In calves with diarrhea and moderate to severe systemic illness, the positive predictive value (0.65) of clinical tests (sensitivity = 0.39, specificity = 0.91) and the positive predictive value (0.77) of laboratory tests (sensitivity = 0.40, specificity = 0.95) for detecting bacteremia are too low assuming reasonable estimates for the prevalence of bacteremia (30%).[77] Accordingly, it is recommended that clinicians routinely assume 30% of ill calves with diarrhea are bacteremic, and that bacteremia constitutes a threat to the life of the calf.

The most logical parenteral treatment is ceftiofur (2.2 mg/kg intramuscularly/subcutaneously every 12 h) for at least 3 days. Ceftiofur is the most appropriate antimicrobial because it is a broad-spectrum beta-lactam antimicrobial that is resistant to the action of beta-lactamase, the MIC_{90} for *E. coli* is less than 0.25 μg/mL, the recommended dosage schedule maintains free plasma beta-lactam antimicrobial concentrations at the desired four times above the MIC_{90} value for the duration of treatment in 7-day-old calves, and 30% of the active metabolite of ceftiofur (desfuroylceftiofur) is excreted into the intestinal tract of cattle, providing antimicrobial activity in both blood and small intestine. Moreover, parenteral (2 mg/kg, intramuscularly once) and oral (0.5 mg/kg, once) administration of ceftiofur hydrochloride decreased mortality rate and the severity of diarrhea in pigs with experimentally induced enteric colibacillosis, although these pigs were not suspected to be bacteremic.[75] The beneficial effects of parenteral ceftiofur in these pigs was attributed to decreasing intestinal luminal concentration of pathogenic *E. coli*. Orally administered ceftiofur sodium (<5 mg/kg daily) was also effective in treating mice with experimentally induced enteric colibacillosis.[75] Administration of ceftiofur to treat bacteremia and diarrhea in calves constitutes extralabel drug use, and ceftiofur should not be administered to calves to be processed as veal.

Another recommended treatment is parenteral amoxicillin trihydrate or ampicillin trihydrate (10 mg/kg intramuscularly every 12 h) for at least 3 days. Although parenteral ampicillin has proven efficacy in treating naturally acquired diarrhea whereas ceftiofur has unproven efficacy, the broad-spectrum beta-lactam antimicrobials amoxicillin and ampicillin are theoretically inferior to ceftiofur because parenterally administered ampicillin and amoxicillin reach lower plasma concentrations and require a higher MIC than ceftiofur, and are not beta-lactamase-resistant.[75] Amoxicillin or ampicillin should be injected into the neck musculature because this site provides the greatest absorption and minimizes damage to

more valuable areas of the carcass. Amoxicillin and ampicillin should not be administered subcutaneously, as the rate and extent of absorption is reduced relative to intramuscular injection.

A third recommended treatment is parenteral potentiated sulfonamides (20 mg/kg sulfadiazine with 5 mg/kg trimethoprim, intravenously or intramuscularly depending upon the formulation characteristics, every 24 h for 5 d). The efficacy of potentiated sulfonamides has only been proved when treatment commenced before clinical signs of diarrhea were present.[75] It is therefore unknown whether potentiated sulfonamides are efficacious when administered to calves with diarrhea and depression, although it is likely that potentiated sulfonamides are efficacious in the treatment of salmonellosis.

Oral administration of potentiated sulfonamides and apramycin is not recommended for the treatment of bacteremia, because of poor oral bioavailability. Oxytetracycline or chlortetracycline are also not recommended for the treatment of bacteremia, although tetracyclines may have some efficacy for treating *E. coli* bacterial overgrowth of the small intestine. Tetracycline antimicrobials are bound to calcium, and oral bioavailability when administered with milk is 46% for oxytetracycline and 24% for chlortetracycline.

Parenteral administration of gentamicin and other aminoglycosides (amikacin, kanamycin) cannot currently be recommended as part of the treatment for calf diarrhea because of the lack of published efficacy studies, prolonged slaughter withdrawal times (15–18 months), potential for nephrotoxicity in dehydrated animals, and availability of ceftiofur, amoxicillin, and ampicillin.

A label indication exists in Europe for parenteral enrofloxacin in the treatment of calf diarrhea. In those countries where administration is permitted to treat calves with diarrhea, parenteral fluoroquinolones are recommended because of their broad-spectrum bactericidal activity, particularly against Gram-negative bacteria. However, it must be emphasized that extra-label use of the fluoroquinolone class of antimicrobials in food-producing animals in the USA is illegal and obviously not recommended.

Chloramphenicol had proven efficacy in treating calf diarrhea due to *Salmonella enterica* serotypes Bredeney and Dublin, although its use is now illegal in the USA. The related antimicrobial florfenicol achieves high concentrations in the lumen of the small intestine and is 89% absorbed when orally administered to milk-fed calves; however, florfenicol does not provide the most appropriate antimicrobial for treating calf diarrhea, as the MIC_{90} for *E. coli* is very high at 25 μg/mL and florfenicol (11 mg/kg orally or 20 mg/kg intramuscularly) failed to reach the MIC_{90} value in plasma, whereas florfenicol (11–20 mg/kg intravenously) only exceeded the MIC_{90} value for less than 60 minutes.[75]

In calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever), we recommend that the clinician monitors the health of the calf and does not administer parenteral antimicrobials.

Immunoglobulin therapy

One of the important factors determining whether or not calves survive enteric colibacillosis is the serum immunoglobulin status of the animal before it develops the disease. The prognosis is unfavorable if the level of immunoglobulins is low at the onset of diarrhea, regardless of intensive fluid and antimicrobial therapy. Most of the literature on therapy omits this information and is therefore difficult to assess. There is ample evidence that the mortality rate will be high in diarrheic calves that are deficient in serum immunoglobulins, particularly IgG, in spite of exhaustive antimicrobial and fluid therapy. This has stimulated interest in the possible use of purified solutions of bovine gammaglobulin in diarrheic calves that are hypogammaglobulinemic. However, they must be given by the intravenous route and in large amounts, the cost of which would be prohibitive. In addition, they are unlikely to be of value once the calf is affected with diarrhea; they are protective and probably not curative. Whole blood transfusion to severely affected calves may be used as a source of gammaglobulins but unless given in large quantities would not significantly elevate serum immunoglobulin levels in deficient calves. Limited controlled trials indicate that there is no significant difference in the survival rate of diarrheic calves treated with either a blood transfusion daily for 3 days; fluid therapy given orally, subcutaneously, or intravenously depending on the severity of the dehydration; or fluid therapy with antibiotics. Those calves that survived, regardless of the type of therapy, had high levels of immunoglobulins before they developed diarrhea. This emphasizes the importance of the calf ingesting liberal quantities of colostrum within the first few hours after birth.

Antimotility drugs and intestinal protectants

There is no good evidence that antimotility drugs are of any therapeutic value for the treatment of enteric colibacillosis. Intestinal protectants such as kaolin and pectin are in general use for diarrheic animals but likewise their value is uncertain. When they are used the feces become bulky but do not have any known effect on the pathogenesis of the disease.

Alteration of the diet

Whether or not diarrheic newborn animals should be deprived of milk during the period of diarrhea is controversial.[72] Diarrheic piglets are usually treated with an antimicrobial orally and left to nurse on the sow. Diarrheic beef calves are commonly treated with oral fluids and electrolytes and left with the cow. However, it is a common practice to reduce the milk intake of diarrheic hand-fed dairy calves for up to 24 hours or until there is clinical evidence of improvement. The withholding of milk from diarrheic calves has been based on the observations that lactose digestion is impaired and that 'resting' the intestine for a few days minimizes additional osmotic diarrhea caused by fermentation of undigested lactose in the large intestine. Thus it has seemed logical not to feed the animal with milk, which must be digested, but rather to provide readily absorbable substances such as oral glucose–electrolyte mixtures. In contrast, the argument in favor of continuous feeding of milk is that the intestinal tract requires a constant source of nutrition, which it receives from the ingesta in the lumen of the intestine. It has also been proposed that starving diarrheic calves from milk can result in malnutrition, suboptimal growth rates and prolonged recovery.[72] In one study it was shown that the offering of milk to diarrheic calves when they were willing to drink following hydration therapy in a clinic resulted in a higher but insignificant improvement in survival rate than in calves that were starved from milk for 24 hours. In another study, the continued feeding of cows' whole milk and fluids and electrolytes to experimentally induced diarrheic calves sustained the growth rate of the animals over the trial period of 10 days even though the diarrhea persisted.[72] The use of whole milk and oral rehydration solutions for calves with naturally occurring diarrhea did not prolong the diarrhea or make it worse[72] but the calves were in the early stages of diarrhea and were neither severely dehydrated nor acidotic.

It has been common practice to use oral fluids and electrolytes as milk replacement during the period of diarrhea. Such mixtures are inexpensive, easy to use, readily available and, if used by the farmer when diarrhea is first noticed, will usually successfully treat existing dehydration and prevent further dehydration and acidosis.

Following recovery, calves should be offered reduced quantities of whole milk three times daily (no more than total daily intake equivalent to 8% BW) on the first day and increased to the normal daily allowance in the next few days. Milk should not be diluted with water as this may interfere with the clotting mechanism in the abomasum.

Clinical management of outbreaks

The following principles should be considered when outbreaks of colibacillosis in neonatal farm animals are encountered:

- The veterinarian should visit the farm and conduct an epidemiological investigation to identify risk factors
- Examine each risk factor and how it can be minimized
- Examine affected animals
- Identify and isolate all affected animals if possible
- Treat all affected animals as necessary
- Take laboratory samples from affected and normal animals
- Make recommendations for the control of diarrhea in animals to be born in the near future
- Prepare and submit a report to the owner describing the clinical and laboratory results and how the disease can be prevented in the future.

Health and welfare of calves

A survey of calf health and welfare on dairy farms in England examined the degree of compliance with the Welfare of Farmed Animals Regulations.[85] The level of veterinary involvement in calf rearing and management on dairy farms was also assessed by questionnaire sent to large-animal practitioners. Compliance with the regulations was variable. The requirements for isolation of sick calves, provision of bovine colostrum within 6 hours after birth, provision of fresh, clean water and restrictions concerning tethering were not well complied with. However, the requirements for twice-daily feeding and inspection, visual and tactile contact between calves, access to forage and the provision of clean, dry bedding were well complied with. The results also suggested that there was some lack of veterinary input into the health and welfare of calves on dairy farms visited by the practices routinely and nonroutinely. These results suggest that there are considerable opportunities to improve calf health and management practices by veterinarians who visit dairy farms. This can be done through animal health management advice provided during routine visits to the farm and encouraging compliance with current welfare regulations and through the use of herd health plans. The major challenge for the veterinarian is to be able to communicate with owners and animal attendants about the care being provided to clinically ill neonates to insure that they are being treated according to their needs and made comfortable during their convalescence.

CONTROL

Because of the complex nature of the disease, it is unrealistic to expect total prevention, and control at an economical level should be the major goal. Effective control of colibacillosis can be accomplished by the application of three principles:

- **Reduction of the degree of exposure of the newborn to the infectious agents**
- **Provision of maximum nonspecific resistance with adequate colostrum and optimum animal management**
- **Increasing the specific resistance of the newborn by vaccination of the dam or the newborn.**

Reduction of the degree of exposure of the newborn to the infectious agents

The emphasis is on insuring that the newborn are born into a clean environment. Barns, confinement pens, and paddocks used as parturition areas must be clean and should preferably have been left vacant for several days before the pregnant dams are placed in them.

Dairy calves

These comments are directed particularly at calves born indoors, where contamination is higher than outdoors.

- Calves should be born in well-bedded box stalls that were previously cleaned out
- The perineum and udder of the dairy cow should be washed shortly before calving
- Immediately after birth the umbilicus of the calf should be swabbed with 2% iodine. Tying the umbilicus at the level of the abdominal wall with cotton thread is also practiced
- Calves affected with diarrhea should be removed from the main calf barn if possible and treated in isolation.

Beef calves

These are usually born on pasture or on confined calving grounds.

- Calving grounds should have been free of animals previous to the calving period; the grounds should be well drained, dry and scraped free of snow if possible. Each cow–calf pair should be provided with at least 2000 square feet of space. Calving on pasture with adequate protection from wind is ideal. Covering the calving grounds with straw or wood shavings provides a comfortable calving environment
- In large beef herds, in a few days following birth when the calf is nursing successfully, the cow–calf pair should be moved to a nursery pasture to avoid overcrowding in the calving grounds.

In beef herds, breeding plans should insure that heifers calve at least 2 weeks before the mature cows. Limiting the breeding and therefore the calving season to 45 days or less for heifers also offers several advantages. A short calving season allows the producer to more effectively and economically concentrate personnel resources to the calving management compared to a longer calving season. Calving heifers earlier allows them additional time required before the next breeding season to be on an increasing plane of nutrition necessary to maintain a high conception rate. The earlier calving of heifers also provides less exposure of their calves to infection pressure from the mature animals in the herd.

The incidence and severity of neonatal disease will typically increase, and the age at disease onset will decrease as the calving season progresses. This phenomenon is common in beef herds because of the effect of the calf as a biological amplifier. The more the calving season is shortened, the more the biological amplification effect is negated.

For beef herds, it is necessary to have a plan for cattle movement throughout the calving season. This requires a minimum of four or five separate pastures. These include a gestation pasture, a calving pasture and a series of nursery pastures. To ensure that beef calves are born in a sanitary environment, the herd should be moved from the gestation pasture to the calving pasture 1–2 weeks before calving. One day after birth, the cow or heifer and her calf should be moved to a nursery pasture. Cow–calf pairs should be added to a single nursery pasture until the appropriate number of pairs has been reached. Thereafter, cow–calf pairs can be added to a second nursery pasture. The difference in age between the oldest and youngest calf in a nursery pasture should never exceed 30 days, and smaller differences are preferable. This negates the biological amplification effect. The longer the calving season, the greater the need for a large number of nursery pastures. Calves that develop diarrhea should be removed immediately to an area away from healthy calves, treated and not returned until all calves in the group are at low risk for developing diarrhea (> 30 days of age).

The nutrition of the pregnant cows, and particularly the first-calf heifers, must

be monitored through gestation to insure an adequate body condition and sufficient resources to provide an adequate supply of good-quality colostrum.

Veal calves

These calves are usually obtained from several different sources and 25–30% or higher may be deficient in serum immunoglobulin.

- On arrival, calves should be placed in their individual calf pens, which were previously cleaned, disinfected and left vacant to dry
- Feeding utensils are a frequent source of pathogenic *E. coli* and should be cleaned and air-dried daily
- Calves affected with diarrhea should be removed and isolated immediately.

Lambs and kids

The principles described above for calves apply to lambs and kids. Lambing sheds can be a source of heavy contamination and must be managed accordingly to reduce infection pressure on newborn lambs.

Piglets

Piglets born in a total-confinement system may be exposed to a high infection rate.

- The all-in/all-out system of batch farrowing, in which groups of sows farrow within a week, is recommended. This system will allow the herdsman to wean the piglets from a group of sows in a day or two and clean, disinfect and leave vacant a battery of farrowing crates for the next group of sows. This system will reduce the total occupation time and the infection rate. The continuous farrowing system without regular breaks is not recommended
- Before being placed in the farrowing crate, sows should be washed with a suitable disinfectant to reduce the bacterial population of the skin.

Provision of maximum nonspecific resistance with adequate colostrum and optimum animal management

This begins with the provision of optimal nutrition to the pregnant dam, which will result in a vigorous newborn animal and adequate quantities of colostrum. At the time of parturition, surveillance of the dams and the provision of any obstetric assistance required will insure that the newborn are born with as much vigor as possible. Parturition injuries and intrapartum hypoxemia must be minimized as much as possible.

Colostrum management

The next most important control measure is to insure that liberal quantities of good-quality colostrum are available and ingested within minutes and no later than a few hours after birth. While the optimum amount of colostrum that should be ingested by a certain time after birth is well known, the major difficulty with all species under practical conditions is to know how much colostrum a particular neonate has ingested. Because modern livestock production has become so intensive, it is imperative that the animal attendants make every effort to insure that sufficient colostrum is ingested by that particular species. In one study, in large dairy herds, 42% of calves left with their dams for 1 day following birth had failed either to suck sufficient colostrum or to absorb sufficient colostral immunoglobulins.

Failure of transfer of passive immunity, as determined by calf serum immunoglobulin IgG_1 concentration below 10 mg/mL at 48 hours of age, occurred in 61.4% of calves from a dairy in which calves were nursed by their dams, 19.3% of calves from a dairy using nipple-bottle feeding and 10.8% of calves from a dairy using tube feeding.[8] A higher prevalence of failure of transfer of passive immunity in dairy calves can occur because an insufficient volume of colostrum is ingested by the calf. When artificial feeding is used, inadequate immunoglobulin concentration in the colostrum fed is the most important factor resulting in failure of transfer of passive immunity.[8] The prevalence of failure of transfer of passive immunity in dairy herds can be minimized by artificially feeding all newborn calves large volumes (3–4 L) of fresh or refrigerated first-milking colostrum from cows that had nonlactating intervals of normal duration. This volume is considerably greater than the intake that Holstein calves usually achieve by sucking, and also exceeds the voluntary intake of most calves fed colostrum by nipple bottle.

Calves need to ingest at least 100 g IgG_1 in the first colostrum feeding to insure adequate transfer of passive immunity. Thus the routine force-feeding of a sufficient amount of pooled colostrum immediately after birth results in high serum levels of colostrum immunoglobulins in dairy calves and is becoming a common practice in dairy herds.

Encouraging and assisting the calf to suck within 1 hour after birth is also effective. The provision of early assisted sucking of colostrum to satiation within 1 hour after birth will result in high concentrations of absorbed immunoglobulins in the majority of calves. The ingestion of 100 g or more of colostral immunoglobulins within a few hours after birth is more effective in achieving high levels of colostral immunoglobulins in calves than either leaving the calf with the cow for the next 12–24 hours or encouraging the calf to suck again at 12 hours, which will not result in a significant increase in absorbed immunoglobulins.

Despite early assisted sucking, a small proportion of calves will remain hypogammaglobulinemic because of low concentrations of immunoglobulins in their dams' colostrum, usually associated with leakage of colostrum from the udder before calving.

In large herds where economics permit, a laboratory surveillance system may be used on batches of calves to determine the serum levels of immunoglobulin acquired. An accurate analysis may be done by electrophoresis or an estimation using the zinc sulfate turbidity test. Blood should be collected from calves at 24 hours of age. Samples taken a few days later may not be a true reflection of the original serum immunoglobulin levels. The information obtained from determination of serum immunoglobulins in calves at 24 hours of age can be used to improve management practices, particularly the early ingestion of colostrum.

Quality of colostrum

Specific gravity

Differentiating high-immunoglobulin-concentration colostrum from low-immunoglobulin-concentration is problematic.[8] Measurement of the specific gravity of the colostrum of dairy cows with a commercially available hydrometer (Colostrometer) has been explored.[86] Originally it was claimed that measurement of specific gravity provided an inexpensive and practical method for estimating colostral Ig concentration. However, the specific gravity of colostrum is more correlated with its protein concentration than Ig concentration and varies with colostral temperature, thus limiting the predictive accuracy of the test. In addition, different relationships between specific gravity and Ig concentration of colostrum have been observed for different populations of Holstein and Jersey cows and between herds. Specific gravity may also vary considerably according to season of the year. Specific gravity was measured in 1085 first-milking colostrum samples from 608 dairy cows of four breeds on a single farm during a 5-year period.[86] The specific gravity more closely reflected protein concentration than IgG_1 concentration and was markedly affected by month of calving. Colostral specific gravity values were highest for Holstein and Jersey cows, cows in third or later lactation and cows calving in autumn. They were lowest in Brown Swiss and Ayrshire cows, cows in first or second lactation, and cows calving in summer. Thus using the specific gravity of colostrum

as an indicator of IgG_1 concentration has potential limitations.

Frozen and thawed colostrum

Colostrum can be banked as frozen colostrum for future use.[87] Excess colostrum can be stored frozen and thawed as necessary to provide an IgG source when administration of dam colostrum is impractical or insufficient. Experience has shown that the composition of frozen colostrum remains constant throughout storage. No significant changes in pH, percentage acidity, milk fat, total solids, total nitrogen, or nonprotein resulted from colostrum being stored. Feeding 4 L of frozen thawed colostrum (which had been frozen at –20°C for 24 h) to calves by oroesophageal tube at 3 hours after birth did not result in a significant difference in IgG absorption when compared to calves receiving fresh colostrum.[87]

Pasteurization of colostrum

Several infectious diseases of cattle can be transmitted from the dam to the calf through colostrum contaminated by direct shedding from the mammary gland or postharvest contamination. These diseases include Johne's disease, bovine leukosis, *Mycoplasma* spp., *Salmonella* spp., and *E. coli*. Strategies to control transmission of infectious agents to calves include pasteurizing colostrum. Pasteurization is effective in destroying *Mycoplasma bovis*, *Mycoplasma californicum*, and *Mycoplasma canadense* if an adequate temperature and time are used.

The method of pasteurization of colostrum affects its quality for calves. The potential disadvantage of heat-treating colostrum is that the immunoglobulins may become denatured. Pasteurization at 76°C for 15 minutes results in a marked decrease in calf serum IgG concentrations, a severe failure of transfer of passive immunity, indicating that the colostral immunoglobulins were either destroyed or altered so that absorption was impaired. Pasteurization at 76°C for 15 minutes destroys or alters colostral proteins and affects the serum concentration of lactoferrin and neutrophil oxidative metabolism.[88] Pasteurization of colostrum at 63°C for 15 minutes causes only negligible decreases in colostral IgG concentrations when fed to calves.[89] However, these lower temperatures are less effective in the destruction of *Mycobacterium avium* subsp. *paratuberculosis* and other infectious agents transmitted through colostrum.

The effect of commercial on-farm batch pasteurization on colostrum IgG concentrations, fluid characteristics and serum IgG concentrations in calves fed fresh versus pasteurized colostrum have been compared.[90] Pasteurization of moderately sized batches (57 L) using a commercial batch pasteurizer consistently produces a product of normal or slightly thickened consistency that can be fed to calves. Batch pasteurization of 57 L at 63°C for 30 minutes results in a significant reduction of IgG in colostrum (26%) but much less than when 95 L is pasteurized. The percentage loss of IgG is significantly reduced when starting with high-quality fresh colostrum (> 60 mg/L). Feeding pasteurized colostrum results in significantly lower serum IgG concentrations in calves. However, acceptable serum IgG levels can be achieved if the pasteurized colostrum is fed immediately after birth, if at least 4 L is fed and if the interval between the first and second feedings of colostrum is shortened.

Colostrum supplements and replacers

Some colostrum-derived oral supplements containing immunoglobulin are available for newborn calves in which colostrum intake is suspected or known to be inadequate. **Colostrum supplement** products have been developed to provide exogenous IgG to calves when the dam's fresh colostrum is of low IgG concentration. Many producers also use these products to replace colostrum when it is unavailable as a result of maternal agalactia, acute mastitis or other causes of inadequate colostrum supply. However, they contain low immunoglobulin concentrations compared to those found in high-quality first-milking colostrum. Most colostral supplements provide only 25–45 g IgG/dose of 454 g, which is reconstituted in 2 L of water. Feeding one or even two doses of such supplements is insufficient to provide a mass of 100 g of IgG within the first 12 hours after birth. **Colostrum replacers** are intended to provide the sole source of IgG and thus must provide at least 100 g IgG. Newborn colostrum-deprived dairy calves fed spray-dried colostrum containing 126 g of immunoglobulin in 3 L of water as their sole source of Ig achieved normal mean serum immunoglobulin concentrations.[91] Whey protein concentrate as a colostrum substitute, administered to calves as a single feeding, was ineffective in preventing neonatal morbidity and mortality compared with a single feeding of pooled colostrum.[92]

The IgG derived from bovine serum or Ig concentrates from bovine plasma are well absorbed by neonatal calves when given in adequate amounts.[93,94] The serum concentration of IgG in calves at 2 days of age force-fed a colostrum supplement containing spray-dried serum (total of 90 g immunoglobulin protein) within 3 hours after birth was much lower than in calves fed 4 L of fresh colostrum.[95] The mass of IgG and the method of processing are critical. Products providing less than 100 g of IgG/dose should not be used to replace colostrum.

To be successful, colostral supplements and replacers must provide enough IgG mass, which results in 24-hour calf serum IgG concentrations of more than 10 g/L.

Purified bovine immunoglobulin

The administration of purified bovine gammaglobulin to calves that are deficient appears to be a logical approach but the results have been unsuccessful. Large doses (30–50 g) of gammaglobulin given intravenously would be required to increase the level of serum gammaglobulin from 0.5 g/dL to 1.5 g/dL of serum, which is considered an adequate level. The cost would be prohibitive. The administration of gammaglobulins by any parenteral route other than the intravenous route does not result in a significant increase in serum levels of the immunoglobulin.

To be effective, infusion of immunoglobulin derived from blood must increase serum IgG concentrations and reduce morbidity and mortality prior to weaning without affecting later production. Parenteral infusions of immunoglobulins will increase the concentrations of serum IgG in calves but may not necessarily have an effect on morbidity or mortality.[96] High levels of specific circulating Ig can serve as a reservoir of antibody to move into the intestine and prevent enteric infection.[97] Thus immunoglobulin sources other than colostrum may not provide Ig that are specific for antigens present in the environment or might be insufficient when calves are exposed to a heavy infection pressure.

The other factors that influence the ingestion of colostrum and the absorption of immunoglobulin are presented in the section on the epidemiology of colibacillosis, above, and in Chapter 3.

Guidelines to insure transfer of colostral immunoglobulins

Some guidelines for insuring that newborn farm animals ingest sufficient quantities of colostrum and absorb adequate amounts of colostral immunoglobulins are summarized here. Additional details are presented in Chapter 3.

Dairy calves

The following should be implemented:

- Immediately after birth, unless the calf is a vigorous sucker, colostrum should be removed from the cow and fed by nipple bottle or by stomach tube at the rate of at least 50 mL/kg BW in the first 2 hours.
  Encouragement and assistance to suck to satiation within the first hour after birth is also highly effective in

achieving high levels of colostral immunoglobulins in the serum of the calf.[98] If pooled colostrum is used, calves should be fed 3–4 L of first-milking colostrum
- The calf can be left with the cow for at least 2 days. This contact will improve the absorption of immunoglobulin. However, there is now a trend, at least in large dairy herds, to remove the calf immediately after birth, place it in a stall and force-feed it colostrum. This practice may also prevent spread of infectious disease from mature cattle to calves
- Following the colostral feeding period, dairy calves are usually placed in individual stalls until weaning. The daily feeding of stored fermented colostrum to newborn calves for up to 3 weeks after birth provides a source of lactoglobulins in the intestinal tract and reduces the incidence of neonatal diarrhea of calves due to a wide variety of pathogens, but this practice may be impractical
- Calves should be fed regularly, and preferably by the same person. One of the most important factors affecting dairy calf mortality is the concern and care provided by the calf rearer. The calf mortality rate is likely to be lower when members of the family care for the calves compared to hired help
- Colostrum stored at room temperature should be handled adequately to minimize bacterial contamination. Up to 36% of colostrum samples from calf nursing bottles in dairy herds may be contaminated with *Staphylococcus* spp., Gram-negative rods, coliforms, and *Streptococcus uberis*.[99] The relative risk of contamination with more than 100 000 bacteria/mL was greater in warm months than in cooler months, and in colostrum fed to male calves. The greater risk to male calves may reflect less attention to hygiene and management procedures compared to female calves
- The housing and ventilation must be adequate to avoid stress.

Beef calves

The management strategies to decrease calf death losses in beef herds has been described.[100] The role of management intervention in the prevention of neonatal deaths includes measures to improve host defenses and environmental hygiene to minimize outbreaks of neonatal disease. Specific attention is centered on preventing dystocia, improving transfer of colostral immunoglobulins, and limiting environmental contamination.[100]

The following should be implemented:

- Management of the beef herd must emphasize prevention of dystocia, which involves limiting calf size and ensuring adequate pelvic area of the dams[100]
- Beef calves should be assisted at birth, if necessary, to avoid exhaustion and weakness from a prolonged parturition[100]
- Normally beef calves will make attempts to get up and suck within 20 minutes after birth but this may be delayed for up to 8 hours or longer. Beef calves that do not suck within 2 hours should be fed colostrum by nipple bottle or stomach tube. Whenever possible they should be encouraged and assisted to suck to satiation within 1 hour after birth. The dam can be restrained and the calf assisted to suck. If the calf is unable or unwilling to suck, the dam should be restrained and milked out by hand, and the calf fed the colostrum with a nipple bottle or stomach tube. The mean volume of colostrum and colostral immunoglobulins produced in beef cows and the absorption of colostral immunoglobulins by their calves can vary widely. Beef calves deserted by indifferent dams need special attention. Failure of transfer of passive immunity is common and estimated at 10–40% of beef calves[100]
- Constant surveillance of the calving grounds is necessary to avoid overcrowding, to detect diarrheic calves that should be removed, to avoid mismothering, and to insure that every calf is seen to nurse its dam. Although up to 25% of beef calves may not have sufficient serum levels of immunoglobulins, the provision of excellent management will minimize the incidence of colibacillosis. The recently developed practice of corticosteroid-induced parturition in cattle may result in a major mismothering problem if too many calves are born too quickly in a confined space. Every management effort must be used to establish the cow/calf herd as soon as possible after birth. This will require high-quality management to reduce even further the infection rate and minimize any stressors in the environment.

Lambs

Lambs require 180–210 mL of colostrum/kg BW during the first 18 hours after birth to provide sufficient energy for heat production.[101] Such an intake will usually also provide enough colostral immunoglobulins. Early encouragement and assistance of the lambs to suck the ewe is important. Well-fed ewes usually have sufficient colostrum for singletons or twins. Underfed ewes may not have sufficient colostrum for one or more lambs and supplementation from stored colostrum obtained by milking other high-producing ewes is a useful practice.

Piglets

The following should be implemented:

- Every possible economical effort must be made to insure that each newborn piglet obtains a liberal supply of colostrum within minutes of birth. The farrowing floor must be well drained and it must be slip-proof to allow the piglets to move easily to the sow's udder. Some herdsmen provide assistance at farrowing, drying off every piglet as it is born and placing it immediately onto a teat
- The washing of the sow's udder immediately before farrowing with warm water and soap will reduce the bacterial population and may provide relief in cases of congested and edematous udders
- The piglet creep area must be dry, appropriately heated for the first week and free from drafts. During farrowing, colostrum is released in discrete ejections, possibly by discrete release of oxytocin associated with parturition. Therefore, as the piglets are born they must be as close to the udder as possible in order to take advantage of these discrete ejections.

Increasing specific resistance of the newborn by vaccinating the pregnant dam or the newborn

The immunization of neonate farm animals against colibacillosis by vaccination of the pregnant dam or by vaccination of the fetus or the neonate has received considerable research attention in recent years and the results appear promising.[102]

Such vaccines are practical and effective because:

- Most fatal enterotoxigenic *E. coli* infections in farm animals occur in the early neonatal period when antibody titers in colostrum and milk are highest
- More than 90% of the enterotoxigenic *E. coli* in farm animals belong to a small family of fimbrial antigens
- Fimbriae consist of good protein antigens on the bacterial surface where they are readily accessible to antibody
- Fimbriae are required for a critical step (adhesion–colonization) early in the pathogenesis of the disease
- Novel or previously low-prevalence fimbrial antigens have not emerged to render the vaccines ineffective.

The pregnant dam is vaccinated 2–4 weeks before parturition to induce specific antibodies to particular strains of enteropathogenic *E. coli*, and the antibodies are then passed on to the newborn through the colostrum. The mechanism of protection is the production of antibodies against the pilus antigens, which are responsible for colonization of the *E. coli* in the intestine.[102]

Vaccination is an aid to good management and not a replacement for inadequate management. Vaccines to prevent enterotoxigenic *E. coli* diarrhea in calves and piglets are based on the prevailing fimbrial antigens for colonization by enterotoxigenic *E. coli* in calves (F5) and newborn pigs (F4, F5, and F6). Reliable data on the efficacy of the commercial vaccines based on randomized clinical field trials are not available but most animal health professionals perceive that the vaccines are effective and that disease occurs primarily in unvaccinated herds. There are unpublished anecdotal reports that use of the vaccine in cattle has shifted the peak occurrence of diarrhea in calves from the first week to the third and fourth week after birth. The extensive use of fimbria-based vaccines can select against the prevailing fimbrial antigen types as reflected in the vaccines, and emergence of new or previously low-prevalence fimbrial antigens may occur. fimbriae antigenically distinct from F1, F4, F6, F41 occur among enterotoxigenic *E. coli*. However, these antigen types are less prevalent than those currently used in commercial vaccines. There is no evidence that enterotoxigenic *E. coli* with novel colonization mechanisms or new fimbrial antigens have emerged under the selection pressure of vaccination. Nor is there evidence that previously 'low-prevalence' fimbrial antigen type enterotoxigenic *E. coli*, not represented in the vaccines, have emerged as 'common pathogens' filling an ecological niche left by the fimbrial antigen types targeted by the vaccines.

Calves

Vaccination of pregnant cattle with either purified *E. coli* K99$^+$ pili or a whole-cell preparation containing sufficient K99$^+$ antigen can significantly reduce the incidence of enterotoxigenic colibacillosis in calves. Good protection is also possible when the dams are vaccinated with a four-strain *E. coli* whole-cell bacterin containing sufficient K99$^+$ pilus antigen and the polysaccharide capsular K antigen. Colostral antibodies specific for K99$^+$ pilus antigen and the polysaccharide capsular K antigen on the surface of the challenge exposure strain of enterotoxigenic *E. coli* are protective. There is a highly significant correlation between the lacteal immunity to the K99$^+$ antigen and the prevention of severe diarrhea or death in calves challenged with enterotoxigenic *E. coli*. The colostral levels of K99$^+$ antibody are highest during the first 2 days after parturition, which is the most susceptible period for enterotoxigenic colibacillosis to occur in the newborn calf. The continuous presence of the K99$^+$ antibody in the lumen of the intestine prevents adherence of the bacteria to the intestinal epithelium. The K99$^+$ antibody is also absorbed during the period of immunoglobulin absorption and may be excreted into the intestine during diarrhea. This may be one of the reasons that mortality is inversely proportional to serum immunoglobulin levels. The pregnant dams are vaccinated twice in the first year, 6 and 2 weeks prior to parturition. Each year thereafter they are given a single booster vaccination. An oil emulsion *E. coli* K99$^+$ bacterin given once or twice to pregnant beef cows 6 weeks before calving elicited high levels of serum antibody that provided protection against experimental infection of newborn calves for up to 87 weeks after vaccination.

