often results in a yellow,

fibrinous deposit on the intestinal mucosa, accompanied by large quantities of watery, lightly bloodstained ingesta in the lumen.

In general, the **histological features** of gut segments affected by these types of enterotoxemia include mucosal hemorrhage, necrosis, fibrin exudation, and a neutrophilic infiltrate. Large numbers of bacterial rods line the luminal surface of these lesions. Unfortunately, postmortem autolysis frequently eliminates the possibility of identifying some of the features.

Smears of intestinal contents can be stained and examined for large numbers of clostridium-like organisms, and filtrates of the contents may be tested for toxin content. Definitive typing of the clostridia has traditionally been via in vivo assays but these are undesirable on humanitarian grounds and are being replaced by immunoassays such as ELISA and passive latex agglutination.[15,19] A rapid passive latex agglutination test (RPLA) permits confirmation of the presence of alpha toxin but does not permit distinction between the various types of *C. perfringens* capable of producing the toxin. A multiplex PCR test enables characterization of *C. perfringens* isolates based on their genotypic potential for toxin production. PCR techniques detect the genes encoding the major toxins and are promoted for replacing in vivo tests for toxin.[20–24] The PCR test can differentiate toxigenic clostridial isolates recovered from diseased animals and nontoxigenic isolates recovered from normal animals.[20]

Samples for confirmation of diagnosis

- Bacteriology – 20–30 mL of intestinal content, **frozen** in a glass or plastic leakproof container (latex agglutination, anaerobic CULT, bioassay, PCR); air-dried smears of mucosal surface from several levels of small intestine (cyto – Gram stain)
- Histology – fixed ileum, jejunum (several segments of each).

TREATMENT

In individual cases the disease is often too acute for effective therapy but fluid and supportive therapy are indicated. Hyperimmune serum is the specific therapy and the major therapy of value. Oral and parenteral administration of penicillin may prevent further proliferation of organisms and production of toxins.

CONTROL

Vaccination, preferably with type-specific toxoid or bacterin, is the specific preventive measure.

Outbreaks

In outbreaks, because of the need for rapid action, it is usually necessary to proceed with vaccination before typing of the organism can be carried out. **Cross-protection** occurs between *C. perfringens* types B and C because the beta toxin is produced by both strains and is central to the disease produced by both strains. Lamb dysentery antiserum will protect against type C infections. Type C toxoid and antiserum are also available.

When an outbreak occurs all pregnant animals should be vaccinated to provide **colostral immunity** to their progeny. However, vaccination of the dam requires a period of at least 2 weeks before there is sufficient protective antibody in colostrum. As a result there will be a period of time between vaccination and protection of the newborn, and animals born during this period need to be provided with protection by the administration of specific antiserum. **Antiserum** will protect susceptible animals and should be administered immediately after birth. An alternate, and sometimes more cost-effective procedure, is to administer benzathine or benethamine penicillin G or depot **amoxicillin** at birth and to repeat as required during the period of susceptibility.

Long-term control

Long-term control rests with vaccination of the dams. To initiate the program two injections of vaccine are necessary 1 month apart, the second injection being given 2–3 weeks before parturition. For the prevention of **lamb dysentery** the two vaccinations of ewes may be spaced 2–5 weeks apart and the second injection can be given as early as 2 months before lambing, thus avoiding handling of heavily pregnant ewes. In subsequent years, ewes require only one booster injection immediately prior to parturition.

For the protection of **piglets** the sow is vaccinated 5 and 3 weeks before farrowing, but vaccination at mating, repeated 2–3 weeks before farrowing, is adequate.

Attention should be given to the unitage of the antigen or antitoxin present in clostridial toxoids and antisera. These vary widely and the manufacturer's instructions should be followed closely. Anaphylaxis may occur with some antisera of equine origin and treated animals should be kept under close observation for 24 hours and treated quickly if signs of dyspnea and muscle shivering occur.

In the face of an outbreak the lambing area should be moved, or with piglets the farrowing rooms vigorously cleaned and disinfected. The feeding of bacitracin (300 mg/kg of feed) or salinomycin (60 mg/kg feed) to the sow for 1–2 weeks before farrowing has been shown to reduce disease incidence, possibly by decreasing the level of excretion of *C. perfringens* by the sow.[24]

DIFFERENTIAL DIAGNOSIS

The rapid course and typical necropsy findings suggest the diagnosis but the major differential is with other causes of diarrhea in young animals.

All species

- Enteritis associated with *C. perfringens* type A
- Salmonellosis
- Enteric colibacillosis
- Cryptosporidiosis

Piglets

- *Isospora suis*
- Transmissible gastroenteritis

Foals

Enteritis associated with:

- *Strongyloides westeri*
- *Clostridium difficile*
- *Actinobacillus equuli*.

Struck is strictly regional in distribution and in affected areas can usually be diagnosed on the basis of necropsy lesions.

ENTEROTOXEMIA ASSOCIATED WITH *CLOSTRIDIUM PERFRINGENS* TYPE D (PULPY KIDNEY, OVEREATING DISEASE)

Synopsis

Etiology An acute toxemia of ruminants associated with the proliferation of *Clostridium perfringens* type D in the intestines and the liberation of epsilon toxin that produces vascular damage and the damage to the nervous system typical of this disease
Epidemiology Lambs 3–10 weeks of age and lambs and calves after weaning. Goats of all ages. Affected animals in good condition and on a rising plane of nutrition
Clinical findings The disease in lambs and calves and young goats has a rapid course with diarrhea, depression, and convulsions. At this age animals are often found dead. Adult goats show more chronic disease with abdominal pain and bloody diarrhea
Clinical pathology Hyperglycemia and glycosuria in sheep
Necropsy findings None specific to all cases. Sheep and some goats may have gross or histological areas of malacia in internal capsule, lateral thalamus and cerebellar peduncles
Diagnostic confirmation Epidemiology, clinical and necropsy findings, demonstration of epsilon toxin
Treatment Anti-epsilon antitoxin
Control Feed restriction, antitoxin, vaccination

ETIOLOGY

Enterotoxemia results from the proliferation of *C. perfringens* type D in the small intestine. This organism produces a number of toxins, of which the **epsilon toxin** is the most important and results in vascular damage and the damage to the nervous system typical of this disease. The presence of *C. perfringens* type D in the intestine does not in itself result in disease unless other factors intercede that promote proliferation and the production of toxin. The natural habitat of the organism is in the intestine and in soil contaminated by feces, although it does not persist in soil for long periods of time.

EPIDEMIOLOGY

Occurrence

Enterotoxemia associated with *C. perfringens* type D is a disease of ruminant animals, primarily of lambs, and is worldwide in its distribution. The common practice of vaccination against this disease has reduced its prevalence but it is still a common disease.

While most common in lambs, it is also an important disease of calves and goats. It occurs rarely in adult cattle, deer, domesticated camels, and possibly horses. In **pastured sheep**, it causes heavy losses, particularly in flocks managed for the production of lamb and mutton. The prevalence in flocks varies a great deal but seldom exceeds 10%. The case fatality rate approximates 100%. In North America enterotoxemia ranks as one of the main causes of loss among **feedlot lambs**. In a survey in two feedlots the disease had an annual prevalence of 3.14% and 1.49%; it ranked third in importance as a cause of death despite a policy of vaccination, and the costs of prevention programs were the largest expenditure of all disease prevention programs in the feedlots.[1]

Experimental reproduction

The disease can be produced experimentally in susceptible sheep, goats, and cattle by the injection into the duodenum of whole culture of *C. perfringens* type D and dextrin or starch. Clinical disease occurs as early as 30 minutes and usually within 6–8 hours of the start of duodenal infusion and death 1–9 hours following the onset of clinical signs.[2–4] The disease has also been reproduced by intravenous infusion of epsilon toxin.[5]

Animal and management risk factors

C. perfringens type D normally inhabits the alimentary tract of sheep and other ruminants but only in small numbers. The extent to which it occurs in the alimentary tract varies widely between flocks, although this accounts only in part for the variable prevalence. The organism does not persist for more than 1 year in the soil.

Under certain conditions, the organisms proliferate rapidly in the intestines and produce lethal quantities of epsilon toxin. In most, if not all circumstances, the affected animals are on **highly nutritious diets** and are in very good condition. The husbandry conditions in which the disease occurs include grazing on lush, rapidly growing pasture or young cereal crops, and heavy grain feeding in feedlots. Lambs on well-fed, heavy-milking ewes are particularly susceptible. The occurrence of the disease under these conditions has given rise to the name '**overeating disease**'.

Sheep

The highest incidence of the disease is in suckling lambs between 3 and 10 weeks of age. The risk for disease in this age group is highest when ewes are grazed on lush pastures that result in profuse lactation. The disease can occur following rain in set stocked flocks, and in flocks newly introduced to lush pastures is often manifest 5–14 days after introduction. Single lambs are more susceptible than twins. Weaned lambs up to 10 months of age are the second most susceptible age group and again the occurrence of disease is associated with highly nutritious diets. Feeder lambs are most commonly affected soon after they are introduced into feedlots.

Calves

Enterotoxemia is most common between 1 and 4 months of age and the same risk factors pertain as for lambs. Veal calves are particularly at risk. Feeder cattle may develop disease shortly after introduction to the lot. It is a common belief among cattlemen and veterinarians that many unexplained sudden deaths in **feeder cattle** after the period of acclimatization are due to this type of enterotoxemia. However, there is no laboratory evidence to support such field observations and a controlled trial found no protective effect of vaccination.[6]

Goats

Enterotoxemia is a common disease in goats under intensive or extensive grazing systems, occurring in many countries,[4] and is particularly important in countries with a large goat population.[4,7,8] The peracute disease in goat kids has the same age occurrence as in lambs but less acute and chronic forms of enterotoxemia occur in adult goats. Sudden changes in diet appear to be the most common predisposing factor. Disease can occur in vaccinated goats, as vaccination is poorly protective against the enteric and chronic form of the disease in this species.[7,9]

Outbreaks in sheep and goats have followed the administration of phenothiazine and other anthelmintics,[4] and a high incidence has been observed in association with heavy tapeworm infestation.

Horses

Type D enterotoxemia is rare in horses but it has been suspect in a group of mature horses fed concentrates during a drought period.[9] *C. perfringens* type D can be isolated in high numbers from gastric reflux of horses with anterior enteritis.[10]

PATHOGENESIS

In the normal course of events, ingested *C. perfringens* type D are destroyed in large numbers in the rumen and abomasum, although some survive to reach the duodenum, where multiplication occurs and toxin is produced. Toxemia does not occur because the movement of ingesta keeps the bacterial population and toxin content down to a low level. In certain circumstances, this does not hold and multiplication of the organisms and the production of toxin proceeds to the point where toxemia occurs. One of the circumstances has been shown to be the passage of large quantities of starch granules into the duodenum when sheep overeat on grain diets or are changed suddenly from a ration consisting largely of roughage to one consisting mainly of

grain. Other factors such as heavy milk feeding may have the same effect. A slowing of alimentary tract movement has also been thought to permit excess toxin accumulation and it may be that any factor that causes **intestinal stasis** will predispose to the disease. The importance of diet in the production of ruminal stasis has been discussed in diseases of the forestomachs of ruminants.

The epsilon toxin of *C. perfringens* type D increases the permeability of the intestinal mucosa to this and other toxins, thereby facilitating its own absorption.

A **receptor for epsilon toxin** has been identified on **vascular endothelial cells**, and the clinical signs and pathological findings can be explained by the widespread vascular damage and increase in vascular permeability.[8,11–13]

Acute cases are characterized by the development in the brain of degeneration of vascular endothelium, perivascular and intercellular edema, and microscopic foci of necrosis in the basal ganglia, thalamus, internal capsule, substantia nigra, subcortical white matter, and cerebellum. The damage to the vascular endothelium leads to the accumulation of protein-rich fluid effusions observable in heart, brain, and lung. The postmortem autolysis of kidney tissue that occurs so rapidly and is the characteristic of 'pulpy kidney' has the same basis.

There is a pronounced **hyperglycemia** due to the mobilization of hepatic glycogen, severe hemoconcentration and elevation of blood concentrations of pyruvate, lactate, and alpha-ketoglutarate.

In contrast to sheep, goats with enterotoxemia produced by *C. perfringens* type D also have a **hemorrhagic enterocolitis** that is present in both the natural and the experimental disease.[4,7,14,15] The genesis of this lesion is uncertain but it is responsible for the major clinical signs that present in goats with this disease.

A degree of natural immunity may be attained by nonlethal exposure to the toxin, as a proportion of lambs and calves appear to be exposed to subclinical but antigenic levels of *C. perfringens* toxin so that they become immune without having shown signs of illness or without having been vaccinated.

CLINICAL FINDINGS

Lambs

The course of the illness is very short, often less than 2 hours and never more than 12 hours. Many lambs are found dead without previously manifesting signs. In closely observed flocks the first signs may be dullness, depression, yawning, facial movements and loss of interest in feed. **Acute cases** may show little more than severe clonic convulsions with frothing at the mouth and rapid death. Cases that survive for a few hours show a green, pasty diarrhea, staggering, recumbency, opisthotonos, and severe clonic convulsions. The temperature is usually normal but may be elevated if convulsions are severe. Death occurs during a convulsion or after a short period of coma.

Adult sheep

These usually survive for longer periods, up to 24 hours. They lag behind the flock and show staggering and knuckling, champing of the jaws, salivation, and rapid, shallow, irregular respiration. There may be bloat in the terminal stages. Irritation signs, including convulsions, muscle tremor, grinding of the teeth, and salivation, may occur but are less common than in lambs.

Calves

The syndrome is similar to that seen in adult sheep, with nervous signs predominating. Peracute cases are found dead without having shown premonitory signs of illness and with no evidence of struggling. The more common, **acute cases** show a sudden onset of bellowing, mania, and convulsions, the convulsions persisting until death occurs 1–2 hours later. Subacute cases, many of which recover, do not drink, are quiet and docile, and appear to be blind, although the eye's preservation reflex persists. They may continue in this state for 2–3 days and then recover quickly and completely. In an outbreak of the disease in calves all three forms of the disease may be seen.

Goats

Diarrhea is a prominent sign in affected goats, especially in those that survive for more than a few days.[7,15–17] In the **peracute form**, which occurs most frequently in **young kids**, there are convulsions after an initial attack of fever (40.5°C, 105°F) with severe abdominal pain and dysentery; death occurs in 4–36 hours. In the **acute form**, which is more common in **adults**, there is usually no fever, and abdominal pain and diarrhea are prominent with death or recovery within 2–4 days. In chronic cases, the goats may be ill for several weeks and show anorexia, intermittent severe diarrhea and, in some cases, dysentery and the presence of epithelial shreds in the feces. Chronic wasting, anemia, and eventual emaciation also occur with chronic disease in goats.

CLINICAL PATHOLOGY

A high blood sugar level of 150–200 mmol/L and marked glycosuria are characteristic of the terminal stages of enterotoxemia in sheep, and are supportive for a diagnosis but are not pathognomonic. Hyperglycemia and glycosuria are variably present in goats with the disease.

NECROPSY FINDINGS

The body condition of the animal is usually good but there is often fecal staining of the perineum and rapid decomposition of the carcass. In peracute cases there may be no gross lesions. More frequently, there is an excess of clear, straw-colored pericardial and thoracic fluid that clots on exposure to air. Many petechiae are present in the epicardium and endocardium and there is pulmonary edema. Patchy congestion of the abomasal and intestinal mucosae is usual and the small intestine often contains a moderate amount of thin, creamy ingesta. The content of the large intestine may be watery and dark green.

The characteristic finding of soft, **pulpy kidneys** is only useful in animals necropsied within a few hours after death, as it is nonspecific and merely correlates to a more rapid rate of autolysis. Microscopy of experimentally induced ovine type D enterotoxemia cases confirms that the renal changes represent autolysis and not a true nephrosis.[18]

The liver is dark and congested. The rumen and abomasum of feedlot lambs may be overloaded with concentrates. In goats there is acute fibrinonecrotic and hemorrhagic enterocolitis, although microscopic examination may be needed to detect this change.[14,15]

In sheep that have not died acutely there may be symmetrical areas of hemorrhage, edema, and liquefaction in the **brain**, especially in the area of the basal nuclei. Again, microscopic evaluation of the tissue is critical.

Gram-stained smears of ingesta from several levels in the small intestine should be examined. In affected animals the short, fat, Gram-positive rods dominate the slide to the almost complete exclusion of other bacteria. Bowel filtrates can be tested for toxicity by **injection into mice**. If the filtrate is toxic, the type of toxin can be determined by protection of the mice with specific antisera, but this does not determine the type of clostridia. The detection of beta toxin indicates the presence of types B or C, and epsilon toxin the presence of B or D.

The time taken for diagnosis by **mouse neutralization tests**, as well as humanitarian considerations, have promoted the development of **alternative tests**. The RPLA test has already been discussed (see *C. perfringens* types B, C, and E). An ELISA test shows good specificity and sensitivity for epsilon toxin[19] and counter-immunoelectrophoresis has an advantage of speed and requires minimal amounts of intestinal content.[20] A recent study showed that a polyclonal capture ELISA could detect lower concentrations of epsilon toxin in intestinal fluid, pericardial

fluid, and aqueous humor than monoclonal capture ELISA, mouse neutralization tests or counterimmunoelectrophoresis but counseled the need to make a diagnosis based on epidemiological, clinical, and pathological data as well as the detection of toxin at postmortem.[21]

At average temperatures one can expect to be able to identify the toxin from the intestine of a sheep dead for up to 12 hours. The addition of one drop of chloroform to each 10 mL of ingesta will **stabilize the toxin** for periods of up to a month.[22] Alternatively, intestinal contents can be absorbed on filter paper and shipped at environmental temperatures with little loss of activity for as long as 74 days as detected by immunoassay.[23] Epsilon toxin is also stable if frozen.[4] Multiplex PCR analysis of *C. perfringens* isolates can confirm the presence of toxigenic strains. Hyperglycemia and **glucosuria** may also be detected in necropsy material.

Samples for confirmation of diagnosis

- Bacteriology – 20–30 mL of intestinal content, frozen in a leakproof glass or plastic container (ELISA, latex agglutination, bioassay, anaerobic CULT, PCR); air-dried smears of ingesta from several levels of gut (cyto-Gram stain)
- Clinical pathology – urine (assay – glucose) (best performed at time of necropsy)
- Histology – fixed colon, ileum, jejunum, entire brain.

DIFFERENTIAL DIAGNOSIS

Lambs
- Acute pasteurellosis
- Septicemia associated with *Histophilus somni* (formerly *Haemophilus agni*)
- *C. sordellii*
- Polioencephalomalacia
- Rumen overload

Sheep
- Hypocalcemia
- Hypomagnesemia
- Focal symmetrical encephalomalacia (chronic enterotoxemia)
- Rabies
- Pregnancy toxemia
- Louping ill

Calves
- Lead poisoning
- Polioencephalomalacia
- Hepatoencephalopathy
- *Histophilus somni* (formerly *Haemophilus somnus*)

Goats
- Salmonellosis
- Coccidiosis

In lambs, but not in goats, a history of vaccination against the disease is a significant consideration in the ranking of a list of differential diagnoses.

TREATMENT

In general, the clinical course of the disease is too acute for effective treatment. **Hyperimmune serum**, an efficient short-term prophylactic, is unlikely to be of much value in sick animals because of the acute nature of the disease. In goats the course is longer, and antitoxin in combination with orally administered sulfadimidine may be effective in treatment.[16]

CONTROL

There are three major control measures available: reduction of the food intake, administration of antitoxin, and vaccination. These may be used individually or in combination.

Reduction in food intake

Reduction in food intake is the cheapest but least effective in control and is used as a short-term control while waiting for immunity to develop after vaccination. Reduction in food intake will cause a setback in the growth of the lambs and for this reason farmers tend to rely more on vaccination as a control measure.

Antitoxin

Antitoxin can be administered to all sheep as soon as an outbreak commences. The administration of epsilon antitoxin 200 IU/kg BW will provide for protective circulating antitoxin levels for 21–29 days.[24] Immediate losses are prevented, and in most instances the disease does not recur. Toxoid is cheaper, but to administer it alone at such times may result in further serious losses before active immunity develops.

Vaccination

Immunity in **sheep** is readily produced by suitable vaccination. A blood level of 0.15 Wellcome unit of epsilon antitoxin per milliliter of serum is sufficient to protect sheep. Vaccines available are toxoids, and adjuvants generally improve the antigenicity. Activated alum-precipitated toxoid is the common vaccine in use.

Vaccination of **maiden ewes** twice at an interval of at least 1 month and with the last vaccination approximately 4 weeks before lambing will result in good passive immunity in young lambs, with 97% of lambs having protective antibody levels at 8 weeks of age and a significant proportion at 12–16 weeks of age.[25,26] This is sufficient to protect lambs during their highest risk period. **Older ewes** that have been vaccinated the previous year receive a single booster vaccination 4 weeks before lambing. Sheep vaccinated for 3 consecutive years can be considered to be permanently immune and to require no further vaccination.

When faced with an **outbreak in lambs** the recommended procedure is to administer antiserum and toxoid immediately and repeat the toxoid in a month's time. The simultaneous administration of hyperimmune serum with this vaccine does not interfere with the stimulation of antibody production, nor does the presence of passively derived colostral immunity.[24]

Lambs can be vaccinated with toxoid when 4–10 weeks of age and again a month later.