Vaccines containing both the K99$^+$ antigen of enterotoxigenic *E. coli* and rotavirus, and in some cases coronavirus, have been evaluated with variable results. The colostral antibodies to the K99$^+$ antigen are higher in vaccinated than unvaccinated dams but the colostral antibodies to rotavirus and coronavirus may not be significantly different between vaccinated and unvaccinated dams. In these field trials vaccination had no effect on the prevalence of diarrhea, calf mortality or the presence of the three enteropathogens. In other field trials the combined vaccine did provide some protection against outbreaks of calf diarrhea. The use of an inactivated oil-adjuvanted rotavirus *E. coli* vaccine given to beef cows in the last trimester of pregnancy decreases the mortality from diarrhea and has a positive influence on the average weight gains of the calves at weaning. To be effective the rotavirus and coronavirus antibodies must be present in the post-colostral milk for several days after parturition during the period when calves are most susceptible to the viral infection. Vaccination of pregnant cows twice during the dry period at intervals of 4 weeks can increase the colostral antibody levels to *E. coli* K99$^+$ by 26 times on day 1 compared to controls. Much lower increases occur at the levels of coronavirus and rotavirus.

A commercially inactivated vaccine containing bovine rotavirus (serotype G6 P5), bovine coronavirus (originally isolated from a calf with diarrhea) and purified cell-free *E. coli* F5 (K99) (adsorbed on to aluminum hydroxide gel), formulated as an emulsion in a light mineral oil has been evaluated in a herd of Ayrshire/Friesian cows vaccinated once 31 days before the first expected calving date.[103] Compared to control cows, a significant increase in the mean specific antibody titer against all three antigens occurred in the serum of vaccinated animals (even in the presence of pre-existing antibody), which was accompanied by increased levels of protective antibody to rotavirus, coronavirus, and *E. coli* F5 (K99) in their colostrum and milk for at least 28 days.

Because naturally acquired antibodies to **the J5 antigen** may have an important role in the control of neonatal disease caused by bacterial infections with associated pathogens that share antigens with *E. coli* (J5 strain), vaccination of calves with an *E. coli* O111:B4(J5) vaccine at 1–3 days of age and 2 weeks later has been evaluated to control morbidity and mortality in dairy calves up to 60 days of age.[29] The use of either a killed *E. coli* O111:B4(J5) bacterin or a modified live, genetically altered (aro-) *Salmonella dublin* vaccine, or both in neonatal calves was effective in reducing mortality due to colibacillosis and salmonellosis.[104] Such a vaccine may be beneficial in controlling mortality in well-managed herds but is contraindicated in poorly managed herds.

Passive immunotherapy of calves under 2 days of age with J5 *E. coli* hyperimmune plasma given subcutaneously at a dose of 5 mL/kg BW has been examined.[105] The plasma was safe and potent. It was not superior to control plasma or to no treatment for calf morbidity and mortality.

The oral administration of a K99$^+$-specific monoclonal antibody to calves during the first 12 hours after birth may be an effective method of reducing the incidence of fatal enterotoxigenic colibacillosis, particularly when outbreaks of the disease occur in unvaccinated herds. Clinical trials indicate that the severity of dehydration, depression, weight loss and duration of diarrhea were significantly reduced in calves that had received the K99$^+$-specific monoclonal antibody. In experimentally challenged calves the mortality was 29% in the treated calves and 82% in the control calves.

The decision to vaccinate in any particular year will depend on the recognition of risk factors. Such risk factors include:

- A definitive diagnosis of enteropathogenic K99$^+$ *E. coli* in the previous year
- A population density in the calving grounds that is conducive to the disease

- Calving during the year when the environmental conditions are wet and uncomfortable for the calves
- A large percentage of primiparous dams that do not have protective levels of $K99^+$ antibody in their colostrum.

Piglets

Piglets born from gilts are more susceptible than those from mature sows, which suggests that immunity improves with parity. On a practical basis this suggests that gilts should be mixed with older sows that have been resident on the premises for some time. The length of time required for such natural immunization to occur is uncertain, but 1 month during late gestation seems logical.

Naturally occurring enteric colibacillosis in newborn piglets can be effectively controlled by vaccination of the pregnant dam. Field trials in large-scale farm conditions indicate that the vaccines are efficacious.[106] Partial budget analysis of vaccinating pregnant sows with *E. coli* vaccines revealed an economic return on investment of 124% because of the decrease in morbidity and mortality due to diarrhea in piglets 1–2 weeks of age.[107] Three antigen types of pili, designated $K88^+$, $K99^+$, and 987P, are now implicated in colonization of the small intestine of newborn piglets by enterotoxigenic *E. coli*. The vaccination of pregnant sows with oral or parenteral vaccines containing these antigens will provide protection against enterotoxigenic colibacillosis associated with *E. coli* bearing pili homologous to those in the vaccines. The parenteral vaccines are cell-free preparations of pili, and the oral vaccines contain live enteropathogenic *E. coli*. The oral vaccine is given 2 weeks before farrowing and is administered in the feed daily for 3 days as 200 mL per day of a broth culture containing 10^{11} *E. coli*. A simple and effective method of immunization of pregnant sows is to feed live cultures of enterotoxigenic *E. coli* isolated from piglets affected with neonatal colibacillosis on the same farm. The oral vaccine can be given in the feed, beginning about 8 weeks after breeding and continued to parturition. The oral vaccine results in the stimulation of IgA antibody in the intestinal tract, which is then transferred to the mammary gland and into the colostrum. A combination of oral and parenteral vaccination is superior to either route alone. The parenteral vaccine is given about 2 weeks after breeding and repeated 2–4 weeks before parturition. The parenteral vaccination results in the production of high levels of IgM antibody for protection against both experimental and naturally occurring enterotoxigenic colibacillosis. This vaccination also reduces the number of *E. coli* excreted in the feces of vaccinated sows, which are major sources of the organism. Immunization of pregnant sows with an *E. coli* bacterin enriched with the $K88^+$ antigen results in the secretion of milk capable of preventing adhesion of $K88^+$ *E. coli* to the gut for at least 5 weeks after birth, at which time the piglet becomes naturally resistant to adhesion by the organism.

The possibility of selecting and breeding from pigs that may be resistant genetically to the disease is being explored. The highest incidence of diarrhea occurs in progeny of resistant dams and sired by susceptible sires. The homozygous dominants (SS) and the heterozygotes (Ss) possess the receptor and are susceptible whereas in the homozygous recessives (ss) it is absent and the pigs are resistant. Sows that are genetically resistant may not be able to mount an immune response to the $K88^+$ antigen because of the inability of the organism to colonize the intestinal tract.

Competitive exclusion culture

An alternative method of control is the use of competitive exclusion cultures.[108] The theory of competitive exclusion technology is to colonize the neonatal gastrointestinal tract with beneficial/commensal bacteria considered to be the normal flora of the healthy animals of a particular species. The mechanism of action is not known but hypotheses include: exclusion of enteropathogens by competitive attachment sites and/or for nutrients; stimulation of the local immune mechanisms, which preclude colonization/invasion by enteric pathogens; and the production of various antimicrobial substances that either have direct action on pathogenic bacteria or produce conditions within the intestine that are unfavorable for the growth and colonization by pathogens. Experimentally, the oral administration of a porcine competitive exclusion culture to piglets within 12 hours after birth resulted in significant reductions in mortality, incidence of fecal shedding, and intestinal colonization by *E. coli* when compared to control values. Mortality decreased from 23% in the control group to 2.7% in the treated group.

Lambs and kids

Vaccination of pregnant ewes with $K99^+$ antigen will confer colostral immunity to lambs challenged with homologous enteropathogenic *E. coli*. The pregnant ewes are vaccinated twice in the first year, at 8–10 weeks and 2–4 weeks before lambing, and in the second year one vaccination 2–4 weeks before lambing is adequate.

Immunization of pregnant goats has been used to stimulate the development of lacteal immunity against naturally occurring colibacillosis in kids.[109] Vaccination of pregnant does 1 month before parturition with a subunit vaccine containing K88, K9, and 987P fimbrial antigens of *E. coli*, and *C. perfringens* types B, C, and D toxins in an aluminum hydroxide adjuvant, along with improved management conditions, was highly successful in reducing neonatal morbidity and mortality due to diarrhea.[40] Compared to two control groups, one in which no improvement in management was made and the second in which improvements were made without vaccination, in the vaccinated group with improved management conditions, neonatal morbidity and mortality were both reduced by a factor of 3 in Group 1 and by factors of 9.5 and 12.5 in Group 3. Also, the duration of diarrhea was 3.7 and 12 times shorter in the kids of Groups 2 and 3, respectively.

ENTEROHEMORRHAGIC *ESCHERICHIA COLI* IN FARM ANIMALS AND ZOONOTIC IMPLICATIONS

Enterohemorrhagic *Escherichia coli*, particularly the O157:H7 serogroup, has become a worldwide public health concern because it is the cause of 'hamburger disease'. This serotype was first recognized as a pathogen in 1982 after two human illness outbreaks in Oregon and Michigan. Since then, *E. coli* O157:H7 has caused major human illness outbreaks worldwide, including one affecting 600 people (two deaths) in the western USA and another 10 000 people (11 deaths) in Japan.

Cattle feces are a major source of *E. coli* O157:H7 that cause human diseases, most of which have been traced to consumption of undercooked beef that had been contaminated with bovine feces. In contrast to humans, cattle infected with *E. coli* O157:H7 remain free of disease and are tolerant of *E. coli* O157:H7 for most of their lives. *E. coli* O157:H7 strains are not pathogenic in calves over 3 weeks of age.

As a consequence, considerable resources have been devoted to defining the epidemiology and ecology of *E. coli* O157:H7 in the cattle environment so that control might begin at the farm level. Sheep also harbor *E. coli* O157:H7 and non-*E. coli* O157:H7 verotoxin-producing *E. coli* at rates similar to or higher than those reported in cattle.

ETIOLOGY

E. coli O157:H7 is the major serotype that was first recognized as a cause of human illness. *E. coli* O157:H7 is one of more than 60 serotypes of verotoxin-producing *E. coli* that cause a variety of human illnesses such as mild diarrhea, hemorrhagic colitis and hemolytic–uremic syndrome. These illnesses result from verotoxins (VT1 and VT2) similar to those produced by *Shigella dysenteriae* and are known for their toxic effects on African–Green Monkey kidney (Vero cells in cultures). These toxins are different proteins, are encoded by different genes and have similar toxic effects.

Several non-O157:H7 verotoxin-producing *E. coli* (O6:H31, O26:H- (nonmotile), O26:H11, O48:H21, O9:H-, O104:H21, O113:H21, and O26:H2) have been associated with human disease outbreaks in the USA and in other countries.[1] Because most of these outbreaks have been traced to consumption of undercooked beef that had been contaminated with bovine feces, cattle have been considered to be reservoirs of verotoxin-producing *E. coli*. Sheep may harbor *E. coli* O157:H7 and non-O157:H7 verotoxin-producing *E. coli* at rates similar to or higher than in cattle.

Naturally occurring cases of **attaching** and **effacing** lesions of the intestines in calves with diarrhea and dysentery and infected with *E. coli* O126:H11, the predominant verotoxin-producing *E. coli* in humans, have been described in the UK.[2] Verotoxin-producing *E. coli* and *eae*-positive non-verotoxin-producing *E. coli* have been isolated from diarrheic dairy calves 1–30 days of age.[3]

EPIDEMIOLOGY

The literature of the epidemiological surveys on the prevalence of contamination of healthy cattle with *Escherichia coli* O157:H7 has been reviewed,[4] as has the literature on the epidemiology and ecology of *E. coli* O157:H7 in bovine production environments.[5]

Occurrence and prevalence of infection

Cattle

Cattle are nonclinical natural reservoirs of *E. coli* O157:H7. Estimates of the prevalence of verotoxin-producing *E. coli* fecal carriage among populations of cattle vary considerably.

The herd prevalence of infection with *E. coli* O157:H7 in North American and European cattle herds ranges from 3–8% and 0.5–1.0% of animals, with a higher prevalence up to 5% in weaned calves and heifers.[4] Some surveys reported the organism in dairy and beef cattle at 0.28% and 0.71%, respectively.[6] Other studies found much higher levels of prevalence, such as 15.7% of cattle over a 1-year period. Monthly prevalences ranged from 4.8–36.8% and were highest in the spring and late summer.

The prevalence of *E. coli* O157:H7 is influenced by numerous variables, including the season, the scope, frequency and timing of sampling, and the conditions of sampling and storage. The organism can be found widely distributed in samples from several types of cattle including beef calves, stocker cattle, feedlot cattle, adult beef cows, dairy calves, water sources and wildlife.[7] The prevalence is commonly higher in feeder-age cattle.

The prevalence of *E. coli* O157:H7 infection in range beef calves at weaning prior to arrival at the feedlot varies from 1.7–20.0% with an average of 7.4%.[8] All herds had high prevalence of anti-O157 antibodies, ranging from 63–100% of individuals within herds. Most calves (83%) and all herds (100%) have been exposed to *E. coli* O157:H7. In a naturally infected cow/calf herd followed over a period of 2 years, postpartum shedding of *E. coli* O157:H7 and cow–calf or calf–calf transmission under confined conditions in the postpartum period appeared to be potentially important factors in initial infection of beef calves.[9] Parturition, calving pens and weaning appear to be important factors in maintaining *E. coli* O157:H7 infections in some herds.

Different serotypes of verotoxin-producing *E. coli* known to cause human illness have been found in the feces of culled beef cows at the time of shipping to slaughter.[10]

The diversity, frequency, and persistence of *E. coli* O157:H7 strains in cattle, wildlife and water sources within range cattle production environments indicates that the molecular epidemiology of the organism is very complex.[11]

The prevalence of *E. coli* O157:H7 in dairy cattle is similar worldwide and ranges from 1–5% in heifers and less than 1% in adult cattle. The herd-level prevalence varies from 0–100%.[4] The herd-prevalence of *E. coli* O157:H7 in dairy cattle in the subtropical southeastern USA in the summer months was 38.5%, and the cow-level prevalence was 6.5%.[12] Among positive herds, prevalence ranged from 3–35%. The prevalence was higher during the spring and summer months compared to the winter season. Site-specific prevalences of *E. coli* O157:H7 from the oral cavity, skin, and fecal samples were 0%, 0.7%, and 25.2% respectively. Interestingly, in these same areas, reported cases of *E. coli* O157:H7 infections in humans are relatively uncommon and do not support the hypothesis that *E. coli* O157:H7 infections in humans are rare in southern states because of the low prevalence in cattle.

Viable *E. coli* O157:H7 can be isolated from the oral cavity, multiple hide surfaces and feces of a high percentage of feedlot beef cattle, and bacterial culture of feces alone generally underestimates the prevalence of *E. coli* O157:H7 in feedlot cattle.[13]

A survey of 60 Danish dairy cattle farms found a herd-prevalence of *E. coli* O157:H7 of 17% and an individual animal prevalence of 3.6%.[14] The high-risk age group for *E. coli* O157:H7 was calves between 2 and 6 months of age (8.6% positive), in contrast to calves under 2 months of age (0.7%) and cows (2.4%).[14]

E. coli O157:H7 is widespread in cattle in England and Wales. During a survey between June and December, the herd-prevalence on positive farms ranged from 1.1–51.4%, and the overall individual animal prevalence was 4.2%, and 10.3% among animals in positive herds.[15] The prevalence of excretion was least in calves under 2 months of age, peaked in calves between 2 and 6 months of age and declined thereafter. Multiple phage types of *E. coli* O157:H7 were isolated from almost a third of the herds, and the phages types were similar to those responsible for human infections in England and Wales during the same period. Similar prevalences have been found in dairy cattle in Brazil.[16]

Attaching and effacing *E. coli* (AEEC) of various strains have been associated with naturally occurring and experimental dysentery in calves, and outbreaks of hemorrhagic enteritis with attaching and effacing lesions of the colon associated with *E. coli* O126 infection have occurred in heifers 8–12 months of age.[17] *E. coli* O126 is recognized as an enterohemorrhagic pathogen in humans.

Prevalence of infection in cattle, sheep, and pigs at slaughter

Based on fecal sampling, the prevalence rate of infection of cattle with *E. coli* O157:H varies considerably. Based on fecal samples from the rectums of cattle at slaughter in the UK, the animal-level prevalence was 7.5% and the group prevalence was 40.4%.[18] Of the infected animals, 9% were high shedders whose feces contained *E. coli* O157:H7 at concentrations of more than 10^4 colony-forming units (cfu)/g. This 9% also represented more than 96% of the total *E. coli* O157:H7 produced by all animals tested. This indicates that the presence of high-shedding animals at the abattoir increases the potential risk of beef contamination during the slaughtering process and stresses the need for correct hazard analysis and critical control points procedures.

There is a correlation between the prevalence of *E. coli* O157:H7 in the feces, hides and carcasses of beef cattle during slaughter.[19] Overall, the prevalence of *E. coli* O157:H7 in feces and on hides was 28% and 11%, respectively. Carcass samples were taken at three points during processing: pre-evisceration, post-evisceration before antimicrobial intervention, and postprocessing after carcasses entered the cooler. The prevalence of *E. coli* O157:H7 in the three post processing samples was 43%, 18%, and 2%, respectively. Antimicrobial intervention included steam pasteurization, hot water washes, organic acid washes, or combinations of these treatments. The reduction in carcass prevalence from pre-evisceration to post-processing suggests that sanitary procedures can be effective within processing plants. Fecal and hide prevalence were significantly correlated with carcass contamination, indicating a role for control of *E. coli* O157:H7 in live cattle.

The prevalence of fecal carriage of *E. coli* O157:H7 in cattle and sheep sampled throughout the year at the abattoir before slaughter was 4.7% for cattle and 1.7% for sheep.[20] The most frequently recovered *E. coli* O157:H7 isolates were phage types 2, 8, and 21/28 in cattle and

4 and 32 in sheep, the five most frequently isolated phage types associated with illness in people in Great Britain during the same survey period. In a commercial beef abattoir in Ireland, carcass contamination with *E. coli* O157:H7 can occur during removal of the hide and tying the bung, and this contamination can remain on the carcass during subsequent processing.[21]

The prevalence of attaching and effacing *E. coli* isolated from cattle, sheep, and pigs at slaughter in England and Wales was 8.1%, with a frequency of 18% in sheep, 6% in cattle, and less than 1% in pigs.[22] Several different *eae*-positive serogroups were isolated; some possessed *stx1* but none had *stx2*.

An overall prevalence of *E. coli* O157:H7 fecal shedding by New York cull dairy cattle of 1.3% was found in specimens just before processing the packing plant.[23]

In a survey of downer cattle submitted to two slaughter facilities in Wisconsin, the prevalence of *E. coli* O157:H7 in the feces and/or tissues of downer dairy cattle was 4.9% compared to 1.5% in healthy cattle.[24]

PCR has been used to detect virulence genes and molecular epidemiology of *E. coli* O157:H7 isolates from abattoirs.[25] Samples included swabs of tools, knives and saws, fecal samples, carcass samples and ears removed after slaughter. From 1432 samples, 143 *E. coli* O157:H7 strains were isolated. These results indicate the increase in contamination frequencies during transportation to the abattoir and the lairage period before slaughter, as a result of cross-infection caused by mixing of animals from different sources.[25] Surveys at the abattoir could be useful in detecting infected cattle herds and allow focusing on potentially infected herds, in concert with on-farm surveys.

Sheep and goats

Sheep and goats can be naturally infected with *E. coli* O157:H7 and sheep have been used as a model of ruminant infection.[26] Sheep may harbor *E. coli* O157:H7 and non-O157:H7 verotoxin-producing *E. coli* at rates similar to or higher than in cattle. Prevalence rates of 67% and 45% have been reported in Germany and Australia, respectively.[1] Worldwide, sheep have been shown to shed several non-O157 verotoxin-producing *E. coli* in their feces.[1] Several of these verotoxin-producing *E. coli* serotypes have been associated with sporadic cases or major outbreaks of human illnesses. Thus lamb, mutton and their products share a food safety risk factor similar to that of beef. Non-O157:H7 verotoxin-producing *E. coli* have been found in sheep grazing irrigated pasture or arid rangeland forage in Nevada.[1] In Norway, sheep have carried Shiga-toxin-producing *E. coli* serogroups O5, O91, and O128, and their virulence factors have been characterized.[27] In Brazil, Shiga-toxin-producing *E. coli* occurred in the feces of 51% of healthy sheep grazing on pasture.[28] The serotypes could cause severe disease in humans.

Wildlife

Based on fecal samples of deer submitted by hunters, *E. coli* O157:H7 have been found in the feces of free-ranging white-tailed deer in Nebraska at a rate of 0.25%.[29] The prevalence of infection of *E. coli* O157:H7 in white-tailed deer sharing rangeland with cattle was 2.4%.[29] The low overall prevalence of *E. coli* O157:H7 and the identification of only one site with positive deer suggest that wild deer are not a major reservoir of *E. coli* O157:H7 in the southeastern USA.[30]

Pigs

E. coli O157:H7 has been found in fecal samples of finished pigs at the time of slaughter but the prevalence was very low at 0.08%. In experimentally infected pigs, *E. coli* O157:H7 can persist for more than 2 months.[31] Pigs may have the potential to be reservoirs hosts for *E. coli* O157:H7 but the magnitude of the risk needs to be determined.

Risk factors

Animal risk factors

Healthy normal cattle are a major reservoir for enterohemorrhagic *E. coli* O157:H7 strains, which cause disease in humans. Cattle that are infected with *E. coli* O157:H7 remain free of disease and are tolerant of *E. coli* O157:H7 for their entire lives. Neonatal calves under 36 hours of age are susceptible to experimental inoculation with *E. coli* O157:H7 and develop attachment and effacing lesions in both the large and small intestines.[32] Neither experimentally infected calves nor older cattle with *E. coli* O157:H7 develop extraintestinal vascular lesions. The lack of vascular receptors for Stx in cattle renders them resistant to the Stx.[33] Neither viable *E. coli* O157:H7 nor Stx-containing extracts caused fluid accumulation in ligated ileal loops of newborn calves, whereas doses of Stx did cause fluid accumulation experimentally in rabbits.[33]

Environmental and management risk factors

The factors associated between management, climate and the prevalence of *E. coli* O157:H7 in feedlot-water tanks and in feedlot-cattle feed have been examined in selected feedlots in the USA.[34] *E. coli* O157:H7 was isolated from 13% of the water tanks and at least one water tank was positive on 60% of the feedlots. The factors associated with *E. coli* O157:H7 in water were a greater percentage of cattle shedding *E. coli* O157:H7 in the feces within the same pen, higher concentrations of total *E. coli* in the water, lack of clarity of the water, the use of fly traps, the reported frequency of rodent sightings in the pen or alley area, and the weather at the time of sampling. *E. coli* O157:H7 was isolated from 14.9% of the feed samples obtained from the feedbunks. Factors positively associated with *E. coli* O157:H7 in the feed were higher heat index at the time of sampling, the presence of cottonseed meal in the ration, and the feedlot location.

The association between management, climate and *E. coli* O157:H7 in the feces of feedlot cattle in the midwestern USA has been examined.[34] The prevalence of *E. coli* O157:H7 was 10.2% at the sample level, 52.0% at the pen-level and 95.9% at the feedlot level. The factors associated with the presence of *E. coli* O157:H7 in cattle feces were the frequency of observing cats in the pens or alleys, the presence of *E. coli* O157:H7 in the water tanks (positive association), the historical use of injectable mass medication (positive association), the use of antibiotics in the ration or water (negative association), the wetness of the pen, number of cattle in the pen (negative association), wind velocity (positive association), and height of the feed bunk (positive association).

Housing and management practices

Environmental dissemination of an inoculated strain of *E. coli* O157:H7 given to dairy calves spreads more quickly when calves are housed in groups compared to calves housed in individual pens from 7–110 days of age.[35] This indicates that control may depend on reduction of horizontal transmission within cattle groups, thus decreasing prevalence. The use of segregated penning systems rather than group housing of weaning calves may reduce the prevalence of these potential pathogens within the calf unit. If this results in a reduction in the general herd or farm Shiga-toxin-producing *E. coli* prevalence, then such changes in calf-rearing practice may offer a control point for preharvest Shiga-toxin-producing *E. coli* risk on dairy farms.

The housing of beef suckler cows in Scotland during the winter months was associated with increased level of shedding of *E. coli* O157:H7.[36]

Pathogen risk factors

Virulence attributes and mechanisms

The primary feature of Shiga-toxin-producing *E. coli* isolates is their ability to produce potent cytotoxins encoded by

stx1 and *stx2*. They also have the ability to adhere to the intestinal mucosa in an intimate manner through the attachment and effacement protein intimin, encoded by the *eaeA* gene, and most produce a plasmid-encoded enterohemolysin, encoded by the *elixA* gene. Shiga-toxin-producing *E. coli* isolates that cause disease in humans usually have one or both of these virulence-associated factors and have been referred to as complex Shiga-toxin-producing *E. coli* (cSTEC). The most often reported Shiga-toxin-producing *E. coli* serotype causing diseases in humans worldwide is *E. coli* O157:H7, but non-O157 serotypes such as O111:H- and O113:H21 are commonly found to cause diseases such as hemolytic–uremic crisis. There are over 160 Shiga-toxin-producing *E. coli* serotypes that have been isolated from human patients around the world. A broad range of cSTEC serotypes have been isolated in Australian cattle[37] and in Argentina.[38]

Molecular typing of *E. coli* O157:H7 strains is done using pulse-field gel electrophoresis (PFGE) and is accepted as the standard technique in epidemiological investigations. The technique can be used to demonstrate horizontal transmission of a single strain type among animals within a farm and comparing sporadic isolates between animals and humans. The technique has been used to study *E. coli* O157:H7 isolates from cattle and human cases isolated in France and in northern Italy and from French and Spanish cattle imported to Sicily.[39]

Acid resistance

E. coli O157:H7 is extremely acid-resistant, which contributes to the low infectious dose for humans, which has been estimated to be fewer than 700 cells and possibly even as low as 10.[26] Certain strains of *E. coli* O157:H7 have been considered to be more acid-tolerant than some commensal *E. coli*. In addition, *E. coli* O157:H7 strains may become acid-habituated by exposure to weak acids in the rumen. Consequently, *E. coli* O157:H7 may survive passage through the acid barrier in the stomach, colonizing and replicating in the ruminant colon. The numbers of *E. coli* O157:H7 are much higher in the colon than the rumen.[40]

The acid-resistance characteristics of *E. coli* O157:H7 led to the hypothesis that feeding grain to cattle created an ideal environment in the gastrointestinal tract to promote the growth and persistence of the organism. The research data on the effects of grain versus forage feeding to cattle and its effects on fecal *E. coli* O157:H7 are limited and conflicting. Some early research indicated that grain feeding increased the dissemination of acid-resistant *E. coli* by cattle, and that feeding hay for a brief period immediately before slaughter would decrease the shedding of *E. coli* O157:H7. The numbers, persistence and acid resistance of generic coliforms and *E. coli* O157:H7 from various gastrointestinal tract sites of cattle fed grain or hay were compared. Grain-feeding or hay-feeding did not affect survival of *E. coli* O157:H7 in the rumen, nor its passage through the abomasum (pH 2.0) to the duodenum.[41] Generic coliforms from the rumen and rectum of hay-fed animals were more sensitive to an acid shock than coliforms from gut locations in grain-fed animals. Thus *E. coli* O157:H7 in bovine ingesta are acid-resistant regardless of animal diet.[41] Abruptly switching cattle from a high-grain diet to a high-quality hay-based diet has been shown to reduce generic *E. coli* and *E. coli* O157:H7 populations but the magnitude of the reduction has varied among studies.[42,43]

Other work has shown that, in the context of acid tolerance, *E. coli* O157:H7 does not appear to be greatly different from commensal *E. coli*.[44] However, *E. coli* O157:H7 may have the ability to generate a higher 'tail' population and this, together with the low infective dose and changes in our lifestyle, has allowed the organism to become a major pathogen. Recent studies on the effect of forage or grain diets have shown that cattle fed forage diets had ruminal persistence of fecal *E. coli* O157:H7 at quantifiable concentrations for twice as long as cattle fed grain diets.[45] Diets high in grain generate high volatile fatty acid concentrations and low pH, creating a less conducive environment for *E. coli* O157:H7, whereas lower volatile fatty acid concentrations and higher pH in forage-fed cattle may be more conducive to the growth and survival of the organism. Monensin supplementation decreased the duration of shedding with forage diet, and the cecum and colon were culture-positive for *E. coli* O157:H7 more often than the rumen of cattle.

Antimicrobial resistance

The prevalence of antimicrobial resistance among isolates of *E. coli* O157:H7 recovered from clinical cases in humans, pigs, cattle, and food over a 15-year period (1985–2000) in the USA has been described.[46] There was a high prevalence of resistance to tetracycline, sulfamethoxazole, cephalothin, and ampicillin. The highest prevalence occurred among isolates from pigs, where more than 50% of all isolates were resistant to sulfamethoxazole, cephalothin, or tetracycline and more than 20% were resistant to ampicillin or gentamicin.

Methods of transmission

Sources of organism

Ruminants as reservoirs

E. coli O157:H7 is a transient inhabitant of the gastrointestinal tract of normal healthy ruminants. Cattle and sheep feces serve as sources for contamination of feed and water sources. Fecal **shedding** is **transient** in cattle, often lasting 1–3 months or less, but the organism can persist on individual farms for up to 2 years.[47] Longitudinal surveys have shown that maintenance of *E. coli* O157:H7 in cattle herds relies on continual reinoculation of individual cattle.[6] Repeated isolations of *E. coli* O157:H7 from healthy beef and dairy cattle demonstrate that cattle are asymptomatic carriers of the organism. Short periods of relatively high prevalence of excretion are separated by longer periods of reduced or undetectable shedding. This has contributed to the variance in prevalence data reported in the literature.

Fecal shedding is more prevalent in the USA and Canada during the summer months and is more prevalent in the UK in the spring and fall. Fecal shedding also varies among different classes of animal. Weaned heifers between 3 months of age and breeding age are more likely to shed *E. coli* O157:H7 in feces than adult cattle or younger calves. Increased shedding is associated with weaning and with the first month of lactation in dairy herds, and culled dairy cattle have a higher prevalence than previously reported. Contaminated water troughs, particularly those that are allowed to develop sediments, provide an environment for survival, proliferation and horizontal spread of *E. coli* O157:H7. The organism can also proliferate to very high levels in moist silage.

In Alberta, Canada, the prevalence of *E. coli* O157:H7 was 12.4% of fecal samples from yearling cattle and 2.0% of the fecal samples from cull cows.[48] The prevalence of *E. coli* O157:H7 in yearling cattle increased from 1.4% in the winter months to 40% in the summer. In feedlots, *E. coli* O157:H7 was isolated in pre-slaughter pens of cattle from the feces (0.8%), feedbunks (1.7%), water troughs (12%) and incoming water supplies (4.5%) but not from fresh total mixed rations. Fresh total mixed rations did not support the growth of *E. coli* O157:H7 from feces following experimental inoculation. Many different subtypes of *E. coli* O157:H7 were isolated from the feces, water and feed in pens of feedlot cattle. This suggests that methods to control *E. coli* O157:H7 in feedlot cattle will have to center not only on reducing fecal shedding of the organism in cattle but on the potential of reinfection from

environmental sources, such as water and feed, both at the feedlot and before the cattle arrive on the premises.

The pattern of fecal carriage of *E. coli* O157:H7 in cattle finished under modern intensive feedlot management conditions has been examined.[49] *E. coli* O157:H7 was isolated from 13% of fecal samples, with highest prevalence values of the organism in pens supplied with chlorinated drinking water compared with nonchlorinated water pens. Over a period of 7 months from April to September, certain specific clonal types of *E. coli* O157:H7 persisted and predominated despite massive cattle population turnover. This suggests that the farm environment, and not necessarily the incoming cattle, is an important potential source of *E. coli* O157:H7 on farms. In a longitudinal study of *E. coli* O157:H7 in a cattle-finishing unit in Finland most farm isolates belonged to one PFGE genotype (79.6%) and the remainder to closely related PFGE genotypes. Thus the finishing unit rather than the introduction of new cattle was the source of *E. coli* O157:H7 at the farm and *E. coli* O157:H7 seemed to persist well on barn surfaces.[50]

One dairy calf infected with and shedding *E. coli* O157:H7 can infect other negative calves in a confined environment within 8 days, and the duration of shedding may range from 17–31 days.[51] Experimentally, some calves may begin prolonged, high-level shedding of *E. coli* O157:H7 after only very low exposure doses, and other calves exposed to calves excreting *E. coli* O157:H7 in their feces are at high risk of infection.[52] Experimentally infected calves may begin shedding within 6 days after oral inoculation and continue shedding for up to 70 days.

Other species

E. coli O157:H7 subtypes indistinguishable from those detected in cattle have been found in pigeons, geese, horses, dogs, opossums, and flies. *E. coli* O157:H7 also has been isolated from insects in cattle environments but their role in dissemination is uncertain.

Wild birds

E. coli O157:H7 has been found in the feces of wild birds, which may be important in the spread of the organism within and between farms.[53] The presence of wild geese was a significant risk factor in the shedding of *E. coli* O157:H7 by beef suckler cows in Scotland.[36]

Flies

The increased presence of flies around cattle during the summer months represents a potential mechanism for the spread of *E. coli* O157:H7 among farm animals. *E. coli* O157:H7 has been isolated from the crop of house flies (*Musca domestica*) immediately after feeding on a bacterial preparation.

Environmental sources

There are many possible sources of *E. coli* O157:H7 in the farm environment, including manure piles, ponds, dams and wells, barns, calf hutches, straw and other bedding, feed and feed troughs, water and water troughs, farm equipment, ground surface and pasture, and watercourses. Once in the environment, the organism can be transferred to other sites by rainwater, wind, and removal and spreading of manure, including animals and humans.[6]

Water supplies for livestock

Drinking water offered to cattle is often of poor microbiological quality and the daily exposure of animals to *E. coli* O157:H7 from this source can be substantial.[54] The degree of *E. coli* exposure is positively associated with proximity of water troughs to the feedbunk, protection of the trough from sunlight, and warmer weather. Cattle water troughs can serve as environmental reservoirs for *E. coli* O157:H7 and as a long-term source infection for cattle.[55]

The experimental inoculation of *E. coli* O157:H7 with 1 L of water into dairy calves in a confined environment resulted in shedding of the organism by the calves within 24 hours after administration.[51] The duration of shedding varied from 18 to more than 43 days and the number of doses necessary to initiate shedding varied among calves.

E. coli O157:H7 is present in as many as 10% of water troughs. *E. coli* O157:H7 was present in the water or water-tank sediment in 13.1% of water tanks in a feedlot in the USA and 60% of feedlots had at least one positive tank.[56] Cattle were more likely to be shedding *E. coli* O157:H7 in pens with positive water tanks, and water was more likely to be positive when *E. coli* O157:H7 was detected in the sediment.

Chlorination of input water in feedlots was unable to reduce the prevalence of *E. coli* O157:H7-contaminated water troughs.[49]

Water trough sediments with feces from cattle excreting *E. coli* O157:H7 may serve as a long-term reservoir of the organism on farms and a source of infection for cattle. The accumulation of large amounts of organic matter would be expected to rapidly inactivate the biocidal activity of chlorine and provide an ideal niche for the survival of the organism.[55] *E. coli* O157:H7 can survive in farm water under field and shed conditions at temperatures less than 15°C for up to 24 days.[57] The addition of feces to water outdoors resulted in survival for 24 days.

E. coli O157:H7 has been isolated from surface waters collected from a Canadian watershed.[58] Systematic sampling of surface water within the Oldman River basin in southern Alberta reveals that it often contaminated with *E. coli* O157:H7 and *Salmonella* spp. The prevalence of *E. coli* O157:H7 and *Salmonella* spp. in water samples was 0.9% and 6.2%, respectively. The region surveyed is noted for high cattle density as well as for one of the highest incidences of gastroenteritis in Canada, resulting from infection by *Salmonella* spp. and *E. coli* O157:H7. While the data indicated a relationship between high livestock density and high pathogen levels in southern Alberta, analysis of the point source data indicates that the predicted manure output from cattle, pig, and poultry feeding operations was not directly associated with the prevalence of either *Salmonella* spp. or *E. coli* O157:H7. Variations in time, amount and frequency of manure applications on to agricultural lands may have influenced levels of surface-water contamination with these bacterial pathogens.

Feed supplies

The prevalence of *E. coli* O157:H7 in cattle feeds in feedlots was 14.9%, higher than previously reported, which may be due to more sensitive detection methods.[59] Feed may be a vehicle for dissemination and colonization; however, the source of the *E. coli* O157:H7 contamination in cattle feed is uncertain. Possible sources include saliva and fecal contamination by cattle or other species, or by wildlife, including birds, rodents, and insects. Another possible source is contaminated feed components mixed into the feed. PFGE profiles of *E. coli* O157:H7 isolated from a component feed sample closely resembled that isolated later from the same farm, suggesting that cattle feed may be an important vector for the transmission of *E. coli* O157:H7.[60]

Manure

Survival of *E. coli* O157:H7 in manure and manure slurry has been observed under various experimental and environmental conditions. The use of manure as fertilizer could explain foodborne outbreaks of *E. coli* O157:H7 associated with unpasteurized apple cider, potatoes, and other vegetables. Because *E. coli* O157:H7 can survive for extended periods of time, proper manure management is of major importance in preventing the spread of this organism to the environment. Composting is an effective method for eliminating pathogens such as *E. coli* O157:H7 from manure.

Soil

E. coli O157:H7 inoculated into loam and clay soils can survive for 25 weeks and in

sandy soil for 8 weeks. The organism was detectable for up to 7 days after inoculation into the uppermost 2.5 cm of the soil, and for up to 7 days on grass plots inoculated with a fecal slurry from dairy cattle at an application rate of *E. coli* O157:H7 of 660 cfu/m^2.

Animal-holding facilities

The organism can be cultured from rope devices in a feedlot pen that cattle rub or chew and there is a correlation with the prevalence of cattle shedding the organism in the feces from within the same pen.[61] This pen-test strategy may be useful to identify pens of cattle posing a higher risk to food safety.

Immune mechanisms

The Esp and Tir proteins secreted by *E. coli* O157:H7 play critical roles in the development of the attaching and effacing lesions and are recognized serologically in human patients with the hemolytic crisis syndrome. Antibodies to intimin, Esp and Tir proteins have been detected in HUS patients following infections with *E. coli* O157:H7.[26]

In contrast, little is known about the immune responses of cattle to infection with *E. coli* O157:H7.[26] *E. coli* O157:H7 and other enterohemorrhagic *E. coli* are shed sporadically by cattle, and it appears that natural exposure to *E. coli* O157:H7 does not confer protection on the host. Calves 13–30 days of age developed anti-O157 IgG responses following experimental oral inoculation with *E. coli* O157:H7.[62] Mature cows did not develop a significant increase in their serum anti-O157 IgG levels following oral inoculation. These observations suggest that local immunity to *E. coli* O157:H7 may not develop to any degree in the intestine and that immunization to reduce fecal shedding of *E. coli* O157:H7 may not be effective.

Vaccination of cattle with antigenic bacterial proteins involved in colonization can significantly reduce fecal shedding and prevalence of *E. coli* O157:H7 in cattle. Vaccination of cattle with *E. coli* O157:H7 type III secreted proteins can reduce the numbers of *E. coli* O157:H7 shed in the feces, and the duration of shedding in experimentally challenged cattle, and in feedlot cattle under field conditions.[63] Vaccination of pregnant gilts with intimin from *E. coli* O157:H7 induced high intimin-specific immune responses in the serum and colostrum, and suckling neonatal piglets had reduced bacterial colonization and intestinal lesions following experimental challenge.[64] These results suggest that vaccination may be a useful preharvest strategy for reducing the prevalence of *E. coli* O157:H7 infection in cattle.

Zoonotic implications

> *However secure and well-regulated civilized life may become, bacteria, protozoa, viruses, and infected fleas, lice, ticks, mosquitoes, and bedbugs will always lurk in the shadows ready to pounce when neglect, poverty, famine, or war lets down the defenses. And even in normal times they prey on the weak, the very young and the very old, living along with us in mysterious obscurity awaiting their opportunities.*
>
> Zinsser, 1934

The above wisdom relates to *E. coli* O157:H7.

Enterohemorrhagic strains of *E. coli*, especially serotype *E. coli* O157:H7, have been linked in humans with hemorrhagic colitis, hemolytic–uremic syndrome and thrombocytopenic purpura from eating contaminated foods, such as beef and dairy products, vegetables, and apple cider, from contaminated drinking water or from contact with infected animals or contaminated environments. As few as 10 *E. coli* O157:H7 bacteria can cause illness in humans.

In 1999, the Centers for Disease Control and Prevention estimated that 73 480 people per year in the USA were infected with *E. coli* O157:H7 and that 61 of these cases were fatal.[26] Most cases of *E. coli* O157:H7 illness are attributable to food-borne infection; however, acquisition of disease by direct contact with animals and manure at petting zoos and dairy farms are of increasing concern. Among *E. coli* O157:H7 foodborne outbreaks in 1999, one-third were due to beef; historically, undercooked ground beef is the most common vehicle. Consumption of pink hamburgers at home or in restaurants is a risk factor for *E. coli* O157:H7 infection. Microbiological testing of ground beef patties from a large outbreak that occurred in the Pacific northwest between November 1992 and February 1993 suggested that the infectious dose for *E. coli* O157:H7 is fewer than 700 organisms. This represents a strong argument for enforcing zero tolerance for this organism in processed food and for markedly decreasing contamination of raw ground beef. A major source of the bacteria in ground beef is bovine feces, which contaminates carcasses before evisceration; the organism is thought to be spread from contaminated hides to the surfaces of carcasses at slaughter. In addition to feces and hides, *E. coli* O157:H7 has been isolated from the oral cavities of cattle.

In May 2000, *E. coli* O157:H7 and *Campylobacter jejuni* contaminated the drinking water supply in Walkerton, Ontario, Canada.[65,66] As a result, seven people died and over 2000 became ill. The pathogens causing the outbreak were attributed to contamination of the town's water well arising from cattle manure from a nearby cattle farm following a period of heavy spring rainfall. Failure to adequately chlorinate the water supply resulted in the contaminated water being consumed by the people in the town.

Argentina has one of the highest recorded incidence of hemolytic–uremic crisis in the world at 300–400 cases per year.[38] It also has the highest per capita consumption of beef of any country in the world.

Visits to farms for recreational or educational purposes have become an important part of the tourism and leisure industries in some countries.[67] The emergence of *E. coli* O157:H7, with its very low infectious dose and associated risks of serious human illness, has greatly increased the potential for zoonotic disease acquired from livestock, including those on open farms. The livestock of these farms may include sheep, goats, mature cattle and calves, pigs, donkeys, ponies, rabbits, guinea pigs, chipmunks, laying hens, bantams, ducks, geese, and a variety of waterfowl. Outbreaks of *E. coli* O157:H7 infection have occurred in people visiting these farms and the *E. coli* O157:H7 has been isolated primarily from the calves and goats.

In a large outbreak of *E. coli* O157:H7 infections among visitors to a dairy farm, predominantly children, high rates of carriage of *E. coli* O157:H7 among calves and young cattle most probably resulted in contamination of both the hides of the animals and the environment.[68,69] Contact with calves and their environment was associated with an increased risk of infection, whereas hand-washing was protective. Thirteen percent of the cattle were colonized with *E. coli* O157:H7, which had the same distinct pattern on PFGE found in isolates from the patients. The organism was also recovered from surfaces that were accessible to the public.

Phenotyping and genotyping of *E. coli* O157:H7 has been used to verify transmission of the organism from dairy cattle to humans with *E. coli* O157:H7 infections.[70] The isolates from cattle and humans were indistinguishable, which indicates that the infection originated from the farms. However, it may not be possible to determine whether the source was unpasteurized milk or direct or indirect contact with cattle.

Transmission of *E. coli* O157:H7 occurs by three major routes: food items such as undercooked meat or unpasteurized milk, person-to-person spread, and direct or indirect contact with animals. Infections

have been associated with visits to cattle farms and farms open to the public, with consumption of farm products, and with camping on a cattle-grazing site. Infections have also been described in farm family members and other farm dwellers.

Undercooked beef products, unpasteurized milk and dairy products, and contaminated water are all potential vehicles for human infection with *E. coli* O157:H7.

Economic importance

The economic consequences of beef contaminated with *E. coli* O157:H7 are enormous. Since 1994 in the USA, millions of kilograms of ground beef have been recalled from retail outlets because of contamination with *E. coli* O157:H7. Such beef products must be destroyed and not used for animal or human food. Human illness associated with the most common food-borne pathogens alone cost the US economy more than $7 billion each year.[71] Some of these human outbreaks have been linked to the consumption of meat-based products or to contact with animals and their wastes.

PATHOGENESIS

Enterohemorrhagic *E. coli* are characterized by the presence of Shiga toxin (Stx) genes, **locus for enterocyte effacement (LEE)** and a high-molecular-weight plasmid that encodes for a hemolysin.[47] These three virulence factors are present in most *E. coli* associated with bloody diarrhea and hemolytic–uremic crisis in humans.

The LEE is a large cluster of genes that are collectively responsible for the intimate attachment of the bacterium to the apical membrane of the enterocyte and subsequent destruction or effacement of the microvilli. The intimate attachment of the bacterial cell to the epithelium is attributed to the adhesin **intimin** and Tir, a bacterial protein, which is inserted into the host membrane and serves as the response for intimin. Both factors are part of the LEE in enteropathogenic *E. coli* and enterohemorrhagic *E. coli*. Intimin appears to be an essential component in initiating attachment, colonization and the subsequent pathological changes that follow infection with enteropathogenic *E. coli* and enterohemorrhagic *E. coli*.

E. coli O157:H7 also possesses a high-molecular-weight plasmid that contains several putative virulence genes, including a pore-forming hemolysin. Virulence plasmids are common features of pathogenic *E. coli*, encoding toxins, adhesins and other factors necessary for colonization, survival, and ability to cause disease in its animal host.

In ruminants, *E. coli* O157:H7 persists and proliferates in the lower gastrointestinal tract and does not remain for long periods in the ruminant stomachs or duodenum.[34] *E. coli* O157:H7 exhibits a novel tropism for the terminal rectum in cattle. In calves experimentally infected with *E. coli* O157:H7, in almost all persistently colonized animals, the majority of tissue-associated bacteria identified are in a region within 3–5 cm proximal to the rectoanal junction.[72] This region contains a high density of lymphoid follicles, and microcolonies of the bacterium are readily detectable on the epithelium of this region by immunofluorescence microscopy. As a consequence of this specific distribution, *E. coli* O157:H7 are present predominantly on the surface of the fecal mass. Sampling the feces and terminal rectum of cattle immediately after slaughter found higher numbers of *E. coli* O157:H7 at the site closer to the rectoanal junction, and low- and high-level carriers were identified.[73] High-level carriage was detected in 3.7% of the animals, and carriage on the mucosal surface of the terminal rectum was associated with high-level fecal excretion. This supports the finding than the mucosal epithelium of the terminal rectum of cattle is an important carriage site for *E. coli* O157:H7, and that high-level fecal shedding of *E. coli* O157:H7 results from colonization of this site.

Experimental reproduction

Experimentally, *E. coli* O157:H7 causes fatal ileocolitis in newborn calves under 36 hours of age.[27] Affected calves developed diarrhea and enterocolitis with attaching and effacing lesions in both the large and small intestines by 18 hours after inoculation.

Natural and experimental infection of calves from 13–30 days of age and mature cows with *E. coli* O157:H7 does not result in any clinical signs of disease and no lesions were present at necropsy.[62] A serological response occurred in the calves but not in the cows.

Attaching and effacing intestinal lesions can be produced by experimental inoculation of 6-day-old conventionally reared lambs with *E. coli* O157:H7.[74] All animals remain normal clinically but attaching and effacing lesions occur in the cecum at 12 and 36 hours post-inoculation and in the terminal colon and rectum at 84 hours. This indicates that the well-characterized mechanisms for intimate attachment encoded by the locus for enterocyte effacement of *E. coli* O157:H7 may contribute to the initial events of colonization. Similar lesions can be produced in ligated intestine loops of 6-month-old sheep using *E. coli* O157:H7.[75]

CLINICAL PATHOLOGY

Detection in feces

A review is available of the details of the culture techniques for the detection of *E. coli* O157:H7 in the feces of cattle.[76]

A number of culture methods for the screening of fecal specimens for *E. coli* O157:H7 are available but no standard protocol is recommended.[77] Because none of the techniques provides 100% sensitivity, the isolation rates of *E. coli* O157:H7 from bovine feces using only one test will result in an underestimation of the incidence of the organism in bovine feces. Performing more than one test must be considered.

Feces may be directly plated on to selective media and/or differential agars or feces may be selectively enriched in a variety of broth enrichment protocols followed by plating on to selective agars. This enrichment step may be followed by immunomagnctic separation with beads coated with O157-specific antibody before plating on to agar.[76] Because *E. coli* O157:H7 often occurs in small numbers in bovine feces, immunomagnetic separation is now in common use. Enrichment broths are comparable to each other but they are superior to direct plating.[23] In addition, regardless of the culture protocol used, recovery of *E. coli* O157:H7 is more likely from fresh fecal samples than from frozen samples.[23]

PFGE has been used extensively to investigate the epidemiology of *E. coli* O157:H7, although it has not been evaluated as a tool for establishing genetic relationships.[78] PCR has been used to detect virulence genes and molecular epidemiology of *E. coli* O157:H7 isolates from abattoirs.[25]

A real-time PCR kit for the detection of *E. coli* O157:H7 in bovine fecal samples is commercially available.[79] Both the sensitivity and specificity of the assay are 99% for isolates in pure culture and the assay detects 1 cfu/g of *E. coli* O157:H7 in artificially inoculated bovine feces following enrichment.

The culture of swabs of the rectoanal junction mucosa is as sensitive and may be more sensitive than culture of feces for the detection of *E. coli* O157:H7 in cattle.[80] This is because the sample site is the location of *E. coli* O157:H7 colonization, which contains high numbers of the organism. For both experimentally and naturally infected cattle, the rectoanal mucosa predicted the duration of infection. Cattle transiently shedding *E. coli* O157:H7 for less than 1 week were positive by fecal culture only and not by rectoanal mucosa culture, whereas colonized animals were positive early on by rectoanal mucosa junction culture.

Detection in ground beef

A rapid, specific and quantitative method to detect *E. coli* O157:H7 in ground beef in a combined immunomagnetic separation for cell capture and concentration with real-time PCR has been developed.[81]

CONTROL

In spite of the large amount of information generated about various aspects of *E. coli* O157:H7 since 1982, reliable management practices to control the infection effectively at all stages of beef production from the farm to the slaughter plant, the retail handling and processing, and finally the consumer, have not been examined scientifically so that recommendations could be made at each stage of production that would result in control of the organism at a very low level.[82] Studying *E. coli* O157:H7 during the entire cattle-production process is problematic because of the complexity of the system and the complexity of the ecology of the organism. The development of economically feasible intervention strategies that are effective in reducing foodborne pathogens is a priority for both the beef and dairy industries.

The effective control of *E. coli* O157:H7 will require the implementation of several different infectious disease control strategies and management procedures extending from the farm environment to the meat processing plant, the retail handling and processing of meat products and the handling and cooking of beef products in the home.

The features of the ecology of *E. coli* O157:H7 that are important to consider in a control program include:[83]

- Lack of a host specificity such that indistinguishable isolates can be found in a variety of species
- Near ubiquitous distribution on cattle farms
- Transient residence in the gastrointestinal tract flora of individual animals that is not associated with disease
- Temporal clustering at the population level such that most fecal shedding is confined to sharp bursts in a high percentage of animals separated by much longer periods of very low prevalence
- A higher prevalence in young animals compared to mature ones
- A higher prevalence in animals with gastrointestinal flora disturbances such as those associated with transit, feed changes, or antimicrobial dosing
- A markedly higher prevalence during warm months
- Molecular subtyping of *E. coli* O157:H7 indicate that certain subtypes can persist on cattle farms for years, supporting the conclusion that cattle farms represent a reservoir
- New subtypes are periodically found on particular farms, and indistinguishable subtypes can be found on farms separated by hundreds of kilometers even in the absence of any obvious animal movements between them
- Commercial feeds are sometimes contaminated with *E. coli* O157:H7 and it seems likely that feeds represent an important route of dissemination
- Mixed feeds collected from feeding troughs are commonly positive for *E. coli* O157:H7, as are water troughs, and feed and water probably represent the most common means of infection
- Environmental replication in feeds and in the sediments of water troughs occurs and may account for the higher level of fecal shedding in the summer months
- Since *E. coli* O157:H7 has been found to persist in and remain infective for at least 6 months in water trough sediments, this may be an important environmental niche where the organism survives during periods when it cannot be detected, especially during cold months
- Traditional means of controlling infectious diseases, such as eradication or test and removal of carrier animals, do not appear to be feasible
- Certain farm management practices, especially those related to maintenance and multiplication of *E. coli* O157:H7 in feed and water, may provide practical means to substantially reduce the prevalence of these agents in cattle on farms and in those arriving at slaughter plants
- It is virtually impossible to exclude *E. coli* O157:H7 from beef-processing plants and carcasses[82]
- Cross-contamination of whole carcasses with fecal-derived bacteria occurs as a result of airborne transmission (during removal of the hide). Contaminated equipment and cross-contamination is inevitable during boning-out and grinding (where portions of carcasses from a large number of animals are commingled or make contact with a common piece of equipment)[82]
- The very small numbers of *E. coli* O157:H7 predicted to contaminate carcasses under highly effective control could be spread to a large volume of beef product during processing and multiply if the product experienced temperature abuse. Because the dose of *E. coli* O157:H7 to cause human illness is very low, this dispersion of the organism throughout a high volume of product may constitute the greatest risk to public health.

The control of *E. coli* O157:H7 will depend on implementation of management procedures which extend from the farm (**preharvest**), slaughtering process (**postharvest**) and retail handling and processing, to ultimately the **consumer**.

Preharvest beef safety production programs – beef quality assurance programs on the farm

Preharvest beef safety production programs consist of policies, strategies, and procedures that are carried out on food-producing animal farms with the objective of producing safe and wholesome product free of antibiotic or chemical residues and with a minimum of pathogens that could be transferred through meat to humans. Some examples follow here.

The **Canadian on-Farm Food Safety (COFFS) Program** is a producer-led, industry/government partnership that provides national commodity groups with the opportunity to develop the strategies and the necessary tools to educate producers and to implement national on-farm food safety initiatives consistent with the Codex Alimentarius Hazard Analysis Critical Control Points (HACCP) definitions and principles and with the Canadian Food Inspection Agency's Food Safety Enhancement Program.

The COFFS Program established in May 1997 is funded by a grant from Agriculture and Agri-food, Canada's Canadian Adaptation and Rural Development Fund. Technical advice is provided by the Canadian Food Inspection Agency and the program is administered by the Canadian Federation of Agriculture.

The beef cattle industry in Canada has begun excellent programs with Canadian Cattlemen – *Quality Starts Here: Good Production Practices for Cow-Calf Producers* and *Recommended Operating Procedures for Feedlot Animal Health.*

The Canadian Cattlemen's Association has developed a number of quality assurance schemes for the various segments of its industry. The *Quality Starts Here* program was developed through collaborative discussions with all those along the food chain – cow–calf operators, feedlots, packers, veterinarians, and pharmaceutical companies. The objective was to develop a set of good production practices to deal with sanitation and feeding issues and to minimize problems arising from lesions and bruising at injection sites and from drug residues. It is important to note that this program was developed to improve

the beef supply chain as a whole and to augment the processing industry's in-plant HACCP programs. In part, it attempts to reduce information costs along the supply chain.

Manuals have been produced and distributed to those interested including: *Good Practice Guides* for cow-calf operators and feedlots and *Recommended Operating Procedures for Feedlot Animal Health*. The procedures are based on HACCP concepts. At present, the CCA schemes do not include provisions for independent monitoring of cow–calf operations or feedlots. This may be a weakness of the scheme as it may not be accepted by those further along the supply chain (by retailers or the hotels, restaurants, and institutions) and, in particular, export markets. Without independent accreditation, this quality assurance scheme cannot claim to be HACCP-based. If, over time, producers feel that they receive a premium for animals raised according to the specifications of the quality assurance scheme, pressure may increase to have independent verification. The CCA has also endorsed a national animal identification scheme. Technical details still need to be worked out to insure that maximum use can be made of the information. The need for the information to be transferred from the live animal to the carcass remains a technological challenge. However, there is cooperation to find a solution. It is intended that, in the event of an incident that requires traceback, it will be possible with this system to identify the last herd (feedlot, pasture group, etc.) in which the subject animal was located and, from the ear tag, the herd of origin.

Specific strategies for control *of Escherichia coli* O157:H7 at preharvest level

The literature on preharvest strategies to reduce the carriage and shedding of *E. coli* O157:H7 in cattle has been reviewed.[71,82] A stochastic simulation model was used to assess the benefit of measures implemented in the preslaughter period that are aimed at reducing the contamination of beef carcasses with Shiga-like-toxin-producing *E. coli* O157:H7.[82] Control measures were based on either reducing the herd prevalence of infection, reducing the opportunity for cross-contamination in the processing plant by reordering of the slaughter procedures, reducing the concentration of *E. coli* O157:H7 in fresh feces or reducing the amount of feces, mud and bedding ('tag') transferred from the hide to the carcass. Simulations suggested that the greatest potential is associated with vaccination and with an agent that reduces shedding of *E. coli* O157:H7 in feces. An industry-wide reduction in the amount of tag attached to hides and addition of a source of cattle having a prolonged average fasting time were not predicted to have a large impact on mean amount of carcass contamination with *E. coli* O157:H7.

Animal management strategies

Water systems and runoff

Interventions at the water trough level offer significant potential to reduce *E. coli* O157:H7 contamination and cross-contamination. Suggested potential strategies to reduce *E. coli* O157:H7 survival in the water supply include chlorination, ozonization, frequent cleaning, and screens that reduce organic solids in water troughs. However, field studies found that chlorination of water troughs did not alter the prevalence of *E. coli* O157:H7 in the troughs, or in the feces of cattle in those pens.[49]

Environmental control of Escherichia coli *O157:H7*

The survival of *E. coli* O157:H7 for extended periods of time (weeks to months) in livestock production environments may enable transfer of the organism back to cattle through contaminated feed or water. This creates a cycle of infection allowing *E. coli* O157:H7 to be maintained in cattle herds. Effective control of *E. coli* O157:H7 requires suppression at as many points in the cycle of infection as possible in order to reduce its spread. Minimizing contamination of water troughs and feed bunks together with adequate manure management should contribute to a significant reduction in the spread of *E. coli* O157:H7 in cattle, crops, and water sources.

The fecal prevalence of *E. coli* O157:H7 among mature dairy cattle is associated with the choice of bedding material used on a farm.[84] The use of sawdust for bedding material for lactating dairy cows, as opposed to sand, was associated with a significantly higher fecal prevalence of *E. coli* O157:H7.[84] The overall average herd prevalence was 3.1% and 1.4%, respectively, for cows on sawdust and on sand.[84] The total number of days on which herds were positive for *E. coli* O157:H7 was higher for sawdust-bedded herds than for sand-bedded herds; 22 versus 14, respectively. These results provide evidence that specific farm management practices can influence the prevalence of *E. coli* O157:H7 on the farm.

Diet changes

The literature on the effects of dietary manipulation of *E. coli* populations in cattle has been reviewed.[43] Feedlot and high-producing dairy cattle are fed rations with a high percentage of grain. When the starches that escape the ruminal microbial degradation move on to the large intestine, enterohemorrhagic *E. coli* ferment the sugars and the populations of *E. coli* increase. Cattle fed grain rations shed larger numbers of *E. coli*, especially *E. coli* O157:H7 in barley-fed cattle. When cattle are abruptly switched from a high-grain ration to a forage diet, generic *E. coli* populations decline by 1000-fold within 5 days. Cattle naturally infected with *E. coli* O157:H7 shed smaller numbers of the organism when the ration is changed to a forage-based diet compared to cattle fed continuously on a high grain diet.[43] However, the magnitude of reduction is highly variable between studies and thus is not currently recommended. Fasting for 48 hours and type of diet prior to fasting has no effect on fecal shedding of *E. coli* O157:H7 in cattle.[42] Thus feed withdrawal prior to slaughter should not increase the risk of *E. coli* O157:H7 entering the food chain. However, re-feeding 100% forage following a 48-hour fast results in a significant increase in the number of animals shedding *E. coli* O157:H7. This may occur when feeder cattle are moved from one farm to another through a sale barn and may be one of the reasons for the higher incidence of *E. coli* O157:H7 shedding by cattle when they first enter the feedlot.

Proposals aimed at dietary modifications must be balanced with the practical applications of commercial livestock feeding operations.

Direct antipathogen strategies

Several strategies have been examined that specifically target and directly kill pathogenic bacteria. These include: the use of antibiotics; antimicrobial proteins produced by bacteria; bacteriophages; compounds that specifically target the physiology of pathogenic bacteria; and vaccination.

Antibiotics

Some preliminary studies have found that feeding neomycin to cattle for 48 hours reduced the populations of generic *E. coli* and *E. coli* O157:H7 in their feces.[71]

Antimicrobial proteins and bacteriophages

Only limited information is available on their effectiveness.

Vaccination against Escherichia coli *O157:H7*

There is evidence that virulence factors secreted by the type III system can be used as effective vaccine components for the reduction of colonization of cattle by *E. coli* O157:H7.[63] Vaccination of cattle with proteins secreted by *E. coli* O157:H7, three times at 3-week intervals,

significantly reduced the numbers of bacteria shed in feces, the numbers of animals that shed and the duration of shedding in an experimental model. Vaccination of cattle also significantly reduced the prevalence of *E. coli* O157:H7 in a clinical trial conducted in a typical feedlot. The pretreatment prevalence of animals shedding *E. coli* O157:H7 averaged 30%. The average proportion of cattle shedding the organism in vaccine-treated pens was 8.8%, and in nonvaccinated pens 21.3%. Since the type III secreted antigens are relatively conserved among non-O157 enterohemorrhagic *E. coli* serotypes, the vaccine formulation might be broadly cross-protective.

Using the pig as an experimental model, pregnant dams were vaccinated with *E. coli* O157:H7 adhesin ($intimin_{O157}$) at 2 and 4 weeks before farrowing.[64] *E. coli* O157:H7 adhesin ($intimin_{O157}$)-specific antibody titers in colostrum and serum of dams were increased after parenteral vaccination. Neonatal piglets were allowed to suck vaccinated dams for up to 8 hours before being inoculated with a Shiga-toxin-negative strain of *E. coli* O157:H7. Piglets that had ingested colostrum containing *E. coli* O157:H7 adhesin ($intimin_{O157}$)-specific antibodies from vaccinated dams, but not those nursing sham-vaccinated dams, were protected from *E. coli* O157:H7 colonization and intestinal lesions. This supports the hypothesis that $intimin_{O157}$ is a potential antigen for an *E. coli* O157:H7 antitransmission vaccine.

A vaccination field trial evaluated the efficacy of *E. coli* O157:H7 vaccine in a sample of feedlots in Alberta and Saskatchewan.[85] Pens of cattle were vaccinated once on arrival processing and again at reimplanting. The *E. coli* O157:H7 vaccine included 50 μg of type III secreted proteins. Fecal samples were collected from 30 fresh fecal droppings within each feedlot pen at arrival, at revaccination and within 2 weeks of slaughter. The mean pen prevalence of *E. coli* O157:H7 in feces was 5.0%, ranging in pens from 0–90%. There was no significant association between vaccination and pen prevalence of fecal *E. coli* O157:H7 following initial vaccination at reimplanting or prior to slaughter.

Competitive enhancement strategies

The use of native or introduced microflora to reduce pathogenic bacteria in the intestine is termed a 'probiotic' or competitive enhancement strategy. The principle is to promote growth of groups of beneficial bacteria that are competitive with, or antagonistic to, pathogens.

Probiotics

Probiotic bacteria are effective in reducing the duration of ruminal carriage of *E. coli* O157:H7 in cattle.[6] Probiotics are live microbial feed supplements that beneficially affect the host animal by improving its intestinal microbial balance. The principle is that these beneficial organisms will combat the effects of stress and prevent undesirable microorganisms from becoming established in the gastrointestinal tract. Dietary supplementation of cattle with *Lactobacillus*- and *Propionibacterium*-based direct-fed microbials reduced the prevalence of *E. coli* O157:H7 in both fecal and hide samples.[86]

Sodium chlorate supplementation

Chlorate supplementation has been investigated as a preharvest strategy to reduce populations of *E. coli* O157:H7 and *Salmonella* spp. in food animals.[87] Certain bacteria can respire anaerobically by reducing nitrate to nitrite via the intracellular enzyme nitrate reductase. This same enzyme also reduces chlorate to chlorite, a cytotoxic end-product. Chlorate significantly reduced *E. coli* O157:H7 populations in ruminal fluid incubations, wild-type *E. coli*, inoculated *E. coli* O157:H7 and total coliforms in cattle, and inoculated *E. coli* O157:H7 in sheep. The administration of sodium chlorate in the feed of cattle preharvest for 24 hours reduced the population of *E. coli* O157:H7 strains approximately by two logs (10^4 to 10^2) in the rumen and three logs (10^6 to 10^3) in the feces.[87]

Control of *Escherichia coli* O157:H7 during slaughtering and postharvest stage

Meat inspection service and surveillance

As a result of public concern about *E. coli* O157:H7, the meat inspection service in many countries has been reorganized to deal with control of the organism in the processing of beef. In the USA, the presence of *E. coli* O157:H7 in ground beef was declared an **adulterant**. Surveillance systems have also been established in many countries to obtain more information about the presence of the organism and to report outbreaks, and considerable research has emerged.

Elaborate *E. coli* O157:H7 detection systems are now in place in abattoirs in many countries as part of the **Hazard Analysis of Critical Points System (HACCP)** to insure that contamination of beef carcasses with *E. coli* O157:H7 is below certain legislated levels.

The surfaces of beef cattle carcasses are contaminated with enteric bacteria immediately after removal of the hide during processing following slaughter. Significant correlations between bovine fecal and hide prevalence with beef carcass contamination indicate a role for controlling *E. coli* O157:H7 in live cattle.[19]

Major progress has been made in the last decade in the processing of beef carcasses following slaughter to reduce the microbial contamination of beef using the HACCP.

The seven Hazard Analysis of Critical Points System principles

HACCP is a process control system designed to identify and prevent microbial and other hazards in food production.

It includes steps designed to prevent problems before they occur and to correct deviations as soon as they are detected. Such preventive control systems with documentation and verification are widely recognized by scientific authorities and international organizations as the most effective approach available for producing safe food.

In the USA, as of 1996, the US Department of Agriculture (USDA) adopted the Pathogen Reduction HACCP system, which includes four major elements:

- Every plant must adopt and carry out its own HACCP plan, which systematically addresses all significant hazards associated with its products
- Mandatory *E. coli* testing in slaughter plants. Every plant must regularly test carcasses for *E. coli* to verify the effectiveness of the plant's procedures for preventing and reducing fecal contamination
- Pathogen reduction performance standards for *Salmonella*. All plants and plants producing raw ground products must insure that their *Salmonella* contamination is below the current national baseline prevalence
- Sanitation standard operating procedures. Every plant must adopt and carry out a written plan for meeting its sanitation responsibilities. Effective sanitation in slaughter and processing plants is essential to prevent adulteration of meat and poultry products.

HACCP is endorsed by such scientific and food safety authorities as the National Academy of Sciences and the National Advisory Committee on Microbiological Criteria for Foods (NACMCF), and by such international organizations as the Codex Alimentarius Commission and the International Commission on Microbiological Specifications for Foods.

HACCP systems must be based on the seven principles articulated by the NACMCF. The seven principles are: (1) hazard analysis, (2) critical control point identification, (3) establishment of critical limits, (4) monitoring procedures, (5) corrective actions, (6) record keeping, and (7) verification procedures.