Any vaccination of sheep is not without **risk** of precipitating blackleg or other clostridial disease, and if these are a severe problem in an area it may be wise to vaccinate a portion of the flock as a pilot test and proceed with vaccination of the remainder only when no complications arise. A **multivalent** bacterin-toxoid containing antigens to all of the clostridial diseases is commonly used in sheep in these circumstances or where all of these diseases are likely to occur. Vaccination should not be done in sheep with wet fleeces.

Vaccination with toxoid is effective in **calves** but is not highly effective in **goats**, having a limited effect in preventing the disease although reducing its incidence and severity.[7,15,16] The anti-epsilon titer in goats following vaccination is variable and has been found equivalent to that obtained by sheep or lower and of shorter duration;[7,15] however, this antibody provides minimal protection against the enterocolitis that occurs with type D infections in goats.[7,15] Vaccination with current commercial vaccines has limited protective value in goats, and owners should be advised of this. The use of serum must be carried out with caution in goats, particularly Saanens, which are very prone to anaphylactic reactions. Despite the limitations of protection against the enteric manifestations of the disease, vaccination is protective against the peracute form of the disease and kids should be vaccinated twice, a month apart, commencing at 4 weeks of age. Subsequent vaccinations are at 6-month intervals.

Local reactions to vaccination are common in both sheep and goats[27] and may be visible for at least 6 months. In sheep these are generally hidden by the wool but the vaccination site should be high on the neck and close to the base of the ear in order to minimize carcass blemish. With goats, especially show goats, the owner should be warned of this occurrence. Goats, especially show goats, should be vaccinated under the loose skin of the axilla where local reactions will be hidden by the elbow.

FOCAL SYMMETRICAL ENCEPHALOMALACIA

Synopsis

Etiology The disease is a chronic neurological manifestation of enterotoxemia associated with *Clostridium perfringens* type D epsilon toxin, with vascular damage and damage to the nervous system
Epidemiology Sporadic disease in weaners and mature sheep, usually following a change of pasture or anthelmintic treatment
Clinical findings Aimless wandering, an inability to eat and a dummy syndrome are predominant findings
Clinical pathology None reported
Necropsy findings Gross or histological areas of malacia in internal capsule, lateral thalamus, and cerebellar peduncles
Diagnostic confirmation Epidemiology, clinical and necropsy findings
Treatment Supportive
Control Complete vaccination

ETIOLOGY

Lesions of focal symmetrical encephalomalacia have been produced in experimental enterotoxemia and by infusion with epsilon toxin of *Clostridium perfringens* type D.[1,2]

EPIDEMIOLOGY

The disease occurs in lambs, weaners, and mature sheep,[3–5] and suspected cases have also been reported in calves.[1] In grazing sheep it has the same seasonal occurrence as enterotoxemia but may occur in sheep of poor body condition. In weaners and mature sheep there is often a history of a move to fresh pasture or of anthelmintic administration 5–14 days preceding the occurrence of initial cases. Several outbreaks have been associated with the grazing of young green cereal crops.[4,5] The morbidity is usually low but may approach 15%. The case fatality rate is high.

CLINICAL FINDINGS

Most commonly, due to infrequent observation of sheep of this age, the finding of dead sheep is the first indication of the disease. Clinically affected sheep are separate from the group or can be detected by slow movement of the flock. They show no fear of humans or dogs and can be examined without restraint. Blindness, aimless wandering, head-pressing, and incoordination are the predominant findings. More severely affected sheep lie quietly in lateral recumbency with moderate dorsiflexion of the head and show infrequent nystagmus with paddling convulsions. The sheep are unable to eat and most cannot drink, although some affected lambs may still retain a suck reflex. The feces of affected sheep are unformed, as are those of a significant number of other apparently normal sheep within the group. The clinical course varies from 1–14 days, with the majority of affected sheep surviving for 5–7 days.

NECROPSY FINDINGS

Lesions are confined to the brain and formalin-fixed samples of this tissue may be required for confirmation of the diagnosis. In many cases the characteristic lesions can be detected on macroscopic examination and consist of areas of hemorrhage and softening in the internal capsule, lateral thalamus, and cerebellar peduncles. Malacia, edema, and hemorrhage are visible histologically.[6] Glycosuria is not a feature and toxin cannot be demonstrated in gut contents.

TREATMENT AND CONTROL

There is no treatment. Less severely affected cases may recover if they are maintained with fluids and nutrients given by stomach tube. Outbreaks cease if the sheep are vaccinated with pulpy kidney vaccine.[4,5]

ENTEROCOLITIS ASSOCIATED WITH *CLOSTRIDIUM DIFFICILE*

Synopsis

Etiology Toxigenic strains of *Clostridium difficile*. Common bacterial etiology in antibiotic-associated diarrhea
Epidemiology Horses: most common in young foals but also occurs in adults. Commonly precipitated by therapy with antimicrobial agents. Pigs: diarrhea and mortality in piglets in first week of life
Clinical findings Profuse watery diarrhea, tachypnea, dehydration, metabolic acidosis. High case fatality – especially in very young foals
Necropsy findings Fibrinous to necrotic enterocolitis. Edema of mesocolon in pigs
Diagnostic confirmation Demonstration of organism and toxins
Treatment Fluids and electrolytes. Horses: metronidazole, if sensitive, or vancomycin
Control Isolation and barrier protection, prophylactic metronidazole

ETIOLOGY

Clostridium difficile is a recognized cause of antibiotic-associated diarrhea and pseudomembranous colitis in humans suffering perturbation of the bowel flora from antibiotic therapy or other causes. There is developing evidence that, in foals and adult horses, *C. difficile* can be associated with diarrheal disease that can vary from mild and self-limiting to an acute and fatal **enterocolitis**. Evidence for this association is the biological plausibility, some evidence that this syndrome can be reproduced experimentally, and the ability to demonstrate the organism or its toxin in the feces of horses with the enterocolitis in comparison with the low prevalence of the organism, and the absence of toxin, in the feces of nondiarrheic horses.[1–7] Commonly this syndrome occurs in horses following antimicrobial therapy and/or hospitalization. It is possible that enterotoxin from intestinal *C. perfringens* may also contribute in horses, and the syndrome has been called **equine clostridiosis**.[8,9]

C. difficile is associated with diarrhea in neonatal pigs and its occurrence, or recognition, appears to be increasing.

EPIDEMIOLOGY

Occurrence

Horses

The disease is sporadic and appears to occur worldwide. In young foals within the first 2 weeks of life it may occur without apparent predisposing causes but

in adult horses it commonly follows the use of antimicrobial agents. Case fatality rates are highest in very young foals, where the disease may also be complicated by other existing neonatal disease problems. In foals, disease may be acute, presenting with rapid recumbency and death within 24 hours of onset despite therapy, or it may present as a nonacute syndrome manifest primarily with diarrhea.

Pigs

The disease has increasing reportage, or recognition, and occurs predominantly in young piglets[10–12] but also is recorded as a major cause of disease and mortality in sows.[13] The disease in piglets occurs predominantly in the first week of life, when the majority of the litter can be affected and the case fatality can approach 50% but is usually lower. Stunting is a common sequel. Outbreaks occur with or without a history of processing with antibiotics.

Experimental reproduction

The disease has not been effectively reproduced with simple challenge of conventional animals, suggesting that *C. difficile* in itself is not a sufficient cause.

Challenge of adult horses with *C. difficile* with and without pretreatment with penicillin did not result in clinical disease in any of the horses, but *C. difficile* was subsequently isolated at greater frequency from the feces of the horses pretreated with penicillin.[14] Challenge of newborn foals with *C. difficile* has resulted in enteric disease and diarrhea, but only in foals not receiving adequate transfer of colostral antibodies.[6] The disease has been reproduced in gnotobiotic but not conventional pigs.[15]

Risk factors

Animal risk factors

C. difficile has been isolated from the feces of 29% of 56 healthy foals less than 2 weeks of age but is not normally present, and its toxins are not commonly demonstrable in the feces of healthy horses over 1 month of age.[6,16] Treatment with antimicrobials increases the likelihood of isolation from feces and occasionally the presence of toxin. In an extensive study in Sweden the feces of horses of varying age and clinical status were tested for the presence of *C. difficile* and positivity to the cytotoxin B test.[16] The feces of 273 adult horses with no signs of enteric disease were negative to both tests; 42% of 43 horses with acute colitis treated with antibiotics were positive to one or both tests; 6% of 72 horses with colitis but no antibiotic treatment were positive to one or both tests; 2% of 47 horses with no enteric disease but treated with antibiotics were positive to both tests and none of 65 horses with colic were positive.

Environmental risk factors

Treatment with antimicrobials is a risk factor for the occurrence of *C. difficile* in the feces of both normal foals and normal adult horses. Antimicrobial therapy is also a risk factor for the occurrence of *C. difficile*-associated enterocolitis.[4] Treatment with penicillin is a major risk factor but the specific incrimination of penicillin may simply reflect its common use as an antimicrobial in horses.[14] There is a risk for mares to develop acute enteritis associated with *C. difficile* when their foals are being treated for *R. equi* pneumonia with erythromycin and rifampicin.[17] It was suspected that the risk occurred as a result of the mares' exposure to these antibiotics from the foal feces or contaminated materials in the environment.

Routine prophylactic antimicrobial treatment of periparturient sows for diseases such as mastitis–metritis–agalactia have resulted in outbreaks of enterocolitis.[18,19]

Pathogen risk factors

Pathogenic strains of *C. difficile* produce an enterotoxin (toxin A) and a cytotoxin (toxin B). There are degrees of virulence between strains but nontoxigenic strains are considered nonpathogenic.[20] Other virulence factors, including an actin-specific adenosine diphosphate (ADP)-ribosylating toxin and an outer cell surface coat S-layer, have been proposed as additional virulence factors.[20]

The organism can be isolated from a number of environmental samples, including soil and the environment of veterinary hospitals. Although it appears that the organism is not commonly present in the feces of normal horses, it can be isolated from those of other animal species and has high prevalence in the feces of dogs and cats.[21] The organism can survive in feces for at least 4 years.[16] Spores are resistant to common disinfectants but a 5% bleach solution is stated to be effective for disinfection.[22]

Zoonotic implications

C. difficile is a cause of diarrhea in humans and most commonly occurs following the administration of antibiotics, although sporadic cases without these risk factors also occur. The disease in humans may be mild and self-limiting or develop to severe pseudomembranous colitis with risk of intestinal perforation. In one study using molecular typing, 25% of isolates from humans were indistinguishable from isolates from animals.[23] The risk for zoonotic infection should be considered but barrier protection and attention to personal hygiene when handling animal cases should limit the risk for infection. Veterinarians and animal handlers undergoing antimicrobial therapy are particularly at risk.[24]

PATHOGENESIS

The disease is associated with severe watery diarrhea and a hemorrhagic necrotizing enterocolitis. The enterotoxin A damages villous tip and brush border membranes and causes necrosis and increased intestinal permeability. The cytotoxin B is lethal to cells once the gut wall has been damaged. Complete erosion of the mucosa may result. Both toxins induce the production of tumor necrosis factor and proinflammatory interleukins, with a resultant inflammatory response and pseudomembrane formation.[25] Lactose intolerance may develop secondary to infection.[26]

CLINICAL FINDINGS

Horses

Disease occurring with onset in the first 2 weeks of life is initially manifest with a decreased interest in sucking, often with signs of colic with increasingly prolonged and severe episodes of rolling and kicking at the abdomen and the occurrence of profuse watery and occasionally hemorrhagic diarrhea. Rectal temperatures are within the normal range but there is severe dehydration, an elevation of heart rate and respiratory rate, acidemia attributable to metabolic acidosis, and the development of septic shock.[6,9] There is progressive enlargement of the abdomen, and transcutaneous ultrasound shows thickened, fluid-filled loops of intestine and fluid in the ventral abdomen.

In adult horses the disease is manifest with acute and often fatal colitis with profuse diarrhea, toxemia, hypovolemia, and metabolic acidosis, and is reported in individuals and as outbreaks in horses hospitalized and treated for various diseases.[3–5]

Pigs

Affected piglets are depressed and have a yellow, mucoid diarrhea with occasional piglets passing feces with specks of blood. As the condition progresses, affected pigs show abdominal distension and tachypnea, and some have scrotal edema. There is progressive dehydration and hypoglycemia.

CLINICAL PATHOLOGY

There is a leukopenia, a toxic left shift, a high hematocrit, and hyperfibrinogenemia. Plasma protein may be normal to low and there are a high bilirubin and elevated liver enzyme values. Metabolic acidosis, as evidenced by an increase in anion gap and decrease in total CO_2 concentration, hyponatremia and azotemia are present. Blood IgG concentrations are commonly within the normal range.

Classic methods of diagnosis are by examination of feces by culture of the organism and demonstration of toxins A and B by cytotoxin assays and enzyme immunoassays.[27] Cycloserine–cefoxitin–fructose agar is commonly used to isolate *C. difficile* from feces. The isolation of *C. difficile*, in itself, is generally not considered to be diagnostic and should be accompanied by demonstration of toxin A in the feces by ELISA, or by tissue culture cytotoxin assays, to allow a putative diagnosis.[28] Fecal toxin testing in live animals is an effective method of diagnostic conformation and correlates highly with toxin tests on intestinal contents at postmortem.[15]

The organism, but not the toxins, is labile when kept aerobically at 4°C, with a significant decrease in recovery after 24 hours.[29] Consequently, samples for culture should be taken in anaerobic transport media and shipped on ice.

ELISA teats may lack sensitivity and only detect toxin A whereas some pathogenic strains produce only toxin B. Consequently PCR may provide a more reliable method of detection. Feces, or isolates, can be tested for genes encoding toxins A and B by PCR[28] and PCR can also be used retrospectively following postmortem for diagnosis in formalin-fixed tissues.[11]

NECROPSY FINDINGS

Horses

Gross findings are of enterocolitis with histological findings that vary from a superficial fibrinous colitis with hemorrhage and edema to a severe hemorrhagic multifocal necrosuppurative and ulcerative enterocolitis.

Pigs

The contents of the small intestine are scant and those of the large intestine yellow to dark yellow in color. Edema of the mesocolon is a common finding, along with increased fluid in the peritoneal and pleural cavities. Histological findings vary from necrosis and exfoliation of the intestinal mucosa to segmental transmural necrosis in the large intestine.[11,15]

DIFFERENTIAL DIAGNOSIS

- Horses – See Table 5.13
- Swine – See Table 5.14

TREATMENT

Horses should be aggressively treated with fluids, plasma, and pressors, to correct the fluid and electrolyte imbalance, correct the metabolic acidosis and control pain. Antimicrobial therapy should be based on sensitivity. Isolates are usually resistant to trimethoprim–sulfamethoxazole and bacitracin, variably resistant to rifampicin and susceptible to vancomycin. Metronidazole, 10 mg/kg intravenously four times daily or 15 mg/kg orally four times daily, has been commonly used for therapy but there is geographical variation in sensitivity.[16,28] Metronidazole and vancomycin are not approved for use in food animal species in most countries.

In vitro studies have shown that di-tri-octahedral (DTO) smectite can bind *C. difficile* toxins A and B and that this can occur without inhibiting the antibacterial action of metronidazole. Clinical trials of efficacy have not been conducted but pharmacological considerations indicate that an initial dose of 1.4 kg of DTO smectite, administered by stomach tube, followed by 454 g every 6–8 hours could be of therapeutic value.[30] Experimental studies in hamsters indicate promise for the use of immune sera and vaccines,[31] but these are not currently available in agricultural animals.

CONTROL

There is no definitive control procedure. The organism is commonly present in veterinary environments and equine environments where there are foals. Foaling areas should be clean and disinfected with a sporicidal disinfectant. Metronidazole, 500 mg administered orally twice a day for 2 weeks, may be indicated for at-risk horses. Clinical cases should be isolated and, in a veterinary environment, strict barrier protection established between them and other animals under antimicrobial therapy. Orally administered probiotics and lactic-acid-producing bacteria are in use as an aid to prevention but there are no data on efficacy.

Diseases associated with bacteria – III

18

Diseases associated with *Escherichia coli*

Colibacillosis, associated with *Escherichia coli*, occurs in all species of newborn farm animals and is a major cause of economic loss in this age group. Gut edema and enteric colibacillosis of recently weaned pigsare also important diseases associated with this organism.

E. coli is a major cause of diarrhea in calves, piglets, and lambs, and the term 'colibacillosis' is commonly used; however, diarrhea in newborn calves, for example (and in other species too), can be associated with several different enteropathogens influenced by several risk factors (Table 18.1). Colibacillosis is presented in this chapter. Information on the viral diarrheas of newborn farm animals is presented in Chapter 21. Diarrhea associated with *Cryptosporidium* is presented in Chapter 26. This section first outlines the general aspects of acute undifferentiated diarrhea of newborn farm animals, with emphasis on the disease in calves. Many of the principles can be applied to the other species. This is followed by the diseases associated with *E. coli.*

Table 18.1 Risk factors and their role in acute undifferentiated diarrhea of newborn calves

Risk factor	Role of risk factor
Colostral immunity of calf	Low levels of serum immunoglobulins render calves highly susceptible to death from diarrhea
Overcrowding	Increased population density increases infection rate and high morbidity and mortality
Parity of dam	Calves born from heifers may not acquire sufficient level of colostral immunoglobulins
Meteorological	Changes in weather; wet, windy and cold weather commonly precedes outbreaks of diarrhea in beef calves. Higher mortality in dairy calves exposed to hot environmental temperatures. High environmental temperatures precipitate outbreaks
Quality of diet	Heat denatured skim-milk used in milk replacers is less digestible than whole milk and precipitates diarrhea
Calf rearer	The concern and care provided by the calf rearer will have a direct effect on morbidity and mortality associated with diarrhea

ACUTE UNDIFFERENTIATED DIARRHEA OF NEWBORN FARM ANIMALS (PARTICULARLY CALVES AND PIGLETS)

Diarrhea in newborn farm animals, particularly calves under 30 days of age and piglets in the first week of life, is one of the most common disease complexes that the large-animal clinician encounters in practice. It is a significant cause of economic loss in cattle and pig herds and continues to assume major importance as livestock production becomes more intensified. The effective treatment and control of herd epidemics of diarrhea in calves and piglets can be frustrating and unreliable. Considerable progress has been made in the treatment of the effects of diarrhea such as dehydration and acidosis but less so in the control of these disease complexes.

The causes of calf and piglet diarrhea are complex and usually involve an

interaction between enteropathogenic bacteria, viruses, and protozoa, the colostral immunity of the animal and the effects of the environment (Tables 18.1–18.3). Thus the term **acute undifferentiated diarrhea of newborn calves** is used to describe the acute diarrhea that occurs in newborn calves under 30 days of age, characterized clinically by acute profuse watery diarrhea, progressive dehydration and acidosis and death in a few days, or earlier after onset if treatment is not provided. Based on clinical findings alone, it is not usually possible to differentiate between the common known causes of diarrhea in newborn calves, which include enterotoxigenic *E. coli* (ETEC), verocytotoxic *E.coli* (VTEC), necrotoxigenic *E.coli* (NTEC), rotavirus, coronavirus, bovine torovirus (Breda virus), calicivirus, norovirus (Norwalk-like virus), *Cryptosporidium* spp., *Giardia* spp., and *Salmonella* spp. The common necropsy findings are dehydration, emaciation, and a fluid-filled intestinal tract, with no other obvious gross lesions. The exceptions are enteritis associated with *Salmonella* spp., *Clostridium perfringens* types B and C, *Eimeria* spp., and attaching and effacing *E. coli*, in which there are usually typical gross lesions at necropsy.

Thus the disease is considered to be a complex syndrome because one or any combination of more than one of the specific etiological agents may be the cause of the disease. Risk factors may also precipitate the disease in calves in which the disease might not normally occur, even though they are infected with a specific enteropathogen. The term acute undifferentiated diarrhea of newborn calves is useful to encompass cases of diarrhea in calves in which the etiological diagnosis is not immediately obvious and may not be determined, even after exhaustive diagnostic work.

RISK FACTORS

A risk factor is any circumstance that can contribute to the occurrence of the disease. Conversely, if that circumstance is not present the disease may not occur. Many interrelated risk factors have been associated with a high incidence of calf diarrhea and have added to the difficulty of understanding the complexity of the disease and controlling it. The identification and modification or removal of these risk factors can be very effective in the clinical management and control of epidemics of the disease.

Animal risk factors

The host risk factors include immaturity of the neonate at birth, age of the neonate, a lack of vigor of the calf or piglet at birth, the presence of intrapartum hypoxemia and acidosis from a difficult birth, and failure to acquire sufficient colostral immunity. The nutrition of the pregnant dam can affect the quantity and quality of colostrum, and consequently the vigor of the calf.

Colostral immunoglobulin status

The role of colostrum in protecting the newborn calf from the effects of enteropathogens is well known. The failure of the newborn calf to ingest an adequate quantity of good-quality colostrum containing a high level of colostral immunoglobulins within a few hours after birth is a major risk factor contributing to acute undifferentiated diarrhea. Complete or partial failure of transfer of passive immunity is highly prevalent in diarrheic veal calves infected with cryptosporidia, coronavirus, and rotavirus.[1] Earlier work centered on the protective effect of colostrum against septicemic and enteric colibacillosis. More recently, the role of colostral and milk antibodies against rotavirus and coronavirus enteritis in newborn calves has been established. Specific protection against these viral diarrheas in the newborn calf depends on the level of antibody in the lumen of the intestine. While it is easy to state that calves should receive liberal quantities of colostrum, the veterinarian in the field who encounters an outbreak of acute diarrhea in beef calves, for example, cannot usually easily determine whether in fact the calves possess protective levels of immunoglobulins.