The Seven HACCP Principles

- **Principle 1: Conduct a hazard analysis**. Plants determine the food safety hazards and identify the preventive measures the plant can apply to control these hazards
- **Principle 2: Identify critical control points**. A critical control point (CCP) is a point, step or procedure in a food process at which control can be applied and, as a result, a food safety hazard can be prevented, eliminated, or reduced to an acceptable level. A food safety hazard is any biological, chemical, or physical property that may cause a food to be unsafe for human consumption
- **Principle 3: Establish critical limits for each critical control point**. A critical limit is the maximum or minimum value to which a physical, biological, or chemical hazard must be controlled at a critical control point to prevent, eliminate, or reduce to an acceptable level.
- **Principle 4: Establish critical control point monitoring requirements**. Monitoring activities are necessary to insure that the process is under control at each critical control point. The Food Safety and Inspection Service (FSIS) requires that each monitoring procedure and its frequency be listed in the HACCP plan
- **Principle 5: Establish corrective actions**. These are actions to be taken when monitoring indicates a deviation from an established critical limit. The final rule requires a plant's HACCP plan to identify the corrective actions to be taken if a critical limit is not met. Corrective actions are intended to insure that no product injurious to health or otherwise adulterated as a result of the deviation enters commerce
- **Principle 6: Establish record keeping procedures**. The HACCP regulation requires that each plant maintains certain documents, including its hazard analysis and written HACCP plan, and records documenting the monitoring of critical control points, critical limits, verification activities, and the handling of processing deviations
- **Principle 7: Establish procedures for verifying the HACCP system is working as intended**. Validation insures that the plans do what they were designed to do, i.e. that they are successful in insuring the production of safe product. Plants will be required to validate their own HACCP plans.

HACCP is a system that identifies potential food safety risks, prevents or corrects them, records what was done and verifies that the system works. The objective is to improve food safety for meat and poultry. It is assumed that a reduction in carcass contamination leads to a proportionate reduction in illness and death. Pathogens can contaminate meat and poultry at any step from production through consumption including final food preparation and handling.

Postharvest decontamination techniques

The literature on the current methods and technologies used to decontaminate food carcasses in the USA has been reviewed.[88] Meat carcasses may become contaminated from fecal material, the stomach contents and the hide. Additional sources of cross-contamination exist in the slaughter process, such as processing tools and equipment, structural components of the facility, human contact, and carcass-to-carcass contact.

Decontamination techniques for carcasses are targeted at reducing or eliminating bacteria that may be human pathogens as well as those that may cause meat spoilage. The pathogenic bacteria of most concern include *E. coli* O157:H7, *Salmonella* spp., *Listeria monocytogenes*, *Campylobacter* spp., *Clostridium botulinum*, *Clostridium perfringens*, *Staphylococcus aureus*, *Aeromonas hydrophilia*, and *Bacillus cereus*.

Meat processors strive to produce raw products that have low levels of bacteria on the surface and no pathogenic bacteria. However, the process is not done in a sterile environment and contamination is unavoidable, and occasionally pathogenic microorganisms may come into contact with the surface of the meat carcass. Routine slaughter practices have evolved over the years to reduce the likelihood of inadvertent microbial contamination. This evolution has led to the adoption of the **hurdle technology** approach to microbial carcass interventions.

The principles of hurdle technology state that, if the initial microbial load is substantially reduced as a result of carcass decontamination procedures, fewer microorganisms are present, which are then more easily inhibited in subsequent processing steps. The effectiveness of hurdle technology has been demonstrated experimentally for beef decontamination technologies under controlled conditions. The concept of hurdle technology for beef carcass decontamination has also been validated to be effective in field studies in beef-processing facilities.

The following are some of the more widely used and researched intervention strategies:

- **Hot water rinse**. There is substantial scientific evidence that hot water (> 74°C) will produce a sanitizing effect on beef carcasses, and this is widely practiced in the industry
- **Steam pasteurization**. The commercialization of the steam pasteurization system has been successful and it is in use in many large beef slaughter facilities in North America. Hot water/steam vacuum systems are designed to remove visible spots of contamination from small areas on the carcass and are used to augment the traditional knife trimming. Steam pasteurization is a process whereby beef carcasses are placed in a slightly pressurized, closed chamber at room temperature and sprayed with steam that blankets and condenses over the entire carcass. This raises the surface temperature to 195°F or 200°F and kills nearly all pathogens. Carcasses then are sprayed with cold water
- **Steam vacuum**. Steam or hot water is sprayed on a beef carcass followed by vacuuming, which has the combined effect of removing and/or inactivating surface contamination. The hand-held device includes a vacuum wand with a hot water spray nozzle, which delivers water at approximately 82–88°C to the carcass surface, as well as the vacuum unit. Steam vacuuming is approved for use by the USDA-FSIS as a substitute for knife trimming for removing fecal and ingesta contamination when such contamination is less than 2.54 cm at its greatest dimension
- **Chemical rinses**. Organic acids are typically applied as a rinse to the entire surface of the carcass. The USDA-FSIS approved the use of organic acid solutions such as acetic, lactic, and citric acids at concentrations of 1.5–2.5%. Acetic and lactic acids have been most widely accepted as carcass decontamination rinses. The effectiveness of organic acids is best achieved shortly after hide removal, when the carcass is still warm.

Progress made with decontamination processes

The multiple decontamination processes, as applied in actual plant settings, have resulted in significant improvements in the microbiological quality of beef.[88] There is considerable evidence to support the effectiveness of in-plant application of multiple decontamination technologies (hurdle technology). Reductions were achieved from 43% of lots sampled pre-evisceration as positive for *E. coli* O157:H7 to 1.9% remaining positive postprocessing after multiple decontamination methods on the slaughter floor.[19]

In February 2005, the beef industry welcomed news from the USDA-FSIS showing a significant drop in *E. coli* O157:H7 prevalence in 2004, as compared to 2003. The FSIS data showed that the percentage of *E. coli*-O157:H7-positive ground beef samples collected in 2004 fell by 43.3% compared with the previous year. The data showed that, between 2000 and 2004, the percentage of positive samples of *E. coli* O157:H7 had declined by more than 80%. FSIS also reported that there were six recalls related to *E. coli* O157:H7 in 2004 compared to 12 in 2003 and 21 in 2002.

This is very good news for consumers and all sectors of the beef industry and represents the coordinated efforts to reduce this pathogen throughout the beef production chain, from farm to kitchen. The Beef Industry Food Safety Council (BIFSCo), which is funded by beef producers with checkoff dollars, directs a broad effort to solve the *E. coli* O157:H7 problem, focusing on research, consumer education, and public policy. BIFSCo has been working toward compiling best practices from across the beef industry, which includes sharing strategies among competitors. The program is coordinated on behalf of the Cattlemen's Beef Board and state beef councils by the National Cattlemen's Beef Association (NCBA). The NCBA serves as one of the Beef Board's contractors for checkoff-funded programs.

Following the *E. coli* summit in January 2003, BIFSCo worked to compile best practices from across the beef industry. Through this effort, all sectors of the beef industry have worked collectively toward the goal of improving safety – from cow–calf producers and feedlot operators to packers and processors, to retailers and foodservice providers. The best practices were completed and distributed throughout the industry.

In addition, checkoff-funded research continues to show promise for interventions such as thermal pasteurization, feed additives, and animal and carcass washes that eliminate or reduce pathogen presence.

Irradiation

Irradiation of beef in the postharvest stage is a process which could be used to inactivate pathogens. At the present time, the percentage of beef being irradiated is very small. Constraints include reluctant consumer acceptance of radiation-treated food, increased price of production, and the irradiation's negative effect on odor and flavor.

Consumer education on handling and cooking meat

To prevent infection with *E. coli* O157:H7, consumers must be encouraged to follow four simple steps: Chill promptly; Clean hand and kitchen surfaces; Separate, don't cross-contaminate; and Cook thoroughly.

Visitors to animal farms

Farm animals and the farm environment present a variety of possible sources of infection with *E. coli* O157:H7. Farm visits are popular among city families for holidays and family gatherings, and schools in urban areas frequently promote educational farm visits for their students. The consumption of unpasteurized milk by visiting children and close physical contact with animals have been documented as most likely sources of infection in some outbreaks of *E. coli* O157:H7 infection. Farm animals and the farm environment present a variety of possible sources of infection. Visitors to animal farms, especially groups such as schoolchildren, must avoid petting animals whose hair coats and skin may harbor *E. coli* O157:H7.[69] Verotoxin-producing *E. coli* of bovine origin can infect humans in the farm environment. Many dairy-farm residents regularly consume unpasteurized milk, a potential source of *E. coli* O157:H7.

Using geographical information system mapping and modeling, studies in Canada have clearly identified a relationship between an increased risk of verotoxin-producing *E. coli* infections and disease among rural populations and cattle density.[69]

Escherichia coli infections in weaned pigs

Diarrhea is most frequent when pigs are exposed to pathogenic *E. coli* strains.[1] The effect of weaning is to produce a marked decrease in the diversity of coliforms in the individual piglet.[2] Different strains of *E. coli* were predominant in different animals,[2] which may in turn facilitate the spread of pathogenic strains.

Escherichia coli in pigs

Many strains are nonpathogenic. Pathogenic *E. coli* can be divided into a variety of pathotypes but there are three major types. These are enterotoxigenic *E. coli*, verotoxin-producing *E. coli* and attaching and effacing *E. coli*. There are two major complicating factors in pigs: one of these is that the intestine has different distributions of receptors with changing age.[3] The other is that nearly all isolates (94.8%) that carry the enterotoxin genes also carry genes for one of the fimbrial adhesins.[4] The two most prominent genotypes are K88, LT1, STb and F18, STa, STb, SLT.

Enterotoxigenic *Escherichia coli*

These have two major virulence factors: (a) adhesins or fimbriae and (b) enterotoxins. The adhesins promote or control the adherence to small intestinal epithelial cells and include K88, K99, F41, 987P, and F18. Only F18 and K88 are frequently associated with disease in weaned pigs. Only young pigs are susceptible to K99 or 987P. Age-related susceptibility is related to the presence or absence of the appropriate receptors in the small intestine. The enterotoxins belong to two groups; heat-labile enterotoxin (LT) and the heat-stable enterotoxins STa or STb. Only weaned pigs are susceptible to F18 and resistance develops by 8 weeks of age, as the binding appears to be blocked. The receptor for F18 has not yet been identified but it is a glycoconjugate in which the attached carbohydrate acts as a target for the fimbriae. The F18 adhesin occurs in two forms: ab (found in verotoxin-producing *E. coli*) and ac (found in enterotoxigenic *E. coli*).[5] There is also an F4 fimbrial antigen which is on a different chromosome from F18. F4 enterotoxigenic *E. coli* cause problems in the first week after weaning but F18 verotoxin-producing *E. coli* cause problems 1–2 weeks after weaning.[6]

Verotoxin-producing *Escherichia coli*

These strains produce Shiga toxin or Shiga-like toxins (verocytotoxins) and cause edema disease. Swine verotoxin-producing *E. coli* colonize the intestine via the F18 pilus, as do some swine enterotoxigenic *E. coli*. It is not uncommon to find F18-positive strains that produce enterotoxins and verotoxins and can cause both diarrhea and edema disease.

Attaching and effacing *Escherichia coli*

These bacteria possess the *eae* gene, which encodes for intimin, which is an adhesin factor that facilitates the attachment of bacteria to intestinal epithelial cells.[7] It is on a plasmid that is distinct from the K88-encoding plasmid[8] in enteropathogenic *E. coli* and enterotoxigenic *E. coli* strains that produce attaching and effacing lesions.

The following strains are found:

- K88 ab, ac, ad
- F18ab (more associated with edema disease); F18ac
- F41, usually associated with K99 fimbriae
- Strains containing LT, STa, STb, Shiga-like toxin 2e (Stx2e), and possibly enteroaggregative *E. coli*.[9]

Twenty years ago most of the pig strains were 987p- or K99-positive. The genes for Stx2e and F18 were rare then but are common now.

O157 in pigs

In a recent survey in Sweden only two O157:H7-positive and four O157:H7-negative strains were found.[10] The O157:H7-positive strains have been described.[11] Pathogenicity is indicated by genes encoding for one or more of the Shiga toxins but several other factors may also be necessary. Most strains do not possess Shiga toxins but do carry the F4 or F18 fimbrial adhesins. A third of strains produced STa or STb but less than a third produce STx and half the eae gene.

Postweaning diarrhea and **edema disease** are two common *E. coli* infections of weaned pigs. In postweaning diarrhea, there is diarrhea, dehydration, and often death. In edema disease or enterotoxemia there is subcutaneous edema of the forehead and eyelids, and neurological clinical signs such as ataxia, convulsions, recumbency, and death. Enterotoxigenic *E. coli* strains isolated from cases of postweaning diarrhea mainly belong to O groups O8, O141, O147, O149, and O157. Strains associated with edema disease predominantly have O groups O138, O139, or O141. Postweaning diarrhea is a significant cause of mortality between weaning and marketing in some herds. Although the clinical signs in these two diseases are different, they occur in similar age groups and the same type of management change may precede their occurrence. Weaning and weaning age are both associated with significant effects on the microbial populations.[12] In postweaning diarrhea the bacteria disappear more quickly, usually by about 7 days post-infection, but in edema disease may still be there 9 days postinfection but with a slower buildup to a peak within 3–5 days postinfection.[13] A typical scenario would be severe diarrhea occurring 4–5 days postweaning followed by clinical edema disease with mortality reaching as high as

50%. Both are associated with the proliferation of predominantly hemolytic serotypes of *E. coli* within the small intestine. However, it is rare to encounter both diseases concurrently on the same farm. In postweaning diarrhea the serotypes are enterotoxigenic and the major manifestation is diarrhea resulting from enterotoxin activity at the time of proliferation. In edema disease nonenterotoxigenic strains produce a verotoxin that, after a period of time, indirectly produces the neurological syndrome characteristic of this disease.

One of the features of virulence in *E. coli* is the presence of mobile genetic elements such as plasmids, bacteriophages, and pathogenicity islands. A pathogenicity island coding for F18-positive fimbriae has been found.[14] Cytolethal distending toxins have also been described.[15] In many countries the prevalence of edema disease has decreased markedly during the past decade, whereas that of coliform gastroenteritis has increased. It is possible that this change reflects the trend towards earlier weaning of pigs, although the emergence and spread of new enterotoxigenic strains may also be a factor. More recently a third disease, cerebrospinal angiopathy, has been attributed to the effects of infection with *E. coli*. Although there are some similarities in the etiology and epidemiology of these diseases they are sufficiently different to warrant a separate description. One of the major features in common is the process of weaning, probably the most serious disturbance a young piglet may face. It alters immune functions and produces stress.[16] It also profoundly alters the intestinal microflora[17,18] particularly the coliform flora.[19] Some strains may increase but others may decrease.

EDEMA DISEASE (GUT EDEMA, *ESCHERICHIA COLI* ENTEROTOXEMIA)

Edema disease occurs in weaner and grower pigs and is characterized by subcutaneous and subserosal edema, progressive ataxia, recumbency, and death.

Synopsis

Etiology *Escherichia coli* strains producing verocytotoxin and Shiga-like toxin
Epidemiology In rapidly growing weaner pigs between 4 and 12 weeks of age following change in diet or feeding practices. Outbreaks occur
Sign sudden death. Incoordination, falling, edema of eyelids and face; piglets die in 6–36 hours
Clinical pathology Culture *E. coli* from feces
Lesions Facial edema, full stomach and mesenteric edema
Diagnostic confirmation Culture specific organism

Differential diagnosis list
- Pseudorabies
- Viral encephalomyelitis of pigs
- Encephalomyocarditis
- Streptococcal meningitis
- Salt poisoning
- Organic arsenic poisoning
- Mulberry heart disease

Treatment None
Control Avoid drastic changes in diet

ETIOLOGY

Edema disease is associated with *E. coli* strains producing a verocytotoxin type II variant (VT2e), and Shiga-like toxin (SLT2e), and belonging to one of the three serogroups that cause edema disease: O138, O139, or O141.[20] The biochemical phenotypes were studied in Sweden and each of the O138, O139, and O141 serotypes is dominated by one phenotypic type even though others do occur within the serotype.[21] The entire pathogenicity island known as ETT2 is necessary for the edema disease virulence factors in O138, O139, or O141.[22] Isolates of *E. coli* have been found in which the toxin or F18 fimbrial types were not related to selected electrophoretic types which suggests that toxin and F18 genes in the isolates from pigs with postweaning diarrhea or edema disease occur in a variety of chromosomal backgrounds.[23] The bacteria colonize the small intestine without causing significant changes by means of the adherence factor F18 (F107).[24] The *E. coli* strains with the highest mucin-binding capacity belonged to potential ST toxin producers, whereas strains without genes encoding for toxin production displayed much weaker binding to mucin capacity.[25] In a recent outbreak in Denmark, where edema disease had not previously been observed, most isolates were of serotype O139 but a few isolates could not be typed by O serotyping.[26] All the isolates from the Danish pigs with edema disease grouped together in one cluster, in contrast to isolates from other countries, which did not form any clusters. In Denmark 563 isolates were serotyped[27] and O149 was found in 49.9% of the isolates, O138 in 14.9%, O139 in 6.9%, O141 in 4.1%, and O8 in 3.7%. The virulence genes were examined and they fell into six pathotypes, which contained 65.7% of all isolates.[27] The F107 fimbriae are a major colonization factor in *E. coli* that cause edema disease.[28,29] The serotypes of *E. coli* isolated from piglets with diarrhea, piglets with edema disease, and healthy piglets have been reported.[30,31]

The inheritance of susceptibility to edema disease has been examined.[32,33] Inheritance of resistance to intestinal colonization with *E. coli* causing edema disease is thought to be under the control of one locus consisting of two alleles with susceptibility (S)-dominating resistance(s).[32] Genetic susceptibility to edema disease is due to the ability of F107-expressing *E. coli* to adhere to and colonize intestinal brush border cells, and not due to toxin susceptibility. There is a high correlation between intestinal F18 receptor genotype and susceptibility to disease[34] but pigs with resistant F18 receptor genotypes were not entirely protected against colonization by *E. coli*.

EPIDEMIOLOGY

The specific serotypes of *E. coli* that are capable of causing the disease are introduced into a piggery and become part of the normal intestinal flora. They may not cause disease until a particular set of environmental conditions arise, when they proliferate excessively within the intestine to produce toxin. The disease occurs predominantly in pigs between 4 and 12 weeks of age. It may occur sporadically but more commonly occurs as an outbreak affecting up to 50% of the pigs within the group. Characteristically the larger and faster-growing pigs within the group are affected. The disease is not common in runt or poorly thriving pigs. Age at weaning, diet, overcrowding, chilling, transportation and other factors influence the susceptibility of pigs to *E. coli* producing SLTIIe and could determine whether subclinical or clinical edema disease occurs following infection. Piglets fed high-protein diets are more susceptible to experimental clinical edema disease than piglets fed low-protein diets.[35] The disease frequently occurs within 1 week following a change in diet or *ad libitum* feeding but may also follow such factors as weaning, vaccination, pen change, and regrouping. A study even found verotoxin-producing *E. coli* O139 in water storage tanks and drinking water.[36]

One of the observations on F18 fimbriae is that they have increased greatly since 1997 from 10% to 70% and this may be tied into the genetic selection of the stress gene.[37]

The outbreak is sudden in onset but short-lived, averaging 8 days and seldom exceeding 15 days. The epidemiology of the disease in affected herds is not characteristic of a highly contagious disease and it does not usually spread to involve other pens of pigs on the same farm.

The disease follows proliferation of the relevant serotypes within the intestine.

Serotypes of *E. coli* associated with gut edema may be isolated from the feces of healthy pigs. The factors initiating proliferation are unknown but changes in the composition or amount of diet commonly precipitate the onset. Management factors that potentiate oral–fecal cycling of these organisms are likely to be of importance in spread within the group.

PATHOGENESIS

It is a simple progression. The intestine of a susceptible pig, which is usually fast-growing and without maternal antibody, has receptors for F18 pili. This appears to be the major factor, and then colonization by *E. coli* occurs with toxin production, absorption of toxin, and damage to vascular epithelium. The endothelium appears to have a specific toxin receptor for Stx2e[38] and finally edema develops in target tissues.

Nutritional factors and gastrointestinal stasis result in proliferation of the *E. coli* strains in the small intestine and toxin production. There is generally a delay between the initial period of maximal intestinal proliferation of the organism and the onset of clinical signs. In the experimental disease, clinical signs occur 5–7 days following initial oral challenge with bacteria and up to 36 hours following intravenous inoculation with toxin. The delay appears to be related to the development of vascular lesions, with increased vascular permeability leading to edema formation and encephalomalacia. The experimental oral inoculation of the edema-disease-producing *E. coli* results in colonization of the organisms in the small intestine, and lesions of the vessels of the intestinal mucosa are detectable as early as 2 days after infection. An experimental model for subclinical edema disease in weaned pigs has been described.[39] Microscopic vascular lesions were found in pigs 14 days after oral inoculation with a SLT2-positive strain of *E. coli*. Once postweaning diarrhea occurs then there is an increased intestinal permeability that predisposes to edema disease and once edema disease has developed the influx of SLT toxin into the bloodstream is facilitated further, thus precipitating the disease.[40] Edema disease is associated with metabolic acidosis, which might be explained by endogenous acid production, and small-intestinal acidosis. Intestinal acidosis is known to cause mucosal hyperexcitability.

CLINICAL FINDINGS

The disease occurs sporadically and unexpectedly in a group, often affecting a number of pigs within a few hours, and shows no tendency to spread from group to group. The thriftiest pigs are most likely to be affected and, once the diagnosis is made, all pigs in the pen should be examined in an attempt to detect other animals in the early stages of the disease. The incidence in a litter will vary up to 50% or more.

The earliest and most obvious sign is incoordination of the hindlimbs, although this may be preceded by an attack of diarrhea. The pig has difficulty in standing and sways and sags in the hindquarters. There is difficulty in getting up and in getting the legs past each other when walking because of a stiff, stringhalt-like action affecting either the forelegs or hindlegs. In some cases there are obvious signs of nervous irritation manifested by muscle tremor, aimless wandering, and clonic convulsions. Complete flaccid paralysis follows.

On close examination, edema of the eyelids and conjunctiva may be visible. This may also involve the front of the face and ears but cannot usually be seen until necropsy. The voice is often hoarse and may become almost inaudible. Blindness may be apparent. The feces are usually firm and rectal temperatures are almost always below normal. The course of the disease may be very short, with some pigs being found dead without signs having been observed. In most cases, illness is observed for 6–36 hours, with a few cases being more prolonged. Recovery does sometimes occur but some degree of incoordination may persist.

CLINICAL PATHOLOGY

As an aid to diagnosis, while affected animals are still alive, fecal samples should be cultured to determine the presence of hemolytic *E. coli*. Knowledge of the drug sensitivity of the organism may be important in prescribing control measures. The edema disease principle is cytotoxic to Vero cells and may be useful in an assay system for diagnosis. The toxin Stx2e has been detected in the peripheral blood of pigs with clinical disease, which not only shows that toxin is transported but may eventually lead to a technique for the detection of early cases.[41]

NECROPSY FINDINGS

The pig is well grown for its age, the stomach is full of feed and the feces are usually normal. Edema of the eyelids, forehead, belly, elbow and hock joints, throat, and ears is accompanied by edema of the stomach wall and mesocolon in classical cases. Excess pleural, peritoneal, and pericardial fluid is also characteristic and the skeletal muscles are pale. The edema may often be slight and quite localized, so examination of suspected areas should be carried out carefully, using multiple incisions, especially along the greater curvature of the stomach near the cardia. Hemolytic *E. coli* can be recovered in almost pure culture from the intestine, particularly the colon and the rectum, and in some cases from the mesenteric lymph nodes. Polyclonal antisera directed against serotypes of *E. coli* associated with edema disease are used to confirm the diagnosis via an agglutination test. Histologically, the important lesions are mural edema, hyaline degeneration and fibrinoid necrosis in arteries and arterioles. In subacute to chronic cases this angiopathy may result in focal brain hemorrhages and encephalomalacia.

Samples for confirmation of diagnosis

- Bacteriology – ileum and colon (CULT). The differentiation of pathogenic and nonpathogenic *E. coli* can be achieved through PCR.[42,43] A multiplex PCR has been developed for STa, STb, K99, 987P, and F41.[44] The tests tell you that the gene is present but not whether it is actually encoding for the proteins
- Histology – formalin-fixed colon, ileum, jejunum, gastric fundus, brain, mesenteric lymph node (LM).

DIFFERENTIAL DIAGNOSIS

Although there are a number of diseases of pigs in the susceptible age group in which nervous signs predominate, gut edema is usually easy to diagnose because of the rapidity with which the disease strikes, the number of pigs affected at one time, the short duration of the outbreak, and the obvious edema of tissues. Affected pigs are usually in prime condition. The ataxia and recumbency must be differentiated from diseases of the nervous system of pigs which cause ataxia and recumbency. These include pseudorabies, viral encephalomyelitis (Teschen's disease), encephalomyocarditis, streptococcal meningitis, salt poisoning, and organic arsenic poisoning. Mulberry heart disease and encephalomyocarditis can produce similar signs, and differentiation on necropsy findings and histopathology is nesessary. In poisoning by *Amaranthus* spp. and *Chenopodium album* the signs may be roughly similar but the edema is limited to the perirenal tissues.

TREATMENT

Treatment is ineffective. Elimination of the toxin-producing bacteria may be attempted by use of antimicrobials in the feed or water supplies. The choice of antimicrobial will vary depending on area variations of the drug sensitivities of *E. coli*. The feed consumption of the unaffected pigs in the group should be reduced immediately and then gradually returned to previous levels over a period of a few days.

CONTROL

Pigs should be kept on the same creep feed for at least 2 weeks after weaning,

and the change in feed should be made gradually over a 3–5-day period. Feed restriction through the critical period is frequently practiced and may reduce the occurrence of gut edema. Similarly an increase in crude fiber and decrease in nutrient quality of the diet through this period may reduce the incidence. However, it is evident that a severe restriction and marked decrease in nutrient quality is required to fully achieve this effect and this is not compatible with the purpose of growing pigs. It is essential that pigs on restricted intakes be provided with adequate trough space to allow an even intake of food among the group. For similar reasons, litters of pigs that are batched at or after weaning should be divided into groups of approximately equal body weight.

The strategic incorporation of an antimicrobial into the feed during the risk period may be necessary on some farms. A reduction in the potential for oral–fecal cycling of organisms in the group may reduce the incidence of gut edema. A reduction in the age of weaning may also reduce the incidence. Both organic acids and medication with 50 ppm of enrofloxacin are useful in controlling and/or preventing postweaning edema disease.[45]

Treatment with anti-VT2E serum can provide protective immunity against edema disease in pigs.[46]

No vaccine is available. Only vaccines with the preformed fimbriae induce protection and this is limited to the homologous variant[47] but, experimentally, vaccination of piglets with a genetically modified Shiga-like toxin 2e prevents edema disease following challenge with the Shiga-like toxin after weaning.[35] The concentration of protein in the diet also influenced susceptibility to edema disease. Pigs fed a low-protein diet and not vaccinated developed subclinical edema disease. Pigs fed a high-protein diet and not vaccinated developed clinical edema disease. Pigs fed a high-protein diet and vaccinated had a reduction in the incidence of subclinical edema and did not develop clinical edema disease.

POSTWEANING DIARRHEA OF PIGS (COLIFORM GASTROENTERITIS)

Postweaning diarrhea occurs commonly within several days after weaning and is characterized by reduced growth rate associated with alterations in the mucosa of the small intestine and, in some pigs, by acute coliform gastroenteritis characterized by sudden death, or severe diarrhea, dehydration, and toxemia. It is a major cause of economic loss from both mortality and inferior growth rate for several days to 2 weeks following weaning. The etiology, epidemiology, and pathogenesis are multifactorial and complex because of the several weaning-associated factors that may interact. In some instances the postweaning diarrhea may be followed by edema disease.

Synopsis

Etiology Specific serotype of enterotoxigenic *E. coli*
Epidemiology 3–10 days post weaning; high morbidity and case-fatality rates. Stressors of weaning are risk factors (change of feed, loss of maternal contact and maternal antibody, mixing litters, environmental changes)
Sign Some pigs found dead. Outbreaks of severe diarrhea a few days post weaning. Fever, dehydration, anorexia, loss of weight, death in a few days
Clinical pathology Culture organism from feces and intestinal contents
Lesions Dehydration, serofibrinous peritonitis, fluid-filled intestines, mesenteric edema
Diagnostic confirmation Isolate specific serotypes of *E. coli*

Differential diagnosis list
- Gut edema
- Swine dysentery
- Salmonellosis
- Erysipelas
- Pasteurellosis

Treatment Antimicrobials in water supply
Control Minimize stress at weaning, antimicrobials in feed and water post weaning. Intestinal acidification. Zinc oxide in diet post-weaning

ETIOLOGY

The disease is associated with enterotoxigenic strains of *E. coli* that produce adhesion factors that allow colonization of the intestine and enterotoxins that induce the intact intestinal mucosa to secrete fluid. A summary would be that postweaning diarrhea is associated with fimbrial types F4 and F18 and carrying the genes for the Shiga-like toxin 2(SLT-2E), labile toxin (LT) and/or Shiga toxin A and B (STa or STb). Toxin and F18 fimbrial genes in *E. coli* isolated from pigs with postweaning diarrhea or edema disease occur in a variety of chromosomal backgrounds.[1]

Most commonly, O groups 8, 138, 139, 141, and 149 are associated with the disease.[2,3] Most appear to be O149: STaSTbLT:F4(K88). The strains of O149 isolated in recent years from weaned pigs with diarrhea possess the gene for an additional enterotoxin STa, which older strains lack. Of the new strains, which correspond to O149 H10, 92% code for this gene.[4] This enteroaggregative *E. coli* heat-stable enterotoxin 1 (*EAST 1*) gene is found in isolates from weaned pigs that have diarrhea or edema disease.[5] The F107 fimbriae can be found in association with postweaning diarrhea isolates[6,7] and other adhesive fimbriae such as Av24 and 2134P have been described.[8] Many enterotoxigenic *E. coli* isolates colonize the small intestine of weaned pigs but lack known colonization factors.[9,10] The

serogroups of *E. coli* isolated from pigs with postweaning diarrhea in piggeries in Spain include strains that produce the enterotoxigenic *E. coli* and verotoxin-producing *E. coli* and cytotoxic necrotizing factor toxins.[11,12] The disease can be reproduced consistently in weaned pigs, provided the pig's epithelial cell brush borders are susceptible to the adhesin of strains of *E. coli* with fimbrial antigen F4 (K88).[13] The DNA sequences coding for the F18 fimbrial antigens and AIDA adhesin are on the same plasmid in *E. coli* isolated from the cecum.[14] Usually they were LTSTb or STb(13%) and 12% were hemolytic and F18-positive. The remainder were nonhemolytic, belonging to the K48 serogroup.

Although there is an etiological similarity between postweaning diarrhea and neonatal enteric colibacillosis in sucking piglets, the relationship is not exact. Strains associated with neonatal enteric colibacillosis may not have the ability to produce postweaning diarrhea and many strains isolated from coliform gastroenteritis lack $K88^+$ antigen.

Cytotoxic necrotizing factor (CNF) strains of *E. coli* have been isolated from weaner pigs with necrotic enteritis in South Africa.[15]

Some non-enterotoxigenic O45 isolates of *E. coli* associated with postweaning diarrhea produce attaching and effacing lesions,[16] and their proliferation may be associated with diet.[17] Dual infection with attaching and effacing and enterotoxigenic *E. coli* may also be associated with postweaning diarrhea.[18]

Infection with rotavirus may be an etiological factor. The rotavirus may infect and destroy villous epithelial cells of the small intestine, which may allow colonization of the *E. coli*. Experimentally, a high nutrient intake fed three times daily to piglets weaned at 3 weeks of age produced the most prolonged diarrhea, colonization of the intestine by hemolytic enteropathogenic *E. coli* and persistent shedding of rotavirus. However, other observations cast doubt on the importance of rotaviruses as a cause of the diarrhea because rotaviruses may be found in the feces of pigs without diarrhea a few days after weaning. The acute disease can be reproduced using K88 *E. coli* strains without concomitant infection with rotavirus.

EPIDEMIOLOGY

Postweaning diarrhea occurs predominantly in pigs 3–10 days after they are weaned. There is considerable variation in the morbidity and mortality between groups, rooms of pigs and buildings. Most outbreaks are in early weaned pigs. Most commonly, pigs are first observed sick or dead on the fourth or fifth day. The spread within affected groups is rapid and a morbidity rate of 80–90% of the group within 2–3 days is not uncommon. Frequently, other pens of susceptible pigs within the same area will also develop the disease within a short period of the initial outbreak. The problem may persist within a herd, affecting successive groups of weaned pigs over a period of weeks or months. The onset of the problem may be associated with the introduction of a different batch or formulation of the creep feed. The case fatality rate may be as high as 30% and survivors may subsequently show a reduced growth rate. The weaning of piglets at 3 weeks of age is commonly followed in a few days by a postweaning reduction in growth rate, variations in total dietary intake and the development of diarrhea. Piglets weaned at 3–4 weeks of age into an uncomfortable unsanitary environment appear especially susceptible.

The proliferation of *E. coli* in the intestine following weaning appears secondary to some underlying gastrointestinal disturbance. After weaning there is a progressive increase in viscosity of the intestinal contents, which alters the intestinal structure and growth and stimulates the proliferation of enterotoxigenic *E. coli* in newly weaned pigs.[19] In all groups of pigs examined the number of serotypes or diversity of intestinal flora was reduced in the first week after weaning.[20] The disease is associated with an earlier, more prolonged and greater proliferation of enterotoxigenic *E. coli* in the small intestines than occurs in healthy pigs after weaning. Some studies have shown that susceptibility to adhesion with $K88^+$ enterotoxigenic *E. coli* is a requirement for the production of the disease. Experimentally, pigs that did not have the adhesin receptor did not develop diarrhea when challenged with $K88^+$ *E. coli* and when in the same environment as the adhesin-positive pigs.

It is believed that several factors commonly associated with weaning predispose pigs to postweaning diarrhea associated with enterotoxigenic *E. coli*. Some of these risk factors include:

- Stress from loss of maternal contact
- Introduction to strange pens and penmates
- Inadequate ventilation in the weaning pens
- Reduction in ambient temperature
- Change in diet
- Cessation of lactation immunoglobulins
- Decreased gastric bactericidal activity attributable to a temporary increase in gastric pH
- Preweaning exposure (creep feeding) to the dietary antigens fed after weaning.[21]

Hand-washing and donning clean outerwear did not prevent the transmission of *E. coli* but showering and donning clean outerwear did prevent transmission.[22]

Experimentally, there is some evidence that the stress of cold ambient temperature (15°C) can result in a greater incidence of diarrhea in weaned pigs than in those housed at 30°C.

The nature and the amount of the diet that the piglet consumes before and after weaning may be a predisposing factor. One hypothesis suggests that a transient hypersensitivity of the intestine may occur if piglets are primed by small amounts of dietary antigen before weaning, by creep feeding, followed by ingestion of greater quantities of the diet after weaning. Pigs that develop diarrhea tend to be those that consume more food after weaning than their contemporaries.

In general, weaning at 3 weeks of age is associated with alterations in the villous epithelium of the small intestine that result in varying degrees of malabsorption and a reduction in daily growth rate that may last for 2 weeks. There are large rapid reductions in intestinal lactase activity, which coincide with reductions in growth rate and a reduced ability to absorb xylose. There is a reduction in villus height and an increase in crypt depth in the small intestine but these alterations are not necessarily associated with the consumption of creep feed before weaning, which does not support the hypothesis that hypersensitivity to a dietary antigen caused by priming prior to weaning is a factor. There is now considerable doubt about the validity of the intestinal hypersensitivity hypothesis. Recent experimental work indicates that creep feeding is not required for the production of the diarrhea and does not induce morphological changes characteristic of an allergic reaction in the small intestine.[23] The presence of nondigested food in the gut lumen favors proliferation of enterotoxigenic *E. coli*. Proteins of animal origin may provide some protection.[24]

Dietary manipulation can modify several changes that normally occur in the small intestine of the piglet after weaning.[25] Feeding a sow milk replacer or a diet based on hydrolyzed casein reduces the increases in crypt depth and the reductions in brush border enzymes. The use of an antibiotic to suppress the microbial activity does not alter the changes in the mucosa after weaning.

The ecology of *E. coli* and rotavirus in the stomach and intestines of healthy unweaned pigs and pigs after weaning has

been examined. Gastric pH is higher in weaned pigs and may not reach a level sufficient to prevent significant numbers gaining access to the small intestine. This factor can be of importance in pigs weaned in pens where oral–fecal cycling of *E. coli* may provide a massive challenge. After weaning, the hemolytic enterotoxigenic *E. coli* serotype O149:K91, K88a,c (Abbotstown strain) commonly colonizes the rostral small intestine from lower down the intestinal tract. This serotype was also never found in the gastric contents of weaned pigs. When this serotype is present it tends to dominate the *E. coli* flora at all levels of the intestine. While rotaviruses are common in the intestinal contents of weaned pigs, the presence of the virus is not necessary for production of the disease.

The loss of lactogenic immunity at weaning may be a risk factor. Milk from sows whose progeny develop postweaning diarrhea contain antibodies capable of neutralizing the enterotoxigenic effect of the homologous *E. coli*. This suggests that the presence of antibody-mediated activity against enteropathogenic *E. coli* may be important in preventing the disease during the nursing period. At weaning this protection is removed and the piglet is unable to produce its own antibodies rapidly enough to prevent the disease. The stress of weaning does not appear to affect the immune mechanisms of the pig.

The weaning of piglets at birth or 1 day old is associated with a high mortality rate due to diarrhea and septicemia. The high mortality rate is associated with a lack of colostral antibodies and the strict hygienic conditions required for the artificial rearing of pigs weaned at birth.

PATHOGENESIS

The colonization and proliferation of *E. coli* in the small intestine originates from organisms in the lower part of the intestinal tract. Serotypes of *E. coli* associated with postweaning diarrhea may be found in the feces of healthy pigs. The virulence factors for postweaning diarrhea are associated with the F4 and F18 fimbrial antigens that carry the genes for the production of toxins (STa, STb, LT, SLT2a, SLX2e). The F18ab variant is expressed by *E. coli* O139 strain producing Shiga-like toxin and causing edema disease. The F18ac fimbrial *E. coli* strains often relating to serogroup O141 or O157 and cause diarrhea by expressing enterotoxins (STa or STb) either together or with or without Shiga-like toxins.[26] Following weaning, their numbers in feces normally increase markedly even in pigs that remain healthy. The *E. coli* proliferate in the small intestine and produce an enterotoxin that causes a net loss of fluid and electrolytes to the lumen and subsequent diarrhea. After weaning the net absorption of fluid and electrolytes in the small intestine of pigs is temporarily decreased.[25]

The number of hemolytic *E. coli* present in the proximal portion of the jejunum may be 10^3–10^5 times higher in affected pigs than in weaned pigs of the same age that do not show signs of disease.[27] The susceptibility of the small intestine to the enterotoxin varies according to the area: the upper small intestine is highly susceptible and susceptibility decreases through the more distal portions. Unlike many other species, the weanling pig depends largely on its large intestine for absorption of fluid and electrolytes with only small changes in net fluid movement occurring along the jejunal and ileal segments. In fatal cases, death results from the combined effects of dehydration and acidosis resulting from fluid and electrolyte losses. In the peracute and acute forms of the disease, there is a shock-like syndrome with marked gastric and enteric congestion, hemorrhagic enteritis, and death.[28]

The experimental model of the disease is characterized by the three syndromes:

- Peracute fatal diarrhea
- Moderate diarrhea of 3–4 days' duration, accompanied by fecal shedding of the inoculated organism and reduced body weight gain
- Fecal shedding of the organism with reduced weight gain but without diarrhea.

The role of the rotavirus in the pathogenesis of postweaning diarrhea is uncertain.[29] The rotavirus can be found in the feces of healthy unweaned and weaned pigs. The virus is capable of infecting and destroying villous epithelial cells which could contribute to the partial villous atrophy, loss of digestive enzyme activity, malabsorption and reduced growth rate. Experimental inoculation of an enteropathogenic *E. coli* and the rotavirus causes a more severe disease than either agent does alone. The effects of experimentally induced villus atrophy in weaned pigs infected with the transmissible gastroenteritis virus and a $K88^+$ enterotoxigenic *E. coli* have been examined.

Changes in the mucosa of the small intestine of recently weaned pigs have been observed and are the subject of much controversy. There is a reduction in the length of the villi, a marked reduction in intestinal disaccharidase activity and an increase in the depth and activity of the intestinal crypts. These changes are maximal at 3–7 days following weaning, persisting until the second week and coinciding with the reduced growth rate.

CLINICAL FINDINGS

The postweaning reduction in growth rate may affect 50–100% of the pigs within a few days after weaning and persist for up to 2 weeks. In some situations diarrhea may not develop in any of the pigs in the group. A reduction in feed intake, gaunt abdomens, and lusterless hair coats are characteristic findings of piglets with postweaning 'check'. They may appear unthrifty for 10 days to 2 weeks, by which time they will improve remarkably.

Most commonly one or two pigs, in good nutritional condition, are found dead with little having been seen in the way of premonitory signs. At this time the others within the group may appear normal but closer examination will reveal several pigs showing mild depression and moderate pyrexia. A postmortem examination of dead pigs should be conducted early in the examination. A proportion of the group will develop diarrhea within 6–24 hours and by 3 days after the initial onset the morbidity may approach 100%. Feed consumption falls precipitously at the early stages of the outbreak but affected pigs will still drink. Affected pigs may show a pink discoloration of the skin of the ears, ventral neck, and belly in the terminal stages. Diarrhea is the cardinal sign – the feces are very watery and yellow in color but may be passed without staining of the buttocks and tail. Pyrexia is not a feature in individual pigs once diarrhea is evident. Affected pigs show a dramatic loss of condition and luster and become progressively dehydrated. Voice changes and staggering, incoordinated movements may be observed in the terminal stage in some pigs. The course of an outbreak within a group is generally 7–10 days and the majority of pigs that die do so within the initial 5 days. Surviving pigs show poor growth rate for a further 2–3 weeks and some individuals show permanent retardation in growth. In outbreaks in early weaned pigs diarrhea is usually evident before death occurs. There is some evidence to show that the postweaning diarrhea may be activated by porcine reproductive and respiratory syndrome.[30]

CLINICAL PATHOLOGY

Culture of the feces and intestinal contents for enterotoxigenic strains of *E. coli* is indicated.

NECROPSY FINDINGS

Pigs dying early in the course of the outbreak are in good nutritional condition but those dying later show weight loss and dehydration. Mild skin discoloration of the ears and ventral areas of the head, neck, and abdomen is usually present. In acute cases there is a moderate increase in

peritoneal fluid and barely perceptible fibrinous tags between loops of the small intestine may be present. The vessels of the mesentery are congested and occasionally petechial hemorrhages and edema are present. The gastric mucosa is congested and an infarct is usually present along the greater curvature. The small intestines are dilated and contain yellow mucoid liquid or occasionally bloodstained material. The mucosa of the small intestine is congested and sometimes there are hemorrhagic areas. The content of the large intestine is fluid to porridge-like in consistency and the mucosa may be congested. In some cases mild mesocolonic edema is visible. Hemolytic *E. coli* can be isolated in large numbers from the small intestine and mesenteric lymph nodes. Polyclonal antisera directed against known pathogenic serotypes are usually employed to test the isolate but a negative result does not preclude the strain from being an enteropathogenic organism.

Microscopically, there is usually bacterial adherence to intestinal villi. Other changes are those commonly associated with endotoxemia, especially microvascular thrombosis in a variety of organs.

Samples for confirmation of diagnosis

- Bacteriology – mesenteric lymph node, segment of ileum, colon (CULT)
- Histology – formalin-fixed stomach, several segments of small intestine, colon, liver, lung, spleen (LM).

DIFFERENTIAL DIAGNOSIS

Postweaning diarrhea is the prime consideration in pigs that are scouring or dying within a 3–10-day period of some feed or management change.

Swine dysentery and salmonellosis are manifested by diarrhea and death but they are not necessarily related to weaning or feed change, and both are more common in older growing pigs. Salmonellosis poses the greatest difficulty in initial diagnosis from coliform gastroenteritis. In salmonellosis, the feces are generally more fetid with more mucus, mucosal shreds, and occasionally blood, and the skin discoloration is more dramatic. On necropsy examination enlarged hemorrhagic peripheral and abdominal lymph nodes and an enlarged pulpy spleen are more suggestive of salmonellosis; however, cultural differentiation is frequently required. If there is doubt the pigs should be treated to cover both conditions until a final decision is obtained. The onset of swine dysentery is comparatively more insidious than that of postweaning diarrhea; the characteristic feces, clinical and epidemiological pattern and postmortem lesions differentiate these two conditions.

Swine fever should always be a consideration in outbreaks in pigs manifested by diarrhea and death. However, the epidemiological and postmortem features are different. Other common causes of acute death in growing pigs such as erysipelas, pasteurellosis, and *Actinobacillus pleuropneumoniae* infection are easily differentiated on necropsy examination.

Edema disease occurs under similar circumstances to coliform gastroenteritis but the clinical manifestation and postmortem findings are entirely different.

TREATMENT

A Swedish study[31] showed that, except for resistance to tetracyclines, sulfamethoxazole, and streptomycin, antibiotic resistance is not unduly spread across *E. coli* isolates. A Spanish study[32] was similar. Tetracyclines should not be the first choice of treatment because of the rapid acquisition of resistance. Nearly all isolates are highly susceptible to enrofloxacin, gentamicin, and neomycin.

It is imperative that treatment of all pigs within the group be instigated at the initial signs of the onset of postweaning diarrhea, even though at that time the majority of pigs may appear clinically normal. Delay will result in high mortality rates. Any pig within the group that shows fever, depression, or diarrhea should be initially treated individually both parenterally and orally and the whole group should then be placed on oral antibacterial medication. Water medication is preferable to medication through the feed as it is easier to institute and affected pigs will generally drink even if they do not eat. Neomycin, tetracyclines, sulfonamides, or trimethoprim-potentiated sulfonamides and ampicillin are the usual drugs of choice. Danofloxacin is safe and highly effective.[33] Experimental infection with K88-positive *E. coli* was controlled by ceftiofur sodium given intramuscularly daily for three consecutive days.[34] When pulse dosing is used there appears to be less resistance.[35] In herds with postweaning problems, prior sensitivity testing will guide the choice of the antibacterial to be used. Antibiotic medication should be continued for a further 2 days after diarrhea is no longer evident and is generally required for a period of 5–7 days.

Consideration should be given to the medication of at-risk equivalent groups of pigs within the same environment. Intraperitoneal fluid and electrolyte replacement for severely dehydrated pigs and electrolytes in the drinking water should also be considered.

CONTROL

Recommendations for effective and economical control of postweaning reduced growth rate and postweaning diarrhea in pigs weaned at 3 weeks of age are difficult because the etiology and pathogenesis of this complex disease are not well understood. Epidemiologically, the disease is associated with weaning and the effects of the diet consumed before and after weaning. In all cases the piglet should be 4.5 kg (10 lb) and preferably 5.5 kg (12 lb) at weaning.

A whole variety of techniques, including intestinal acidification, antimicrobial medication in water or feed, environmental modifications, competitive exclusion, feeding probiotics, binding agents such as eggs, milk, or bacterial byproducts (most of these studies show they do not work), zinc oxide, or vaccination of sows and piglets with toxoids have been tried. The use of dietary egg yolk antibodies also does not appear to be effective.[36]

Intestinal acidification reduces the binding of the *E. coli* to the epithelial surface and a pH of 3.5–4.0 at the trough or nipple drinker is best. Citric acid, formic acid, propionic acid, or a citric acid/copper sulfate mixture can be used.

Zinc oxide in particular stabilizes the intestinal flora. Piglets given lactose and fiber were least affected and the next least affected were animals that received zinc oxide.[37] Pigs fed dietary antibiotic growth promoters and zinc oxide had lower counts of anaerobic bacteria in their feces than control piglets. The removal of these ingredients from the diet will increase days to slaughter.[38]

It has been traditionally accepted, without reliable evidence, that the sudden transition in diet at weaning is the major predisposing factor. However, as presented under Epidemiology, the experimental observations are conflicting. One set of observations indicates that, if pigs eat a small quantity of creep feed before weaning, they are then 'primed' and develop an intestinal hypersensitivity that, following the ingestion of the same diet after weaning, results in the disease. It has been suggested that piglets should consume at least 600 g of creep feed before weaning in order to develop a mature digestive system. Another set of observations indicates that those pigs that consumed an excessive quantity of feed after weaning developed the disease.

The complete withholding of creep feed followed by abrupt weaning at 3 weeks of age seemed to have a protective effect, possibly associated with a low dietary intake. Farms with lower rates of postweaning diarrhea used their first piglet ration (phase 1 feeding) for much longer and also changed over to the second ration over a much longer period. Competitive exclusion has been shown to be of benefit.[39–41]

The recommendations set out here are based on the hypothesis that the consumption of adequate quantities of creep feed prior to weaning is the most effective and economical practice.

Every effort should be made to minimize the stress associated with weaning. Stressors influence the fecal shedding of enterotoxigenic *E. coli* by young piglets by a mechanism that may not involve modulation of the immune response.[42] In order to avoid a sudden transition in diet at weaning, creep feed should be introduced to the suckling piglets by at least 10 days of age. It is important that the creep feed and feeder area be kept fresh to maintain palatability. The same feed should be fed for at least 2 weeks following weaning and all subsequent feed changes should be made gradually over a 3–5-day period. Feed restriction in the immediate 2-week period following weaning may reduce the incidence but generally is not successful. It is a common field observation that the incidence of diarrhea varies with different sources of feed but experimental studies to confirm this relationship are not available.

Where possible, at weaning the sow should be removed and the pigs should be kept as single litters in the same pen for the immediate postweaning period. If grouping of litters is practiced at this time, or later, the pigs should be grouped in equivalent sizes. Multiple suckling in the preweaning period may reduce stress associated with grouping of part-weaned pigs. With all pigs, but especially those weaned earlier than 6 weeks, the pen construction should be such as to encourage proper eliminative patterns by the pigs and good pen hygiene (see Salmonellosis) so as to minimize oral–fecal cycling of hemolytic *E. coli*. The environment also appears especially important in this group and draft-free pen construction should be such as to encourage proper ventilation. It is preferable to wean pigs on weight rather than age and in many piggeries a weaning weight of less than 6 kg is associated with a high incidence of postweaning enteric disease.

The inclusion of an antimicrobial in the feed or water to cover the critical period of susceptibility (generally for 7–10 days after weaning) can be used as a preventive measure. Apramycin at the rate of 150 g/tonne of feed for 2 weeks after weaning may be associated with improved growth rates and a reduction in mortality. The high incidence of drug resistance in isolates of *E. coli*[43] makes prior sensitivity testing mandatory and the antibiotic may need to be changed if new strains gain access to the herd. The routine use of prophylactic antibiotics for this purpose needs to be considered in relation to the problem of genetically transmitted drug resistance, however it is currently often necessary for short-term control of a problem.

Vaccination may offer an alternative method of control. However, currently there are no vaccines available for the control of colibacillosis in weaned pigs. Oral inoculation with 5×10^8–10^9 of nontoxigenic strains can be followed with K88 at day 1 of move, K88/F18ab at day 7 and F18 at days 13–15. Only the oral vaccines with the preformed fimbriae appear to produce any protection to homologous fimbrial variant.[44] The results vary and some authors think that the prolonged transit time in the stomach after weaning may deactivate the F4 fimbriae when this has been used as a fimbrial vaccine.[45] Microencapsulated enterotoxigenic *E. coli* and detached fimbriae have been used for peroral vaccination in pigs.[46,47] Parenteral vaccination for the control of coliform gastroenteritis has proved of variable value, probably because parenterally administered antigens do not usually stimulate the production of IgA antibodies and intestinal immunity. Oral immunization by the incorporation of *E. coli* antigens into creep feed has been shown to reduce the incidence and severity of postweaning diarrhea. A live avirulent *E. coli* vaccine for $K88^+$, LT^+ enterotoxigenic colibacillosis in weaned pigs provided protection experimentally. Rearing early-weaned piglets artificially for the purpose of increasing the efficiency of the sow is an attractive management concept. However, high death losses from diarrhea have slowed progress in this new development. The incorporation of antibodies in the diet of such piglets as a prophylactic measure should be possible and is being explored.

The ultimate control is by removing the receptor gene in the population and although this has been done experimentally these animals are not yet available in large numbers commercially.

CEREBROSPINAL ANGIOPATHY

Cerebrospinal angiopathy is a sporadic disease of recently weaned pigs manifested primarily by neurological signs. In some areas the disease is the more common cause of central nervous system disorders in this age group of pigs.[1] The disease affects only one or a few pigs within a litter of a group occurring up to 5 weeks after weaning.[1,2] although a similar condition has been reported in fattening and adult pigs.[3] The disease is characterized by the variety of neurological signs that it presents. Incoordination and a decreased central awareness are common presenting signs but abnormal head position, aimless wandering and persistent circling may also be observed.

There is usually apparent impairment of vision. Fever is not a feature and the clinical course may last for several days. Affected animals may die but more commonly are destroyed because of their emaciated condition.[2,4] Wasting without neurological disorder may also occur.[5] They are also prone to savaging by unaffected penmates.

Histologically the disease is characterized by an angiopathy that is not restricted to the central nervous system. The similarity of the angiopathy to that seen in chronic edema disease[6] has led to postulation[1,2,4] that this disease is a sequel to subclinical edema disease. The disease has been reported occurring in pigs 15–27 days after experimental *E. coli* infection.[5] The characteristic feature is the presence of perivascular eosinophilic droplets.[7]

The main differential diagnosis is that of spinal or brain abscess and the porcine viral encephalomyelitides. Affected pigs should be housed separately as soon as clinical signs are observed. In view of the nature of the lesion, therapy is unlikely to be of value; however, recovery following treatment with oxytetracycline has been reported.[1]

Diseases associated with *Salmonella* species

SALMONELLOSIS (PARATYPHOID)

Synopsis

Etiology *Salmonella* spp. Cattle: *Salmonella typhimurium, Salmonella dublin, Salmonella newport*. Sheep and goats: *S. typhimurium, S. dublin*. Horses: *S. typhimurium*. Pigs: *Salmonella choleraesuis*

Epidemiology Worldwide. Important zoonosis and foodborne illness. Prevalence of infection in healthy animals varies according to species and country. Incidence of clinical disease lower than prevalence; outbreaks occur precipitated by stressors. Spread by direct or indirect means; infected animal source of organism, which contaminates feed and water supplies. Disease may become endemic on farm. Carrier animals shed organism and may introduce infection into herd. Deprivation of feed and water, transportation, drought, intensive grazing and housing, mixing animals from different sources contribute to onset of disease. Antimicrobial resistance major public health problem. Subclinical infection in pigs potential zoonosis

Signs Septicemia in neonatal ruminants and foals, and in pigs up to 4 months of age with high case fatality rate. Acute diarrhea and dysentery, fibrinous fecal casts, fever, marked dehydration, toxemia; chronic enteritis; abortion; dry gangrene of extremities; arthritis and foci of osteomyelitis. Severe diarrhea and dehydration characteristic in horse

Clinical pathology Culture organism from feces; detect organism with special tests; hematology for changes in leukon and clinical chemistry electrolyte changes

Lesions Septicemic hemorrhages. Mucoenteritis to marked fibrinohemorrhagic necrotic enteritis; enlarged mesenteric lymph nodes. Kidney petechiation in pigs. Foci of necrosis and thickened intestinal wall in chronic enteritis. Culture organism from blood, spleen, liver, lymph nodes

Differential diagnosis list

- Septicemia of neonates
  - Coliform septicemia of calves, foals, piglets, lambs
  - *Actinobacillus equuli* infection of foals
- Septicemia of growing pigs
  - Hog cholera
  - Erysipelas
  - Pasteurellosis
  - Swine dysentery
- Acute enteritis of cattle
  - Coccidiosis
  - Winter dysentery
  - Acute intestinal obstruction
- Chronic enteritis of cattle
  - Johne's disease
  - Copper poisoning
  - Intestinal parasitism
- Acute enteritis of horses
  - Idiopathic colitis
  - Potomac horse fever
- Abortion: see Table 18.7

Treatment Antimicrobials. Supportive fluid and electrolyte therapy

Control Prevent introduction of infection into herd. Limit spread of infection within herd by identification of carrier animals, prophylactic antimicrobials, restricting movement of animals, clean water supply, hygiene and disinfection of buildings. Avoid spread of infection in veterinary clinics, dispose of infective materials. Vaccines for immunization are available but not effective

ETIOLOGY

The genus *Salmonella* belongs to the family Enterobacteriaceae. Currently there are 2463 serotypes (serovars) of *Salmonella*.[1] The antigenic formulae of *Salmonella* serotypes are defined and maintained by the World Health Organization (WHO) Collaborating Centre for Reference and Research on Salmonella at the Pasteur Institute, Paris, France, and new serotypes are listed in annual updates of the Kaufmann–White scheme.

In 1986, the Subcommittee of Enterobacteriaceae of the International Committee on Systematic Bacteriology recommended that the type species for *Salmonella* be changed to *Salmonella enterica*. However, *Salmonella typhi* and *Salmonella choleraesuis* were maintained as type species.[1] The literature on *Salmonella* nomenclature has been reviewed.[1]

According to the current system used by the Centers for Disease Control, the genus *Salmonella* contains two species, each of which contains multiple serotypes.[1] The two species are *S. enterica*, the type species, and *Salmonella bongori*. *S. enterica* subsp. *enterica* is divided into six subspecies. *S. enterica* subsp. *enterica* I is divided into serotypes, for example serotypes *enteriditis, typhimurium, typhi*, and *choleraesuis*. At the first citation of a serotype the genus name is given followed by the word 'serotype' or the abbreviation 'ser.' and then the serotype name (e.g. *Salmonella* serotype or ser. *typhimurium*). Subsequently, the name may be written with the genus followed directly by the serotype name (e.g *Salmonella typhimurium* or *S. typhimurium*). The majority (59%) of the 2463 *Salmonella* serotypes belong to *S. enterica* subsp. I (*S. enterica* subsp. *enterica*).

Serovars of *S. enterica* subsp. I are associated mainly with warm-blooded vertebrates and are responsible for most *Salmonella* infections in humans and domesticated animals. *Salmonella* serovars differ in the range of hosts they can infect and in the nature of disease that may result: this difference is referred to as **serovar–host specificity**. Some *Salmonella* serovars, for example *typhimurium* and *enteritidis*, can infect a wide range of hosts and are termed ubiquitous. They are usually associated with a relatively mild enteric disease, although in some hosts, such as mice, the disease can be systemic and severe. Other serovars are very restricted in their host range, causing severe systemic disease in only one host. For example, *S. typhi* is restricted to infection in humans, *Salmonella abortusovis* to infections in sheep, *Salmonella dublin* in cattle, *Salmonella abortusequi* in horses, and *Salmonella choleraesuis* in pigs.

A third group of serovars is associated predominantly with disease in one species but may also infect a limited number of other hosts. For example, *S. dublin* is usually associated with cattle but natural infection by this serovar may also occur in other animals, including humans and sheep. The nature of disease associated with this third group of serovars is variable, depending on the specific combination of serovar and host, although

in the predominant serovar–host combination the disease is usually systemic.

The serotypes (serovars) that most commonly cause salmonellosis in farm animal species are as follows:

- **Cattle**: *S. typhimurium*, *S. dublin*, *Salmonella newport*
- **Sheep and goats**: *S. abortusovis*, *S. typhimurium*, *S. dublin*, *Salmonella anatum*
- **Pigs**: *S. typhimurium*, *S. choleraesuis*
- **Horses**: *S. typhimurium*, *S. abortusequi*, *S. anatum*, *S. newport*, *S. enteritidis*, *Salmonella heidelberg*, *Salmonella arizona*, *Salmonella angona.*

The molecular methods are now available for epidemiological investigation of *S. enterica* subsp. *enterica* infections.[2]

EPIDEMIOLOGY

The epidemiology of salmonellosis is complex, which often makes control of the disease difficult. The epidemiological patterns of prevalence of infection and incidence of disease differ greatly between geographical areas depending on climate, population density, land use, farming practices, food harvesting and processing technologies, and consumer habits. In addition, the biology of the serovars differs so widely that considerations of salmonellosis, *Salmonella* infections or *Salmonella* contamination are inevitably complex.

Prevalence of infection

Surveys from various countries indicate a 13–15% infection rate in dairy cows in New Zealand, with similar rates in calves and sheep, and 4% in beef cattle. In the Netherlands, the infection rate is 25% in healthy pigs at abattoirs but similar investigations elsewhere record 10% (New Zealand) and 6% (UK). American figures indicate a 10–13% infection rate. Salmonellas were isolated from the mesenteric lymph nodes and cecal contents of 84% of slaughtered sows in a Minnesota abattoir. These data are based on abattoir material and should be viewed with caution because of the very rapid increase in infection rate which occurs when animals are held over in yards for several days.

A national survey of the prevalence of fecal carriage of *Salmonella* in healthy pigs, cattle, and sheep at slaughter, and of pig carcass contamination with *Salmonella* in Great Britain found the carriage rate in prime slaughter cattle and sheep was very low compared with pigs.[3] In pigs, the cecal carriage rate was 23.0%, although carcasses were only moderately contaminated at 5.3%. The meat juice ELISA results indicated that 152% of tissue fluid samples were positive at the 40% cutoff level and 35.7% at the 10% experimental cutoff level. This indicates that pigs are exposed to a relatively high level of *Salmonella* during the weeks prior to slaughter. The carriage rate in cattle and sheep was very low, ranging from 0.1–1.7%.

In the UK, *S. dublin* and *S. typhimurium* account for nearly 90% of bovine salmonellosis. *S. typhimurium* is endemic in calves, especially those purchased at livestock markets and raised for beef or veal. In the USA, the organism is shed by calves on 16% of farms sampled; in Ontario, calves on 22% of farms surveyed were found to shed *Salmonella* spp. In a survey of 47 dairy farms in Ohio, of 452 calves sampled, 10 calves from seven farms were culture-positive.[4] *Salmonella* serotypes isolated were *S. dublin*, *S. typhimurium*, *S. enteritidis*, *S. agona*, *Salmonella mbandaka*, and *Salmonella montevideo.* Bulk milk tank filters from these dairies were also submitted for culture; *Salmonella* spp. were isolated from one of 50 filters and two calves from this herd were found to be shedding *Salmonella* spp. of the same serotype.

The geographical distribution of the serotypes differs: *S. typhimurium* has a universal distribution; *S. dublin* has a more patchy habitat. In the USA, up until 1948, it was limited to California and as recently as 1971 it had not been reported in cattle east of the Rocky Mountains. In 1980, the first case of *S. dublin* occurred in Indiana. The movement of infected adult cattle and calves is responsible for the introduction of infection to areas where it had not previously been diagnosed. In a California survey of 60 dairy herds, milk samples and serum samples tested with an ELISA for antibodies against *Salmonella* serogroup B, C1, and D1 antigens found that 75% of dairy herds surveyed had cows with serological evidence of recent exposure to salmonellas, especially *S. typhimurium* and *S. dublin*. The prevalence of fecal shedding of *Salmonella* by cull dairy cattle marketed in Washington state is estimated to be 4.6 per 1000 head. Neonatal calves under 28 days of age may be shedding *Salmonella* without any evidence or recent herd history of clinical disease. Australia has had little *S. dublin* but there has been a marked increase in outbreaks of abortions, gastroenteritis and calf deaths due to *S. dublin* infection in Queensland dairy cattle since 1983. South Africa, South America, the UK, and Europe have had *S. dublin* as the principal pathogen for cattle for some time. It has also come to surpass *S. abortusovis* as a cause of abortion in sheep.

In Danish pig herds, *Salmonella* infections are usually subclinical. A survey in 1993–94 found that 22% of 1368 larger herds were infected with *Salmonella.* The most prevalent serotypes were *S. typhimurium* (62% of infected herds), *Salmonella infantis* (10%), *Salmonella* 4.12:b (8%), and *Salmonella panama* (5%). Phage typing of isolates of *S. typhimurium* from pigs and humans reveals that pigs are probably a major source of the infection in humans in Denmark.

In Sweden the prevalence of salmonellosis in food-producing animals is low because of the *Salmonella* control programs, which started in 1961 with the aim of keeping meat-producing animals free from *Salmonella* in Sweden.[5] When Sweden joined the European Union in 1995, surveillance of *Salmonella* in cattle, pigs, and poultry at slaughter was included in the control programs. Any finding of *Salmonella* from animals or in feeds or feed production, regardless of serotype, is notifiable to the Swedish Board of Agriculture. The occurrence of *Salmonella* in animals and in the feed production in Sweden remained relatively stable from 1993–97.[5]

The incidence of salmonellosis in animals and humans may change within a geographical area over a period of years.[6] In Scotland, the incidence of *S. typhimurium* DT104 in cattle peaked in 1996 and then decreased annually to 2001.[6] Similar declines have been observed in its incidence in sheep and pigs. In humans, the number of reports of *S. enteritidis* PT4 peaked in 1997 and then declined to a low level by 2001.

S. infantis and *S. typhimurium* persist among cattle in Finland, with a low prevalence rate of 2% of farms, but these serovars play a major role in human salmonellosis.[7] Molecular epidemiology is now used to determine if strains isolated from cattle are the same as those affecting humans.[2,6] Multiple genetic typing of *S. typhimurium* isolates of different phage types (DT104, U302, DT204B, and DT 49) from animals and humans in England, Wales, and Northern Ireland identified different degrees of polymorphism.[8] A prevalent genomic clone, as well as a variety of less frequent clones, is present for each of the phage types. Molecular epidemiology of *S. typhimurium* isolates from wild-living birds, domestic animals and the environment was investigated in Norway using pulse-field gel electrophoresis.[9] Passerines (perching birds) constitute an important source of infection for humans in Norway, whereas gulls and pigeons represent only a minor source of human *S. typhimurium* infections. Passerines, gulls, and pigeons may constitute a source of infection of domestic animals and feed plants. Some isolates from cattle were confirmed as mr *S. typhimurium* DT104 for the first time.

The serotype and phage type distribution of *Salmonella* strains isolated from humans, cattle, pigs, and chickens in the

Netherlands from 1984–2001 were determined.[10] The most prevalent serotypes were as follows: in humans, serovars *typhimurium* and *enteritidis*; in cattle, serovars *typhimurium* and *dublin*; in pigs, serovar *typhimurium*; and in chickens, serovars *enteritidis*, *infantis*, and *typhimurium*. In general, similar sero- and phage types were found in humans and animals, although distinct types were more common in animals.

Monitoring of the population and herd *Salmonella* seroprevalence in finishing pigs and sows provided a baseline for the success of future intervention and control strategies for *Salmonella* in pork. The seroprevalence of *Salmonella* in sows and finishing pigs in the Netherlands was determined using indirect ELISA on blood samples collected at the abattoirs.[11] The population prevalence for finishing pigs in 1996 and 1999 was 23.7% and 24.5%, respectively, and for sows 40.5% and 60.4%, respectively. The prevalence in free-ranging finishing pigs was higher, at 44.6%, than in intensively housed finishing pigs. In 46 multiplying sow herds, the average herd prevalences were 54, 44, and 19%, respectively. The prevalence of *Salmonella* in Danish pork decreased from 3.5% in 1993 to 0.7% in 2000 following introduction of a national program to reduce the prevalence of salmonellas in pork.[12]

Occurrence

Salmonellosis occurs universally in all species.

Cattle

The disease has assumed major importance because of outbreaks in dairy cattle and the occurrence of infections in humans. Of major concern is the increased incidence of outbreaks of salmonellosis in dairy cattle and humans associated with *S. typhimurium* definitive type (DT)104 in the USA[6] and the UK. This strain is multiple-antibiotic-resistant and is classified as R-type ACSSuT by being resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. The strain is now the second most prevalent *Salmonella* serotype in humans in England and Wales and the most common *Salmonella* serotype isolated from cattle. A case-control study identified the following risk factors associated with infection with the multiple-resistant *S. typhimurium* DT104:

- A high population density of feral cats around the farm
- Evidence of wild bird access to feed supplies
- Purchase of animals from dealers.

A high frequency of antibiotic-resistant phage types of *S. typhimurium* has been reported from Australia. The intensification of cattle production and management has played a large part, but the emergence of *S. dublin* as a common pathogen has been most important. In recent years there has also been a large increase in notifications of exotic species of *Salmonella* such as *S. agona* and *S. newport*, which have mostly originated from the use of unusual food materials of animal and fish origin.

Horses

The incidence of salmonellosis has been increasing in the horse population, particularly where horses are assembled at large clinical centers and breeding farms. Moreover, nosocomial salmonellosis is an important problem for horses in veterinary hospitals. It is also possible that many of the unidentified enteritides of horses may have been associated with *Salmonella* spp.

Pigs

In the midwestern USA, salmonellosis associated with the host-adapted facultative intracellular *S. choleraesuis* is an important cause of economic loss in pig herds because of death and reduced productivity. It is the most frequent serotype recovered from pigs and is isolated from more than 95% of porcine salmonellosis outbreaks in Iowa. The incidence has been increasing in some geographical areas. *S. typhimurium* causes enterocolitis in young pigs.