Lactose intolerance as a cause of diarrhea has been reported in a calf but its occurrence is rare.[2]

Cases of diarrhea due to specific **nutritional deficiencies** are reported rarely and not well documented. However, field observations indicate that outbreaks of diarrhea in sucking beef calves may have been associated with specific nutrient deficiencies such as copper or selenium. These are not documented but should be considered in certain situations where these deficiencies are known to be present in the herd. An epidemic of intractable diarrhea in 2-month-old beef calves was associated with deficient tissue and plasma levels of vitamin E in the affected calves, which also had lesions of skeletal and myocardial muscular dystrophy with adequate levels of selenium.[3] A combination of low vitamin E status and low immunoglobulin status may be a contributing factor in neonatal diarrhea of calves,[4] but this is not well documented.

Environmental and management risk factors

Veterinarians have commonly observed a relationship between adverse climatic conditions and epidemics of diarrhea in calves. During inclement weather, such as a snowstorm, a common practice in beef herds is to confine the calving cows in a small area where they can be fed and watered, and observed, more easily. The overcrowding may be followed by an outbreak of calf diarrhea. Cold, wet, windy weather during the winter months in temperate climates and hot humid weather during the summer months may be associated with an increased incidence of dairy calf mortality due to diarrhea. Changes in weather and wet, windy and cold weather are commonly associated with subsequent outbreaks of the disease in beef calves raised outdoors. Increases in population density in calf houses, and on calving grounds, resulting in highly contaminated calving grounds, are important risk factors. In beef herds in the USA and Canada, the risk factors that are associated with an increase in calf mortality from diarrhea include:

- The herd of origin. This is because of the genetic composition of the cattle, environmental conditions, degree of exposure to pathogens and management practices unique to the herd
- Increasing the percentage of heifers calving in the herd. The risk of diarrhea in calves born to heifers may be about four times greater than in calves born to cows[5]
- The odds of diarrhea occurring in calves born on or after the median calving date is twice that of calves born before the median calving date.[5] This may be because of increased pathogen exposure as the calving season progresses
- Poor drainage and limited shelter in the nursery yards
- A decrease in the size of the effective calving yards because of poor drainage and wetness
- Wintering and calving cows and heifers on the same grounds [6]

Some studies have shown that the major contributing factor to dairy calf mortality is the care provided by the calf attendant. Not infrequently, however, outbreaks can occur in herds in which the management is excellent and not uncommonly an etiological diagnosis cannot be made.

Certain herd characteristics and herd management practices are associated with an increased incidence of diarrhea in dairy herds.[7] Larger herd size is associated with an increased incidence of diarrhea.[7] The greater disease rate may be associated with a greater possibility of a large epidemic in a larger population, and cows in larger herds may be more densely housed. In dairy herds with 10–49 cows, the number of young stock at the end of the month, the incidence density of

respiratory disease in the calves per herd per calf-month, and the cumulative incidence of vaccinations for calves given to prevent diarrhea may be associated with increased incidence of diarrhea. As the incidence of respiratory disease increases in large dairy herds, the incidence of diarrhea in the calves increases, especially in large herds of over 200 cows.[7] Reduction of the incidence of respiratory disease in calves will result in a decrease in the incidence of diarrheal disease. The use of individual maternity stalls and regular removal of bedding between calvings is associated with a decrease in the incidence of neonatal calf diarrhea. As the number of calves in the herd increases, calf attendants may become too busy to perform duties of calf care thoroughly. Overcrowding may also be a risk factor.

Dairy calves fed milk replacers may develop diarrhea because of the inferior quality of some milk replacers.[8]

Epidemics of diarrhea in piglets are commonly associated with inadequate sanitation and hygiene in the farrowing rooms, which may be under continuous use without sufficient time for cleaning and disinfection between farrowings. Certain management procedures may be associated with differences in the prevalence of enteropathogens.

In dairy calves fed on nipple feeders there may be increased probability of the calves shedding detectable fecal levels of *Salmonella*, *E. coli*, rotavirus, or coronavirus. The use of group pens has been associated with increased odds of encountering *Campylobacter jejuni*, the presence of which is of uncertain significance. Calves with diarrhea on these farms tend to have increased odds of shedding rotavirus and K99$^+$ *E. coli*.

Pathogen risk factors

Calves

The distribution and occurrence of enteropathogens in the feces of diarrheic and normal healthy calves varies depending on the geographical location, the farm, the age and type of calves being examined, and the extent to which the diagnostic laboratory is capable of isolating or demonstrating the pathogens.[9] Rotavirus, *Cryptosporidium* spp., coronavirus, and enterotoxigenic *E. coli*, collectively, are responsible for 75–95% of infections in neonatal calves worldwide. The relative frequencies of each of the four differ between locations and between seasons and years.[10] Any one of the common pathogens may predominate or be absent in a certain group of animals.[11] Mixed infections are common.[12] Rotavirus will be most common in some groups, especially housed calves.[12] Coronavirus may predominate in beef calves in some countries and not in others, and *Cryptosporidium* may occur in 30–50% of diarrheic calves on a worldwide basis.[13] A survey of veal calf farms revealed that *Cryptosporidium* infection is an important cause of transient diarrhea and that there was no association between diarrhea and infection with either *Salmonella* spp., enterotoxigenic *E. coli*, rotaviruses, or verocytogenic *E. coli* in the population examined.[14] Cryptosporidia, rotavirus, and coronavirus are the most commonly identified enteropathogens in intensively reared veal calves.[1] In dairy calves, the prevalences of giardiosis and cryptosporidiosis may be high and both parasites may be associated with diarrhea. *Cryptosporidium parvum* is an important pathogen in calves under 1 month of age, but *Giardia duodenalis* may be more important when calves are older. Calves may clear *C. parvum* infections within 2 weeks; however, *G. duodenalis* infections may become chronic in the same calves.[15] The combination of *Cryptosporidium* sp. and rotavirus may predominate in some situations. *Cryptosporidium* spp. were the second most commonly detected pathogens next to rotavirus, and case-control studies indicated a highly significant association with diarrhea. Enteropathogens may not be detectable in up to 30% of diarrheic calves. *Eimeria* spp. can cause coccidiosis in calves any time after about 21 days after birth but the disease is more common in calves several months old.

In some countries, enterotoxigenic K99$^+$ *E. coli* may occur in 30–40% of diarrheic calves, while in others the incidence may be as low as 3–6%. Attaching and effacing *E. coli* that cause hemorrhagic colitis and blood in the feces of diarrheic calves about 2 weeks of age are being recognized with increasing frequency. They may occur concurrently with other enteropathogens (cryptosporidia, rotavirus, coronavirus, enterotoxigenic *E. coli*, bovine virus diarrhea virus (BVDV), and coccidia). Some isolates of attaching and effacing *E. coli* produce verocytotoxin.

The age occurrence of the common enteropathogens associated with diarrhea in calves is shown in Table 18.2. Case-control studies of diarrheic and healthy calves from the same groups indicate that the enteropathogens commonly found in diarrheic calves can also be found in healthy calves but at a lower frequency, with the exception of rotavirus, which may be excreted by up to 50% of healthy calves. The prevalence of enteropathogens in healthy calves on farms where there is no recent history of diarrhea indicates an absence of *Salmonella* spp., enterotoxigenic *E. coli*, *Cryptosporidium*, and coronavirus, but the presence of rotavirus in some calves. It appears that healthy calves may be infected more often with enterotoxigenic *E. coli*, *Cryptosporidium*, coronavirus, and rotavirus in herds in which some calves have or recently have had enteric disease than in herds free from major enteric disease.

Table 18.2 Age occurrence of the common enteropathogens in calves

Enteropathogen	Age (days)
Enterotoxigenic *Escherichia coli*	<3
Attaching and effacing *E. coli*	20–30
Rotavirus	5–15
Coronavirus	5–21
Other viruses (Breda virus, parvovirus, bovine virus, diarrhea virus)	14–30 (and older, up to several weeks)
Cryptosporidium spp.	5–35
Salmonella spp.	5–42
Clostridium perfringens types B and C	5–15
Eimeria spp.	>30
Giardia spp.	10–30

Campylobacter spp. and *Yersinia* spp. are well adapted to the bovine host and can be found in the feces of diarrheic and healthy calves at a similar prevalence.[16] Their significance as pathogens in newborn calves is questionable. They are probably part of the normal enteric flora of ruminants. However, as they represent a source of gastrointestinal infections in humans, management factors limiting intestinal colonization of these bacteria should be considered in beef cow/calf herds.[16]

Rotavirus and coronavirus occur with almost equal frequency in the intestinal tracts of normal and diarrheic calves of some studies. Intestinal lesions compatible with the viral infections are found in about 70% of diarrheic calves. Thus, these viruses are widespread in the bovine population and only under some circumstances will the infection be severe enough to cause lesions and diarrhea. Other viruses, such as parvovirus, astrovirus, Breda virus, and calici-like virus, have been isolated from the feces of diarrheic calves but their role in the etiology is yet to be defined.

A necrotizing enteritis of suckled beef calves 7–10 weeks of age on pasture in Scotland has been reported.[17] Fever, acute diarrhea and dysentery, and a case fatality rate of 25% are characteristic. No etiological agent has been identified.

Lambs and goat kids

The *E. coli* strains isolated from diarrheic lambs and goat kids on Spanish farms are not generally toxigenic and belong to a large number of O serogroups.[18]

Piglets

In outbreaks of diarrhea in neonatal piglets during the first 5 days of life, the

enteropathogens that are commonly present in the feces include the transmissible gastroenteritis (TGE) virus, enterotoxigenic *E. coli*, *Isospora* spp., rotavirus, *C. perfringens* type C, and adenovirus. *Clostridium difficile* has emerged as an important pathogen causing enteritis in suckling piglets.[19,20] The TGE virus causes diarrhea in piglets under 15 days of age, enterotoxigenic *E. coli* under 5 days of age, *Isospora* sp. between 5 and 15 days of age, and rotavirus in piglets over 10 days of age. During the second and third weeks of life, *Isospora suis* is the most common pathogen in outbreaks of diarrhea in litters of piglets. While individual piglets may be infected by a single pathogen, it is common for more than one pathogen to be present in the litter. This stresses the importance of submitting to the diagnostic laboratory some piglets that are representative of the problem. A seasonal occurrence of the common enteropathogens has also been observed. The prevalence of the TGE virus may be highest during the fall, winter, and spring months, and the coccidia and *E. coli* are more common during the summer, fall, and early winter, with the lowest prevalence in the spring.

Foals

Diarrhea in foals is common but most cases are mild, transient and not associated with infectious agents. Diarrhea is the most commonly reported disease in foals under 7 days of age.[21] The most common occurrence is associated with 'foal heat' in the mare. Group A rotavirus is the most common cause of epidemics of diarrhea in foals.[22] Enterotoxigenic *E. coli* has been isolated from a diarrheic foal. Other pathogens that have been isolated from foals with diarrhea include *C. jejuni*, *C. perfringens*, and *Rhodococcus equi*.

CLINICAL MANAGEMENT OF EPIDEMICS

When faced with an outbreak of acute diarrhea in newborn calves in which there is profuse watery diarrhea, progressive dehydration, and death in a few days or earlier, the following steps are recommended:

1. Visit the herd and do an epidemiological investigation to identify the risk factors that may have been responsible for the outbreak. Most outbreaks are multifactorial and an interaction between the environment, management, feeding and the pathogens.[23,24] The investigation of the underlying causes of the outbreak should involve an examination of:
   - Dry cow management
   - Calving management
   - Colostrum management
   - Calf management
   - Calf feeding
   - Feeds used
   - History of the present outbreak
   - The affected calves
   - Results of necropsy and pathology and microbiology
   - The pathogens identified
   - What has changed in the management of the herd
2. Each of the commonly recognized risk factors must be examined for its possible role in the particular outbreak:
   - In beef herds the most common one is overcrowding in the calving yards, which results in increased contamination and a high infection rate
   - Recent changes in climate and recent stress of any kind on the herd are common
   - In dairy herds, the quality of the milk replacer should be investigated
   - Any recent introductions of replacement calves into the herd should be considered as possible sources of pathogens
   - The failure of calves to ingest an adequate quantity of colostrum within hours after birth is also an important risk factor. However, it is usually not possible to determine how much colostrum calves have ingested, and measurement of serum immunoglobulins of calves about 3 days of age may be necessary to determine the level of colostral immunity in the calf crop. The concentrations of total serum protein and serum gammaglobulin are usually lower in calves with diarrhea, and calves born between May and October have higher levels than calves born in April
3. Affected calves should be examined clinically, dead ones by necropsy, and a case definition should be determined to insure that diarrhea is the major problem
4. All affected calves should be identified, isolated and treated immediately with oral and parenteral fluid therapy as indicated. The use of oral fluid and electrolyte therapy for the treatment of dehydration and acidosis as soon as the calves are seen to be diarrheic must be emphasized
5. Antibacterials may be given orally and parenterally for the treatment of enteric and septicemic colibacillosis. When large numbers of calves are affected at one time it is not usually possible clinically or with the aid of a laboratory to determine which calf is septicemic, and thus all acutely affected calves should be treated. Treatment, however, should not be continued beyond 3 days
6. Fecal samples (30–50 g) should be collected from diarrheic calves at the first sign of diarrhea, and from normal calves, and submitted to a laboratory for the attempted isolation and characterization of enterotoxigenic *E. coli*, rotaviruses, and *Salmonella* spp. A rapid enzyme-linked immunosorbent assay (ELISA) test is available for the simultaneous detection of *Escherichia coli* K99 antigen, bovine coronavirus, and rotavirus in the feces of diarrheic calves during the acute phase of the infection. The Enterosure Kit is a monoclonal antibody ELISA for the detection of bovine coronavirus, rotavirus serogroup A, and K99$^+$ *E. coli* antigen. The Cryptosure Kit is a substantial improvement over the stain method for detecting cryptosporidia in the feces. Blood samples from affected and normal calves and colostrum samples, if available, are useful for immunoglobulin and antibody studies. All moribund calves should be submitted for necropsy before they die naturally
7. Pregnant cows that are due to calve shortly should be moved to a new calving area. In a dairy herd this means a different, clean calving stall, preferably in another barn not previously occupied by cattle; in beef herds it may mean moving a large number of cows to a new, uncontaminated calving pasture
8. The control of the disease in future calf crops will depend on application of the principles of control, which are described under colibacillosis and viral diarrhea of calves. If a significant number of cows are due to calve in more than 3–6 weeks, vaccination with the calf diarrhea vaccines can be considered
9. A report should be submitted to the owner that records the observations made at the farm visit and outlines specific recommendations for clinical management of affected calves and for control of the disease in the future.

CONTROL

The principles of control are presented in detail in the sections on colibacillosis of newborn calves, piglets, lambs, kids, and foals, and viral diarrhea in calves, lambs, kids, piglets, and foals, using the following principles:

- Reduction of the degree of exposure of the newborn to the infectious agents

- Provision of maximum nonspecific resistance with adequate colostrum and optimum animal management
- Increasing the specific resistance of the newborn by vaccination of the dam or the newborn.

COLIBACILLOSIS OF NEWBORN CALVES, PIGLETS, LAMBS, KIDS, AND FOALS

Synopsis

Etiology Pathogenic serotypes of *Escherichia coli*: septicemic, enterotoxigenic, enteropathogenic (EPEC), enterohemorrhagic (EHEC), also referred to as verocytotoxigenic (VTEC) or Shiga-toxin-producing (STEC), and necrotoxigenic *E. coli* (NTEC)
Epidemiology Newborn calves, piglets, lambs, goat kids, foals. Risk factors include colostrum deprivation, overcrowding, adverse climatic conditions, inferior milk replacers. Prevalence of enteropathogenic *E. coli* varies between herds. Enterohemorrhagic *E. coli* (O157:H7) in cattle is of major zoonotic concern
Signs Weakness and collapse (septicemia). Diarrhea. Dehydration. Complications such as meningitis
Clinical pathology Isolate organism from feces. Hematology and serum biochemistry to evaluate inflammation and acid–base and electrolyte imbalance
Lesions Septicemic lesions. Dehydration, enteritis
Diagnostic confirmation Culture of organism and serotyping
Differential diagnosis See Table 18.3. *E. coli* infections causing septicemia and diarrhea in newborn farm animals must be differentiated from the following:

- Septicemia in calves
  - *Salmonella* spp.
  - *Listeria monocytogenes*
  - *Mannheimia haemolytica*
  - *Streptococcus* spp.
  - *Pneumococcus*
- Septicemia in piglets
  - *Streptococcus* spp.
  - *Listeria monocytogenes*
- Septicemia in lambs and kids
  - *Salmonella* spp.
  - *Listeria monocytogenes*
  - *Erysipelothrix insidiosa*
- Septicemia in foals
  - *Actinobacillus equuli*
  - *Salmonella abortusequi*
  - *Salmonella typhimurium*
  - *Streptococcus pyogenes*
  - *Listeria monocytogenes*
- Acute neonatal diarrhea in calves
  - Rotavirus and coronavirus
  - *Cryptosporidium* spp.
  - *Salmonella* spp.
  - *Eimeria* spp.
  - *Clostridium perfringens* type C
- Acute neonatal diarrhea in piglets
  - Rotavirus
  - Transmissible gastroenteritis virus
  - *Clostridium perfringens* type C
  - *Isospora* spp.
- Acute neonatal diarrhea in lambs and kids
  - Coronavirus
  - *Cryptosporidium* spp.
  - *Clostridium perfringens* type C
  - Rotavirus
- Acute neonatal diarrhea of foals
  - *Salmonella* spp.
  - *Eimeria* spp.
  - Foal heat diarrhea

Treatment Antimicrobials. Fluid and electrolyte therapy
Control Reduce infection pressure on neonate. Insure adequate intake of colostrum. Vaccinate pregnant dam to induce specific colostrum antibody. Minimize stressors and their effect on neonates

ETIOLOGY

Colibacillosis is associated with pathogenic serotypes of *Escherichia coli*.[1,2] The prevalence of the different pathogenic serotypes of *E. coli* in farm animals has remained relatively unchanged for many years. Certain serotypes cause diarrhea and others cause septicemia.

- **Enterotoxigenic *E. coli*** is the most common enteropathogen that causes diarrhea in newborn farm animals. The bacteria cause diarrhea by adhering to, colonizing and producing enterotoxins in the small intestine; they are not invasive[3]
- **Enteropathogenic *E. coli*** are the **'attaching and effacing'** strains that colonize the small intestine, where they attach tightly to the epithelial cells of the villus and cause typical attaching and effacing lesions. They do not produce toxins and seldom invade the intestinal mucosa
- **Enterohemorrhagic *E. coli*** strains elaborate very potent Shiga toxins. The enterohemorrhagic *E. coli* are considered to be a subset of Shiga-toxin-producing or verotoxin-producing strains of *E. coli*. They are not an important cause of diarrhea in farm animals but some Shiga-toxin-producing *E. coli* have been responsible for diarrhea in calves. Cattle are an important reservoir of ***E. coli*** O157:H7, one of the important enterohemorrhagic *E. coli* strains, causing a broad range of clinical disease in humans including diarrhea and hemorrhagic colitis, and the highly fatal hemolytic–uremic syndrome in children.[4,5] See 'Enterohemorrhagic *Escherichia coli* in farm animals and zoonotic implications', below
- **Necrotoxigenic *E. coli* (NTEC)** strains produce cytotoxic necrotizing factor (CNF)1 or 2. NTEC2 isolates are restricted to calves and lambs with diarrhea and septicemia[2]
- **Septicemic *E. coli*** strains of serogroup 078 are invasive and cause septicemia in calves, piglets, and lambs.[1] Their powerful endotoxins cause endotoxic shock with a high case fatality rate.

EPIDEMIOLOGY

Occurrence and prevalence of infection

The prevalence of colibacillosis has increased in recent years. There are several possible reasons for this, including size of herds, shortage of qualified labor, automated livestock rearing systems, and increased population density.

Colibacillosis occurs most commonly in newborn farm animals and is a significant cause of economic loss in raising livestock. It is a complex disease in which several different risk factors interact with certain pathogens, resulting in the disease. There are at least two different types of the disease: **enteric colibacillosis** is characterized by varying degrees of diarrhea, dehydration, acidosis, and death in a few days if not treated; **coliform septicemia** is characterized by severe illness and rapid death in several hours.

Calves

The prevalence of enterotoxigenic *E. coli* in diarrheic calves varies widely geographically, between herds and depending on

Table 18.3 Possible causes of bacteremia/septicemia and acute neonatal diarrhea in farm animals

Calves	Piglets	Lambs and kids	Foals
Bacteremia/septicemia			
Escherichia coli	*Escherichia coli*	*Escherichia coli*	*Escherichia coli*
Salmonella spp.	*Streptococcus*	*Salmonella* spp.	*Actinobacillus equuli*
Listeria monocytogenes	*Listeria monocytogenes*	*Listeria monocytogenes*	*Salmonella abortivoequina*
Pasteurella spp.		*Erysipelothrix rhusiopathiae*	*Salmonella typhimurium*
Streptococcus spp.			*Streptococcus pyogenes*
Pneumococcus spp.			*Listeria monocytogenes*
Acute neonatal diarrhea			
Enteropathogenic and enterotoxigenic *E. coli*	Enteropathogenic *E. coli*	*Clostridium perfringens* type C	Foal-heat diarrhea
Rotavirus	*Salmonella* spp.	*C. perfringens* type B	Rotavirus
Coronavirus	Transmissible	(lamb dysentery)	*Clostridium perfringens* type B
Bovine torovirus (Breda virus)	gastroenteritis virus	Rotavirus	
Bovine calicivirus	*Clostridium perfringens* type C	Caprine herpesvirus	
Bovine norovirus	(rarely A)		
Cryptosporidium spp.	*Clostridium difficile*		
Giardia spp.	Rotavirus		
Salmonella spp.	PRRSV		
Eimeria spp. (calves at least 3 weeks old)	*Isospora* spp.		
Clostridium perfringens type C			

PRRSV, porcine reproductive and respiratory syndrome virus

the age of the animals. The prevalence can be as high as 50–60% in diarrheic calves under 3 days of age and only 5–10% in diarrheic calves 8 days of age. In some countries the prevalence is only 5–8% in diarrheic calves under 3 days of age. Thus enterotoxigenic colibacillosis is a major cause of diarrhea in calves less than 3 days of age and is not associated with outbreaks of diarrhea in calves older than 3 days. Enterotoxigenic *E. coli* infection in calves older than 2–3 days will in most cases be associated with a virus infection. The prevalence of the organism is also very low or not present in clinically normal calves in herds that have not had a problem with diarrhea. In some beef herds affected with diarrhea in young calves there may be little evidence of infection with enterotoxigenic *E. coli*, and other factors need to be examined.

Piglets

The prevalence of enterotoxigenic *E. coli* in diarrheic piglets also varies geographically and with herds. In some areas the $K99^+$ pilus was found more frequently than the $K88^+$ or 987P, whereas in other regions the $K88^+$ is more common.

Morbidity and mortality rates

Calves

In dairy calves raised under intensive and poorly managed conditions the morbidity rate may reach 75% but is usually about 30%. Case fatality rates vary from 10–50% depending on the level of clinical management.

In beef calves the morbidity rates vary from 10–50% and the case fatality rates from 5–25% or even higher in some years. The population mortality rate in both beef and dairy calves can vary from a low of 3% in well-managed herds to a high of 60% in problem herds in certain years.

Piglets

In piglets the morbidity rate of preweaning diarrhea varies widely between herds but averages about 6% of litters, mostly in the first week of life. The morbidity rates increase with increased litter size and decrease with increasing parity of the sow. Losses due to stillbirths, traumatic injuries, starvation, and undersize at birth account for a much greater combined total preweaning loss but colibacillosis accounts for approximately 50% of the gastroenteropathies encountered during the preweaning period.

Foals and lambs

Incidence rates are not readily available for foals and lambs, but *E. coli* is the most commonly isolated organism from the tissues and blood of septic foals.

Risk factors

Several risk factors influence the occurrence of the disease, each one of which must be considered, evaluated and modified or removed if necessary when investigating the cause of an outbreak so that effective clinical management and control of the disease may be achieved.

Animal risk factors

Age and birth weight

Colibacillosis is most common in animals under 3 days of age but it may occur as early as 12–18 hours after birth and occasionally occurs in calves up to several days of age when there is a mixed infection with viral enteropathogens. Diarrhea associated with enterotoxigenic *E. coli* occurs in **calves** mainly during the first few days of life, rarely in older calves and never in adults. Epidemiological studies of both beef and dairy calves indicate that more than 80% of clinical cases associated with $K99^+$ enterotoxigenic *E. coli* occur in calves younger than 4 days of age. The mechanism of this age-related resistance is not well understood but may be related to development of resistance to colonization of the small intestine as the calf becomes older. This could be associated with the replacement of villous epithelial cells that occurs in the first few days after birth.

Mortality due to colibacillosis is significantly higher in **goat kids** that are underweight at birth because of multiple births, which may result in the ingestion of inadequate amounts of colostrum.[6]

The disease is more common in **piglets** born from gilts than from sows, which suggests that immunity develops with developing age in the sow and is transferred to the piglets. In a survey of approximately 4400 litters of piglets over a period of 4 years in a large piggery, 64% of the litters were treated for diarrhea before weaning, and piglets born to sows under parity 2 were 1.7 times more likely to develop diarrhea before weaning than litters born to sows over parity 3. The susceptibility or resistance to *E. coli* diarrhea in piglets has an inherited basis.[7] The cell surface receptor for the $K88^+$ antigen is inherited in a simple mendelian way with adherence (*S*) dominant over nonadherence (*s*). Homozygous dominants (*SS*) and heterozygotes (*Ss*) possess the receptor and are susceptible, whereas in the homozygous recessive (*ss*) the receptor is absent and the pigs are resistant. The highest incidence of diarrhea occurs in susceptible progeny born from resistant

dams and sired by susceptible sires. Most if not all pigs have intestinal receptors for $K99^+$ pili and an inheritance pattern similar to $K88^+$ receptors does not exist for $K99^+$ receptors.

Immunity and colostrum

Newborn farm animals are agammaglobulinemic and must ingest colostrum and absorb colostral immunoglobulins within hours of birth to obtain protection against septicemic and enteric colibacillosis. The transfer of immunoglobulins from the dam to the neonate is termed transfer of passive immunity. ***Failure of transfer of passive immunity*** predisposes the neonate to development of infectious diseases.[8]

Calves Transfer of maternal immunoglobulins to calves depends on three successive processes:

- **Formation of colostrum with a high concentration of immunoglobulin by the dam**
- **Ingestion of an adequate volume of colostrum by the calf**
- **Efficient absorption of colostral immunoglobulins by the calf.**

Colostral immunoglobulins are absorbed for up to 24 hours after birth in calves and up to 48 hours in piglets. However, in calves maximum efficiency of absorption occurs during the first 6–12 hours after birth and decreases rapidly from 12–24 hours after birth. Following absorption, transfer to the intestinal lumen is a major means of IgG_1 clearance in calves, and this transfer results in antigen-binding antibody in the intestinal lumen. Both blood-derived antibody and lactogenic antibody are significant sources of passive antibody in the intestinal lumen of the neonatal calf. Maintenance of high concentrations of milk-derived antibodies in the small intestinal lumen may require more than twice-a-day feedings, since antibodies derived from a milk diet are predominantly cleared from the intestinal lumen by 12 hours after feeding.

Passively acquired antibody from the circulation entering the small intestinal lumen is, therefore, a reasonable hypothesis to explain the strong association between high serum passive immunoglobulin concentrations and reduced morbidity in neonatal calves.

Newborn dairy calves should ingest 80–100 g of colostral immunoglobulin G_1, and ideally up to 150 g, within a few hours after birth in order to achieve serum immunoglobulins of 10 mg/mL.[8] Calves fed colostrum containing less than 100 g immunoglobulin are at increased risk for failure of transfer of passive immunity. The highest levels of serum immunoglobulins are achieved by the ingestion of colostrum containing high concentrations of immunoglobulins within a few hours after birth. The concentrations of immunoglobulins in first-milking colostrum from dairy cows can vary from 20–150 g/L, with mean levels varying from 40–50 mg/mL.[8] In one study of 919 first-milking colostrums from Holstein cows during a 4-year period on a commercial dairy farm, the colostral immunoglobulin G_1 concentrations varied greatly, with a mean of 48.2 mg/mL and a standard deviation of 21.9 mg/mL. Immunoglobulin (Ig) concentration in colostrum is lower in first- and second-calf heifers than in third or subsequent lactations. It is also lower in colostrum from high-producing dairy cows. Natural sucking by the calf may enhance the efficiency of absorption of colostral immunoglobulins, but the volume of colostrum ingested by sucking calves is frequently inadequate. In dairy herds that allowed calves to suck naturally, the prevalence of failure of transfer of passive immunity was greater than 50% even among calves nursed by cows with above-average colostral immunoglobulin concentration.[8] In order to ingest 100–150 g of immunoglobulins, newborn dairy calves should be artificially fed 3–4 L of fresh or refrigerated first-milking colostrum from cows that have had nonlactating intervals of normal duration.[8] In beef cattle, the concentration of immunoglobulin in colostrum is generally higher than in dairy cattle but there can be deficiencies of volume production, especially in first-calf heifers.

The maximum level of serum immunoglobulins is reached in the calf at 24 hours after birth and the factors that reduce those levels below an adequate level include the effects of maternal behavior and conformation, the vigor of the calf and environmental influences. Before the newborn calf manages to suck for the first time, a chain of specific events occurs. The calf first recovers from the birth process, attempts and is successful in standing up and then begins to search for a teat. The calf must find its dam and then locate the udder and teats. There are wide variations in the length of each interval and many factors can affect the variation in the intervals, and consequently the calf's first suck and acquisition of passive immunity. The risk of diarrhea in calves born to heifers may be about four times greater than calves born to cows, which may reflect maternal behavior and colostral immunity.[9] Some first-calf heifers do not lick and stimulate their calves to get up and suck immediately after birth as does the mature cow with an ostentatious maternal instinct. Others ignore their calves completely. The conformation of the udder and the shape of the teats may be undesirable in that the calf cannot find the teat so easily on badly shaped udders or the teat may be misshapen, which makes it difficult for the calf to suck. first-calf heifers do not have as much colostrum or as wide a spectrum of specific antibodies as do mature cows.

Calves that receive their first colostrum by bucket do not acquire the same high levels of serum colostral immunoglobulins as calves which receive their first colostrum by natural sucking of the teat. In both cases the presence of the dam improves the absorption. Calves that are weak or have an edematous tongue from a prolonged, difficult parturition may not be able to suck for several hours, by which time the ability to absorb colostral immunoglobulins has decreased markedly. Postnatal respiratory acidosis in calves can adversely affect colostral immunoglobulin absorption, despite adequate colostral intake early in the absorptive period.[8] Risk factors predictive of postnatal acidosis are duration of second-stage parturition greater than 1 hour, dystocia requiring traction, and weakness of the calf at birth. Beef calves born outdoors may be subjected to several influences that affect colostral intake. They may be born during a snowstorm and suffer severe cold exposure; when born they may be dropped in a snow-bank and be unable to get up, even with the assistance of the dam. In crowded calving grounds, mismothering due to mistaken identity may occur, resulting in the calf receiving no or very little colostrum.

Certain parameters measurable in dairy calves at, or shortly after birth may have important prognostic value in evaluating the risk of calf diarrhea.[10] High levels of serum immunoglobulins decrease the length of an episode of diarrhea.[10] The age at onset of diarrhea may be lower in lighter and in heavier newborn calves: lighter calves may be premature and unable to suck adequately, and heavier calves may have experienced dystocia.

Dairy calves. The mortality rate from enteric disease is much higher in calves with low levels of serum immunoglobulins than in calves with adequate levels. From the evidence of surveys, up to 40% of newborn dairy calves do not acquire adequate levels of serum colostral immunoglobulins because they do not ingest a sufficient amount of high-quality colostrum soon enough after birth; this makes them very susceptible to neonatal disease, especially enteric disease. In New Zealand, about 50% of dairy calves may not receive colostrum from their dams even when they are left together for up to 24 hours after the birth of the calf.[11] The failure of transfer of passive immunity

was due primarily to calves not sucking soon enough after birth. Of the calves that did suck, the time between birth and first sucking ranged between 0.9 and 19.1 hours.

Beef calves. The prevalence of failure of transfer of passive immunity in beef calves in North America ranges from 11–31%. In beef cow/calf herds averaging 56 cows in Quebec, Canada, failure of transfer of passive immunity occurred in 19% of the calves The risk factors for failure of transfer of passive immunity (serum concentrations < 10 g/L) in the newborn included being born in a stanchion-stall (odds ratio (OR) 10.2). Calves bottle-fed colostrum were less at risk of failure of transfer of passive immunity (OR = 0.06). Calf gender, month of birth, dam parity and dam body condition were not associated with failure of transfer of passive immunity.[12]

Lambs Lambs with low serum colostral immunoglobulin levels are also highly susceptible to enteric colibacillosis. The factors related to the risk of neonatal mortality, birth weight and serum immunoglobulin concentrations in lambs in the UK indicate that low birth weight and low serum immunoglobulin concentration were associated with increased odds of mortality.[13] Fifty-six percent of the variation in immunoglobulin concentration was at the lamb level, 36% at the ewe level and only 7% at the farm level. Factors associated with reduced serum immunoglobulin concentration included early or late birth in the lambing season, being born later than 14 days after the first lamb born on the farm, multiple-birth litters and maternal mastitis.

Piglets Newborn piglets that do not obtain a liberal quantity of colostrum within a few hours after birth are very susceptible to colibacillosis. Prolonged parturition, weak piglets, slippery floors, cold drafty farrowing crates and the condition of the sow and her colostrum supply all influence the amount of colostrum ingested by the newborn piglet. Enteric colibacillosis is the major disease in piglets that are weaned from the sow immediately after birth and reared on milk replacers. A crude preparation of porcine immunoglobulin added to the milk replacer of colostrum-deprived pigs provided good protection against enteric colibacillosis when fed for the experimental period of 21 days.

Environmental and management risk factors

Meteorological influences

While few epidemiological data are available to support the claim, many veterinarians have observed a relationship between adverse climatic conditions and colibacillosis in both calves and piglets. During inclement weather, such as a snowstorm, a common practice in beef herds is to confine the calving cows in a small area, where they can be fed and watered more easily. The overcrowding is commonly followed by an outbreak of acute diarrhea in the calves. There is evidence that cold, wet, windy weather during the winter months and hot, dry weather during the summer months has a significant effect on the incidence of dairy calf mortality.

The risk factors for mortality from diarrhea in beef calves in Alberta, Canada, have been examined.[14] The odds of increased mortality were increased when the cows and heifers were wintered on the same grounds, when the herd was wintered and calved on the same grounds, and if the cows and heifers calved on the same grounds. The morbidity and mortality rates from diarrhea during the first 30 days of life increased with an increasing percentage of heifers calving in the herd. Heifers are commonly more closely confined during the calving season for more effective observation and assistance at parturition. This may lead to increased contamination of the environment and the abdominal wall and udder of the heifers. Additional factors in heifers include a higher incidence of dystocia and maternal misbehavior, and lower volume and quality of colostrum, all of which can result in weak calves that may not acquire sufficient colostral immunity.

Nutrition and feeding methods

Dairy calves fed milk substitutes may be more susceptible to acute undifferentiated diarrhea, some of which may be due to enteric colibacillosis, compared to those fed cows'whole milk. Extreme heat treatment of the liquid skim-milk in the processing of dried skim-milk for use as milk substitutes for calves results in denaturation of the whey protein, which interferes with digestibility of the nutrients and destruction of any lactoglobulins that are present and may have a protective effect in the young calf.

Irregular feeding practices resulting in dietetic diarrhea may contribute to a higher incidence of enteric colibacillosis in calves. The person feeding and caring for the calves has been an important factor influencing calf mortality due to diarrhea. While it is generally believed that general or specific nutritional deficiencies such as a lack of energy, protein or vitamin A in the maternal diet predispose to colibacillosis, particularly in calves and piglets, there is no direct evidence that specific nutritional deficiencies are risk factors. They probably are, at least in indirect ways, for example by having an effect on the amount of colostrum available at the first milking after parturition in first-calf heifers underfed during pregnancy.

Standard of housing and hygiene

Housing and hygienic practices are probably the most important risk factors influencing the incidence of colibacillosis in calves and piglets but have received the least amount of research effort compared to other aspects, for example control of the disease through vaccination. As the size of herds has increased, and as livestock production has become more intensified, the quality of hygiene and sanitation, particularly in housed animals, assumes major importance. Where calves are run at pasture or are individually tethered, or penned, on grass the disease is much less common.

Source of the organism and its ecology and transmission

Ingestion is the most likely portal of infection in calves, piglets, and lambs, although infection via the umbilical vessels and nasopharyngeal mucosa can occur. It has been suggested that certain serotypes of *E. coli* may enter by the latter route and lead to the development of meningitis.

In most species, it is assumed that the primary source of the infection is the feces of infected animals, including the healthy dams and neonates, and diarrheic newborn animals, which act as multipliers of the organisms. In some cases the organism may be cultured from the vagina or uterus of sows whose litters become affected. In pig herds the total number of organisms on each sow is highest in the farrowing barn, decreases when the sow is returned to the breeding barn, and is lowest when the sow is in the gestation barn.

Calves Calves acquire the infection from contaminated bedding and calf pails, dirty calf pens, nearby diarrheic calves, overcrowded calving grounds, and from the skin of the perineum and udder of the cow. The organism is spread within a herd through the feces of infected animals and all the inanimate objects that can be contaminated by feces, including bedding, pails, boots, tools, clothing, and feed and water supplies. The organism is one of the first encountered by newborn farm animals within minutes after birth. In cattle, the tonsil can be a reservoir for Shiga-like positive *E. coli* in healthy animals.[15] It is possible that virulent *E. coli* can be present and may be transferred to calves when they are licked by their dams at birth. The high population density of animals that occurs in overcrowded calving grounds in beef herds, heavily used calving pens in dairy herds and the continuous successive use of farrowing crates without

a break for clean-up contributes to a large dynamic population of *E. coli*. The population of bacteria in an animal barn will continue to increase with the length of time the barn is occupied by animals without depopulation, clean-out, disinfection and a period of vacancy. In some countries, where lambing must be done in buildings to avoid exposure to cold weather, the lambing sheds may become heavily contaminated within a few weeks, resulting in outbreaks of septicemic and enteric colibacillosis.

Infected animals are the main reservoir for enterotoxigenic *E. coli* and their feces are the major source of environmental contamination with the bacteria. Passage of the *E. coli* through animals causes a 'multiplier effect', as each infected animal excretes many more bacteria than it originally ingested. Diarrheic calves are the most extreme multipliers, because they often pass 1 L or more of liquid feces containing 10^{10}/g enterotoxigenic *E. coli* within 12 hours, and recovered calves can continue to shed bacteria for several months.

Normal calves and adult cows can serve as reservoirs of infection, and the bacteria can persist in a herd by circulating through animals of all ages. Carrier animals introduced to an uninfected herd are thought to be one of the main causes of natural outbreaks. The duration and amount of shedding probably depends on the degree of confinement, resulting population density, herd immunity, environmental conditions and perhaps the serotype of the organism.

Pathogen risk factors

Virulence attributes of E. coli

The virulence attributes of **enterotoxigenic *E. coli*** include the adhesins in their pili or fimbriae that allow them to adhere to intestinal villous epithelial cells and prevent peristaltic elimination by the gut, and the production of heat-stable (ST) and heat-labile (LT) enterotoxins. The **septicemic strains** are invasive and commonly cause rapid death due to the effects of a septicemia involving multiple body systems. In animals that do not die of septicemia, localization of the bacteria may also occur in joints and other organs and tissues. Certain strains such as the O115:KXVX 165 can cause either diarrhea or septicemia in piglets and calves.[16]

The virulence attributes are relevant to vaccine efficacy. The species-specific adhesin antigens must be identified and incorporated into vaccines, which are given to pregnant females in an attempt to stimulate the production of specific antibody in the colostrum, which will provide protection against enterotoxigenic colibacillosis. An essential element of vaccine development is the detection of common fimbrial antigens occurring among most pathogenic isolates and able to induce antibodies that block bacterial adhesion. The great diversity of potential pathogenic serotypes encountered in colisepticemia and the failure of serotype-specific antibody to cross-protect against a heterologous challenge in experimental infection have made it difficult to develop vaccines against septicemic colibacillosis.

Calves The major virulence attributes of the **enterotoxigenic strains of *E. coli*** in calves are the K99$^+$ adhesin antigen and the heat-stable enterotoxin.[1] The colonization in the small intestine of calves by K99$^+$ enterotoxigenic *E. coli* appears to be site-specific, having a predilection for the ileum. Some serogroups also elaborate the F41 adhesin to the K99. Other surface-adhesive antigens such as Att 25 and F17 have been identified on bovine enteropathogenic and septicemic *E. coli*.[1] The F17a-positive enterotoxigenic *E. coli* strains are no longer isolated from diarrheic calves in some countries. It is postulated that the use of a vaccine including O101, K32, and H9 antigens in addition to K99 (F5) explains the strongly reduced incidence of the O101:K32:H9, K99(F5) *E. coli* clone.[17] A K88-related fimbrial antigen occurs on some enterotoxigenic and septicemic strains.

The heat-stable enterotoxin from bovine enterotoxigenic *E. coli* has been purified and characterized. There is evidence of a form of heat-stable enterotoxin that is common to bovine, porcine, and human strains of enterotoxigenic *E. coli*.