The majority of *Salmonella* infections are subclinical, associated with a large number of serotypes. A national US survey for fecal *Salmonella* shedding by pigs most frequently found *S. enterica* serotypes *derby*, *agona*, *typhimurium*, *brandenburg*, *mbendaka*, and *heidelberg*.[13]

Sheep

Salmonellosis is commonly encountered when sheep are assembled at high stocking rates. It was one of the main contributing causes of death in sheep exported by sea from Australia to the Middle East, although inanition is usually the primary cause.

In the 1990s there was an increase in the incidence of salmonellosis in sheep associated with *S. enterica* subsp. *diarizonae* serovar 61:k:1,5[14] in the UK[10,15] and Norway.[16,17]

Morbidity and case fatality

The morbidity rate in outbreaks of salmonellosis in pigs, sheep, and calves is usually high, often reaching 50% or more. Morbidity and mortality are usually highest in calves under 12 weeks of age. In all species the case fatality rate often reaches 100% if treatment is not provided. In outbreaks in out-wintered suckler cattle herds, the morbidity varied from 14–60% and mortality in adult cattle from 0–14%. In a review of 40 cases of clinical salmonellosis in horses that were diagnosed in one clinic, the case-fatality rate was 60%. Epidemics of salmonellosis affecting up to 40% of foals under 8 days of age on one Thoroughbred horse farm have been reported.

Methods of transmission

Salmonellas are spread by direct or indirect means. Infected animals are the source of the organisms; they excrete them and infect other animals, directly or indirectly by contamination of the environment, primarily feed and water supplies. The farm animal may be infected in different ways: by animal-to-animal transmission, especially of host-adapted serovars; by contaminated animal feed; and by a contaminated environment (soil, birds, rodents, insects, water supplies). Liquid wastes from infected animals may contaminate the environment directly, including streams, rivers, and pastures. Bacteria may also be disseminated during the transport of infected animals and during the holding of animals in a lairage prior to slaughter. In both situations, the excretion of salmonellas is exacerbated by the stress imposed.

In the UK, surplus calves from dairy farms are sold at public market and moved to rearing farms. The mixing of young susceptible calves and their subsequent transportation is an efficient mechanism for the rapid dissemination of *Salmonella*. The dealers' premises can serve as reservoirs of infection despite cleaning and disinfection. Many vehicles and markets are contaminated with *Salmonella*, and *S. typhimurium* DT204C, the most common *Salmonella* isolated from calves, is the most frequent isolation.

The introduction of infected carrier animals into a herd is a common cause of outbreaks of clinical salmonellosis in dairy herds that are expanding in size.

The organism can persist for an average of 14 months in the environment where calves are reared. *Salmonella* does not survive for more than 5 days in bovine urine not mixed with feces but will survive in dried bovine feces for up to 6 years. After a clinical outbreak of salmonellosis, for example in a dairy herd raising its own replacements, the premises cannot be declared to be *Salmonella*-free solely on the basis of freedom from clinical cases over the next few years or on the basis of comparatively high herd performance. In large dairy herds with modern free-stalls that recycle water in their manure flush systems, it may be possible to isolate *Salmonella* serovars for several years following an outbreak of clinical salmonellosis. The organisms may be found in recycled water samples, bulk tank milk

filters and the feces of calves and adult cows.

Salmonellas can be isolated from piggery waste water after orthodox pondage treatment, and the recirculation of contaminated water through the piggery serves as a constant source of the organism. Housing of finishing-age pigs in barns with open-flush gutters may contribute to increased shedding of *Salmonella* compared to pigs housed on partially slotted floors. Methanogenic fermentation in waste ponds does not eliminate *Salmonella* from piggery waste; acidogenic fermentation with the production of free acid can destroy salmonellas and other potential pathogens.

During slaughter, fecal contamination of the carcass commonly occurs and can be carried through all slaughter procedures up to the processing of the raw products. Milk can be contaminated directly by cows that excrete the organism in the udder, especially those cattle infected with *S. dublin* and *Salmonella muenster*,[18] both of which have adapted to colonize the bovine mammary gland. Although *S. typhimurium* is not usually excreted in the milk, except during the febrile stage of clinical disease, it has been reported to have been persistently isolated from the milk of a healthy cow. *S. enteritidis* has been isolated from ill humans, milking filters, milk from a bulk tank and milk from one quarter of a 5-year-old dairy cow that persistently shed the organism in the milk for several months. Milk is most likely to become contaminated by feces, either from an animal with clinical salmonellosis or from a healthy carrier animal, during the milking process. Additional sources of contamination during milking are use of polluted water or contaminated equipment. Workers who lack personal hygiene skills and have clinical salmonellosis or are chronic shedders of the organism may also contaminate milk supplies.

Airborne transmission can be a primary mode of infection of *S. typhimurium*. Studies have shown that the organism can survive in air sufficiently long to present a significant hazard of air-borne spread.

The carrier state

Because salmonellas are facultative intracellular organisms that survive in the phagolysosome of macrophages, they can evade the bactericidal effects of antibody and complement. Thus, persistence of infection in animals and in the environment is an important epidemiological feature of salmonellosis. When an animal is infected with *S. dublin* it may become a clinical case or an **active carrier,** shedding organisms constantly or intermittently in the feces. It may also become a latent carrier with infection persisting in lymph nodes or tonsils but no salmonellas in the feces, or even a **passive carrier** which is constantly acquiring infection from pasture or the calf-pen floor. But invasion of tissues may not occur and when the animal is removed from the environment the infection disappears. However, these animals probably multiply the salmonellas without becoming permanent carriers. The importance of the latent carriers is that they can become active carriers or even clinical cases under stress, especially at calving time. The cattle themselves then become the means by which the infection is retained in the herd for long periods. A major problem with the control of *S. dublin* infection is that latent carriers of the organism, unlike persistent excreters, cannot be readily identified by fecal culture or serological methods. In a 3-year study of one dairy herd, the organism was isolated occasionally from the feces of adult cattle, from some cattle after parturition, and from some calves within 24 hours after birth. In some dairy herds, the organism may persist for many years with a low incidence rate of clinical disease.

For *S. typhimurium* the donor can be any domestic animal species, including humans, or any wild animal or bird. Although all infected adults become carriers it is rarely for any length of time, and calves rarely become carriers. In sheep and cattle the carrier state may persist for as long as 10 weeks, and in horses up to 14 months.

Experimental infection of pigs at 7–8 weeks of age with a single oral dose of *S. typhimurium* can persist continually at least until market age. Regardless of the route of infection, *S. choleraesuis* can persist in the tonsil and ileocolic lymph nodes, ileocolic junction and colon, and can be excreted in the feces of experimentally infected pigs for at least 12 weeks. The amount of shedding and persistence of infection is dose dependent. Low doses of *S. choleraesuis* can be easily cleared, moderate doses can persist for at least 2 months, and high doses result in long-term carrier states. After intranasal inoculation of *S. typhimurium*, the organism rapidly appears in the intestines, suggesting that the tonsils and lungs may be important sites for invasion and dissemination of *Salmonella* species. Experimental infection with a zoonotic strain of *S. newport* can also be established in pigs at 7 weeks of age to persist until market age. Long-term persistence of infection is limited generally to the palatine tonsils, the intestinal tract caudal to the mid-jejunum and their lymph nodes. The prevalence of the organism in pigs creates a reservoir of infection for animals and humans. The transmission of salmonellosis in pigs can occur in a few days. Exposure to relatively low levels of *S. choleraesuis* may result in high morbidity and initiate a severe outbreak in naive pigs within several days of being exposed to infected pigs. Only a small fraction of carrier pigs are responsible for the maintenance of the pathogen in a pig population.

Risk factors predisposing to clinical disease

The clinical characteristics of salmonellosis in large animals vary depending on the various management systems used, the intensity of stocking, whether or not the animals are housed, and the epidemiological characteristics of the different *Salmonella* species. Thus, salmonellosis in cattle is a very serious and persistent disease in areas where it is caused principally by *S. dublin*. But where it is associated with *S. typhimurium* the disease is sporadic and, even though it is highly fatal to individual animals, it is not a serious disease. Although there are probably similar differences with the other species, they are not particularly well defined. The difference between the diseases associated with *S. dublin* and *S. typhimurium* is the marked tendency for *S. dublin* to persist in adult cattle and create a significant reservoir of carrier animals. *S. typhimurium* does not do so as much, so that the disease is likely to subside after an initial exposure and to recur only when the source of infection, from rodents or feedstuffs, or sewage or slurry, reappears. This does not of course preclude the disease from persisting in a flock or herd for long periods. *S. typhimurium* infection persisted in a large dairy herd for 3.5 years. While the incidence rate of clinical disease declined over the study period, the organism could still be cultured from the bulk tank milk filters, which may have been associated with one cow identified as a milk excretor. Three associated human disease incidents occurred following the consumption of raw milk.

Animal risk factors

Except in the newborn, especially foals, infection with a *Salmonella* sp. is usually not a sufficient cause of clinical salmonellosis. The response to infection with a *Salmonella* sp. varies depending on the size of the challenge dose and the immunological status of the animal, itself dependent on colostrum intake in neonates, previous exposure to infection and exposure to stressors, particularly in older animals. It is generally accepted that the intervention of some precipitating factor such as transport, intercurrent disease, anesthesia and surgery, dosing with

antimicrobials or anthelmintics, acute deprivation of food, or parturition is usually necessary to cause the disease salmonellosis, as distinct from infection with *Salmonella* sp.

The portal of infection in salmonellosis is almost always the mouth, so that the severity of the disease in an individual, or of an outbreak in a group, depends on the degree of contamination and the environmental conditions of temperature and dryness that determine the survival time of the salmonellas. Just as important is the influence of the host on the outcome of the infection. Many animals become infected naturally and are passive carriers; they shed salmonellas in their feces without clinical disease but only for the duration of their cohabitation with other infected animals. It is also possible to reproduce salmonellosis experimentally in most animals using a sufficiently large dose of a virulent strain of the organism. There still remains the common occurrence of the animal that is a subclinical carrier of the infection but develops clinical salmonellosis when exposed to stressors such as long transportation, hospitalization, severe feed deprivation or parturition.

Genetic resistance to salmonellosis in domestic animals

There is evidence of a strong genetic association with resistance to salmonellosis in several economically important domestic animal species.[19] However, as yet, selective breeding for resistance traits is not utilized in control of diseases or the carriage of *Salmonella* in any of these species. The value of a particular resistance trait in reduction of disease must be balanced against other factors such as productivity of meat and milk. The control of *Salmonella* colonization of the gastrointestinal tract of food animals, particularly where intensive rearing occurs, as in pig units, would appear to be a particularly useful objective with enormous potential public health benefits. There may be a role for several inherited immunological traits, including polymorphonuclear leukocyte function and lecithin-induced mitogenic proliferation.

The interrelationships between the risk factors of the host, the environment, and the pathogen are described here according to species differences.

Dairy cattle

In calves, the disease is usually endemic on a particular farm, although outbreaks can occur. In adult cattle at pasture the disease is less common. This is particularly so with *S. typhimurium* infections, but *S. dublin* affects both young and adult cattle. Spread between calves in communal pens is by fecal–oral contamination. Infection of the newborn calf may be from the dam because many cows that are latent shedders become active shedders at parturition. The calves are not infected at birth but become infected from the environment. In adult cattle, *S. dublin* is the common infection and occurs sporadically, but as outbreaks when stressors occur. Spread is usually by the oral route and in cattle at pasture is greatly enhanced by persistently wet conditions. Wild mice are potential reservoirs of *S. dublin* in dairy herds.

Risk factors identified in dairy and beef cattle herds with clinical salmonellosis in Virginia included herd size, exposure to wild geese, rodent activity in housing and feed areas and spreading manure on bordering property.[20] Previous antimicrobial treatment of cattle with laboratory-confirmed *Salmonella* infections increases the probability of isolating salmonellas.[21]

In cattle, deprivation of feed and water is a common risk factor, usually as a result of transportation, but recent calving, sudden changes in the composition of the diet, vaccination with a living vaccine that produces a systemic reaction, treatment with irritant compounds such as carbon tetrachloride for fluke, and fluke infestation can precipitate clinical disease. However, prior infection of calves can provide resistance to experimental infection. In some herds there are sporadic cases in cows as they calve, usually within 1 week afterwards. In grazing cattle there is a distinct seasonal incidence in late summer, fall, and early winter, probably because of greater exposure to infection at pasture.

The pH of rumen contents has been shown to affect the number of salmonellas surviving passage through the rumen. A high volatile fatty acid content and a low pH, such as prevails when a ruminant is on full feed, is unfavorable to salmonellas passing through the forestomachs.

The epidemiological and biological characteristics of three dairy herds in California have been examined and several risk factors were identified that varied between dairies.[22] The various sources of salmonellas in dairy farms indicate that they are part of a larger ecosystem. The prevalence of fecal shedding indicated the magnitude of environmental contamination possible. Animals were exposed to many *Salmonella* serotypes via feed contaminated through irrigation of crops with effluent or dairy wastes. *Salmonella* contamination of irrigation water by human sewage was identified as a potential source of exposure with *S. agona*, *S. montevideo*, and *Salmonella manila*. Nutritional stress caused by transition diets and heat stress was associated with outbreaks in some herds. Salmonellas were isolated from aseptically collected composite milk samples, and from bulk-tank milk and inline milk filters. Such contamination can result in contamination of human dairy products. A large number of *Salmonella* serotypes were present in cull dairy cows at slaughter with *S. montevideo* being most common.[23] The overall prevalence of *Salmonella* spp. in cull dairy cows at slaughter across the USA was 23.1%, with a range accounting for location and season between 4.3% and 54.5%.[24] This could burden the Hazard Analysis Critical Points Programs implemented in abattoirs. Procedures to reduce *Salmonella* infection at the farm and during transport to slaughter could reduce the risk of spread during the slaughter process.

The water supplies of dairy calves in California dairy herds may be contaminated with *S. typhimurium*.[25] Water offered to weaned dairy calves in a continuous water-tank-filling method was a risk factor compared to a valve on demand and a water pH of more than 8.

Subclinical fecal shedding of *Salmonella* can persist in dairy herds for up to 18 months with no measurable effects on health or production on individual cows.[26] Large herd size and intensive management may provide an environment conducive to *Salmonella* shedding and chronic dairy herd infection.[27] *Salmonella* spp. can be isolated from the environment of free stalls in dairy herds in Wisconsin without any history of clinical salmonellosis.[28] Birds that commonly inhabit California dairy farms harbor *Salmonella* organisms but the low prevalence of infection in birds and the serotypes isolated are not important reservoirs of infection.[29]

The risk factors for fecal shedding of *Salmonella* in US dairy herds were herd size, region of country, use of flush water systems, and feeding brewers' products to lactating cows.[30] The estimated population attributable risks for all four factors combined was 0.95. These factors can be used to predict the presence of *Salmonella* shedders in a herd. *Salmonella* can be isolated from more than 90% of dairy farms but 25% of farms account for more than 75% of *Salmonella*-positive samples.[31] Concentrating control efforts on farms with a high prevalence may be the most effective means of control of the infection in dairy herds.

The risk factors for becoming a carrier of *S. dublin* in dairy cattle in Denmark include heifers infected between the age of 1 year of age and first calving, and cows infected around the time of calving.[32] The risk was higher in the first two quarters of the year (late winter to spring). Herds with the highest risk of

carrier development were those with clinical disease outbreaks.

Beef cattle herds and feedlots

While salmonellosis can cause significant economic losses in beef herds and feedlots it is not as important as in dairy cattle. Low numbers of beef cattle are found to shed *Salmonella* at the time of slaughter and beef cattle do not appear to be a major risk of carcass contamination. In Australian cattle, the prevalence of *Salmonella* in the feces of cattle at slaughter was 6.8%.[33] In grass-fed cattle the prevalence was 4.5% and not much different to that found in feedlot cattle. In the US, fewer than 7% of cattle in feedlots shed *Salmonella* in their feces.[34] In European cattle, the prevalence of *Salmonella* in feces has ranged from less than 1% to 42%.[33] *S. montevideo* has been the cause of large economic losses due to abortion and cow mortality in an out-wintered beef herd in Scotland.[35] Up to 25% of the cows aborted and the overall herd mortality was 7%. The organism had been the cause of abortion in a neighboring sheep flock.

Case-control studies of risk factors for clinical salmonellosis in cattle herds in Virginia, USA, found that larger herd size, exposure to wild geese, rodent activity in housing and feed areas, and spreading poultry manure on bordering property had positive associations with the occurrence of the disease.[20] Case farms were less likely than control farms to have calves born primarily in a building and had smaller percentage changes in the number of mature cows during the previous year. In contrast, in the UK, farms with housed cattle had increased risk of *S. typhimurium* DT104. Feeding recycled poultry bedding that had been stored and stacked properly for 51 days prior to feeding, to feedlot cattle did not increase the prevalence of detectable *Salmonella* in calves.[36]

Changes in the incidence of shedding *Salmonella* in the feces of cattle being transported from the farm to slaughter plant have been examined.[37] In feedlot cattle, fecal shedding remains fairly constant before and after transport (3–5%); in adult cattle the shedding rate increased from 1% to 21%. Contamination of hides increased for both animal types from 18–20% to 50–56%. Nineteen percent of feedlot cattle carcasses and 54% of adult cattle tested positive for *Salmonella*. Feed withdrawal, transport stress, and the commingling of animals prior to slaughter can affect the number of cattle that are contaminated with bacterial pathogens such as *Salmonella*. However, none of the risk factors evaluated prior to or throughout the transport process had an impact on fecal shedding, hide contamination or carcass contamination.

Feedlot playas (temporary shallow lakes) are frequently contaminated with many *Salmonella* serotypes.[38] Using playas as a source of water for feedlots can be a source of *Salmonella* and they should not be used to cool cattle in the summer months, or for dust abatement, or for irrigation of crops. Wildlife, birds, and migratory waterfowl have access to these bodies of water and, because of their size and number, there is little which can be done to prevent them from becoming contaminated.

Sheep

Salmonellosis in sheep may occur with a range of different syndromes of variable severity, depending mainly on the particular serovar involved. Serovars *abortuovis*, *dublin*, and *typhimurium*, which each have different degrees of host restriction, are associated with disease in sheep. Serovar *dublin* can cause both enteritis and abortion in adult sheep, and the disease is often associated with metritis, anorexia, and loss of wool. Newborn lambs may develop diarrhea with a high mortality rate. Serovar *typhimurium* is associated with acute disease, enteritis but not usually abortion.[39]

A new strain of *Salmonella brandenburg* has affected livestock and humans in the South Island of New Zealand.[40]The strain has caused abortions in sheep, abortions in cattle and gastroenteritis in calves and adult cattle. The same strain also caused disease in horses, goats, deer, pigs, and humans. Spread of the disease on farms was strongly associated with aborting ewes, which resulted in considerable environmental contamination. During the abortion season, black-backed gulls appeared to spread the disease to other farms. Other potential sources of infection were carrier sheep, contaminated water sources, and contaminated sheep dust.

Salmonella infections of sheep and human food poisoning are rare. However, outbreaks of food poisoning in Iceland associated with *Salmonella* were traced to the consumption of singed sheep heads.[41] The organism could be isolated from 20% of the specimens sampled. The prevalence of infection of the sheep population in Iceland is low, at 1.3%. Infection occurs on mountain pastures, which may be contaminated by wild birds, especially gulls.

In range sheep, the commonest occurrence of the disease is during a drought when sheep are concentrated in small areas of surviving grass heavily contaminated by feces. Sheep held in holding yards or transport vehicles previously occupied by sheep for long periods are also susceptible to clinical disease. This is most likely to occur when they drink from puddles of water, especially in heavily contaminated yards, or when they are exposed to recycled dip wash. In sheep, the disease is commonly associated with deprivation of feed when animals are assembled for vaccination, anthelmintic administration or shipment over long distances. Lambs in feedlots are susceptible to salmonellosis within a few weeks after arrival in the lot.

The modern development of pen-lambing in which ewes about to lamb are brought into small pens is also a means of potentiating spread from a chronic shedder. In all these situations feed stress by deprivation is likely to contribute to susceptibility. Field outbreaks in range sheep have been recorded. In some instances they have been caused by the use of unsterilized bone meal as a phosphorus supplement. Outbreaks occurring in sheep on a number of farms in the same area at the same time have been ascribed to contamination of drinking water by birds eating carrion. Heavy dosing with zinc oxide as a prophylaxis against facial eczema is also credited with precipitating outbreaks of salmonellosis in young sheep.

Goats

Outbreaks in goats occur in the same circumstances as in other ruminant species. Transportation and capture are additional stressors in feral goats used for embryo transplantation.

Pigs

The epidemiology of *S. choleraesuis* infection in pigs is well documented and has changed remarkably since the mid-1960s, when explosive outbreaks occurred that could easily be mistaken for hog cholera. The morbidity and mortality rates were high and the disease spread rapidly through commercial pig-finishing units. These outbreaks are now rare and small in scope, largely because of the restriction of garbage feeding, much less movement and mixing of pigs through public auction marts, and disease-prevention strategies such as the use of specific pathogen-free pigs, an all-in/all-out policy in commercial finishing units, and the vertical integration of pig-producing enterprises. This insures a constant supply of disease-free growing hogs to finishing units and the assumption of a pyramid-type responsibility at all levels of the enterprise. The marked decline in the prevalence of swine salmonellosis coincided with the decline in and eradication of hog cholera. However, modern methods of raising pigs in multiple-site production systems, using all-in/all-out management of finishing pigs, appear to

have no benefit in reducing the prevalence of *Salmonella* compared with conventional farrow–finish systems.

S. enterica does not normally cause clinical disease in pigs but subclinical infections constitute an important food safety problem throughout the world.[42] Comprehensive longitudinal studies of two multiple-site pig production systems in the USA revealed considerable temporal variability in *Salmonella* prevalence between cohorts of pigs.[43] Cohorts of sows and individually identified growing pigs from their litters were serially sampled to determine the prevalence and serotypes of *Salmonella*s in each stage of production based on fecal culture, and feed and environmental samples. A total of 15 different serotypes were isolated from the two systems. Pig prevalence estimates ranged from 0–48.1%. Environmental contamination was frequently encountered despite cleaning and disinfection. Feed was only rarely contaminated. The prevalence of infection within and among cohorts of pigs was highly variable, which indicates that point estimates of *Salmonella* prevalence and serotypes are not reliable indicators of the *Salmonella* status on farms, and that uncontrolled studies of interventions to control *Salmonella* on pig farms may yield misleading results.[43]

In the USA, new regulations regarding the safety of meat products have been implemented in response to public concerns about food-borne disease outbreaks. The salient features of the regulations are requirements for approved systems of microbiological monitoring of *S. enterica*, *E. coli* O157:H7, and generic *E. coli* as an indicator of contamination by gastrointestinal contents. From the perspectives of public health, regulatory compliance and international competitiveness, *S. enterica* is the most important foodborne pathogen for the US pig industry. This has resulted in longitudinal epidemiological studies of fecal shedding of *S. enterica* in both breeding and growing pig populations.[43]

A quantitative risk analysis model simulating *Salmonella* prevalence in growing pigs and at slaughter would be of great value for food safety. However, sampling strategies for input information to a model are difficult to establish as the relationship between subclinical infections at the levels of the herd, the individual pig, and at slaughter is complex. The onset and duration of *Salmonella* shedding and the patterns of transmission between individual pigs and between different age groups during the growing period all have influence. Bacteriology and serology can be used to assess this relationship but repeated sampling in different cohorts of animals is required to correctly assess the infection dynamics.[78]

Longitudinal studies of *S. typhimurium* infection in farrow–finish pig herds in Denmark reveal that *Salmonella* occurrence varies between and within age groups within herds, even in herds with an apparent moderate-to-high infection level. *Salmonella* was predominant in weaners, growers, and finishers, and was only occasionally detected in sows and gilts. In Denmark, *Salmonella* is typically detected in the nursery and rarely in the sow unit, suggesting that the infection level among sows is low. This is contrary to the results of studies in the USA, where *Salmonella* was found to be common in sows.[44] In the Danish study, there was a rapid increase in *Salmonella* prevalence in the nursery, which may be associated with the stressors of weaning such as change in feed, commingling of litters and piglets being deprived of the antibodies in sow's milk before activation of their own immune response. The observation that no piglets were shedding *Salmonella* just before weaning but 3–4 weeks later in the nursery between 5% and 50% of the piglets were shedding suggests that horizontal transmission occurred in the nursery.[42] During the finishing period *Salmonella* shedding decreased, but with considerable variation. Some pigs cleared themselves of the infection whereas others continued shedding. Average shedding time was estimated to be 18–26 days. Seroprevalence peaked approximately 60 days after peak prevalence in culture. At slaughter there is a marked increase in the prevalence of *Salmonella* infection. This increase may be due to rapid cross-contamination during transport and lairage.[45] Rapid infection during transport, and particularly during holding, is a major reason for increased *Salmonella* prevalence in pigs.[46] A high degree of carcass contamination occurs at slaughter due to the delivery of *Salmonella*-positive pigs and cross-contamination from the slaughterhouse environment.[47] Contaminated feed trucks may also serve as a potential source of *Salmonella* contamination.[48] The withdrawal of feed from pigs prior to slaughter does not increase the prevalence of *Salmonella* colonization or the risk of carcass contamination.[49]

Risk factors associated with serological *Salmonella* prevalence in finishing pig herds in the Netherlands have been examined.[50] Feeding a complete liquid feed containing fermented byproducts and the omission of disinfection after pressure washing a compartment as part of an all-in/all-out procedure were both associated with a lower *Salmonella* seroprevalence. A small to moderate herd size (< 800 finishing pigs), a previous diagnosis of clinical *Salmonella* infection in the herd, the use of tylosin as an antimicrobial growth promoter in finishing feed, and herds that have more than 16% of their pigs' livers condemned at slaughter because of white spots were associated with a higher *Salmonella* seroprevalence. There was no effect on experimental *Salmonella* infection of the use of tylosin as an antimicrobial growth promoter.[51]

In those herds where the disease does occur, introduction is usually associated with the importation of infected carrier pigs. However, it is possible for the infection to be spread by flies and the movement of inanimate objects such as cleaning equipment and utensils. Feedstuffs do not provide a favorable environment for *S. choleraesuis*, so food-borne infection is not common. Survival in soil and water is approximately 6 months and in slurry up to 5 weeks. Persistence in streams fouled by piggery effluent is unlikely. Susceptibility to salmonellosis in pigs is thought to be increased by intercurrent disease, especially hog cholera, nutritional deficiency of nicotinic acid, and other nutritional stress such as a sudden change in diet.

Horses

Based on the culture of single fecal samples from horses on 972 operations in 28 states, the national prevalence of fecal shedding of *Salmonella* spp. among horses in the US horse population was 0.8%. The overall prevalence of operations positive for fecal shedding of *Salmonella* was 0.8%. Based on feed samples taken from the same operations, the prevalence of *Salmonella* spp. in grain and other concentrates used for horse feed was 0.4%.[52]

In adult horses, most clinical salmonellosis occurs after the stress of transport and mostly in horses that are overfed before shipment, receive little or no food or water for the duration of a protracted journey, and are fed excessively on arrival, cases appearing 1–4 days later. Groups of horses that have been exposed to a contaminated environment, such as saleyards or railroad yards, may experience outbreaks in which up to 50% are affected. As with other species, the presence of an asymptomatic carrier in a group of horses is often credited with initiating an outbreak, but the search for the carrier is always laborious and often fruitless. At least five negative cultural examinations of feces should be made before acquitting a suspected donor. On the other hand, the cultural examination of large numbers of horses often reveals up to 50% of the population to be carriers. Multiple serotypes of *S. enteritidis* have been isolated from the mesenteric lymph nodes of 71% of healthy horses examined at an abattoir, which indicates that extraintestinal infection occurs in the horse as it does in other

species. In the light of the high carrier rate in this species it is surprising that there are not more outbreaks.

The occurrence of salmonellosis in horses hospitalized for another disease has become a major problem for veterinary teaching hospitals and private equine practices that provide surgical veterinary care. In these circumstances there is a constant reintroduction of carriers of the disease, a persisting contamination of the environment, and a large population of horses, all of which are under physiological stress because of anesthesia, surgical invasion, or intercurrent disease and many of which are exposed to oral and parenteral treatment with antibiotics, which appears to greatly increase their chances of acquiring salmonellosis. Horses in which nasogastric tubes were passed were at 2.9 times greater risk of having salmonellas isolated than horses that did not undergo this procedure. Horses treated with antibiotics parenterally were at 6.4 times greater risk, and those treated with antibiotics orally and parenterally were at 40 times greater risk of developing salmonellosis, compared with horses not receiving such treatment. In hospitalized horses, the factors found to be associated with fecal shedding of salmonellas included diarrhea at the time of admission, fever while hospitalized, and a change of diet while hospitalized.

The extent of environmental contamination with *Salmonella enterica* in a veterinary teaching hospital in Colorado was examined.[53] The results indicate that environments in veterinary teaching hospitals can frequently be contaminated with *S. enterica* near where infected animals are managed and fecal specimens containing the bacteria are processed for culture in a laboratory. The bacteriological culture of environmental samples collected with electrostatic wipes is an effective method of detecting contamination in a veterinary teaching hospital and may be beneficial as part of surveillance activity for other veterinary and animal-rearing facilities.

Outbreaks of nosocomial salmonellosis among horses in a veterinary teaching hospital have been described.[54] Case fatality rates may be high, necessitating closure of the hospital for complete disinfection and systematic sampling of the environment to detect the presence of persistent *Salmonella*. Strict isolation of hospitalized horses that have been shedding *Salmonella* is necessary. The organisms can be isolated from the feces of hospitalized horses and many different environmental surfaces in the hospital.[55] *Salmonella* may be detected in 5.5% of hospitalized horses. The planning and implementation of infectious disease control throughout the hospital is then necessary. Bleach is the most effective disinfectant on the largest number of surfaces.

Several variables have been associated with nosocomial *Salmonella* infections in hospitalized horses:[56] the mean number of horses in the hospital shedding *Salmonella krefeld* during the first 4 days prior to and the day of admission, the mean number of horses shedding *S. typhimurium* during this period, a diagnosis of large colon impaction, withholding feed, the number of days fed bran mash, the duration of treatment with potassium penicillin G, and the mean daily ambient temperature.[56]

The factors potentially associated with *Salmonella* shedding among horses hospitalized for colic at a veterinary teaching hospital were examined.[57] *Salmonella* spp. were detected in the feces 9% of patients at least once during hospitalization. They were more likely to shed *Salmonella* if diarrhea was evident 6 hours or less after hospitalization and duration of hospitalization exceeded 8 days (OR 20.3), laminitis developed during hospitalization (OR 12.0), results of nasogastric intubation were abnormal (OR 4.9), leukopenia was evident 6 hours or less after hospitalization (OR 4.6), or travel time to the teaching hospital exceeded 1 hour (OR 3.5). Horses treated with a probiotic did not differ from control horses in likelihood of fecal shedding of *Salmonella* (OR 1.5) or prevalence of clinical signs.

Occasionally, outbreaks occur in young horses at pasture when they are heavily infested with worms. Salmonellosis is also one of the common neonatal septicemias of foals, and the disease may occur as endemic on particular studs or there may be outbreaks with many foals being affected at the one time. The common management strategy on 'visiting stud-farms' of bringing mares and newborn foals to communal studs and then bringing them daily to a central point for observation and teasing is also likely to facilitate spread of an infection through a group of foals.

Immune mechanisms

Most information on the mechanisms of immunity to *Salmonella*, including the safety and immunogenicity of most *Salmonella* vaccines, has been done experimentally in mice. In primary infections in mice, early bacterial growth in the reticuloendothelial system is controlled by the contribution of both macrophages and polymorphonuclear cells and is affected by the virulence of the strain.[58] In lethal infections, the early growth of the bacteria is the tissues results in high bacterial numbers that lead to death of the animal. Following natural infection with *Salmonella* antibody responses to lipopolysaccharides and protein determinants can be detected.[58] Anti-*Salmonella* IgM appear in serum early after infection followed by IgG. T-cells have a critical role in the later stages of primary infection.

Environmental and management risk factors

Farming practice in general

Intensification of husbandry in all species is recognized as a factor contributing significantly to an increase in the new infection rate. A typical example is the carrier rate of 54% observed in intensive piggeries in New Guinea compared to the 9% in village pigs. Any significant change in management of the herd or a group of animals can precipitate the onset of clinical salmonellosis if the infection pre-exists in those animals.

Intensive pasture utilization

The means of infection is principally ingestion of feed, especially pasture, contaminated by the feces of an infected animal, so that the new infection rate is dependent on all those factors that govern the bacterial population in the environment.

Temperature and wetness are most important, as salmonellas are susceptible to drying and sunlight. *S. typhimurium* can remain viable on pasture and in soil, still water, and feces for up to 7 months. Survival times of the bacteria in soil are influenced by too many variables to make any overall statement meaningful.

As well as infection of pasture by cattle or other domestic animal species, the use of 'slurry' as a means of disposal of animal manure from cow housing or zero grazing areas has led to a highly efficient means of spreading *Salmonella* infections. The chance of cows becoming infected increases considerably if they are grazed soon after the slurry is applied, and is less likely during dry, sunny periods and when there is sufficient pasture growth to avoid it being eaten right down to the ground surface. The survival time of *Salmonella* spp. in cold liquid manure depends on several factors, including pH of the slurry and the serotype of the organism. It can be as long as 28 weeks.

Pasture contaminated by human sewage, especially septic tank or sewage plant effluent or sludge, is also credited with being a potential source of *Salmonella* infection for cattle, but there are a number of reports that do not support this view. Drinking water can remain infected for long periods, as long as 9 months, and in cattle at extensive pasture infected drinking water in stagnant ponds is a significant source of infection.

Housed animals

In housed animals the same factors apply to the spread of infection as apply to pastured animals. Thus, infection can be introduced by infected domestic animal carriers. For example, in large-scale calf-rearing units, where the disease is often of diabolical severity, many of the calves are infected when they are picked up from their home farms and, if they are penned in groups, all calves in the group are soon infected. The infection can spread among calves penned individually, which suggests that aerosol spread may occur. *S. typhimurium* type 204C can survive for several months in calf-rearing premises despite depopulation, cleansing, and disinfection. However, because of the failure of most calves to continue as carriers, they are usually free of infection within 6 weeks of arrival.