Most strains of septicemic *E. coli* belong to certain serogroups with virulence properties that enable them to resist the defense mechanisms that would normally eliminate other *E. coli*. Septicemic strains produce endotoxin, which results in shock and rapid death, usually in calves that are less than 5 days of age and are agammaglobulinemic because of failure of transfer of colostral immunity. Isolates of *E. coli* from the blood of critically ill bacteremic calves on a calf-rearing farm in California constituted a heterogeneous group and were aerobactin positive and often resistant to the bactericidal effects of serum.[18] The P fimbriae F11 and F165 have been identified in septicemic *E. coli* strains isolated from calves.[19]

Enterohemorrhagic *E. coli* and verocytotoxin-producing *E. coli* are being recognized in humans and animals with increased frequency[20] and constitute a major zoonotic concern. These organisms are members of O111, O1O3, O5, and O26 serogroups, and none produces heat-stable or heat-labile enterotoxin, nor do they possess the K99 pili.[3] They produce potent verotoxins, also known as the Shiga-like toxins, SLT1 and SLT2; and some strains, the **attaching and effacing *E. coli*** (**AEEC**), attach to and efface the microvilli of the enterocytes, causing diarrhea and dysentery due to a hemorrhagic colitis in calves 2–5 weeks of age. The effacing (*eae*) gene and the gene coding for the Shiga-like toxin 1 (*SLT1*) are associated with most isolates of AEEC in cattle.[21] They have been isolated from both diarrheic and healthy sheep and goats.[22]

A study of the onset and subsequent pattern of shedding of verotoxin-producing *E. coli* O26, O103, O111, O145, and O157 in a cohort of beef calves on a mixed cattle and sheep farm in Scotland found that O26 was shed by 94% of the calves and that 90% of the O26 isolates carried the *vtx1*, *eae*, and *ehl* genes.[23] *E. coli* O103 was the second most commonly shed serogroup of the tested calves and the pattern of shedding was sporadic and random. There was an absence of shedding of *E. coli* O111 and the prevalence of shedding of O145 was low. While some shedding of O157 occurred, shedding in calves was sporadic and infrequent. For O26, O103, and O157, there was no association between shedding by calves and shedding by dams within 1 week of birth. For O26 and O103, there was no association between shedding and diarrhea, and no significant change in shedding following housing. In a sample of Australian dairy farms, calves as young as 48–72 hours had evidence of fecal excretion of Shiga-toxin-producing *E. coli*, indicating that dairy cattle are exposed to Shiga-toxin-producing *E. coli* from birth.[24] Calves at weaning are most likely to be shedding Shiga-toxin-producing *E. coli* O26 or *E. coli* O157, similar to the prevalence surveys in the northern hemispheres.

Naturally occurring cases of attaching and effacing lesions of the intestines in calves with diarrhea and dysentery and infected with *E. coli* O126:H11, the predominant verotoxin-producing *E. coli* in humans, have been described in the UK.[25] Verotoxin-producing *E. coli* and *eae*-positive non-verotoxin-producing *E. coli* have been isolated from diarrheic dairy calves 1–30 days of age.[26]

E. coli O157 has been isolated from neonatal calves and has been implicated as a cause of diarrhea in calves.[27] The isolates carried various virulence genes such as *Ehly*, *eae*, *stx1*, and *stx2*. The *Ehly* gene may be a virulence marker for bovine enterohemorrhagic *E. coli* O157 strains. Similar findings have been reported in dairy cattle herds in Brazil.[28] Strains of *E. coli*, possessing a subtype beta intimin, normally found in human enteropathogenic *E. coli*, have been found in diarrheic calves in Brazil.[29]

Non-O157 Shiga-toxin-producing *E. coli* have been isolated from diarrheic calves in Argentina and the serotypes carried virulence traits associated with increased pathogenicity in humans and cattle.[30] Severe clinical syndromes associated with non-O157 Shiga-toxin-producing *E. coli* are common in children under 4 years of age and may be associated with diarrheic calves, which shed highly virulent Shiga-toxin-producing *E. coli* strains and could act as a reservoir and contamination source in these areas.

E. coli O116, a serogroup previously associated with cases of hemolytic–uremic syndrome in humans, has been associated with an outbreak of diarrhea and dysentery in 1–16-week-old calves in India.[31] *E. coli* O103:H2, a Shiga toxin strain causing disease in humans, has been isolated from calves with dysentery, and from a sheep in Australia.[32]

Necrotoxigenic *E. coli*, which produce **cytotoxic necrotizing factor**, have been isolated from cattle in Northern Ireland[33] and Spain, and from diarrheic piglets in England.[34] NTEC1 strains from cattle, pigs, and humans can belong to the same sero/biogroups, carry genes coding for adhesions belonging to the same families, and possess other identical virulence-associated properties, and therefore do not exclude the possibility of cross-infection between humans and farm animals in some cases.[35] Necrotoxigenic *E. coli* were detected by tissue culture and polymerase chain reaction (PCR) in 15.8% of diarrheic dairy calves in Spain from 1–90 days of age; the majority were necrotoxigenic *E. coli* producing CNF2 and the risk increased with age. There was also a strong association between CNF2 and F17 fimbriae.[36] The necrotoxigenic *E. coli* with their associated adhesins and toxins were present in diarrheic and septicemic calves as early as 1958 and their prevalence seems to be increasing.[37] Their role in causing disease needs further examination.

Piglets Most enteropathogenic *E. coli* from neonatal pigs belong to the so-called 'classical serogroups' O8:K87, O45, O138:K81, O141:K85, O147:K89, O149:K91, and O157:KXVX17.[1] Strains of these serogroups usually express and produce $K88^+$, $987P^+$, or $K99^+$ pilus antigens, which adhere to ileal villi, colonize intensively and cause profuse diarrhea when given to newborn pigs. The K88, K99, and 987P pili are also designated F4, F5, and F6, respectively. However, there are also some enterotoxigenic strains that produce none of the three antigens.[38] $K88^+$ produces heat-labile enterotoxin (LT), the $987P^+$ and the $K99^+$ do not produce LT, and all three types produce heat-stable enterotoxin STa in infant mice. Some isolates produce neither LT or STa but produce enterotoxin in ligated intestinal loops of pigs (STb). The $K99^+$ piliated strains are a major cause of enteric disease in piglets under 2 weeks of age.[1] Strains of enterotoxigenic *E. coli* that produce 987P pili colonize the small intestines and cause diarrhea in neonatal pigs under 6 days of age but not older pigs. Other 'nonclassical' strains colonize the small intestine to a certain extent, do not strongly adhere to the intestinal epithelium, and produce enterotoxin and diarrhea in neonatal piglets. Vaccination of a sow population for several years with vaccines containing O149 and K88 antigens may change the pattern of virulent *E. coli* inducing neonatal diarrhea during the first week of life so that other serogroups may dominate.

The **porcine enterotoxigenic *E. coli*** strains which induce fluid secretion in the intestine of piglets less than 2 weeks of age but not in older pigs are designated class 2, whereas those strains which induce fluid secretion in the intestines of older pigs are class 1 enterotoxigenic *E. coli*. The bovine strains of enterotoxigenic *E. coli* have several features in common with the porcine class 2 organisms which include the possession of the 0 antigens 8, 9, 20, or 101, characterization as mucoid colonies, possession of $K99^+$ pili and production of heat-stable enterotoxin. Most strains of enterotoxigenic *E. coli* of pigs belong to a restricted number of serogroups.

Lambs Enterotoxigenic strains of *E. coli* can be isolated from the feces of approximately 35% of diarrheic lambs. Enterotoxigenic strains of *E. coli* have also been isolated from the blood of a small percentage of diarrheic lambs. K99 piliated *E. coli* are associated with outbreaks of diarrhea in lambs under a few days of age. F17 fimbriae *E. coli* have been isolated from diarrheic lambs and kids but none of the isolates produced any of the toxins normally associated with enteropathogenic strains. Attaching and effacing *E. coli* negative for verocytotoxin but positive for *eae* have been isolated from goat kids affected with severe diarrhea with a high case fatality rate.

Foals An enterotoxigenic strain of *E. coli* with some evidence of K99 and F41 pilus antigens, K87 capsular antigens and serotype 101 somatic antigen has been isolated from newborn foals affected with diarrhea. However, they are not considered to be major pathogens in foals. The strains of *E. coli* isolated from the feces of diarrheic and healthy foals are very diverse and enterotoxigenic strains of the organism are not implicated in sporadic foal diarrhea. The isolates of *E. coli* obtained from the blood and tissues of septic foals are different from those obtained from the feces of healthy foals.[39] Isolates from septic foals were resistant to equine serum. Some isolates of *E. coli* from septic foals contained conjugal plasmids that encoded resistance to multiple antimicrobial agents linked to equine serum resistance and to the production of aerobactin, which permits the growth of the organisms in an iron-limited environment, a trait considered a virulence determinant.

Zoonotic implications of *E. coli*

Cattle are a major source of *E. coli* O157:H7, which infects and causes foodborne disease in humans.[4,5] Several strains of enterohemorrhagic *E. coli* associated with enteric disease in humans produce a verotoxin also known as a Shiga-like toxin. The literature on the epidemiology and virulence mechanisms of *E. coli* **O157:H7** has been reviewed.[4,5] (See 'Enterohemorrhagic *Escherichia coli* in farm animals and zoonotic implications', below.)

PATHOGENESIS

The factors important in understanding the pathogenesis of colibacillosis are the immune status of the animal and the virulence attributes of the strain of *E. coli*, particularly its capacity to invade tissues and produce a septicemia, or to produce an enterotoxin that causes varying degrees of severity of diarrhea. Septicemia, bacteremia, diarrhea, dehydration, and metabolic acidosis are the major pathogenetic events in the various forms of colibacillosis.

Septicemic colibacillosis (coliform septicemia)

This occurs in all species as a result of invasive strains of *E. coli* invading the tissues and systemic circulation via the intestinal lumen, nasopharyngeal mucosa and tonsillar crypts, or umbilical vessels. The intestinal permeability to macromolecules in the newborn piglet may predispose to the invasion of septicemia-inducing *E. coli*. These strains are able to invade extraintestinal tissues, to resist the bactericidal effect of complement, to survive and multiply in body fluids, to escape phagocytosis and intracellular killing by phagocytes, and to induce tissue damage by the release of cytotoxins. Calves and piglets that are deficient in colostral immunoglobulins are highly susceptible to septicemia. Colostrum provides protection against colisepticemia but may not prevent diarrhea associated with *E. coli*. Also, colostrum-fed calves are much more resistant to endotoxin than colostrum-deprived calves. Calves, piglets, and lambs that have normal levels of serum

immunoglobulins are generally protected from septicemia. The clinical findings and lesions in septicemic colibacillosis are attributable to the effects of endotoxin, which causes shock. The general effects of endotoxin in cattle include hypothermia, decreased systemic blood pressure, tachycardia and decreased cardiac output, changes in blood counts, alterations in blood coagulation, hyperglycemia followed by hypoglycemia, and depletion of liver glycogen. Animals that recover from septicemia or bacteremia may develop lesions due to localization in other organs at varying periods of time later. Arthritis is a common sequel in calves, foals, and lambs. Meningitis is common in calves and piglets. Polyserositis due to *E. coli* has been recorded in pigs.

Enteric colibacillosis

Enterotoxigenic colibacillosis

Enterotoxigenic strains of *E. coli* colonize and proliferate in the upper small intestine and produce enterotoxins, which cause an increase in net secretion of fluid and electrolytes from the systemic circulation. The adhesion of *E. coli* to the intestinal epithelial cells is mediated by bacterial pili. The enterotoxigenic form of colibacillosis occurs most commonly in calves and piglets and less commonly in foals and lambs.

The factors that allow or control the colonization and proliferation of these strains and their production of enterotoxin are not well understood. The bacterial fimbriae attach to specific receptor sites on villous epithelial cells, following which the bacteria multiply and form microcolonies that cover the surface of the villi. The capsular polysaccharide of *E. coli* may also be involved in adhesion and colonization. The fimbriae of *E. coli* are strongly immunogenic, a factor that is utilized in the production of vaccines. Experimentally, the intestinal fluid from the most proximal small intestine of calves is more suppressive of $K99^+$ pilus expression than fluid from more distal segments of the small intestine. Thus any factor that results in an increase of the pH in the lumen may allow the proliferation of the organism and, conversely, lowering the pH may reduce the severity of colibacillosis.

Diarrhea, dehydration, metabolic acidosis and electrolyte imbalance

The production of the enterotoxin results in net secretion of fluid and electrolytes from the systemic circulation into the lumen of the intestine, resulting in varying degrees of diarrhea, dehydration, electrolyte imbalances, acidosis, hyperkalemia when the acidosis is severe, circulatory failure, shock and death. The hyperkalemia in calves with neonatal diarrhea and acidosis has been associated with cardiac rate and rhythm abnormalities, including bradycardia and atrial standstill.[40] The response to the enterotoxin in calves and piglets is similar to cholera enterotoxin in humans and takes place through an intact mucosa. Enterotoxin stimulates mucosal adenylcyclase activity, leading to an increase in cyclic adenosine monophosphate (AMP), which increases intestinal fluid secretion. The secretion originates primarily in the intestinal crypts but the villous epithelium also has a secretory function. The fluids secreted are alkaline and, in comparison to serum, isotonic, low in protein and high in sodium and bicarbonate ions. Distension of the right abdomen of diarrheic calves may occur, which may be associated with fluid distension of the abomasum and the intestines.[41]

When the disease is confined to the intestine, it responds reasonably well to treatment in the early stages. If death occurs, it is due to acidosis, electrolyte imbalance, and dehydration. The acid–base and electrolyte changes in piglets 1–3 days of age infected naturally and experimentally with enterotoxigenic *E. coli* reveal a severe dehydration and metabolic acidosis.

Severe metabolic changes can occur in calves with diarrhea. If the disease is progressive, the acidosis becomes more severe, lactic acidosis develops because of a reduced ability to utilize lactic acid, and severe hypoglycemia may occur because of a reduced rate of conversion of lactic acid to glucose. If extensive fluids are lost, hypovolemia and shock occur. The blood oxygen-binding capacity may be impaired in calves with diarrhea and severe dehydration.[39]

The most commonly accepted explanations of the **metabolic acidosis** in diarrheic calves are fecal bicarbonate loss and L-lactic acidosis. L-lactic acidosis is thought to occur from inadequate perfusion because of dehydration or endotoxemia, with subsequent anaerobic glycolysis and decreased clearance of L-lactate. However, neonatal diarrheic calves have high serum concentrations of D-lactate, with relatively low serum L-lactate concentrations.[42–44] D-lactic acidosis is a contributory factor in calves with high anion gap acidosis. The anion gap significantly correlates with D- and total DL-lactate concentrations in serum but not with serum L-lactate concentrations.[44] The elevated serum and urine concentrations of serum D-lactate are probably gastrointestinal in origin and the rumen and colon in diarrheic calves are considered as sites for the sources of D-lactate.[43]

The anion gap is defined as the sum of the major cations minus the sum of the major anions and is a measure of 'unmeasured anions':

$$\text{Anion gap} = [Na^+] + [K^+] - [Cl^-] - [HCO_3^-].$$

The anion gap may be changed in numerous disturbances, including those of acid–base imbalance, and is useful in the interpretation of acid–base findings, but is of no value in assessing the intrinsic severity of acid–base disturbances.

Diarrheic calves are generally hyperkalemic with a high serum anion gap, a depressed serum bicarbonate and a low blood pH.

The severity and nature of the acidosis in diarrheic calves varies with the age of the calf. Diarrheic calves under 1 week of age often have a lactic acidosis, while those over 1 week of age have a nonlactic acidosis. Younger calves tend to dehydrate more rapidly and severely than older calves, which may be related to the greater incidence of enterotoxigenic colibacillosis in the young age group. The severity of dehydration, hypothermia, and metabolic acidosis is associated with the level of mental depression.[45] The clinical signs and age of the calf can be used to predict the severity of acidosis; the more severe the acidosis, the greater the depression.

Metabolic acidosis without clinical evidence of dehydration occurs in some calves that have had a history of diarrhea in the previous several days.[46] A similar syndrome has been described in goat kids. The pathogenesis is unclear but is thought to be associated with diarrhea in the preceding several days. One possibility is an inadequate amount of bicarbonate in the fluids and electrolytes used for the treatment of the dehydration.

Hyperkalemia in the diarrheic calf

Hyperkalemia is most common in dehydrated diarrheic calves that are severely acidotic. The potassium moves out of the intracellular space into the extracellular space, resulting in hyperkalemia. The predominant clinical finding is bradycardia (heart rate < 90 bpm) in a dehydrated diarrheic calf. However, hypoglycemia and hypothermia may be associated with bradycardia in a similar calf.

Hypernatremia in the diarrheic calf

Acute hypernatremia may occur in diarrheic calves.[46,47] Clinical findings are nonspecific and include depression, weakness, dehydration, and diarrhea. Laboratory determination of serum electrolytes is necessary to make the diagnosis. The serum sodium concentration is above 160 mEq/L. It is presumed that mixing errors in the preparation of oral electrolyte solutions for diarrhea is the cause. The experimental oral administration of 1 L of electrolyte concentrate containing

2750 mEq sodium found that calves would willingly consume the solution mixed with milk and developed signs of hypernatremia within 6 hours of administration.

Hypernatremia (serum sodium > 153 mEq/L) in neonatal elk calves has been described.[48] The most common clinical findings were diarrhea, dehydration, depression, and anorexia.

Effect of colostral immunoglobulin status

An adequate level of serum immunoglobulins protects calves from death due to the effects of diarrhea, but not necessarily from diarrhea. The best protection is provided if both the immunoglobulin levels in the serum and the levels in the colostrum and milk during the first week after birth are high. The immunoglobulin subclasses in the plasma of calves that have received sufficient colostrum are IgG, IgM (and IgM is probably the more important of the two for the prevention of septicemia) and IgA. The serum IgG concentrations of calves under 3 weeks of age dying from infectious disease were much lower than in normal calves. Of the dead calves 50% had serum IgG levels that were more than 2 standard deviations below the normal mean, and an additional 35% had concentrations greater than 1 standard deviation below the normal mean. In the intestine, no single subclass of immunoglobulin is known to be responsible for protection against the fatal effects of diarrhea. Individually, each immunoglobulin subclass can prevent death from diarrhea even though calves may be affected with varying degrees of diarrhea. In contrast to the situation in the pig, IgA appears to be least effective.

In pigs, IgA becomes the dominant immunoglobulin in sow colostrum after the first few days of lactation, and this is the immunoglobulin that is not absorbed but is retained in, and reaches a high level in, the gut and plays a major role in providing local protection against enteric colibacillosis in piglets. Porcine colostral IgA is more resistant to gastrointestinal proteolytic enzymes than IgG_2 and IgM. On the other hand, IgG is at a peak concentration in colostrum in the first day after parturition, is readily absorbed by the newborn piglet and is vital in providing protection against septicemia. Lysozyme in sows' milk may assist in the control of the bacterial population in the gut of the unweaned piglet.

Intestinal mucosa

In general, the enterotoxigenic *E. coli* exert their effects by the enterotoxin causing hypersecretion through an intact intestinal epithelium. However, the intraluminal exposure of the jejunum of 3-week-old pigs to sterile crude culture filtrates from strains of *E. coli* known to produce two types of heat-stable enterotoxin will induce microscopic alterations of the villous epithelium. Focal emigration of neutrophils, especially through the epithelium above aggregated lymphatic follicles, stunting of jejunal and ileal villi, and adherence of bacteria to jejunal and ileal mucosae are the most consistent finding. These changes are useful in making the diagnosis of enterotoxigenic colibacillosis in calves. While enterotoxigenic strains are considered to be noninvasive this does not preclude the possibility that invasion into the systemic circulation may occur, resulting in septicemia, or that septicemic strains may not also be present.

Enzyme histochemistry studies of the small intestinal mucosa in experimental infections of calves with rotavirus and enterotoxigenic *E. coli* indicate a marked decrease in enzyme activity in dual infections and a lesser decrease in monoinfections. Increased enzyme activity occurred in parts of the intestinal mucosa that were not affected or only slightly affected by the enteropathogens, which may be an adaptation of the mucosa to maintain absorptive function. Lactose digestion is slightly impaired in calves with mild diarrhea. Calves with acute diarrhea are in a catabolic state and respond with a larger increase of plasma glucose concentration to a given amount of absorbed glucose than do healthy calves.[49] Fat and carbohydrate malabsorption frequently occurs in diarrheic calves over 5 days of age and may contribute to the death of these animals in cold weather.

Attaching and effacing colibacillosis

Attaching and effacing enteropathogenic *E. coli* can cause naturally occurring diarrhea and dysentery in calves at 18–21 days.[1] They do not produce enterotoxin but adhere to the surface of the enterocytes of the large intestine. Affected calves pass bright red blood in the diarrheic feces. The lesions in experimentally infected calves are indistinguishable from those produced by some *E. coli* that are enteropathogenic for humans, rabbits, and pigs. They do not produce enterotoxin. The bovine O118:H16 enterohemorrhagic *E. coli* strain is able to colonize the intestine of newborn calves and to induce diarrhea 24 hours after challenge and to produce attaching and effacing lesions in the small and large intestines.[50]

Synergism between enteropathogens

Enterotoxigenic colibacillosis occurs naturally and can be reproduced experimentally using enterotoxigenic *E. coli* in calves under 2 days of age but not in calves 1 week of age. Diarrheic calves older than 3 days of age may be infected with enterotoxigenic $K99^+$ *E. coli* and rotavirus. There is evidence that prior or simultaneous infection of the intestine with rotavirus will enable the *E. coli* to colonize in older calves.[1] Thus, there may be synergism between rotavirus and enterotoxigenic *E. coli* in calves older than 2 days; this may explain the fatal diarrhea that can occur in calves at 1 week of age, which normally would not be fatal with a single infection. The rotavirus may enhance colonization of the *E. coli*. In the Kashmir valley of India, diarrheic lambs from birth to 3 months of age are commonly infected with group A rotavirus and pathogenic serogroups of *E. coli* O26, O113, O157, all of which are pathogenic to humans.[51]

The simultaneous experimental infection of neonatal gnotobiotic calves at 24 hours of age with rotavirus and enterotoxigenic *E. coli* results in a severe diarrheal disease. The same situation occurs in piglets. However, in both species the effect was considered to be additive rather than synergistic.

Summary of pathogenesis

Septicemic colibacillosis occurs in newborn animals that are agammaglobulinemic because they have not ingested sufficient colostrum early enough, or have absorbed insufficient colostral immunoglobulins, thus rendering them highly susceptible. Enteric colibacillosis occurs in colostrum-fed animals and is associated with the colonization and proliferation of enteropathogenic *E. coli*, which produce enterotoxin and cause varying degrees of diarrhea and acidosis and dehydration. While single infections occur commonly, as in piglet diarrhea, and what was previously described as enteric–toxemic colibacillosis in calves, multiple infections with enteropathogenic *E. coli* and viruses and other agents are more common.

CLINICAL FINDINGS

Calves

Coliform septicemia

This is most common in calves during the first 4 days of life. Most affected calves have low levels of serum colostral immunoglobulins because of inadequate transfer of colostral immunoglobulins.[16] The illness is peracute, the course varying from 24–96 hours with a survival rate of less than 12%.[16] There are no diagnostic clinical signs. Affected animals are depressed and weak, commonly recumbent, and dehydrated; tachycardia is present and, although the temperature may be high initially, it falls rapidly to subnormal levels when the calf becomes weak and moribund. The suck reflex is weak or absent, the oral mucous membranes are dry and cool, and the capillary refill time may be prolonged. Cold extremities, weak peripheral pulse and prolonged

capillary refill time are common. Scleral injection is common. Diarrhea and dysentery may occur but are uncommon.

Multiple body system and organ involvement is characteristic of neonatal septicemia and careful clinical examination is required to detect abnormalities. If a calf survives the septicemic state, clinical evidence of postsepticemic localization may appear in about 1 week. This includes arthritis, meningitis, panophthalmitis and, less commonly, pneumonia. In a series of 32 cases of meningitis in neonatal calves, the most frequent clinical findings were lethargy, anorexia, recumbency, loss of the suck reflex, stupor, and coma.[52] Opisthotonos, convulsions, tremors, and hyperesthesia were seen less frequently. The case fatality rate was 100% in spite of intensive therapy, and lesions of septicemia were present at necropsy.

Predictors of septicemia

The early clinical findings of septicemia in neonatal foals and calves are vague and nonspecific and are often indistinguishable from the findings of noninfectious diseases or those of focal infections such as diarrhea. Positive blood cultures are required for a definitive diagnosis of septicemia, but results are not usually available for 48–72 hours, and false negatives are common. A clinical sepsis scoring system for predicting bacteremia in neonatal dairy calves has been described but has not been adequately evaluated in the field.[53,54]

No single laboratory test has emerged as being completely reliable for the early diagnosis of septicemia in farm animal neonates and therefore scoring systems and predictive models using obtainable historical, clinical and clinicopathological data have been developed. The goal of these mathematical models is to identify septicemic neonates early in the course of disease when appropriate therapy would be most likely to result in a favorable outcome.[55] In a study of diarrheic calves under 28 days of age submitted to a referral clinic for treatment, 31% of the calves were septicemic, based on blood culture.[55] Two models to predict septicemia were used. Clinicopathological variables associated with an increased risk of septicemia were moderate (1.99–5.55 mg/dL) and marked (> 5.66 mg/dL) increases in serum creatinine (OR 8.63), moderate to marked toxic changes in neutrophils (OR 2.88), and failure of transfer of passive immunity (IgG concentrations β 800 mg/dL, globulin β 2 g/dL (OR 2.72), and total serum protein β 5 g/dL). The clinical variables associated with an increased risk of septicemia were age under 5 days (OR 2.58), focal infection (OR 2.45), recumbency (OR 2.98), and weak suck reflex (OR 4.10).[55]

Enteric colibacillosis

This is the most common form of colibacillosis in newborn calves, primarily 3–5 days of age. It may occur in calves as early as 1 day of age and only rarely up to 3 weeks. The clinical severity will vary depending upon the number and kind of organisms causing the disease. The presence of a single enterotoxigenic strain of *E. coli* may cause a state of collapse usually designated as **enteric toxemia**. In this form of the disease the outstanding clinical signs include severe weakness, coma, subnormal temperature, a cold clammy skin, pale mucosae, wetness around the mouth, collapse of superficial veins, slowness and irregularity of the heart, mild convulsive movements, and periodic apnea. Diarrhea is usually not evident, although the abdomen may be slightly distended and succussion and auscultation may reveal fluid-splashing sounds suggesting a fluid-filled intestine.[41] The prognosis for these calves is poor and they commonly die 2–6 hours after the onset of signs.

In the more common form of the disease in calves, there is diarrhea in which the feces are profuse and watery to pasty, usually pale yellow to white in color, and occasionally streaked with blood flecks and very foul-smelling. The dry matter content of the feces is commonly below 10%. Defecation is frequent and effortless, and the tail and perineum are soiled with feces. The temperature is usually normal in the initial stages but becomes subnormal as the disease worsens. Affected calves may or may not suck or drink depending on the degrees of acidosis, dehydration, and weakness. Calves under 8 days of age may be weak, primarily from the effects of rapid and severe dehydration; in calves older than 8 days the acidosis may be more severe and makes a greater contribution to depression and weakness. In the early stages of the disease, the abdomen may be slightly distended as a result of distension of fluid-filled intestines, which can be detected by succussion and auscultation of the abdomen. In some of these calves the diarrhea is not obvious but is delayed for several hours, when it can be quite profuse. Mildly to moderately affected calves may be diarrheic for a few days and recover spontaneously with or without treatment. However, 15–20% of calves with enteric colibacillosis become progressively worse over a period of 3–5 days, gradually become more weak, lose the desire to suck and progressively appear more obviously clinically dehydrated.

Throughout the course of the diarrhea the degree of dehydration will vary from just barely detectable clinically (4–6% body weight (BW)) to up to 10–16% of body weight. It is best assessed by 'tenting' the skin of the lateral portion of the cervical region and measuring the time required for the skin fold to return to normal.[56] In calves with 8% of dehydration, 5–10 seconds will be required for the skin fold to return to normal; in 10–12% dehydration up to 30 seconds. Recession of the eyeball (enophthalmos) is a reliable and obvious indication of the degree of dehydration. Slight sinking of the eyeball without an obvious space between the eyeball and the orbit represents 6–8% dehydration; moderate separation of the eyeball from the orbit represents 9–12% dehydration; and marked separation of the eyeball from the orbit represents over 12% and up to 16% dehydration. A summary of the relationship between degree of dehydration (% BW), depth of enophthalmos (mm), cervical skin tent duration in seconds and the state of the mucous membranes and extremities in calves with experimentally induced diarrhea is set out in Table 18.4.[56]

Death usually occurs in 3–5 days. Affected calves can lose 10–16% of their original body weight during the first 24–48 hours of the diarrhea. The hyperkalemia in calves with neonatal diarrhea and acidosis has been associated with cardiac rate and rhythm abnormalities including bradycardia and atrial standstill. Herd outbreaks of the disease in beef calves may last for several weeks, during which time almost every calf will be affected within several days after birth.

Veal calf hemorrhagic enteritis is a fatal syndrome of veal calves charac-

Table 18.4 Degree of dehydration in calves with experimentally induced diarrhea

Degree of dehydration (% BW)	Depth of enophthalmos (mm)	Cervical skin-tent duration (s)	Mucous membranes and extremities
0	None	Less than 2	Moist
2	1	3	Dry
4	2	4	Dry
6	3	5	Dry
8	4	6	Cool extremities
10	6	7	Cool extremities
12	7	> 8	Cool extremities
> 14	> 8	> 10	White mucous membranes

terized by anorexia, fever, diarrhea with mucus-containing feces which become bloody in the later stages, and hemorrhagic diathesis on the conjunctivae and mucous membranes of the mouth and nose. The etiology is unknown; the *E. coli* strains isolated from the feces of affected calves produced enterotoxins and verocytotoxins but their significance is uncertain.

In some calves between 10 and 20 days of age with a history of diarrhea in the previous several days, from which they have recovered, there will be metabolic acidosis without clinical signs of dehydration.[45] Affected calves are depressed, weak, ataxic and sometimes recumbent, and appear comatose. Affected calves respond quickly to treatment with intravenous sodium bicarbonate. A similar syndrome occurs in goat kids.

Lambs and goat kids

Although some cases manifest enteric signs, and chronic cases may occur, colibacillosis in lambs is commonly septicemic and peracute. Two age groups appear to be susceptible: lambs 1–2 days of age and lambs 3–8 weeks old. Peracute cases are found dead without premonitory signs. Acute cases show collapse and occasionally signs of acute meningitis manifested by a stiff gait in the early stages, followed by recumbency with hyperesthesia and tetanic convulsions. Chronic cases are usually manifested by arthritis. The disease in goat kids is similar to that in lambs.

Piglets

Coliform septicemia

This is uncommon but occurs in piglets within 24–48 hours of birth. Some are found dead without any premonitory signs. Usually more than one, and sometimes the entire litter, are affected. Severely affected piglets seen clinically are weak, almost comatose, appear cyanotic, and feel cold and clammy and have a subnormal temperature. Usually there is no diarrhea. The prognosis for these is poor and most will die in spite of therapy.

Enterotoxigenic colibacillosis (newborn piglet diarrhea)

This is the most common form of colibacillosis in piglets and occurs from 12 hours of age up to several days of age, with a peak incidence at 3 days of age. As with the septicemic form, usually more than one pig or the entire litter is affected. The first sign usually noticed is the fecal puddles on the floor. Affected piglets may still nurse in the early stages but gradually lose their appetite as the disease progresses. The feces vary from a pasty to watery consistency and are usually yellow to brown in color. When the diarrhea is profuse and watery there will be no obvious staining of the perineum and hindquarters with feces but the tails of the piglets will be straight and wet. The temperature is usually normal or subnormal. The disease is progressive; diarrhea and dehydration continues, the piglets become very weak and lie in lateral recumbency and make weak paddling movements. Within several hours they appear very dehydrated and shrunken, and commonly die within 24 hours after the onset of signs. In severe outbreaks the entire litter may be affected and die within a few hours of birth. The prognosis is favorable if treatment is started early before significant dehydration and acidosis occur.

CLINICAL PATHOLOGY

Culture and detection of organism

If septicemia is suspected, blood should be submitted for isolation of the organism and determination of its drug sensitivity. Blood for culture is taken aseptically from the jugular vein and inoculated directly into brain–heart infusion broth.[16] At least one additional blood sample is taken a few hours later in order to enhance recovery rate and confirm septicemia.

The **definitive etiological diagnosis of enteric colibacillosis** depends on the isolation and characterization of the *E. coli* from the intestines and the feces of affected animals. The best opportunity of making a diagnosis is when untreated representative affected animals are submitted for pathological and microbiological examination. The distribution of the organism in the intestine and determination of the presence of $K88^+$, $K99^+$ or 987P antigens, the demonstration of enterotoxin by infant mouse test or ligated intestinal loops, and the histopathological appearance of the mucosa all contribute to the diagnosis.

The routine culture of feces and intestinal contents for *E. coli* without determining their virulence determinants is of limited value. The laboratory tests used to identify enterotoxigenic $K99^+$ *E. coli* include a direct fluorescent antibody technique with conventional culturing methods and the ELISA, with or without monoclonal antibody, to detect the organism or the enterotoxin in the feces. DNA gene probes specific for genes encoding enterotoxin and adhesins are available and are being used to evaluate *E. coli* isolated from diarrheic animals. Isolates of the organism can also be examined for the presence of toxins using an enzyme immune assay test and latex agglutination test.

Detection of verocytotoxic *E. coli* in feces has relied on cytotoxicity testing and DNA hybridization. Several ELISAs are available, and monoclonal antibodies to the verocytotoxins VT1 and VT2 have been used to examine feces from animals.[57] The isolation of *E. coli* **O157H:7** has relied on its ability to ferment sorbitol. A sandwich ELISA using monoclonal antibodies to *E. coli* verocytotoxins 1 and 2 for capture and detection is available for detection of verocytotoxin-producing *E. coli* in animal feces.[57] A PCR test is also available for detection of verocytotoxin genes in *E. coli* isolated from cattle, sheep, and pigs affected with diarrhea.[58]

The determination of drug sensitivity of the *E. coli* isolated from the feces of diarrheic calves and piglets is commonly done but is of limited value without determining which isolate is enteropathogenic.

Hematology and serum biochemistry

A total and differential leukocyte count and remarkable changes in the fibrinogen concentration may indicate the presence of a septicemia or severe intestinal infection.[16] However, severely affected calves may not have grossly abnormal hemograms. In enteric disease, the major changes in plasma composition are dehydration, electrolyte imbalance, and acidosis. The total plasma osmolality is decreased.

The changes in the blood biochemical and hematological profile of normal neonatal calves with age have been described.[59] The packed cell volume and the total solids concentration of the blood will indicate the degree of dehydration, and the blood urea nitrogen may be increased in severe cases because of inadequate renal perfusion. The blood bicarbonate values are markedly reduced, blood pH values represent acidosis, and the other serum electrolytes are variable. Calves with a venous blood pH below 7.0 are at high risk and require immediate parenteral therapy for acidosis. There is usually a decrease in serum sodium, chloride, and potassium. In severe cases of acidosis, hyperkalemia may occur; this is cardiotoxic and affected calves may die while being handled in preparation for intravenous therapy.

Harleco apparatus

The acid–base status of individual calves can be determined in the field using a simple total carbon dioxide apparatus, which provides values close to blood bicarbonate concentrations.[60] Unlike the blood gas machines, the Harleco apparatus offers clinicians in practice an affordable means of diagnosing metabolic acidosis.[61] The Harleco measures 'total carbon dioxide', the carbon dioxide liberated from a blood sample by adding strong acid. Nearly all the carbon dioxide is derived from bicarbonate rather than blood carbon dioxide. The CO_2 liberated is derived from bicarbonate and from dissolved CO_2, but there is so little dissolved CO_2 in blood that the TCO_2 may

be taken for clinical purposes as a measurement of plasma bicarbonate. The level of acidosis in calves can be classified according to the Harleco readings (total carbon dioxide, mmol/L) as follows:

Normal	21.1–28
Mild	16.6–21
Moderate	12.1–16.5
Severe	8.1–12.0
Very severe	< 8.

The strong ion difference method of evaluating acid–base balance in cattle has been described and justified to identify the mechanism for a change in acid–base balance and thereby to focus treatment on the inciting cause, and to quantify unmeasured strong anion concentration in plasma.[62] A comparison of the measurement of total carbon dioxide and strong ion difference (SID) for the evaluation of metabolic acidosis in calves did not find any advantage to the SID.[61]

Portable pH meter

A portal pH meter has been evaluated to measure blood pH in neonatal calves.[63] Compared to a blood gas analyzer, the portable pH meter was more accurate in measuring urine pH and ruminal fluid pH in cows than blood pH in neonatal calves.

Serum immunoglobulins

The determination of the level of serum immunoglobulins of diarrheic calves may be valuable in assessing prognosis and to determine the intensity of the therapy required for survival. However, the level of serum immunoglobulins as a measure of susceptibility or prognosis is most accurate at 24 hours after birth. After this period, it is unreliable because the serum immunoglobulins may be increased in response to septicemia, increased spuriously in dehydration and decreased in enteric disease.

Several tests are available to assess transfer of passive immunity status in domestic animals.[8] The radial immunodiffusion test and the ELISA are the only tests that directly measure serum IgG concentration. All other available tests, including serum total solids by refractometry, sodium sulfite turbidity tests, zinc sulfate turbidity tests, serum gamma-glutamyl transferase (GGT) and whole-blood glutaraldehyde coagulation, estimate serum IgG concentration based on concentration of total globulins or other proteins whose transfer is statistically associated with that of IgG.

Radial immunodiffusion

The radial immunodiffusion is the gold standard for measurement of serum IgG concentration. However, it is too expensive for most situations and requires considerable time before results are available.

Commercial immunoassay

An immunoassay using blood is now available for evaluating transfer of passive immunity in calves.[64] The whole blood immunoassay kit consists of a 4 mm lateral flow membrane strip enclosed in a plastic test device. Test kits are incubated for 20 minutes. If the sample IgG concentration is 10 mg/mL or more, a single red line develops, indicating adequate transfer of passive immunity and a negative test result. If the sample IgG concentration is <10 mg/mL, two lines develop on the membrane slip, indicating failure of transfer of passive immunity and a positive test. The sensitivity and specificity of the blood IgG immunoassay were 0.93 and 0.88 respectively, compared with 1.00 and 0.53 for the sodium sulfite test. For refractometry, sensitivity and specificity were 0.71 and 0.83 respectively, when a serum total solids concentration of 5.2 g/dL was used as the cutoff between positive and negative results.

Serum total solid concentration by refractometer

The measurement of serum total protein by refractometer is an estimate of serum immunoglobulin concentration.[65] Recommended test endpoints for serum protein concentrations have varied from 5.0–6.0 g/dL. Three refractometers, including a non-temperature-compensating instrument, provided similar results. Serum protein concentration test endpoints of 5.0 and 5.2 g/dL gave accurate results in the assessment of adequacy of transfer of passive immunity; lower or higher test endpoints misclassified large numbers of calves. The test is excellent for herd monitoring and is easily performed in the field. In clinically ill dehydrated calves, a test endpoint of 5.5 g/dL should be used when assessing adequacy of transfer of passive immunity.[66] In a healthy, adequately hydrated calf a serum total protein of 5.2 g/dL or greater is associated with adequate transfer of passive immunity.[8]

The mortality risk associated with inadequate transfer of passive immunity in dairy calves can be partitioned using the observed population mortality and the relative risk of mortality in each serum protein concentration stratum.[67] For a total of 3479 calves studied, 8.2% died before 16 weeks of age. The population baseline mortality rate was 5.0% and the mortality rate due to inadequate transfer of passive immunity was 3.2%. Thirty-nine percent of the observed mortality was attributed to inadequate transfer of passive immunity. Such partitioning of risk between sources related and unrelated to transfer of passive immunity can be useful in conducting investigations of calf mortality in dairy herds.

Sodium sulfite turbidity test

The sodium sulfite turbidity test is a three-step semiquantitative test using 1, 4, 16, and 18% sodium sulfite test solutions. The solutions cause selective precipitation of high-molecular-weight proteins, including immunoglobulins. Optimum diagnostic utility is attained using a 18% test solution. The mean serum IgG concentrations of calves at the 1+, 2+, and 3+ endpoints of test turbidity were 1250, 2116, and 2948 mg/dL, respectively.[8]

Serum gamma-glutamyl transferase activity

The serum levels of GGT are also reliable indicators of the level of transfer of passive immunity in newborn calves.[68] Calves classified as having failure of transfer of passive immunity (< 800 mg IgG/dL) had a 9.5 times greater risk of becoming sick prior to weaning at 5 months of age compared with calves determined to have partial failure of transfer of passive immunity and clinically normal calves. In 1-day-old calves, serum GGT activity should be more than 200 IU/L; in 4-day-old calves it should be more than 100 IU/L and in 1-week-old calves more than 75 IU/L. Calves with GGT activity below 50 IU/L within the first 2 weeks of life should be considered to have failure of transfer of passive immunity. The sensitivity and specificity of cutoff value of 200 IU of GGT of serum for a diagnosis of failure of transfer of passive immunity are 80% and 97%, respectively. The sensitivity and specificity of a cutoff value of 4.2 g of protein/dL of serum for diagnosing failure of transfer of passive immunity were 80% and 100%, respectively.[68]

Recent studies have shown that GGT activity has no apparent advantage relative to other tests for predicting transfer of passive immunity in beef calves [8]

The relationships between serum and colostrum/milk GGT activities and IgG concentration can be used to assess the transfer of passive immunity status of lambs.[69] Regression models were used to calculate serum and colostrum/milk GGT activities, and it was moderately accurate in predicting serum IgG concentration. The GGT activity can be used as an alternative to single radial immunodiffusion, which is complex, expensive, and time-consuming for estimation of IgG concentration.

NECROPSY FINDINGS

In **coliform septicemia** there may be no gross lesions and the diagnosis may depend upon the isolation of the organism from the filtering organs. In less severe cases there may be subserosal and submucosal hemorrhages. A degree of enteritis and gastritis may be present. Occasionally, fibrinous exudates are found

in the joints and serous cavities, and there may be omphalophlebitis, pneumonia, and meningitis. The histological features of such presentations of colibacillosis are those of septicemia and toxemia.

In **enteric colibacillosis** of piglets and calves the carcass appears dehydrated but the intestine is flaccid and fluid-filled. In calves, the abomasum is usually distended with fluid and may contain a milk clot. This clot is typically absent in calves fed milk replacers containing heat-denatured skim milk powder or noncasein milk products such as whey powder. The abomasal mucosa may contain numerous small hemorrhages. In both calves and pigs, the intestinal mucosae may appear normal or hyperemic and there may be edema of the mesenteric lymph nodes. Mild atrophy or even fusion of jejunal and ileal villi is often seen, but the key microscopic observation is the presence of bacilli adherent to the brush borders of enterocytes. Ultrastructurally, there is increased epithelial cell loss from the villus about 12 hours after experimental inoculation of calves with an enterotoxigenic *E. coli*.