The premixing of food into a liquid form for pumping to feeding stations in piggeries and calf-rearing units is an effective way of spreading salmonellosis if infection is present in the feedstuffs and the mix is allowed to stand before feeding. The feeding of medicated milk replacer and hay to dairy heifers from 24 hours of age until weaning was associated with a reduced risk of *Salmonella* shedding, as was calving in an individual area within a building.

Contaminated feedstuffs

Housed animals are generally more susceptible to infection from purchased feeds containing animal byproducts than are pastured animals, which are again more susceptible to animal-product-based fertilizers. Organic feedstuffs, including bonemeal, are being increasingly incriminated in the spread of salmonellosis and although the usual figure, for example in the UK, is 23% of consignments being infected, the figure may be as high as 70%. Most of the contamination of meat and bonemeal occurs after heat sterilization, especially if the material is left in digester tanks. Fishmeal is one of the most frequently and badly contaminated feedstuffs. For example, most of a recent increase in reported isolations of salmonellas in the USA was due to *S. agona* introduced in Peruvian fish meal. These feed meals need to be heated at 82°C (180°F) for an hour to be sterilized. The infection of these materials may derive from antemortem infections in the animals used to make the byproduct, but soiling of the material at the preparation plant or abattoir or during storage may also occur. Stored feed not of animal origin, especially grain, is also commonly contaminated by the droppings of rodents that infest it and this can lead to sharp outbreaks of salmonellosis due to *S. typhimurium*. Of special importance is colostrum stored without refrigeration. If the colostrum is contaminated initially, multiplication of salmonellas may occur and transmission of the infection is likely. Dried milk products appear to be relatively safe.

A case-control study of an outbreak of salmonellosis due to *Salmonella menhaden* in dairy herds was associated with one particular feed mill and feeding animal fat.

Some *Salmonella* serotypes such as *S. typhimurium* have been isolated from 2.8% of pig feed and feed ingredient samples and from 46% of farm feed samples tested. *S. choleraesuis* was not isolated from pig feed.

Introduction of the infection to a farm

Contaminated feedstuffs, carrier animals and infected clothing of visitors and casual workers are the most common methods of introducing infection. Less common methods include free-flying birds such as the herring gull, and nematode larvae that are already infected with the salmonellas. Salmonellas have been isolated from a wide variety of wild animals, which could act as reservoirs for infection of domestic animals under certain conditions.

Pathogen risk factors

Salmonellas are facultative intracellular organisms that survive in the phagolysosome of macrophages and can therefore evade the bactericidal effect of antibody. Compared to other organisms of the same family, salmonellas are relatively resistant to various environmental factors. They multiply at temperatures between 8° and 45°C, at water activities above 0.94, and in a pH range of 4–8. They are also able to multiply in an environment with a low level of or no oxygen. The bacterium is sensitive to heat and will not survive temperatures above 70°C. It is sensitive to pasteurization. Salmonellas have been shown to be resistant to drying, even for years, especially in dried feces, dust and other dry materials such as feeds and certain foods. Prolonged survival in water and soil has also been described. They are quite sensitive to beta- and gamma-irradiation. The O-antigen lipopolysaccharide of salmonellas is toxic and an important virulence factor, and immunity directed against the lipopolysaccharide is thought to be of major importance in the host defense against salmonellosis.

Fimbrial antigens of some *Salmonella* species have been described and characterized.[59] The fimbriae mediate a variety of virulence factors important for the maintenance and survival of the organisms in the host and environment, including initiation and stabilization of the organism to epithelial cells, colonization of the organism to receptor sites, maintenance of persistent infection in the host by mediating selective bacterial trapping by phagocytic cells, and evasion of the host's specific immunological defense mechanisms. The fimbriae are also useful in diagnostic tests.

Naturally occurring strains with varying virulence factors and antimicrobial susceptibility patterns can be identified in herds with endemic infection. Strains of *S. dublin* with distinct antimicrobial susceptibility patterns and/or plasmid profiles have been repeatedly isolated from calves in a calf-rearing facility over a period of years.[60] Some of the strains were isolated from numerous calves during outbreaks of clinical salmonellosis, while other strains were not.

The literature on the molecular basis of *Salmonella*-induced enteritis has been reviewed.[61] Most of the *Salmonella* virulence genes have been identified. The effector proteins of *S. typhimurium*, which act in concert to induce experimental diarrhea in calves, have been characterized.[62] There are several differences between *S. dublin* and *S. typhimurium* in the phenotypes, caused by inactivation of genes encoding effector proteins. The literature on the molecular methods for epidemiological investigations of *S. enterica* infections has been reviewed.[2]

Antimicrobial resistance of Salmonella

Strains of *Salmonella* spp. with resistance to antimicrobials are now widespread in both developed and developing countries.[63] Since 1990 there have been dramatic increases in the occurrence of multiply-resistant strains of *Salmonella* spp. in many developed countries. Of particular note has been the epidemic spread of *S. typhimurium* DT104, which now has a worldwide distribution. Antimicrobial resistance in zoonotically transmitted salmonellas is an undesirable but almost inevitable consequence of the use of antimicrobials in food animals. In general, such use is legitimate. Recommendations have been made that new antimicrobials with cross-resistance to those used in human medicine should not be used for prophylaxis in food animal production. For example, it is argued that the use of antimicrobials in food animals has been a major factor in the development of decreased susceptibility to antibiotics such as ciprofloxacin in zoonotically transmitted salmonellas.[63]

Antimicrobial resistance of salmonellas has been a major controversial concern in veterinary medicine and human public health.[64] Antimicrobials are used in food-producing animals for the treatment of infectious diseases and for growth-promoting effects. Their continued use

has long been incriminated as a major cause of selective pressure that leads to the appearance and persistence of resistant strains. The resistance is usually to multiple antimicrobials and its existence is considered as a potential risk factor. The significance of antimicrobial resistance is most obvious in its impact on the treatment of human infections. If the frequency of drug resistance increases, the choice of antimicrobials for the treatment of systemic salmonellosis in humans becomes more limited. There is also an association between drug-resistant salmonellas and the routine clinical use of antimicrobials for infections other than salmonellosis. Antimicrobial-resistant *Salmonella* infections can complicate antimicrobial therapy of other infections; prior antimicrobial therapy allows fewer numbers of antimicrobial-resistant salmonellas to cause symptomatic infections, and an increase in the proportion of salmonellas that are antimicrobial-resistant will increase the overall frequency of salmonellosis. *S. anatum* isolates from horses have developed multiple drug resistance; this is a public health concern because the serotype has been isolated from humans, and individuals who have contact with infected horses are at risk of becoming infected.

Infections in humans associated with antimicrobial-resistant salmonellas are increasing and have become a cause for public health concern.[14] Prospective studies in the USA claim to show that human infections with antimicrobial-resistant salmonellas are increasing, and that these resistant strains can be traced to foods of animal origin. There are wide variations from country to country in the percentage of *Salmonella* isolates that are antimicrobial-resistant. In general, antimicrobial resistance among salmonellas is much higher in the USA than in other countries. In the UK, over a period of about 20 years, little change has occurred in the antimicrobial resistance patterns of salmonellas isolated from animals. *S. dublin* remains predominantly sensitive to most antimicrobials. Most of the resistance in *S. typhimurium* is associated with phage type DT204C. Serotypes other than *S. dublin* and *S. typhimurium* show low levels of resistance to most antimicrobials, with the exception of sulfonamides and tetracyclines, to which resistance is increasing. The prevalence of antimicrobial resistance among salmonellas in New Zealand is low relative to many other countries.

The occurrence of the same clone of tetracycline- and streptomycin-resistant *S. typhimurium* in several dairy herds closely related geographically, and within a few months, suggests that spread of a single clone can occur quickly and may have been introduced into the herds by feed, wild animals, use of the same machinery, or a human vector.

Antimicrobial resistance in salmonellas in the UK has been monitored since 1970 using disk diffusion tests. A total of 76% of all *Salmonella* isolates are still sensitive to all 16 antimicrobials used for testing. Most antimicrobial resistance is encountered in bovine isolations of *S. typhimurium* phage type DT204C. This phage type, which was initially resistant to at least seven antimicrobials, has become more sensitive in recent years. Ninety-eight percent of *S. dublin* strains from cattle are still sensitive to all the antimicrobials used for testing. Treatment of calves with apramycin has selected for apramycin resistance in *E. coli* and *S. typhimurium* in the intestine, and plasmid transfer from the *E. coli* to *S. typhimurium* is suspected because the plasmids were similar.[25]

The incidence of antimicrobial resistance in strains of *Salmonella* isolated from Canadian agricultural products and imported fish has increased over specified study periods and emphasizes the need to reassess the benefits of subtherapeutically medicated feeds in current animal management practices.

Multi-drug-resistant *S. newport* has been spreading on an epidemic scale in both animals and humans throughout the USA.[14] In addition to the resistance to five drugs found in *S. typhimurium* DT104, *S. newport*, called Newport MDR-AmpC, is also resistant to amoxicillin–clavulinic acid, cephalothin, cefoxitin, and ceftiofur and exhibits decreased susceptibility to ceftriaxone. The emergence of Newport MDR-AmpC strains in humans has coincided with the emergence of Newport MDRAmpC infections in cattle.[65] In Massachusetts, the prevalence of the strain among *S. newport* isolates obtained from humans increased from 0% in 1998 to 53% in 2001. Case-control studies found an association with exposure to a dairy farm. Isolates from both humans and cattle had indistinguishable or closely related antibiograms and pulse-field gel electrophoresis patterns. The data document the widespread emergence of Newport MDR-AmpC strains in the USA and show that the fivefold increase, between 1998 and 2001, in the prevalence of *Salmonella* resistant to expanded-spectrum cephalosporins is primarily due to the emergence of that MDR-AmpC strain. The strain was isolated from humans, cattle, or ground beef in 27 states.

Molecular epidemiology of cephalosporin-resistant *S. newport* from animals in Pennsylvania, some from a single farm that experienced an outbreak of clinical salmonellosis in periparturient dairy cows, found integrons in about 38% of the isolates.[66] (Integrons are potentially independently mobile DNA elements that encode a recA-independent, site-specific integration system responsible for the acquisition of multiple small mobile elements called gene cassettes that, in turn, encode antibiotic resistance genes. Integrons have been shown to be integrated within the chromosome in *S. typhimurium* DT104 and have also been described on plasmid DNA in *S. enteritidis*.) There is also evidence that common plasmids have been transferred between animal-associated *Salmonella* and *E. coli* and identical *CMY-2* genes carried by similar plasmids have been identified in humans, suggesting that the *CMY-2* plasmid has undergone transfer between different bacterial species and may have been transmitted between food animals and humans.[67] The prevalence of *Salmonella* resistant to extended-spectrum cephalosporins from food-producing animals in Canada is very low.[68]

The antimicrobial susceptibilities of *Salmonella* strains isolated from humans, cattle, pigs, and chickens in the Netherlands from 1984–2001 have been monitored.[69] Resistance was most common in *S. typhimurium* and among the strains from humans, pigs, and chickens, the level of resistance to tetracycline, ampicillin, chloramphenicol, and trimethoprim–sulfamethoxazole increased over the 17 years. The increase could be attributed to the emergence of *S. typhimurium* DT104. Among the strains from cattle, resistance levels were high in the 1980s and then declined during the study period to the levels of the other species from 1996–2001. This indicates that the levels and patterns of resistance differ considerably among serovars isolated from one host species. A similar finding occurred in England and Wales from 1988–1999.[70]

Since their introduction into veterinary medicine in Europe in the late 1980s and early 1990s, the susceptibility of several bacterial species to fluoroquinolones has increasingly been reported to be decreasing and their resistance to quinolones has been reported to be increasing.[63] The incidence of quinolone resistance in strains of *Salmonella* isolated from poultry, cattle, and pigs in Germany between 1998 and 2001 has increased.[71]

In Canada, resistance to *S. typhimurium* isolated from animals, animal food products and the environment of animals to each of seven antibiotics – ampicillin, chloramphenicol, kanamycin, neomycin, streptomycin, sulfisoxazole, and tetracycline – increased persistently during each of the years 1994–97[72] but none of the isolates showed decreased sensitivity to ciprofloxacin.

Studies on one dairy calf farm rearing animals for dairy–beef production found that 70% of the fecal samples were positive for *Salmonella*, and also found high rates of resistance to several antibiotics commonly used for the treatment of calf diarrhea.[73]

The susceptibility patterns of *Salmonella* isolates from feedlot cattle across the USA have been examined. In general, with the exception of tetracycline and sulfamethoxazole, most isolates have been susceptible to all antimicrobials tested.[34] Also, resistance was not related to the use of antimicrobials in the rations being fed. The prevalence of *Salmonella* on beef animal hides and carcasses was 15.4% and 1.4%, respectively, and the percentage of isolates resistant to commonly used antimicrobials was low.[74,75]

The prevalence of *S. typhimurium* and *S. choleraesuis* isolates from pigs and humans that are fluoroquinolone-resistant and multi-drug-resistant has increased in Taiwan and the isolates have become widespread across the country.[76] The *S. choleraesuis* isolates from humans and pigs were closely related genotypically, suggesting the nationwide dissemination of the organism from pigs to humans.

During an 8-year period, 232 *Salmonella* strains from horses with salmonellosis in the Netherlands were studied.[77] *S. typhimurium* was the predominant serovar, accounting for 71%, followed by *S. enteritidis* at 8%. Resistance was common against tetracycline and ampicillin. *S. typhimurium* DT104 was most frequent and was more resistant to antimicrobials than other serovars, and had the pentadrug resistance pattern of ASSuT. The most common *S. typhimurium* phage type in horses corresponded with those found in humans, pigs, and cattle during the same period in the Netherlands.

Zoonotic implications

Salmonellosis, a common human intestinal disorder primarily associated with *Salmonella*-contaminated meats and poultry, is estimated to cost Americans about US$1 billion or more annually. The Centers for Disease Control report approximately 40 000 confirmed cases of salmonellosis annually.[1] A Canadian study estimated the total cost of salmonellosis in humans at US$100 million per year in Canada; this included hospital and medical costs, lost production, lost leisure, investigating costs and loss of life. Contaminated poultry is a common source of human infection.[78] The cumulative losses are due to medical costs, productivity losses and absenteeism, pain and suffering, lost leisure time, and chronic disease costs. The costs of food safety regulatory programs and costs to the food industry for product recalls and plant closures due to food-borne salmonellosis outbreaks, if included, would also increase the size of the estimates.

The disease has assumed increasing importance in recent years because of the much more frequent occurrence of human salmonellosis, with animal salmonellosis as the principal reservoir.[78] Although transmission to humans does occur via contaminated drinking water, raw milk, and meat, particularly sausage, the important pathway today has become that through pigs and poultry. In Denmark, this was an important source of human salmonellosis until control measures were instituted. In most instances the increase in human infections is with 'exotic' serotypes other than *S. typhimurium* that come by animal feedstuffs to pigs and chicken, and then to humans through pork and chicken products. The most serious risk is that the transmitted bacteria will have acquired resistance to specific antibiotics because the animals from which they originate have been treated with the particular antibiotics repeatedly or over a long period.

An epidemic of salmonellosis associated with *S. typhimurium* DT 160 in wild birds and humans in New Zealand has been described.[79] Sparrows and other birds usually die of an acute septicemia and the organism is considered to be a serious zoonotic risk.

The USDA-FSIS issued the Pathogen Reduction: Hazard Analysis and Critical Control Points Systems regulation to encourage effective pathogen reduction systems in meat and poultry processing facilities. This has been successful and is being followed by measures to reduce the numbers of *Salmonella* entering processing plants through live animals.[1]

Salmonella serovar *typhimurium* DT104

The increasingly common isolation of *S. typhimurium* DT104 (definitive phage type) is of major concern for public health officials.[4] *S. typhimurium* DT104 was first reported in the UK in 1984 and emerged in the 1990s as an increasing cause of *Salmonella* infections in humans and animals in England, Wales, Scotland, other European countries such as Germany, France, Austria, and Denmark, and Canada.[80] A wide range of potential reservoirs is associated with this infectious strain, from humans to the traditional food animals such as poultry, cattle, sheep,[81] and pigs. Over a 1-year period in Scotland it was the predominant *Salmonella* isolated from nine species of animal (cattle, pigs, sheep, chickens, pigeons, horses, cats, dogs, and rabbits). All isolates were resistant to at least one antimicrobial and 98% were resistant to multiple antimicrobials, with R-type ACTSp being the predominant resistance pattern. In the UK, a clonal strain of multiply resistant (mr)DT104 that is resistant to at least five antimicrobials (ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline) (R-type ACSSu T) was detected in humans in 1984 and cattle in 1988.[4]

The organism has emerged as an important cause of diarrhea in horses in Ontario[82] and is a public health concern because of its multiple drug resistance and the close relationship of the horse with humans.

The organism has been found in a variety of human foods, including salami, sausages, chicken, burgers, oysters, and vegetables. Human infections may result from contact with farm animals (cattle and sheep transmit infections to humans) and from consumption of contaminated foods such as chicken, pork, sausages, meat pastes, and beef. The organism is widespread in the USA. It has been isolated from elementary school children in a Nebraska farming community after they experienced an episode of diarrhea. Farm families are particularly at risk of acquiring infection by contact with infected animals or drinking unpasteurized milk.[80] The organism's ecology, its precise reservoirs, and its distribution in the human food chain are unclear. Clinical signs in humans infected with DT104 include diarrhea, fever, headache, nausea, and vomiting. Septicemia may develop in a small percentage of cases with potential complications of meningitis and foci of infection in bones and joints.

The antimicrobial resistance factor of DT104 is a major concern. Resistance to ampicillin, chloramphenicol, streptomycin, tetracyclines, and sulfisoxazole is characteristic of the organism. There is now evidence that DT104 is developing resistance to trimethoprim and fluoroquinolones such as ciprofloxacin, the drug of choice for treating human adult *Salmonella* infections. A large outbreak of salmonellosis due to mrDT104 occurred in people in England who had consumed milk from a dairy that received raw milk supplied by two farms. DT104 was isolated from the milk filter and failure of on-farm pasteurization was thought to be the cause. Strains of the organism from humans, the dairy cattle, and the milk filter showed decreased susceptibility to ciprofloxacin.[83]

Control and prevention of infection with DT104 will depend on increasing surveillance activities, investigating outbreaks, and identifying vehicles and risks of infections.

Contamination of milk usually occurs after the milk leaves the cow, even though the organism can be excreted into the milk

during the acute phase of the disease, and occasionally by carrier animals. In a Canadian study of families from dairy farms with and without *Salmonella*-positive bulk tank filters, 41 of 43 of participating families regularly consumed nonpasteurized milk. Of 22 farms with *Salmonella*-positive milk filters, five had at least one farm family member shedding *Salmonella* sp. In all cases, the organism shed was of the same serotype, biotype, antimicrobial susceptibility pattern, and plasmid profile as the organism isolated from the filters. Of the individuals in these five families, 63% were shedding *Salmonella* sp. There is also the chance that contact between animals and humans in agriculture, and in a companion animal relationship, especially with horses, can cause interspecies spread. An unusual but predictable transmission from lambs to humans occurs when sick lambs are foster-fed, especially by children.

Various clinical forms of salmonellosis can occur in veterinarians working with *Salmonella*-infected animals. Gastroenteritis, bacteremia and other systemic abnormalities can occur. Cutaneous salmonellosis has been reported in veterinarians attending to infected cattle at the time of parturition. The disease was characterized by pustular dermatitis from which *Salmonella virchow* and *S. dublin* were isolated. Veterinarians may develop skin lesions after obstetric deliveries, even after hygienic precautions and the use of abundant amounts of disinfectant creams and careful washing of the arms and hands.

Economic importance

Salmonellosis is a significant cause of economic loss in farm animals because of the costs of clinical disease, which include deaths, diagnosis and treatment of clinical cases, diagnostic laboratory costs, the costs of cleaning and disinfection, and the costs of control and prevention. In addition, when the disease is diagnosed in a herd it can create considerable apprehension in the producer because of the difficulty in identifying infected animals. The veterinarian is also often in a difficult position because the diagnosis, treatment, and control of the disease are less than reliable and it is difficult to provide advice with confidence. An estimation of the economic impact of an outbreak of *S. dublin* infection in a calf-rearing unit indicated that the cost of disease represented a substantial proportion of the gross margin of rearing calves. The losses incurred by livestock producers include reduced feed efficiency, and reduced weight gains or deaths because of salmonellosis.

PATHOGENESIS

The pathogenesis of salmonellosis is a complex and multifactorial phenomenon. The nature of the disease that occurs following infection is dependent on the specific combination of serovar and host known as serovar–host specificity. A range of infections is included in the term 'salmonellosis'. The most common type of infection is known as 'the carrier state', in which carriage of the organism is not accompanied by clinical abnormalities or clinical disease. In production animals, these carriers are of importance because they may serve as reservoirs for further spread of infection through shedding and may be present as contaminated food products.

The evolution of host-specific *Salmonella* serovars is considered to be associated with an increase in pathogenicity for the specific host.[84] The hypothesis is based on the fact that broad-range serovars (*typhimurium* and *enteritidis*) are generally associated with severe disease only in young animals, whereas host-restricted serovars cause high mortality in both young and adult hosts.

The pathogenesis of different *Salmonella* serovars possessing different degrees of host restriction have been studied in young lambs to evaluate the basis of the serovar–host specificity in sheep.[39] Infection with *S. abortusovis* resulted in clinical signs of salmonellosis, including a fever and bacterial dissemination to systemic tissues. This confirms the virulence of the strain with sheep. *Salmonella gallinarum* caused relatively mild disease but is virulent in chickens. *S. dublin* was virulent in sheep, confirming its association with ovine salmonellosis. The apparent specificity of a serovar for a particular host or range of hosts as defined by epidemiological data is influenced not only by bacterial virulence but also by the ability of the serovar to circulate within the population of the host.

Infection

Salmonella infects animals and humans by the oral route. Following ingestion, a proportion of the organisms resist the low pH of the stomach, reach the distal ileum and the cecum, invade the mucosa, and replicate in the submucosa and Peyer's patches.

In young animals, and in adults whose resistance has been lowered, spread beyond the mesenteric lymph nodes occurs and the infection is established in the reticuloendothelial cells of the liver; from there it invades the bloodstream. These steps in the infection process can occur very rapidly. For example, in newborn calves, *S. dublin* when taken by mouth can be found in the bloodstream 15 minutes later. In older calves bacteria can be isolated from the intestinal lymph nodes 18 hours after their oral administration. Provided a sufficient number of a sufficiently pathogenic serotype is used, the disease is reproducible with pure cultures, for example of *S. typhimurium* in lambs, *S. choleraesuis* in pigs, *S. dublin*, *S. typhimurium*, and *S. enteritidis* in calves, and *S. typhimurium* in horses. Once systemic infection has been established, salmonellosis as a disease can develop. Its principal manifestations are as septicemia, enteritis, abortion, and a group of localizations in various tissues as a result of bacteremia.

Septicemia, bacteremia and the carrier state

After invasion of the bloodstream occurs a febrile reaction follows in 24–48 hours, and the acute phase of the disease, similar to that seen in natural cases, is present 3–9 days later. The early septicemia may be rapidly fatal. If the systemic invasion is sufficient to cause only a bacteremia, acute enteritis may develop, and abortion is a common final sequel in sheep and cattle. Many animals survive this stage of the disease but localization of the salmonellas occurs in mesenteric lymph nodes, liver, spleen, and particularly the gallbladder. In experimental *S. typhimurium* infection in pigs, the organism can persist from 6–8 weeks of age until market age with long-term persistence in the palatine tonsils, gastrointestinal tract, and adjacent lymph nodes. In healthy adults there may be no clinical illness when infection first occurs but there may be localization in abdominal viscera. In either instance the animals become chronic carriers and discharge salmonellas intermittently from the gallbladder and foci of infection in the intestinal wall into the feces and occasionally into the milk. For this reason they are important sources of infection for other animals and for humans. Carrier animals may also develop an acute septicemia or enteritis if their resistance is lowered by environmental stresses or intercurrent infection. Salmonellas can reside intracellularly where they are able to escape antibody-mediated killing, and the numbers of organisms are controlled by cellular defense mechanisms involving the macrophages in which they reside.

Septicemia in pigs associated with *S. choleraesuis* can cause pneumonia in pigs similar to the pneumonia in pasteurellosis and infection with *Actinobacillus pleuropneumoniae*, hepatitis, enterocolitis, and encephalitis.

S. arizonae may colonize the upper respiratory tract of sheep and induce a mild proliferative response in lambs.

Enteritis

Enteritis may develop at the time of first infection or at some other time in carrier animals. The best information available

on the pathogenesis of enteritis is derived from the experimentally produced disease. In most instances the disease is produced by the administration of massive doses of bacteria, and this may result in the production of a different syndrome from that which occurs naturally. The pathogenesis of enteric salmonellosis is much more complex than cholera, involving an increase in mucosal cell cyclic AMP content and prostaglandin concentration, as well as an inflammatory response to the invading bacteria. Intestinal invasion is a characteristic feature of *Salmonella* pathogenesis. Within minutes of injecting ileal loops in calves, *Salmonella* can be seen to invade both M cells and enterocytes that overlie domed villi associated with lymphoid follicles and absorptive villi.[61] The organism must invade the intestinal mucosal epithelium to cause disease.

S. typhimurium requires a functional type III secretion system encoded by *Salmonella* pathogenicity island I (SPII) to cause diarrhea.[61,62] The SP II secretion system mediates the translocation of secreted effector proteins into target epithelial cells. These effector proteins are key virulence factors required for *Salmonella* intestinal invasion and the induction of fluid secretion and inflammatory responses.

After oral infection with *S. dublin*, invasion occurs through the intestinal wall in the terminal ileum and cecum and progresses as far only as the mesenteric lymph nodes. Progress beyond this point, and the development of the disease, salmonellosis, is determined by factors such as immune status and age of the animal, whether or not it is exposed to stress, and the virulence of the strains. A number of characteristics of the bacteria influence their virulence, including the presence of adhesin-pili and flagellae, cytotoxin, enterotoxin, lipopolysaccharide and the inflammatory response that they initiate in the intestinal wall. The effects of some of these factors are not limited to the intestinal tract and also contribute to the systemic complications of salmonellosis. The *S. dublin* virulence plasmid mediates systemic infection in cattle by causing macrophage dysfunction.

S. dublin infections in calves have been used to create the disease experimentally. In calves 6–7 weeks of age, an oral dose of the organisms is fatal within 24 hours, with the animals dying of septicemia and an acute necrotizing panenteritis. Calves 12–14 weeks of age developed a progressive fatal diarrhea within 1 week following infection. Experimental infection of ligated ileal loops from calves with *S. typhimurium* results in an acute neutrophilic inflammatory response associated with invasion of Peyer's patches.[85]

In calves, infection is initiated by bacterial invasion of the mucosal epithelium of the distal ileum or proximal colon causing extensive local tissue damage that leads to shortening of the villi and degeneration of the enterocyte layer. *Salmonella* invasion induces potent inflammatory response characterized by a massive infiltrate of polymorphonuclear cells into the lamina propria and submucosa, and secretion of fluid into the intestinal lumen.[86] Damage to the enterocyte layer and the secretion of fluid into the intestinal lumen results in diarrhea, and the fever is due to circulating inflammatory cytokines. The molecular basis of *Salmonella*-induced enteritis has been described.[61]

Experimentally induced *Salmonella* infection in calves results in an increase in serum haptoglobin levels within 3 days of challenge.[87] By day 3 after experimental infection the serum haptoglobin levels increased to a median level of 212 μg/mL while placebo controls had median levels of 0 μg/mL. The increased levels closely reflected the clinical findings of infection and are considered useful markers of infection severity in salmonellosis in calves.

In **sheep**, the experimental disease produced by oral dosing with *S. typhimurium* includes an early acute enteritis of the small intestine at 24 hours. At 5–8 days there is hemorrhagic and necrotic typhlitis and the infection is established in mesenteric lymph nodes and the liver. Experimental *S. dublin* infection of the mammary gland of dairy cattle results in a persistent infection associated with a chronic active mastitis similar to carriers with naturally acquired *S. dublin* infection.

In ponies with experimental infection with *S. typhimurium* orally, there is much variation in the time after infection that the various signs appear. Pyrexia, neutropenia, and high fecal *Salmonella* counts coincided on the second and fourth days, but diarrhea occurred in only some ponies and then on the third to 11th days after inoculation. Positive agglutination tests were recorded from day 1 but were mostly during the period 6–12 days post-inoculation. The neutropenia of the early stages of the disease is transient, and neutrophilia occurs when diarrhea commences.

The characteristic **fever** and **leukopenia** of **equine salmonellosis** have been attributed to the release of endotoxin from the bacteria during invasion of, and replication within, the intestinal epithelium. The equine colonic mucosa can respond to cholera toxin, which causes an increased secretion of chloride, sodium, and water into the intestinal lumen. The enterotoxin activity of *S. typhimurium* of equine origin has been compared to cholera enterotoxin.

Although there is sufficient obvious enteritis to account for the diarrhea that characterizes the disease, there appear to be other factors involved. For example, it has been shown experimentally that in *Salmonella* enteritis there is stimulation of active chloride secretion combined with inhibition of sodium absorption, but invasion of the mucosa is not essential for these changes to occur. These observations are of interest in the light of the known hyponatremia that characterizes the disease. Studies of calves with salmonellosis have shown that the fluid loss associated with the diarrhea of this disease is much greater than in other calf diarrheas. This, together with a large solid matter output, contributes to the significant weight loss occurring in salmonellosis. In pigs and to a lesser extent in cattle, ulcerative lesions may develop in the intestinal mucosa and may be of sufficient size to cause chronic intermittent diarrhea. In pigs it has also been observed that villous atrophy is a sequel to infection with *S. choleraesuis*.

In pigs, most clinical cases of salmonellosis are associated with *S. choleraesuis* or *typhimurium*. *S. choleraesuis* is host-adapted to pigs, causing a systemic, typhoid-like disease. *S. typhimurium* is not host-adapted to pigs, and infection results in a localized enterocolitis.

In the **pig** the development of enteritis associated with *S. choleraesuis* begins 36 hours after infection with the appearance of erosions and edema of the cecal mucosa. At 64 hours the wall is thickened and there is diffuse caseation overlying the erosions. The necrotic membrane sloughs at 96 hours and at 128 hours all function is lost and the entire intestinal wall is involved in the inflammatory process, the muscular coat being obliterated by 176 hours. The colon is usually the major organ affected in *S. typhimurium* infections in pigs, causing either focal or diffuse necrotizing colitis. The organisms proliferate in the intestine, invade the intestinal epithelium, stimulate fluid secretion and disseminate from the intestine to mesenteric lymph nodes and other organs. *S. choleraesuis* invades enterocytes by penetration of the brush border, resulting in focal loss of microvilli, and the bacteria are endocytosed into membrane-bound vacuoles. Experimental infection of ileal–gut loops of pigs with *S. enterica* results in preferential bacterial adherence to microfold cells (M cells) within 5 minutes, and by 10 minutes bacterial invasion of the apical membrane occurs in M cells, goblet cells, and enterocytes.[88] Experimental perfusion of porcine livers with polysaccharide or live

S. choleraesuis results in the release of mediators that mediate biological activities that have an important role in reducing the severity of bacterial infections. The comparison between early invasion of ileal loops by *S. enterica* and *S. choleraesuis* in the pig has been described.[89]

Abomasitis

S. typhimurium DT104 has been associated with some independent outbreaks of abomasitis in veal calves.[90] Abomasitis was reproduced experimentally by oral infection of calves.

Abortion

Abortion is a common manifestation of salmonellosis in cattle between days 124 and 270 of gestation. When infection is associated with *S. dublin*, the organism multiplies in the placenta, having been seeded there from a primary lesion in other maternal tissues. Fetal death has already occurred in many cases, because of its invasion by bacteria, but live calves also occur, suggesting that the placental lesion is the critical one. *S. montevideo* has been associated with a significant number of outbreaks of abortion in ewes.

Terminal dry gangrene, osteitis, and polyarthritis

Terminal dry gangrene due to endarteritis of the extremities of the limbs, ears, and tail may occur in calves with *S. dublin* infection. Epiphyseal osteomyelitis affecting the metaphyses, and polysynovitis and arthritis are also possible sequelae.

CLINICAL FINDINGS

The disease is most satisfactorily described as three syndromes, classified arbitrarily according to severity as **septicemia, acute enteritis, and chronic enteritis.** These are described first but the differences between the animal species are sufficiently significant to justify describing the disease separately in each of them. There are no significant differences between infections associated with the different *Salmonella* species.

Septicemia

This is the characteristic form of the disease in newborn foals and calves, and in young pigs up to 4 months old. Commonly, there is profound depression, dullness, prostration, high fever (40.5–42°C, 105–107°F) and death within 24–48 hours.

Acute enteritis

This is the common form in adult animals of all species. There is a high fever (40–41°C, 104–106°F) with severe, fluid diarrhea, sometimes dysentery, and occasionally tenesmus. The fever often subsides precipitously with the onset of diarrhea. The feces have a putrid smell and contain mucus, sometimes blood, fibrinous casts, which may appear as complete tubular casts of intestine, and intestinal mucosa in sheets or casts. There is complete anorexia but in some cases increased thirst. The heart rate is rapid, the respirations are rapid and shallow and the mucosae are congested. Pregnant animals commonly abort. The case fatality rate without early treatment may reach 75%. In all species, severe dehydration and toxemia occur and the animal loses weight, becomes weak and recumbent, and dies in 2–5 days. Newborn animals that survive the septicemic state usually develop severe enteritis, with diarrhea becoming evident at 12–24 hours after the illness commences. If they survive this stage of the illness, residual polyarthritis or pneumonia may complicate the recovery phase.

Chronic enteritis

This is a common form in pigs following a severe outbreak, and occurs occasionally in cattle and adult horses. In calves there is intermittent or persistent diarrhea, with the occasional passage of spots of blood, mucus and firm fibrinous casts, intermittent moderate fever (39°C, 102°F), and loss of weight leading to emaciation. Although chronic enteritis may occur initially it usually succeeds an acute episode.

Bovine salmonellosis

The disease associated with *S. dublin* is usually endemic on a particular farm, with sporadic cases occurring when individual animals are exposed to stress. Severe outbreaks are rare but do occur when there is severe stress, usually acute nutritional deprivation, applied to the entire herd.