In calves affected with attaching and effacing *E. coli* there is pseudomembranous ileitis as well as mucohemorrhagic colitis and proctitis. Microscopic examination of well-preserved gut segments reveals bacterial adherence, atrophy of ileal villi, and erosion of enterocytes.

In addition to traditional bacteriological culture techniques, the enterotoxigenic *E. coli* may be identified by several tests, including indirect fluorescent antibody tests (IFA) specific for $K88^+$, $K99^+$, and 987P pilus antigens. The IFA tests can be perfonned on impression smears or frozen sections of ileal tissue and the results are available within a few hours. Newer techniques such as DNA gene probes,[12] enzyme immune assays and latex agglutination tests are now available to identify those isolates that are enterotoxin producers and have adhesin properties.

During severe disease outbreaks it is often necessary to conduct the necropsy examination on diarrheic animals that have been killed specifically for the purpose of obtaining a definitive etiological diagnosis. The combined use of bacteriological, parasitological, and virological methods, together with histological and immunofluorescent studies of fresh intestinal tissue, will provide the most useful information about the location of the lesions and the presence of enteropathogens. Postmortem autolysis of the intestinal mucosae and invasion of the tissues by intestinal microflora occurs within minutes after death, so gut samples should be collected immediately following euthanasia of the animal.

Samples for confirmation of diagnosis

Coliform septicemia

- Bacteriology – chilled spleen, lung, liver, culture swabs of exudates, umbilicus, meninges (CULT)
- Histology – fixed samples spleen, lung, liver, kidney, brain, and any gross lesions.

Enteric colibacillosis

- Bacteriology – chilled segments of ileum and colon (including content) (CULT and/or FAT, latex agglutination, PCR)
- Histology – fixed duodenum, jejunum, ileum, colon, and mesenteric lymph node.

DIFFERENTIAL DIAGNOSIS

The definitive etiological diagnosis of septicemic colibacillosis is dependent on the laboratory isolation of the causative agent, which is usually a single species or organism. The septicemias of the newborn cannot be distinguished from each other clinically. The definitive etiological diagnosis of enteric colibacillosis in newborn calves and piglets may be difficult and often inconclusive because the significance of other organisms in the intestinal tract and feces of diarrheic animals cannot be easily determined.

Table 18.3 lists the possible causative agents of diarrhea and septicemia in newborn farm animals. Using the combined diagnostic approach of detection of enteropathogens in the feces before death, and in the intestinal mucosa after death, it is possible to identify where enterotoxigenic *E. coli*, rotavirus, coronavirus, *Salmonella* sp., and *Cryptosporidium* sp. appear to be the only or principal causative agents. However, as described earlier under acute undifferentiated diarrhea of newborn farm animals, mixed infections are more common than single infections.

Every effort that is economically possible should be made to obtain an etiological diagnosis. This is especially important when outbreaks of diarrhea occur in a herd or where the disease appears to be endemic. The use of an interdisciplinary approach will increase the success of diagnosis. This includes making a visit to the farm or herd and making a detailed epidemiological investigation of the problem. The diagnosis depends heavily on the epidemiological findings, the microbiological and pathological findings, and sometimes on the results of treatment.

The major difficulty is to determine whether or not the diarrhea is infectious in origin and to differentiate it from dietetic diarrhea, which is most common in hand-fed calves and in all newborn species that are sucking high-producing dams. In dietetic diarrhea the feces are voluminous and pasty to gelatinous in consistency; the animal is bright and alert and is usually still sucking, but some may be inappetent.

TREATMENT

Coliform septicemia

Intensive critical care is required for the treatment of neonatal coliform septicemia. Early identification of septicemia and early therapeutic intervention can improve treatment success. While *E. coli* may be cultured from the blood of septicemic calves, a significant percentage of isolates are Gram-positive, which justifies the use of antimicrobials that have a broad spectrum.[16] Antimicrobials are given parenterally and may be given continuously intravenously, more than once daily and daily until recovery is apparent. Isolation of the organisms from blood and determination of drug sensitivity is the ideal protocol. Intravenous fluid and electrolyte therapy are administered continuously until recovery is apparent. Whole blood transfusions are used in calves and foals, especially when immunoglobulin deficiency is suspected from the history or is determined by measurement of serum immunoglobulins of blood (see Chapter 3 for details on measuring immunoglobulins using various tests). In one series on neonatal septicemia in calves, in which *E. coli* accounted for 50% of the bacterial isolates, the survival rate was only 12%.[16]

Enteric colibacillosis

The considerations for treatment of enteric colibacillosis include the following:

- Fluid and electrolyte replacement
- Antimicrobial and immunoglobulin therapy
- Antimotility drugs and intestinal protectants
- Alteration of the diet
- Clinical management of outbreaks.

Fluid and electrolyte replacement

The dehydration, acidosis and electrolyte imbalance are corrected by the parenteral and oral use of simple or balanced electrolyte solutions. The provision of fluid therapy in diarrheic dehydrated calves under field conditions in veterinary practice has been described.[68] It is important to obtain an adequate history of the case including age of the calf, duration of the diarrhea and all treatments already given by the owner. The physical examination of the calf includes a standard clinical examination with emphasis on evaluating the degree of dehydration and acidosis.

Dehydration is evaluated by two clinical observations:

- **Skin elasticity**. The skin of the middle of the neck is better than the eyelid. A portion of the skin is tented and twisted for 1 second, and then the time to return to the initial position is measured – less than 2 seconds in the normal calf, 6 seconds in moderate (8%)

dehydration and more than 8 seconds in severe (12%) dehydration

- **Position of eyeball in the orbit and extent of enophthalmos**. This is determined by measuring the distance between the globe and the orbit. The eyeball is not sunken in healthy calves. Degrees of dehydration of 4%, 8, and 12% are represented by a 2 mm, 4 mm, and 7 mm enophthalmos, respectively.

Acidosis can be evaluated using the clinical findings of mental status, muscular tone, ability to stand, intensity of the sucking reflex, temperature of the inside of the oral cavity, and age of the calf that correlate with an estimate of the **base deficit**. The following categories for diarrheic calves are being used under field conditions:

1. Calves with good muscular tone and the ability to stand, strong suck reflex and warm oral cavity have no base deficit if younger than 8 days of age, and up to 5 mEq/L if older than 5 days
2. Calves that can stand, have a slightly cool oral cavity and weak suck reflex have a base deficit of 5 mEq/L if under 8 days of age and 10 mEq/L if older than 8 days
3. Calves in sternal recumbency with a cool oral cavity and no suck reflex have a base deficit of 10 mEq/L if under 8 days of age and 15 mEq/L if older than 8 days
4. Calves in lateral recumbency that lack a suck reflex and have a cold oral cavity have a base deficit of 10 mEq/L if under 8 days of age and 20 mEq/L if older than 8 days.

Categorizing diarrheic calves into treatment groups

Based on the history and clinical findings, affected calves can be divided into categories according to the type of therapy required and which is most economical.

1. **Oral fluid therapy**. Calves with a history of acute diarrhea, less than 7% dehydrated, slightly dry oral mucosa, good suck reflex, good muscle tone, alert, able to stand and warm mouth. These can be treated with oral fluids and electrolytes
2. **Oral fluid therapy and hypertonic saline**. Calves with 7–9% dehydration and slight acidosis, weak suck reflex, good muscular tone, warm mouth. Administer hypertonic saline (7.5% NaCl) intravenously at 3–4 mL/kg BW in 5 minutes. Administer oral fluids and electrolytes by stomach tube at 40–60 mL/kg BW. Re-evaluate in 6–8 hours
3. **Intravenous fluid therapy with alkalinizing agents**. Calves are more than 9% dehydrated, dry and cool oral mucous membranes, recumbent, no suck reflex, very depressed. Provide intravenous replacement and maintenance fluid and electrolyte therapy for a period of 6–8 hours and up to 24–36 hours if necessary.

The details for parenteral and oral fluid and electrolyte therapy are described here.

Parenteral fluid and electrolyte therapy

In severe dehydration and acidosis, solutions containing the bicarbonate ion are indicated.

Parenteral fluid composition

An equal mixture of isotonic saline (0.85%), isotonic sodium bicarbonate (1.3%), and isotonic dextrose (5%) is a simple, effective solution for parenteral use. Sodium bicarbonate as an alkalinizing compound in the parenteral fluids is superior to the use of compounds such as sodium acetate or sodium lactate, which must be metabolized by the liver, myocardium, and other tissues in order to have an alkalinizing effect. The simple replacement of fluid losses using saline or fluids without alkalinizing compounds is likewise not as effective as sodium bicarbonate. Many commercial preparations are effective in correcting the dehydration and electrolyte imbalances, but only those containing bicarbonate or its precursors are effective in correcting the metabolic acidosis.[45]

Bicarbonate requirements to treat acidosis

The bicarbonate requirements (mmol) are calculated using the equation:

weight (kg) × base deficit (mmol/L) × 0.6 (extracelluiar fluid space).

The base deficit will range from –5 to –20 mmol/L with an average of about –15 mmol/L. The bicarbonate requirements for a 45 kg calf with a base deficit of 15 mmol/L, are 45 × 15 × 0.6 = 405 mmol, which requires 33.75 g of sodium bicarbonate (1 g of sodium bicarbonate yields 12 mmol of bicarbonate), which can be delivered in 2.5 L of 1.3% isotonic solution. Diarrheic calves over 8 days of age may be nearly twice as acidotic as younger calves and will require more bicarbonate to correct the acidosis. It is estimated that sternally recumbent calves under 8 days of age require 1 L of isotonic sodium bicarbonate to correct the acidosis, in addition to the necessary amounts of saline to correct the dehydration; for calves over 8 days of age, 2 L of isotonic sodium bicarbonate is necessary. For laterally recumbent diarrheic calves under and over 8 days of age, 1 and 3 L, respectively, is required. Isotonic sodium bicarbonate is a safe solution intravenously; when the degree of acidosis is uncertain, up to several liters can be used safely for the correction of acidosis and volume depletion.

For severe dehydration (10–12% BW) fluids should be replaced as follows: hydration therapy 100 mL/kg BW intravenously in the first 1–2 hours at the rate of 50–80 mL/kg BW per hour followed by maintenance therapy at 140 mL/kg BW over the next 8–10 hours at the rate of about 20 mL/kg BW per hour. For example, a 45 kg calf that is 10% dehydrated should receive 4.5 L of fluid in the first 1–2 hours as hydration therapy, followed by 6–8 L of fluid over the next 8–10 hours. Initially, both the acidosis and the dehydration can be treated by the use of isotonic sodium bicarbonate followed by the use of a combined mixture of isotonic saline and isotonic sodium bicarbonate or multiple electrolyte solutions for maintenance therapy. For moderate dehydration (6–8% of BW), fluids should be replaced as follows: hydration therapy 50 mL/kg BW intravenously in the first 1–2 hours at the rate of 50–80 mL/kg BW per hour followed by maintenance therapy as described above.

Maintenance therapy may be provided using oral fluids and electrolytes if the calf is well enough to suck from a nipple bottle or drink from a pail. The use of solutions containing potassium chloride is sometimes recommended, on the basis that total potassium stores may be depleted in severely affected calves. However, they should be used with caution because a severe hyperkalemia may be present when there is a severe acidosis. If the acidosis and hypoglycemia are corrected with glucose and bicarbonate, the administration of potassium may be beneficial in restoring total potassium stores. However, solutions containing potassium can be cardiotoxic, especially if renal function is not restored.

Hyperkalemia in the diarrheic calf

Treatment of the acidosis and expanding plasma volume and increasing the serum sodium concentration will correct hyperkalemia in dehydrated diarrheic calves.

Hypernatremia in the diarrheic calf

The treatment of hypernatremia is difficult and unreliable.[46] If there is a concurrent acidosis it should be treated with a bicarbonate solution. The objective is to decrease serum sodium concentration more slowly than is possible with traditional isotonic fluids. It is recommended that a sodium-containing fluid containing sodium equal to 95–100% of the animal's serum sodium concentration, or with a fluid containing 170 mEq/L of sodium, be used initially.[47] The animal's serum sodium concentration is monitored so as not to

exceed a change of 0.3–0.5 mEq/h in serum sodium. Cerebral edema may be treated with mannitol.

Acidosis without dehydration

Some calves 10–20 days of age with a history of diarrhea in the previous several days may be affected with metabolic acidosis without obvious clinical evidence of dehydration.[45] They are ataxic, weak, sometimes recumbent, and may appear comatose. The intravenous administration of 2–3 L of isotonic (1.3%) sodium bicarbonate results in recovery within an hour.

Hypertonic saline

Because the administration of large quantities of isotonic fluids may be impractical in a farm situation because it requires long-term venous catheterization, appropriate restraint and periodic monitoring, the use of hypertonic saline has been explored as a rapid, inexpensive, effective method of fluid administration in severely dehydrated calves.[68,70] Hypertonic saline (7.2% NaCl) solution and 6% Dextran 70 solution have been used successfully to resuscitate animals with hypovolemic endotoxemic shock. Administration of 7.2% hypertonic saline and 6% Dextran 70 solution rapidly increases plasma volume, cardiac output and mean arterial pressure in hypovolemic and endotoxemic shock.[69] The hypertonic saline and Dextran 70 are given intravenously at a rate of 4–5 mL/kg BW over a period of 4 minutes followed by allowing the calf to suck an isotonic alkalinizing oral electrolyte solution at 50 mL/kg BW.[69] Calves that do not suck are given the oral fluids by stomach tube. An additional dose of oral fluids at 50 mL/kg BW is given 12 hours later. This regime provides a rapid, practical, economical and effective method for the treatment of dehydrated diarrheic calves.

Intravenous catheterization of calves

Catheterization of the **jugular vein** is the most widely used approach for continuous long-term intravenous fluid therapy in calves. The jugular vein may be difficult to catheterize in severely dehydrated calves when the vein is collapsed and not visible even after prolonged occlusion. In addition, the tough and dry skin makes catheterization difficult. To increase distension of the vein, calves may be raised by their pelvic limbs, thus increasing blood flow to the head and neck regions. An incision of the skin (a cut-down) makes placement of a catheter easier. A major advantage of jugular vein catheterization is the more rapid flow rate that is possible because 14-gauge catheters are commonly used.

Catheterization of the **auricular veins** in calves is becoming common, especially in Europe.[71] Even in severely dehydrated calves, ear vein catheterization is successful. Ear catheters allow the application of sufficient amounts of fluids by continuous drip infusion and there are fewer complications compared to jugular vein catheters. In vitro flow rates for 22-gauge catheters range between 28 and 36 mL/min, providing an in vivo flow rate into the calf's ear catheter of approximately 1.2–2.2 L/h.

Oral fluid and electrolyte therapy

Oral fluid and electrolyte therapy are indicated for calves in the early stages of diarrhea or after they have been successfully hydrated following parenteral fluid therapy. Severely dehydrated or moribund calves may not respond favorably to oral fluid therapy alone. Owners must be encouraged to provide oral fluid and electrolyte therapy to diarrheic neonatal farm animals as soon as possible after the onset of diarrhea. Almost all the information available on oral fluids has been developed following clinical studies in diarrheic calves, and the recommendations here reflect those studies.[72]

In neonatal calves, the ideal oral electrolyte solution should: (a) supply sufficient sodium to facilitate normalization of extracellular fluid deficits; (b) provide two or more agents (such as glucose, acetate, propionate, or glycine) that facilitate intestinal absorption of sodium and water; (c) provide an alkalinizing agent (such as acetate, propionate, citrate, or bicarbonate) to treat the metabolic acidosis often present in dehydrated diarrheic calves; (d) not interfere with milk clotting in the abomasum; (e) provide sufficient energy, as these electrolyte solutions may be administered instead of milk or milk replacer for short periods of time; and (f) facilitate repair of damaged intestinal epithelium.[73]

Acetate and propionate are the preferred alkalinizing agents for treating dehydrated calves with mild metabolic acidosis. Acetate and propionate have similar alkalinizing ability to bicarbonate on an equimolar basis, with the advantage that acetate and propionate produce energy. Acetate and propionate also stimulate sodium and water absorption in the calf small intestine, but in the jejunum to a greater extent than the ileum. Acetate and propionate are readily metabolized by both fed and fasted calves. Moreover, acetate and propionate are metabolized by peripheral tissues, are not produced endogenously in shock and dehydration (as is lactate) and do not have an unmetabolized isomer (D-lactate). Finally, acetate and propionate do not alkalinize the abomasum and intestine, whereas bicarbonate can permit bacteria to proliferate in an alkalinized abomasum, while also inhibiting the normal clotting of milk.

The ideal electrolyte concentration, osmolarity and energy source for an oral electrolyte solution to treat neonatal calf diarrhea remain controversial. The optimal solution should have a sodium concentration between 60 and 120 mmol/L, a potassium concentration between 10 and 20 mmol/L, a chloride concentration between 40 and 80 mmol/L, 40–80 mmol/L of metabolizable (nonbicarbonate) base, such as acetate or propionate, and glucose as an energy source. Some investigators have suggested that the optimal oral electrolyte solution required a higher sodium concentration (120–133 mmol/L) to rapidly correct extracellular electrolyte and fluid losses that typically develop in calves with diarrhea and dehydration. Combined administration of sodium and glucose is beneficial because glucose facilitates sodium absorption via the small intestinal sodium/glucose co-transport mechanism.

Oral fluid and electrolyte therapy is effective in enteric colibacillosis of neonatal farm animals because glucose continues to be absorbed by the small intestine by an active transport mechanism accompanied by glucose-coupled sodium absorption and absorption of water. In enterotoxigenic colibacillosis, while there is net hypersecretion caused by the enterotoxin, the intestinal mucosa is sufficiently intact so that water and sodium will be absorbed in the presence of glucose. Most oral electrolytes intended for the treatment of dehydration and acidosis in diarrheic calves contain sodium chloride and sodium bicarbonate with one or some of the following substances: glucose, acetates and citrates, phosphates, potassium salts, glycine and amino acids.

Several commercial oral preparations are available. The ideal solutions should be palatable and provide rapid rehydration and correction of acidosis. Diarrheic calves must receive sufficient fluid therapy to compensate for the fluid and electrolyte losses that occur and for maintenance and contemporary losses during the period of clinical diarrhea and convalescence. However, the calf must be returned to a milk diet within a few days in order to avoid the effects of malnutrition. Oral fluid and electrolyte formulas cannot provide the daily maintenance requirements of energy, protein, and fat. Some formulas contain a large quantity of glucose and are supplemented with glycine, sodium acetate, and citric acid, thus making a calorie-dense, partially nitrogen-balanced hyperosmolal solution. A glutamine-containing oral rehydration solution for the treatment of experimental *E. coli* calf diarrhea was more effective in correcting and sustaining plasma, extracellular fluid, and blood volume compared

with standard World Health Organization solutions without the glutamine.[74]

There are marked variations in the alkalinizing abilities of the oral electrolyte solutions that are available commercially.[72] Those that contain at least 80 mmol/L of bicarbonate are much more effective for the rapid correction of acidosis and depression in diarrheic calves than administration of rehydrating electrolyte solutions alone. The bicarbonate-rich preparations have the best alkalinizing response when given to calves affected with acidosis from experimentally induced diarrhea. Oral electrolyte solutions containing acid phosphate salts are undesirable because they cause net acidification of the blood, with a fall in blood pH. One possible theoretical disadvantage of an alkaline electrolyte solution (containing sodium bicarbonate) is that it may prolong the clotting of milk by rennin in the abomasum, which could cause maldigestion and prolong the diarrhea, especially if the oral fluids and electrolytes are diluted 1:1 with whole milk.

Several commercially available oral electrolyte solutions contain metabolizable bases such as acetate instead of bicarbonate and are formulated to correct and maintain acid–base imbalance and maintain normal milk digestion.[72] Those preparations that contain either bicarbonate or acetate provide good therapeutic results and have been evaluated in experimentally induced diarrheic calves, which were also offered milk at the rate of 5% of their body weight twice daily.[72] Offering milk along with the oral electrolytes is effective in maintaining body weight in experimental calves. No scientific information is available on the effects of milk and oral electrolytes in naturally occurring cases. Those preparations not containing any alkalinizing agent do not correct the acid–base imbalance and result in poor recovery rates in experimental calves.

Ideally, the oral fluids and electrolytes should not be mixed with milk but fed or offered between feedings of milk. The oral fluids should be given by nipple bottle if the animal will suck but the use of a stomach tube or esophageal feeder is satisfactory. Fluids can be administered to the dehydrated calf using an esophageal feeder, even though the reticular groove does not close. At least 2 L of fluid should be given, which results in a transfer of fluids from the rumen to the abomasum. If larger doses are required they should be divided and given at intervals of 2 hours or more to avoid abdominal discomfort from distension.

Fecal consistency is not a highly reliable criterion of success in the evaluation of oral fluid therapy for calf diarrhea. Calves with the greatest improvement in fecal consistency had no greater increase in plasma volume than calves that did not improve their fecal consistency. Thus improvement of the feces may not offer a reliable guide to the rehydration of the calf.

Response to therapy

Calves that respond and recover usually show marked improvement from intravenous and/or oral fluid therapy within 24–36 hours. Calves that respond to the hydration therapy begin to urinate within an hour after fluid administration is begun, and usually maintain hydration thereafter. Calves that do not respond will not hydrate normally; they may not begin to urinate because of irreversible renal failure, their feces remain watery, they remain depressed and not strong enough to suck or drink, and continued fluid therapy beyond 3 days is usually futile. Those calves that respond favorably to the initial fluid therapy and then become depressed 12–18 hours later may have returned to a state of metabolic acidosis. Mental depression, the loss of the suck reflex and muscular weakness are indications of acidosis, and affected calves will require retreatment with sodium bicarbonate.

Overhydration and overinfusion at too rapid an administration rate increases intravascular pressure, resulting in pulmonary edema characterized by hyperpnea, tachypnea, tachycardia, and death.

Antimicrobial therapy

Antimicrobials have been used extensively for the specific treatment of colibacillosis in calves and piglets because it was assumed that an infectious enteritis was present that had the potential of developing into a bacteremia or septicemia. Some preparations consist of a single antimicrobial, while others are mixtures with or without absorbents, astringents, and electrolytes. They have been used on an empirical basis, since few randomized controlled trials have been conducted.

It has been difficult to evaluate the efficacy of antimicrobials for the treatment of enteric colibacillosis because of the complex nature of the interactive factors that affect the outcome in naturally occurring cases. These include the presence of mixed infections, the effects of whether or not milk is withheld from the diarrheic calves, the effects of the immune status of individual calves, the variable times after the onset of diarrhea when the drugs are given, the possible presence of antimicrobial resistance, and the effects of supportive treatment such as electrolyte and fluid therapy.

The literature on the use of antimicrobials in the treatment of calf diarrhea has been critically reviewed by Constable[75] and the following discussion strongly reflects his review and his evidence-based recommendations for the use of antimicrobials to treat calf diarrhea.

Change in small intestinal bacterial flora in calves with diarrhea

There has been a paradigm shift in the last 40 years towards categorizing an episode of calf diarrhea as being due to a specific etiologic agent, such as rotavirus, coronavirus, cryptosporidia, *Salmonella* spp., or enterotoxigenic *E. coli*. While the etiologic approach has correctly focused attention on preventive programs, including vaccination and optimizing transfer of colostral immunity, the approach has diverted attention from the universal finding of all studies, that calves with diarrhea have coliform bacterial overgrowth of the small intestine.[75]

Studies completed more than 70 years ago documented increased numbers of *E. coli* bacteria in the abomasum, duodenum, and jejunum of scouring calves. Moreover, calves severely affected with diarrhea had increased numbers of *E. coli* bacteria in the anterior portion of their intestinal tracts compared to mildly affected animals. More recent studies have consistently documented the fact that calves with naturally acquired diarrhea, regardless of age and the etiological cause for the diarrhea, have altered small intestinal bacterial flora. Specifically, *E. coli* bacterial numbers are increased 5–10 000-fold in the duodenum, jejunum, and ileum of calves with naturally acquired diarrhea, even when the diarrhea was not due to enterotoxigenic strains of *E. coli*, and where rotavirus and coronavirus were identified in the feces. The largest increase in *E. coli* bacterial numbers occurs in the distal jejunum and ileum, whereas the *E. coli* or coliform bacterial numbers in the colon and feces are similar or higher for calves with diarrhea than calves without diarrhea, with *E. coli* being more numerous in the feces of colostrum-deprived than colostrum-fed calves. Small intestinal overgrowth with coliform bacteria can persist after departure of the initiating enteric pathogen.

In calves with naturally acquired diarrhea, increased small-intestinal colonization with *E. coli* has been associated with impaired glucose, xylose, and fat absorption.

Mixed infections with enteric pathogens are commonly diagnosed in calves with naturally acquired diarrhea, and the clinical signs and pathological damage associated with rotavirus infection are more severe when *E. coli* is present than when it is absent. Primary viral morphologic damage to the small intestine also facilitates systemic invasion by normal intestinal flora, including *E. coli*.

In calves with experimentally induced enterotoxigenic *E. coli* diarrhea, colonization of the small intestine by *E. coli* has been associated with impaired glucose and lactose absorption, decreased serum glucose concentration and possibly increased susceptibility to cryptosporidial infection.

In summary, calves with diarrhea have increased coliform bacterial numbers in the small intestine, regardless of etiology, and this colonization is associated with altered small-intestinal function, morphological damage, and increased susceptibility to bacteremia. It therefore follows that administration of antimicrobials that decrease small intestinal coliform bacterial numbers in calves with diarrhea may prevent the development of bacteremia, decrease mortality, and decrease morphological damage to the small intestine, thereby facilitating digestion and absorption and increasing growth rate.

Incidence of bacteremia in calves with diarrhea

Calves with diarrhea are more likely to have failure of transfer of passive immunity or partial failure of transfer of passive immunity, and this group of calves, in turn, is more likely to be bacteremic. This is an additional reason that antimicrobials may be indicated in the treatment of calf diarrhea. Colostrum-deprived calves that subsequently developed diarrhea were frequently bacteremic, whereas bacteremia occurred much less frequently in colostrum-fed calves that developed diarrhea.

Based on field studies of diarrheic calves, it can be assumed that, on average, 30% of severely ill calves with diarrhea are bacteremic, that the risk of bacteremia is higher in calves with failure of transfer of passive immunity than in calves with adequate transfer of passive immunity, and that the risk of bacteremia is higher in calves 5 days of age or older. The frequency of bacteremia is sufficiently high that treatment of calves with diarrhea that are severely ill (as manifest by reduced suck reflex, > 6% dehydration, weakness, inability to stand or clinical depression) should include routine treatment against bacteremia, with emphasis on treating potential *E. coli* bacteremia. Veterinarians should also assume that 8–18% of diarrheic calves with adequate transfer of passive immunity and systemic illness are bacteremic. The prevalence of bacteremia is sufficiently high in systemically ill calves that effective antimicrobial treatment for potential bacteremia should be routinely instituted, regardless of transfer of passive immunity status and treatment cost. Withholding an effective treatment for a life-threatening condition, such as bacteremia in calves with diarrhea, cannot be condoned on animal welfare grounds.

Antimicrobial susceptibility of fecal *Escherichia coli* isolates

The most important determinant of antimicrobial efficacy in calf diarrhea is obtaining an effective antimicrobial concentration against bacteria at the sites of infection (small intestine and blood). The results of fecal antimicrobial susceptibility testing have traditionally been used to guide treatment decisions; however, susceptibility testing in calf diarrhea probably has clinical relevance only when applied to fecal isolates of enterotoxigenic strains of *E. coli* or pathogenic *Salmonella* spp., and blood culture isolates from calves with bacteremia. Validation of susceptibility testing as being predictive of treatment outcome for calves with diarrhea is currently lacking.

The ability of fecal bacterial culture and antimicrobial susceptibility testing using the Kirby Bauer technique to guide treatment in calf diarrhea is questionable when applied to fecal *E. coli* isolates that have not been identified as enterotoxigenic.[75] There do not appear to be any data demonstrating that fecal bacterial flora is representative of the bacterial flora of the small intestine, which is the physiologically important site of infection in calf diarrhea. Marked changes in small-intestinal bacterial populations can occur without changes in fecal bacterial populations, and the predominant strain of *E. coli* in the feces of a diarrheic calf can change several times during the diarrhea episode. Furthermore, and most importantly, 45% of calves with diarrhea had different strains of *E. coli* isolated from the upper and lower small intestine, indicating that fecal *E. coli* strains are not always representative of small-intestinal *E. coli* strains.

An additional bias present in most antimicrobial susceptibility studies conducted on fecal *E. coli* isolates is that data are frequently obtained from dead calves, which are likely to be treatment failures. The time since death is also likely to be an important determinant of the value of fecal culture, because such a rapid proliferation of bacteria occurs in the alimentary tract after death that the results of examinations made on dead calves received at the laboratory can have little significance. Calves that die from diarrhea are likely to have received multiple antimicrobial treatments, and preferential growth of antimicrobial-resistant *E. coli* strains starts within 3 hours of antimicrobial administration. A further concern with fecal susceptibility testing is that the Kirby Bauer breakpoints (minimum inhibitory concentration (MIC)) are not based on typical antimicrobial concentrations in the small intestine and blood of calves. What are urgently needed are studies documenting the antimicrobial susceptibility of *E. coli* isolates from the small intestine of untreated calves, based on achievable drug concentrations and dosage regimens. Until these data are available, it appears that antimicrobial efficacy is best evaluated by the clinical response to treatment, rather than the results of in vitro antimicrobial susceptibility testing performed on fecal *E. coli* isolates.

A comparison of antibiotic resistance for *E. coli* populations isolated from groups of diarrheic and control calves in the UK found a higher incidence of antibiotic-resistant *E. coli* in samples obtained from farms with calf diarrhea than from farms without the disease.[76] Considering all samples, bacterial colonies in 84% were resistant to ampicillin, in 13% to apramycin and in 6% to nalidixic acid. Antibiotic resistance among enterotoxigenic *E. coli* from piglets and calves with diarrhea in a diagnostic laboratory survey of one geographic area in Canada over a 13-year period found that least resistance occurred against ceftiofur for all, followed by apramycin and gentamicin for porcine and florfenicol for bovine isolates.[77]

Passive surveillance for antimicrobial resistance in *E. coli* isolates from diarrheic food animals continues to indicate that resistance to many of the common antimicrobials is increasing. In a UK study over a 5-year period, *E. coli* isolates from calves with diarrhea become more resistant to furazolidone, trimethoprim-potentiated sulfonamide, clavulanic-acid-potentiated amoxicillin, and tetracycline.[78] *E. coli* strains from outbreaks of diarrhea in lambs in Spain became increasingly resistant to nalidixic acid, enoxacin, and enrofloxacin on the basis of the National Committee on Clinical Laboratory Standards (NCCL) breakpoints for human and animal isolates.[79,80] Among the fluoroquinolones used for treatment of domestic animals in Spain, enrofloxacin is approved for use for the treatment of colibacillosis and diarrhea in lambs. However, the bovine and ovine strains of *E. coli* that possess potential virulence factors were more sensitive to quinolones than those that do not express those factors. Some antimicrobial-resistant *E. coli* strains from diarrheic calves in the USA may possess a chromosomal *flo* gene that specifies cross-resistance to both florfenicol and chloramphenicol, and its presence among *E. coli* isolates of diverse genetic backgrounds indicates a distribution much wider than previously thought.[81] In Spain, 5.9% of *E. coli* strains from cattle were resistant to nalidixic acid and 4.9% were resistant to enrofloxacin and ciprofloxacin.[82] In sheep and goats only 0.5% and 1.4%, respectively, of the strains were resistant

to nalidixic acid and none to fluoroquinolones. Most of the quinolone-resistant strains were nonpathogenic strains isolated from cattle.

The CTX-M-14-like enzyme has been detected in *E. coli* recovered from the feces of diarrheic dairy calves in Wales.[74] The enzyme is an extended-spectrum beta-lactamase (ESBL), which confers resistance to a wide range of beta-lactam (penicillin and cephalosporin) compounds. Organisms possessing ESBLs are considered to be resistant to second-, third-, and fourth-generation cephalosporins, and in vitro resistance to amoxicillin/clavulanate among producers is variable, reflecting the amount of beta-lactamase produced. In addition to this enzyme, the isolates produced a TEM-35 (IRT-4) beta-lactamase that conferred resistance to the amoxicillin/clavulanate combination. These two enzymes confer resistance to all the beta-lactamase compounds approved for veterinary use in the UK. Thus their occurrence in animals may be an important development for both animal and public health. ESBLs in human infections have emerged as a significant and developing problem, occurring in patients in the community as well as in those with recent hospital contact. Spread of this form of resistance in bacteria affecting the animal population could have serious implications for animal health, rendering many therapeutic options redundant.

Antibiotic resistance to intestinal bacteria also occurs in dairy calves fed milk from cows treated with antibiotics.[83] The resistance increases with higher concentrations of antibiotics in the milk.

Antimicrobial susceptibility of blood *Escherichia coli* isolates

The Kirby Bauer technique for antimicrobial susceptibility testing has more clinical relevance for predicting the clinical response to antimicrobial treatment when applied to blood isolates rather than fecal isolates.[75] This is because the Kirby Bauer breakpoints (MICs) are based on achievable antimicrobial concentrations in human plasma and MIC_{90} values for human *E. coli* isolates, which provide a reasonable approximation to achievable MIC values in calf plasma and MIC_{90} values for bovine *E. coli* isolates. Unfortunately, susceptibility results are not available for at least 48 hours, and very few studies have documented the antimicrobial susceptibility of blood isolates in calves with diarrhea. In a 1997 study of dairy calves in California, the antimicrobial susceptibility of isolates from the blood of calves with severe diarrhea or illness produced the following results; ceftiofur, 19/25 (76%) sensitive; potentiated sulfonamides, 14/25 (56%) sensitive; gentamicin, 12/25 (48%) sensitive; ampicillin, 11/25 (44%) sensitive; tetracycline, 3/25 (12%) sensitive, although there was a clinically significant year-to-year difference in the results of susceptibility testing that may have reflected different antimicrobial administration protocols on the farm.[75]

Evidence-based recommendations for antimicrobial treatment of diarrheic calves

The four critical measures of success of antimicrobial therapy in calf diarrhea are (in decreasing order of importance): (1) mortality rate, (2) growth rate in survivors, (3) severity of diarrhea in survivors, and (4) duration of diarrhea in survivors.

Success of antimicrobial therapy can vary with the route of administration and whether the antimicrobial is dissolved in milk, oral electrolyte solutions, or water. Oral antimicrobials administered as a bolus or contained in a gelatin capsule are deposited into the rumen and therefore have a different serum concentration–time profile from antimicrobials dissolved in milk replacer that are suckled by the calf or administered as an oral drench at the back of the pharynx. Antimicrobials that bypass the rumen are not thought to alter rumen microflora, potentially permitting bacterial recolonization of the small intestine from the rumen. Finally, when oral antimicrobials are administered to calves with diarrhea, the antimicrobial concentration in the lumen of the small intestine is lower and the rate of antimicrobial elimination faster than in healthy calves.

Orally administered amoxicillin, chlortetracycline, neomycin, oxytetracycline, streptomycin, sulfachloropyridazine, sulfamethazine, and tetracycline are currently labeled in the USA for the treatment of calf diarrhea. No parenteral antimicrobials have a label claim in the USA for treating calf diarrhea.

In his review of the literature on the use of antibiotics for the treatment of calf diarrhea, Constable[75] concluded that recommendations by some veterinarians that oral or parenteral antimicrobials should not be used were not supported by a critical evidence-based review of the literature. The arguments used to support a nonantimicrobial treatment approach have included:

- Orally administered antimicrobials alter intestinal flora and function and thereby induce diarrhea, which has been documented on more than one occasion with chloramphenicol, neomycin, and penicillin
- Antimicrobials harm the 'good' bacteria in the small intestine more than the 'bad' bacteria (an undocumented claim in the calf)
- Antimicrobials are not effective (a statement that is clearly not supported by the results of some published peer-reviewed studies)
- Antimicrobial administration promotes the selection of antimicrobial resistance in enteric bacteria.

Constable[75] concluded that antimicrobial treatment of diarrheic calves should be practiced and focused against *E. coli* in the small intestine and blood, as these constitute the two sites of infection. Fecal bacterial culture and antimicrobial susceptibility testing is not recommended in calves with diarrhea, because fecal bacterial populations do not accurately reflect small-intestinal or blood bacterial populations and the breakpoints for susceptibility test results have not been validated. Antimicrobial efficacy is therefore best evaluated by the clinical response to treatment.

In the USA parenterally administered oxytetracycline and sulfachloropyridiazine and orally administered amoxicillin, chlortetracycline, neomycin, oxytetracycline, streptomycin, sulfachloropyridazine, sulfamethazine, and tetracycline are currently labeled for the treatment of calf diarrhea. Unfortunately, there is little published data supporting their efficacy in treating calves with diarrhea.[75] Extralabel antimicrobial use (excluding prohibited antimicrobials) is therefore justified in treating calf diarrhea because of the apparent lack of published studies documenting clinical efficacy of antimicrobials with a label claim, and because the health of the animal is threatened and suffering or death may result from failure to treat systemically ill calves.

Because the two sites of infection in calf diarrhea are the small intestine and blood, administered antimicrobials should have both local (small intestinal) and systemic effects. In addition, the antimicrobial must reach therapeutic concentrations at the site of infection for a long enough period and, ideally, have only a narrow Gram-negative spectrum of activity in order to minimize collateral damage to other enteric bacteria. In general, oral and parenteral administration of broad-spectrum beta-lactam and fluoroquinolone antimicrobials have proven efficacy in treating naturally acquired and experimentally induced diarrhea, parenteral administration of trimethoprim–sulfadiazine has proven efficacy in treating experimentally induced *Salmonella enterica* serotype Dublin (although efficacy has only been demonstrated when antimicrobial administration starts before diarrhea is present), and oral administration of the predominantly Gram-negative-spectrum

antimicrobial apramycin has proven efficacy in treating naturally acquired diarrhea. Because use of fluoroquinolone antimicrobials in an extralabel manner is illegal in the USA, and apramycin is an aminocyclitol antimicrobial that is poorly absorbed after oral administration (oral bioavailability <15%) and has relatively high MIC values against *Salmonella* spp. and *E. coli* (MIC_{90} > 3 μg/mL) in the calf, treatment recommendations will focus on the use of broad-spectrum beta-lactam antimicrobials such as amoxicillin, ampicillin, ceftiofur, and potentiated sulfonamides (trimethoprim– sulfadiazine).

Administration of oral antimicrobials to treat Escherichia coli *overgrowth of the small intestine*

Based on published evidence for the oral administration of these antimicrobial agents, only amoxicillin can be recommended for the treatment of diarrhea; dosage recommendations are amoxicillin trihydrate (10 mg/kg every 12 h) or amoxicillin trihydrate–clavulanate potassium (12.5 mg combined drug/kg every 12 h) for at least 3 days; the latter constitutes extralabel drug use. Parenteral administration of broad-spectrum beta-lactam antimicrobials (ceftiofur, 2.2 mg/kg intramuscularly or subcutaneously every 12 h; amoxicillin or ampicillin, 10 mg/kg intramuscularly every 12 h) or potentiated sulfonamides (25 mg/kg intravenously or intramuscularly every 12 h) is recommended for treating calves with diarrhea and systemic illness; both constitute extralabel drug use.

Concurrent feeding of milk and amoxicillin does not change the bioavailability of amoxicillin, although amoxicillin is absorbed faster when dissolved in an oral electrolyte solution than in milk replacer and absorption is slowed during endotoxemia, presumably because of a decrease in abomasal emptying rate. Amoxicillin trihydrate is preferred to ampicillin trihydrate for oral administration in calves because it is labeled for the treatment of calf diarrhea in the USA and is absorbed to a much greater extent. However, a field study comparing oral amoxicillin (400 mg every 12 h) and ampicillin (400 mg every 12 h) treatments for diarrhea reported similar proportions of calves with a good to excellent clinical response (79%, 49/62 for amoxicillin bolus; 80%, 59/74 for amoxicillin powder; 65%, 47/65 for ampicillin bolus; p >0.30 for all comparisons). The addition of clavulanate potassium to amoxicillin trihydrate is recommended because clavulanate potassium is a potent irreversible inhibitor of beta-lactamase, increasing the antimicrobial spectrum of activity.

Sulbactam/ampicillin was effective for the treatment of experimentally induced diarrhea in calves infected with *E. coli* strain B44 (O9:K30:K99H).[84] The survival rate in treated calves was 100% compared to 22% in control calves treated only with saline. Ceftiofur hydrochloride – a broad-spectrum, beta-lactamase-resistant cephalosporin – at an oral dose of 10 mg/kg BW given once was effective for the treatment of experimentally induced enteric colibacillosis in piglets.

Oral administration of potentiated sulfonamides is not recommended for treating calf diarrhea because of the lack of efficacy studies. Gentamicin (50 mg/calf orally every 12 h) markedly decreased *E. coli* bacterial concentrations in the feces of healthy calves and treatment with gentamicin has improved stool consistency in calves with experimentally induced *E. coli* diarrhea.[75] However, oral administration of gentamicin is not recommended, because antimicrobials administered to calves with diarrhea should have both local and systemic effects, and orally administered gentamicin is poorly absorbed.

Fluoroquinolones clearly have proven efficacy in treating calf diarrhea and a label indication exists in Europe for oral and parenteral enrofloxacin and oral marbofloxacin for the treatment of calf diarrhea. In those countries where their administration is permitted to treat calf diarrhea, oral fluoroquinolones are recommended because of their high oral bioavailability. However, it must be emphasized that extralabel use of the fluoroquinolone class of antimicrobials in food-producing animals in the US is illegal and obviously not recommended.

Also, in other countries it may be illegal to use some of the antimicrobials mentioned here because of the regulations regarding their use in food-producing animals. Some are available to farmers on a prescription-only basis, which makes examination of the animals and a diagnosis necessary before recommendations are made. The indiscriminate use of antibiotics in milk replacers for the treatment of newborn calves and piglets is widespread and must be viewed with concern when the problem of drug resistance transfer from animal to animal and to humans is considered.

In calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever), it is recommended that the clinician monitors the health of the calf, and does not administer oral antimicrobials.

Administration of parenteral antimicrobials to treat Escherichia coli *bacteremia*