When *S. typhimurium* is the cause, it is usual to have a single animal or a small number of animals affected at one time. When the disease is in the calf population it is usual for it to be much more severe, with many affected, either as a point outbreak or, when there is a succession of calves, a continuing occurrence of the disease. The emphasis, therefore, is generally on the occurrence of individual, sporadic cases in newborn calves and recently calved cows. *S. muenster* in a dairy herd has been associated with abortions, diarrhea in adults and calves, and shedding of the organism in the milk of about 8% of the cows.[18]

Septicemia is the common form of the disease in newborn calves under a few weeks of age. There is depression, toxemia, fever, dyspnea, and weakness; nervous signs, including incoordination and nystagmus, may occur. Diarrhea and dysentery may occur but are not common.

Calves older than a week, and adults, are usually affected by **acute enteritis**, followed in survivors by abortion in pregnant cows and polyarthritis in calves. In severe cases of enteritis, there is often dysentery, with whole blood passed in large clots, and complete agalactia in lactating cows. Abdominal pain, with kicking at the abdomen, rolling, crouching, groaning, and looking at the flanks, may occur in adult cattle. Rectal examination at this stage usually causes severe distress.

Chronic enteritis with inappetence, reduced weight gain, and unthriftiness may follow an attack of acute enteritis or be the only manifestation of the disease. Abortion is a common sequel in pregnant cows that survive an attack of acute enteritis. However, infection with *S. dublin* is also a significant cause of abortion in cattle without there having been any clinical signs other than retained placenta. A sequel to some cases of apparent enteric salmonellosis is the development of terminal dry gangrene due to endarteritis of the extremities, including eartips, tailtip, and the limbs from the fetlock down.

Terminal dry gangrene of the extremities of calves is characterized by lameness, swelling of the hindlimbs below the fetlocks, and separation of the skin above the fetlock. The distal portion of the limb is cool, not painful, and the skin is dry or moist. There is a clear line of demarcation of the skin at the level of the fetlock joints between the normal proximal skin and the distal necrotic tissue. The phalanges may be separated from the metatarsus. The tips of the ears may be indurated and deviated medially and the distal aspect of the tail may be dry and shriveled.

Abortion due to *S. dublin* may occur spontaneously without any previous clinical evidence of salmonellosis in the herd. Abortion has occurred from days 124 to 270 of gestation. Cows that abort may be ill with a fever, anorexia and hypogalactia and some will retain fetal membranes. In some cases, calves may be born shortly before term and die in the perinatal period. *S. muenster* has also been implicated in abortions in a dairy herd.[18]

The experimental disease produced by infecting adult cattle with *S. dublin* by mouth varies from no clinical illness to fatal dysentery. Abortion occurs in some pregnant females. Many suffer pyrexia, anorexia, and mild diarrhea. Experimental infection of calves with *S. typhimurium* has the same general effect, with more severe syndromes occurring in younger calves. Chronic cases may develop bone lesions, including osteoperiostitis and osteomyelitis, sometimes with epiphyseal separation. Experimental infection with *S. enteritidis* causes profuse yellow diarrhea, fever, dehydration, frequent cough, and a mucopurulent nasal discharge.

Ovine and caprine salmonellosis

The only recognized form of the disease in sheep is acute enteritis on a flock scale. However, in the early stages of the outbreak there may be some cases of the septicemic form. After experimental infection of sheep with *S. dublin*, fever and diarrhea are followed in pregnant ewes by abortion. Abortion is also common in the naturally occurring disease and has come to exceed *S. abortusovis* as a cause of abortion in sheep in the UK. Some ewes die after abortion and many of the lambs born alive die subsequently. Fever and diarrhea, followed by abortion, have also been produced experimentally in sheep by the administration of *S. dublin*.

In goats, naturally occurring cases are not often reported. *S. dublin* is the usual pathogen in those countries where it is a resident, but *S. typhimurium* is also recorded as a cause. Peracute septicemia, in newborn animals, and acute enteritis occur with signs and lesions similar to those in cattle.

Porcine salmonellosis

In pigs, the disease varies widely and, although all forms occur in this species, there is often a tendency for one form to be more common in any particular outbreak. In the septicemic form in pigs affected by *S. choleraesuis* a dark red to purple discoloration of the skin is evident, especially on the abdomen and ears, and subcutaneous petechial hemorrhages may also be visible. Nervous signs, including tremor, weakness, paralysis, and convulsions, may be prominent and occur in a large proportion of affected pigs. The case-fatality rate in this form is usually 100%.

A semispecific entity occurring in pigs up to 4 weeks old is manifested by meningitis and clinical signs of prostration and clonic convulsions.

In the acute form there is also a tendency for pulmonary involvement to occur, but the main feature of the disease is enteritis, with pneumonia and occasionally encephalitis present as only secondary signs. In some situations pigs dying of septicemia more commonly yield *S. choleraesuis*, while those with acute enteritis are usually infected with *S. typhimurium*. Acute pneumonia is a common accompaniment of this form of the disease in pigs, and nervous signs and cutaneous discoloration as described in the septicemic form may also be present. Meningitis due to *S. typhimurium* DT104 in 1-week-old piglets has been reported.[91] Incoordination, paralysis, opisthotonos, paddling, and polyarthritis resulting in runts and deaths were common. Bronchopneumonia resembling pasteurellosis, and pleuropneumonia resembling *A. pleuropneumoniae* infection can be associated with *S. choleraesuis* in pigs.

A syndrome of rectal stricture occurs in feeder pigs as a sequel to enteric salmonellosis associated with *S. typhimurium* and is described under that heading.

Equine salmonellosis

The disease in horses usually occurs in a single animal and sporadically. However, outbreaks do occur in newborn foals, in groups of horses recently transported, and in horses hospitalized in veterinary clinics. Analysis of spatial and temporal clustering of horses with salmonellosis in an intensive care unit of a veterinary teaching hospital suggested that affected horses were grouped in time. Experimental infection of horses by oral administration of *S. typhimurium* produces a disease similar to the natural disease. The incubation period may be as short as 24 hours. Four syndromes occur:

- **Asymptomatic shedding** of *S. typhimurium* in feces intermittently or continuously for short periods of 4–6 days
- A **subacute enteric form in adult horses** on farms where the disease is endemic, with fever, depression, anorexia but without severe diarrhea, although the feces may have the consistency of soft bovine feces. There is no other obvious intestinal abnormality. There may be a neutropenia with a left shift
- Severe, acute fulminating enteritis with diarrhea, fever, dehydration, and neutropenia. There is abdominal pain, which may be sufficiently severe to stimulate violent actions. This is the common form of the disease, occurring commonly in adults that are exposed to stress in one form or another. Newborn and young foals up to 8 days of age also often have this form of the disease,[36] characterized by depression, anorexia, and diarrhea
- **In foals up to about 2 days of age there is a highly fatal septicemia.** Localization in survivors includes lesions in the brain, causing meningoencephalitis, polyarthritis, and many other sites. Fatal meningoencephalomyelitis due to *S. agona* has been described in a 7-day-old foal.[92] Clinical findings included head tilt, seizures, and diarrhea.

CLINICAL PATHOLOGY

A definitive etiological diagnosis of salmonellosis depends on culture of the organism from feces, blood, milk, and other body fluids or tissues. Feed and water samples may also be cultured to determine the source of the organism. Numerous serological tests are available but lack sensitivity and specificity.

The three aspects of cases of salmonellosis that profit by clinicopathological support are:

- Diagnosis in the individual animal, when its treatment and prognosis depend on a definitive diagnosis
- Diagnosis of a herd problem to insure that expensive herd-wide control measures are not implemented unnecessarily
- Monitoring the biochemical status of a sick animal in order to determine most accurately its requirements for supportive therapy, especially fluid and electrolytes.

The diagnostic techniques available are as follows.

Bacterial culture and detection

This is the only way of making a definitive etiological diagnosis of salmonellosis and of exactly determining the serotype. However, culturing the organism is unreliable for various factors including the method used to collect samples, the amount of sample submitted, variation in the shedding of the organism, and the bacteriological method used. A major complicating factor is the occurrence of apparently healthy carriers, which shed the organism intermittently in the feces, and silent carriers, which do not shed but harbor the organism in mesenteric lymph nodes or in the mucosa of the cecum and colon. The difficulty varies according to genotype. In cattle with *S. dublin* infections, the bacteria are present in the blood and milk for a very brief period during the bacteremic phase and before diarrhea commences.

The organism can be cultured from fecal samples, bulk tank milk, milk filters, water and feed sources, and environmental sites.[93] When sampling dairy farms weekly for 7–8 weeks, the prevalence of fecal shedding from different groups of cattle may vary widely among herds, indicating that herds with infected cattle may be classified incorrectly if only one group is tested. Cows near calving are most likely to be shedding *Salmonella* in the feces. Testing environmental sample sources is more efficient for identifying infected premises than using individual cattle fecal samples.

Fecal culture

The culturing of salmonellas from feces is done commonly but can be unreliable. This difficulty is noticeable with *S. dublin* infection in cattle, *S. choleraesuis* infections in pigs and *S. typhimurium* infection in horses. The discrepancy in *S. dublin* infections in calves may be as great as 55% accuracy only and in horses only 50%. The difficulties relate to dilution by

diarrhea and the heavily contaminated nature of the sample; a sample of fluid feces collected in a container is superior to a fecal swab. Clinical laboratories generally require at least 48 hours for presumptive diagnosis of *Salmonella* spp. in feces. Biochemical and serological confirmation of the genotype and the antibiogram may require an additional 24–48 hours. The use of extended enrichment of fecal samples with tetrathionate broth is superior to primary enrichment for detection of salmonellas from cattle.

A special feature of *S. dublin* is the tendency to produce persistent infections without clinical manifestations in some infected cattle – also called carriers. The organism is harbored in lymph nodes and other internal organs, and is only periodically shed in milk and/or feces. The rate of fecal culture of *S. dublin* from known carrier cows and calves is low even when sampled over a period of 12 months – 3.35–17.26%.[94] Carriers frequently have continuously high immunoglobulin levels in serum and milk and ELISAs are used as an alternative.[94]

Because culture of a large number of individual fecal samples is expensive and time-consuming, pooled fecal samples from individual animals provides excellent agreement for detection of *S. infantis* when the number of samples per pool is 20 or less.[95] With the kappa test, the agreement ranged in two groups of pooled fecal samples from 0.81–0.98.

Multiple fecal cultures

Multiple cultures at 24-hour intervals are superior to single fecal cultures for the diagnosis of clinical salmonellosis in horses.[40] Fecal samples should be cultured directly on Brilliant Green Agar and an additional sample inoculated in Selenite broth and incubated for 24–48 hours followed by culture on Brilliant Green Agar.[54] Simultaneous culture of a pinch biopsy of rectal mucosa may increase the number of isolations of salmonellas in cattle and horses.

Antigen-capture enzyme-linked immunosorbent assay

An antigen-capture ELISA with enrichment culture for detection of salmonellas from fecal samples is more rapid than routine culture techniques, with a test sensitivity of 69% and specificity of 97%.

Polymerase chain reaction

A PCR assay is a highly specific and sensitive test for the detection of salmonellas in fecal samples from horses.[96] The test is genotype specific, is much more sensitive than microbiological culture for detecting the organism from fecal swab specimens, requires fewer samples, and can provide results 24 hours after receipt of fecal samples. Direct detection is done by amplification of part of omp C after extraction of DNA from feces.[96] *Salmonella* DNA was detected in 40% of fecal samples, while *Salmonella* was cultured from only 2% of the samples. The PCR assay has been used to detect *Salmonella* DNA persisting in the environment of a veterinary teaching hospital.[54] Pulse-field gel electrophoresis can be used to characterize the types of *S. enterica* isolate.[54]

A real-time PCR assay uses enrichment of fecal specimens, followed by genomic DNA extraction to detect *Salmonella* ssp.-specific DNA segment.[97] Relative sensitivity was 100% and specificity 98.2% compared with bacterial culture.

Bulk tank milk filters

The bulk tank milk filter is collected immediately after milking and submitted for culture. Samples of bulk tank milk are also submitted.

DNA probes

The use of the DNA probe encoding a well-conserved virulence gene of the *Salmonella* virulence plasmid is a sensitive method for screening large numbers of samples to detect potentially virulent *Salmonella* spp.

Serial blood culture

In the early stages of the disease when the animal is likely to be bacteremic this is not a practicable technique because of the need to collect serial samples and the cost of blood cultures.

Serology

Serum enzyme-linked immunosorbent assay

Serological testing using ELISA tests on serum or milk can be used in herds to identify *S. dublin* carriers, which can then be culled.[94] The test is based on immunoglobulins to the O antigens of the lipopolysaccharide of the organism. The superior sensitivity and negative predictive value of the serum ELISA is preferable to fecal culture as an initial screening test and for herds not infected with *S. dublin*.[94] It may be able to differentiate between uninfected, recently infected recovered, and milk-shedding (mammary-gland-infected) carrier cows; it can also be used for assessing infection rates and vaccine responses. ELISA testing of individual milk samples can be used for surveillance of herds infected with *S. typhimurium* or *S. dublin*.

An ELISA test using lipopolysaccharide antigen is highly O-antigen-specific and predictable. A serum with a positive result on the screening antigen can then be tested on the other antigens to determine the specific serotype that has infected the animal. The ELISA is suitable for screening for the presence of infection with *S. typhimurium* or *S. infantis* on a herd basis.

Using a variety of ELISA tests, muscle fluid samples from cattle taken at slaughter can be used as an alternative to serum to detect antibodies to *Salmonella* polysaccharide. Bulk tank milk can be tested for antibodies to *S. dublin* and used as a national screening diagnostic aid.[98] The *S. dublin* ELISA had a high sensitivity (97%) and specificity (97%) for muscle fluid samples, compared with serum samples; the relationship for *S. typhimurium* was also good.

Meat juice enzyme-linked immunosorbent assay: Danish mix-ELISA

The Danish mix-ELISA (DME) is a combination of lipopolysaccharide extractions of *S. choleraesuis* (O antigens 6 and 7) and *typhimurium* (O antigens 1, 4, 5, and 12), used to assay serum samples collected from live animals on the farm or from meat juice (collected when a meat sample from the carcass is frozen and thawed).[12] The DME was designed for surveillance and is recommended for monitoring herds and detecting high levels of *Salmonella* infection.[99] The test has been the basis for national *Salmonella* control programs in Denmark (SALINPORK), Germany, and the UK and is being considered in the Netherlands and Belgium. In a series of studies using pigs experimentally infected with either *S. typhimurium* or *S. infantis*, the sensitivity of the DME was more than 95% and the specificity 100% when compared to culture used to determine the positive or negative status of the pigs.[12] There is a strong association between herd serology and the prevalence of *Salmonella* measured at three sampling sites: cecal content, pharynx, and carcass surface.[100]

Indirect tests

These include a total and differential white cell count. A leukopenia, neutropenia and severe degenerative left shift are highly suggestive. There is also a marked hyponatremia and a mild hypokalemia. These tests are well established in horses, and the leukopenia has been observed in acute salmonellosis in cattle. The fecal leukocyte count is also a worthwhile supportive test in the search for salmonellosis. A high count is strongly suggestive, but many horses with acute or severe diarrhea have high fecal leukocyte counts in the absence of salmonellas in the feces.

Laboratory diagnosis in a suspected sick animal

A positive diagnosis depends on culture of the organism, usually from feces but possibly from blood in the septicemic stage. If serological diagnosis is available a serum sample should also be submitted.

Indirect tests are very valuable and, if laboratory availability is good, a total white cell count and estimation of serum sodium levels should be undertaken urgently. A presumptive diagnosis is often all that can be stated, and this may be supported by a herd diagnosis – a diagnosis that the disease or infection is present in the herd and that it is presumed that the subject case is one of the group.

Herd diagnosis

A serological examination of a sample of animals is a first step. A completely negative serological test would indicate that the infection is not present. Positive results indicate a need for further examination, and periodic fecal cultures at 15-day intervals using enriching media should be undertaken. When *S. typhimurium* is the causative bacteria, the feces of other species of animals on the farm should be examined, because ducks, dogs, horses, pigs, sheep, and cattle may be sources of infection for each other. It is always advisable to examine the drinking water and feed for evidence of infection.

Detection of clinically normal carrier animals

The most difficult diagnostic problem in salmonellosis is the detection of the clinically normal carrier animal. The recommended procedure is to do fecal cultures on all cows at 14-day intervals for 3 examinations, and repeat the examination on the day of calving. At that time, swabs are taken from feces and the vagina of the cow, and the feces of the calf. The sampling should preferably be done when the cows are tied in stanchions and not grazing pasture, because of the large number of passive carriers of the infection in the latter circumstance.

The reliability of diagnosis based solely on culture of fecal swabs is not high and represents the major difficulty in detecting carriers. A combination of fecal culture and serological tests offers some improvement in accuracy, but even with the agglutination or complement fixation tests accuracy is insufficient.

Determination of prevalence of infection in population of animals

In food-producing animals it is particularly important to determine the prevalence of *Salmonella* infection in a population of cattle or pigs. Pork and pork products are important sources of nontyphoidal *Salmonella* for humans consuming these products if they are not handled with care. Pigs entering the abattoir that are carriers of *Salmonella* are the most important source of carcass and product contamination. In order to be able to estimate the number of infected animals entering the abattoir and estimate the size of the *Salmonella* problem in pig herds, the population and herd level prevalence of *Salmonella* have to be investigated. An estimation of the prevalence of *S. enterica* infection in finishing pigs in Iowa was done using on-farm fecal cultures, culture of on-farm necropsy and abattoir-collected samples, and serum ELISA using serum exudate (meat juice).[101] Fecal samples collected on the farm detected only 13.3% of all positive pigs necropsied on the farm. Abattoir and on-farm results combined, the fecal sample detected 57.4% of positive pigs. Abattoir-collected samples provided prevalence estimates much higher than on-farm collected samples (39.9 vs 5.3%). Thus fecal samples have a low sensitivity for detecting infected pigs and abattoir-collected samples overestimate the on-farm *S. enterica* prevalence. Pigs can become infected during routine testing or holding periods during marketing when exposed to relatively low numbers of *Salmonella* in the preslaughter environment. Intervention this step on the production process may have a major impact on the safety of pork products.

The probability of detecting *Salmonella* in seropositive pig herds and thereby correlation between serological and fecal culture results were examined in pig herds as part of an international research program sponsored by the European Commission, Salmonella on Pork.[102] Samples were examined from herds in Denmark, the Netherlands, Greece, and Germany. The serological herd status was determined by blood-sampling 50 finishing pigs. There was an increased probability of recovering *Salmonella* with increasing within-herd seroprevalence but the correlation was only moderate.

NECROPSY FINDINGS

Septicemia

There may be no gross lesions in animals that have died peracutely but extensive submucosal and subserosal petechial hemorrhages are usually evident. In pigs, the petechiae are very prominent and may give the kidney the 'turkey-egg' appearance usually associated with hog cholera. A rhomboidal area of gastric mucosal infarction is usually present in pigs. Congestion and hepatization of lung tissue may also be present in this species. Skin discoloration is marked in pigs and, depending on the severity of the case, this varies from extreme erythema with hemorrhage, to plaques and circumscribed scabby lesions similar to those of swine pox. In some cases the necropsy findings may include splenomegaly and pinpoint white foci in the liver (paratyphoid nodules). The histological lesions are nonspecific, with the exception of the somewhat granulomatous character of the older paratyphoid nodules. The placentas of cattle and sheep aborting due to *Salmonella* spp. often contain very large numbers of intravascular bacteria.

Acute enteritis

Some of the changes associated with the septicemic form are often present but the most consistent damage is found in the large and small intestines. The character of the inflammation here varies from a mucoenteritis with submucosal petechiation to diffuse hemorrhagic enteritis. Similar lesions may be present in the abomasum, and in *S. dublin* infections in calves multiple mucosal erosions and petechiation of the abomasal wall are common. In porcine enteric salmonellosis, congestion and infarction of the gastric mucosa is often seen. Infections with *S. typhimurium* are characterized by severe necrotic enteritis in the ileum and large intestine. The intestinal contents are watery, have a putrid odor and may contain mucus or whole blood. In cases that have survived for longer periods, superficial necrosis and fibrin exudation may proceed to the development of an extensive diphtheritic pseudomembrane and fibrin casts. The mesenteric lymph nodes are enlarged, edematous, and hemorrhagic. The wall of the gallbladder may be thickened and inflamed. In pigs, survivors of the septicemic and acute enteric forms of salmonellosis may develop rectal strictures.

Chronic enteritis

In cattle, the chronic form is usually manifested by discrete areas of necrosis of the wall of the cecum and colon. The wall is thickened and covered with a yellow-gray necrotic material overlying a red, granular mucosal surface. In pigs the lesion is similar but usually more diffuse. Less commonly the lesions are discrete in the form of button ulcers, occurring most frequently in the cecum around the ileocecal valve. The mesenteric lymph nodes and the spleen are swollen. In all species, chronic pneumonia and a variety of other localized inflammatory processes such as polyarthritis and osteomyelitis may be found.

*Salmonella*s are present in the heart, blood, spleen, liver, bile, mesenteric lymph nodes, and intestinal contents in both septicemic and acute enteric forms. In the chronic form, the bacteria may be isolated from the intestinal lesions and less commonly from other viscera. Culture is more successful if enrichment media such as tetrathionate broth are employed. In pigs experimentally infected with *S. typhimurium* and *S. choleraesuis* var. *kunzendorf* the organisms can be detected with peroxidase–antiperoxidase

immunoenzymetric labeling and immunogold techniques.[51] Surveys that set out to determine the percentage of carriers in animal populations by examining abattoir material show that by far the largest number of isolations are made from the lymph nodes draining the cecum and lower small intestine.

Samples for confirmation of diagnosis

- Bacteriology – ileocecal lymph node, ileum, colon, spleen, lung, liver, culture swab from gall bladder (CULT)
- Histology – formalin-fixed samples from these tissues plus kidney, stomach, brain (LM).

Note the zoonotic potential of these organisms when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of salmonellosis is difficult because of the number of other diseases that resemble each form of the disease. Salmonellosis is characterized by septicemia in young animals and acute and chronic enteritis in adults, although acute enteritis can occur in neonates. Thus the septicemic form of the disease must be differentiated from all other causes of septicemia, and the enteric forms from all other causes of diarrhea in both young and adult animals. At necropsy the isolation of salmonellas from tissues and intestinal contents, although suggestive of the presence of salmonellosis, does not of itself confirm the diagnosis, and care must be taken to ascertain whether other disease is present.

Cattle

Septicemia

The septicemic form of salmonellosis in calves resembles coliform septicemia and differentiation is possible only by bacteriological examination of blood, feces, and tissues. Salmonellosis occurs most commonly during the second and third weeks of life in contrast to coliform septicemia which occurs most commonly in the first few days of life. Both are characterized by weakness, depression, polypnea, tachycardia, fever or hypothermia, scleral injection and hemorrhages, diarrhea, and rapid death.

Acute enteritis

Acute enteric salmonellosis in adult cattle or calves is characterized by fever, anorexia, toxemia, abdominal pain, diarrhea and dysentery, excessive mucus and fibrinous casts and strands in the feces, and dehydration.

- **Coccidiosis** occurs most commonly in young cattle 2–8 months of age and is characterized by diarrhea with frank blood in the feces, tenesmus, only occasionally systemic signs of dehydration and anemia, and spontaneous recovery in a few days; rarely there are nervous signs and death
- **Acute intestinal obstruction** is characterized by abdominal pain, scant or absent feces, blood-stained feces, tenesmus, anorexia, and palpable abnormalities on rectal examination
- **Winter dysentery** occurs in explosive outbreaks in housed adult cattle; the feces are gray with flecks of blood, there is no toxemia, no dehydration, and the disease is self-limiting in 24–48 hours
- **Mucosal disease** is characterized by typical oral erosions, anorexia, fever, persistent diarrhea, dehydration, lesions in the interdigital clefts and a high case-fatality rate
- **Bracken fern poisoning** is characterized by dysentery, scleral hemorrhages and a history of access to the bracken plant
- **Other poisonings,** especially arsenic and to a lesser extent lead and a number of miscellaneous weeds, may cause a similar acute enteritis.

Chronic enteritis

Chronic enteric salmonellosis may resemble **Johne's disease** or **chronic molybdenum poisoning**, but dysentery and epithelial casts do not occur in these diseases. Massive **stomach fluke infestations** may also cause diarrhea and dysentery.

Abortion

Abortion due to salmonellosis requires laboratory examination of the fetus, fetal fluids, vaginal mucus, feces, and milk of the aborting animals.

Sheep

Diarrhea associated with infections with coccidia or *Campylobacter* spp. or by parasitic infestation may resemble enteric salmonellosis in sheep but the latter is usually more acute and more highly fatal.

Horses

Septicemia

Septicemic salmonellosis in foals may resemble the septicemias associated with *E. coli* and *Actinobacillus equuli.*

Acute enteritis

Acute enteric salmonellosis in adult horses causes profuse diarrhea, dehydration, severe depression, and weakness. A history of recent transportation often helps in suggesting the diagnosis of salmonellosis in adult horses, in which colitis X is the important differential diagnosis.

Idiopathic equine colitis X is a severe enterocolitis of adult horses characterized by profuse diarrhea, marked dehydration and a high case-fatality rate in spite of intensive fluid therapy. Many cases are considered to be enteric salmonellosis but the definitive etiological diagnosis is often not obtained.

Other diagnoses that must be considered include:

- **Clostridiosis** due to *Clostridium perfringens* type A, *Clostridium difficile*, may result in peracute hemorrhagic diarrhea, marked dehydration and rapid death.

Chronic enteritis

Chronic diarrhea due to salmonellosis may resemble **parasitism, granulomatous enteritis**, or **lymphosarcom.**

Pigs

Septicemic salmonellosis occurs in pigs 1–4 months of age and is characterized by fever, depression, skin color changes, diarrhea, and rapid death.

- **Hog cholera, ASF coliform gastroenteritis of recently weaned pigs**, and **pasteurellosis** may resemble septicemic salmonellosis very closely and laboratory examination is usually necessary for identification
- **Acute erysipelas** is characterized by typical skin lesions, fever, swollen joints, and typical lesions at necropsy
- **Swine dysentery** is characterized by mucoid feces with dysentery and typical lesions of the large intestine.

TREATMENT

Primary treatment – antimicrobial therapy

The use of antimicrobials for the treatment of clinical salmonellosis is controversial and different approaches to the problem exist among veterinarians. The controversy centers on two parts of the response to treatment, and which view is taken depends to a large extent on the experience one has with respect to them.

The first issue is that of the success of treatment in saving the lives of clinically affected animals. It is our experience that early treatment with broad-spectrum antimicrobials is highly effective in reducing mortality and returning animals to normal function. It is generally agreed that treatment must be early, because delay means loss of the integrity of intestinal mucosa. A common pattern of response to treatment in a herd is that the first one or two cases are regarded lightly by the owner and they are treated 24–48 hours after diarrhea begins. When these cases die, a more prompt regimen is instituted in which the farmer has the approved drug on-hand and begins treatment as soon as diarrhea with fever is observed. The cure rate is then likely to be of the order of 100%, except in the case of foals and calves, in which a fulminating septicemia is apt to defeat even the best treatment program.

The second issue in the controversy about antimicrobial therapy for salmonellosis is the risk of inducing 'carrier' animals. In humans and in animals there is some evidence that antimicrobials can prolong the duration of the period after clinical recovery during which the causative bacteria can be isolated from

the intestine. It is accepted that this can occur and that the use of antimicrobials can theoretically contribute to the spread of disease. However, because of the way in which animals are kept, and because they constantly ingest contaminated pasture or other feed, there is an almost universal carrier segment in animal populations, and to regard another survivor from salmonellosis as a significant contributor to the carrier frequency seems an exaggeration. In many situations this appears to be the correct view, but in other situations an animal can become infected, for example, in a veterinary hospital or at an exhibition or show, recover clinically with treatment and, after returning to its parent herd, initiate an outbreak of fatal and debilitating salmonellosis. Both epidemiological patterns occur, and they seem to occur in different places, so that the most appropriate attitude to take seems to be the one that fits local circumstances. In an area where only sporadic cases of the disease occur in herds, it would be professionally negligent not to treat infected animals with appropriate antimicrobials. In endemic areas, recovered animals should not be sent into herds until they are known not to be carriers.

Other related issues are the creation of drug-resistant strains of the bacteria and the effect on the normal intestinal flora that results from oral medication. The problem with resistant strains would not have become a significant one if only individual animals had been treated, but mass medication of in-contact animals and prophylactic treatments have generally resulted in a large population of resistant strains.

Oral treatment in cattle and pigs is recognized as a satisfactory treatment but it is not recommended in horses in which an immediate worsening of the diarrhea, or its prolongation as a persisting chronic diarrhea, may be encountered. It is thought that both sequelae result from an alteration of the normal population of intestinal microflora resulting from the 8–10 times greater concentration of drug that occurs in the intestine after oral treatment, compared to the concentration resulting from parenteral injection.

In summary, antimicrobials are recommended for all clinically affected animals as set out below. The choice of antimicrobials depends on a test of drug sensitivity in each case or outbreak but failing this the following generalizations can be applied.

Ruminants

Currently there are no antimicrobials labeled for treatment of bovine salmonellosis in the USA. As a result, treatment of salmonellosis in cattle is largely empirical and extralabel use of certain antimicrobials is common in veterinary practice.[103] Ceftiofur at 5 mg/kg BW intramuscularly/24 hours is effective for the treatment of experimental salmonellosis in neonatal calves.[103] It promotes animal welfare, reduces fecal shedding of *Salmonella*, and may prolong clearance of *Salmonella* infections when plasma ceftiofur concentrations are maintained above MICs.

In calves with *S. dublin* infections trimethoprim–sulfadoxine is recommended, given parenterally daily until clinical recovery occurs. Ampicillin and amoxicillin are also effective. Oral dosing is satisfactory in preruminant calves but it is much less effective when given to grazing ruminants. Trimethoprim and sulfadiazine are very effective for the treatment of experimental salmonellosis in calves with *S. dublin*. There is marked synergism of the two drugs and both parenteral and oral therapy are effective. Sulfadimidine and framycetin are also widely used and recommended. Chloramphenicol was once a commonly used antimicrobial for salmonellosis but is now banned for use in food-producing animals in many countries. Nitrofurazone given orally to calves and adult cattle affected with salmonellosis also was used commonly but is now similarly banned.

Horses

Antimicrobial therapy in equine salmonellosis should be based on drug sensitivity of the organisms isolated. Based on some studies of isolates from horses, gentamicin at 3 mg/kg BW combined with ampicillin at 20 mg/kg BW given intravenously at 8–12-hour intervals is reommended. An alternative is trimethoprim–sulfonamide given twice daily intravenously at a combined dose of 30 mg/kg BW. Sulfadiazine, sulfadoxine, and sulfamethoxazole are the best sulfonamides to combine with trimethoprim for salmonellosis in the horse. In a double-blind prospective study, 220 horses undergoing surgery were given a probiotic orally once daily for 7 days postoperatively and fecal cultures for *Salmonella* were done daily for 10 days. The commercial probiotics had no effect on *Salmonella* shedding, prevalence of diarrhea, length of antimicrobial therapy, or length of hospitalization.[104]

Foals

Foals with septicemic salmonellosis are usually treated both systemically and orally with antimicrobials, sometimes a different one by each route. Treatment must be given at least at 6-hourly intervals and accompanied by a supportive fluid therapy. Antimicrobials recommended include gentamicin (250 mg intravenously, twice daily), ampicillin (1 g, 6-hourly), and chloramphenicol (20 mg/kg BW intravenously, 6-hourly). Care needs to be exercised when treating adult horses for salmonellosis because of the tendency for antimicrobials, especially tetracyclines, to precipitate attacks of diarrhea. Parenteral treatment with ampicillin or sulfonamide combinations is recommended.

Pigs

For pigs with septicemic salmonellosis, trimethoprim–sulfadoxine is recommended, along with a combination of mass medication of the water supply with chlortetracycline and sulfamethazine (75 mg of each per liter of water). Where large numbers of pigs are affected, mass medication via the feed or drinking water is usually practiced. Because sick pigs do not eat, water treatment is necessary and if drugs are unpalatable individual treatment is the last recourse. Drugs that dissolve readily and are palatable are therefore in demand. Experimental disease of pigs with *Salmonella typhisuis* can be controlled by the inclusion of low concentrations of chlortetracycline, penicillin, and sulfamethazine in the feed.

Supportive therapy

Horses

Fluid and electrolyte therapy

In adult horses affected with acute salmonellosis, the dehydration, acidosis and loss of electrolytes are severe. The loss of sodium is most serious, followed by potassium and chloride in that order. A solution of 5% sodium bicarbonate at the rate of 5–8 L/400 kg BW given intravenously over a period of 2 hours as the initial electrolyte replacement therapy will usually help to convert the hyponatremia and acidosis. The hypertonic solution is considered necessary to correct the severe loss of sodium. Following this initial therapy, equal mixtures of isotonic saline (0.9%) and isotonic sodium bicarbonate (1.3%) may be given as maintenance fluid and electrolyte therapy in amounts as indicated. The hypokalemia may be severe in some horses and is recognized clinically by muscular weakness and trembling. It may be corrected by adding potassium chloride to the saline and bicarbonate solution at the rate of 1–2 g/L for a total of 4–6 g of potassium chloride given over 2–4 hours. Concentrated solutions of potassium must be given slowly and the heart monitored for evidence of arrhythmia. However, provided that renal function has been restored, the hyperkalemia that may result from electrolyte therapy or that which could occur following correction of the acidosis should not be hazardous, since the kidney will excrete excess potassium. A safer method would be the oral administration of 30 g of potassium chloride in 8 L of water given twice daily.

Under practical conditions, without the aid of a laboratory for serial evaluation of serum electrolytes, the field veterinarian is faced with using hypertonic solutions as described above or balanced electrolyte solutions and careful clinical monitoring for evidence of overhydration or electrolyte imbalances.

The administration of electrolyte solutions by the oral route is gaining popularity because of the ease of administration and relative safety. Large quantities of fluids (10–30 L) can be administered orally, either all at once, for example in a mature cow, or in smaller quantities (5–10 L) three to four times daily in mature horses. This has been discussed in more detail under fluid therapy in Chapter 2.

CONTROL

Prevention of introduction of infection (biosecurity)

Avoidance of infection is the major objective but is not easily achieved. The principal sources of infection are carrier animals and contaminated feeds containing foodstuffs of animal origin. There is a critical need to develop methods to control the spread of *Salmonella* infections on dairy farms by instituting biosecurity and biocontainment practices in addition to enhanced farm management. This would result in a reduction in the use of excessive antibiotic treatment of individual animals or herds.

A closed herd minimizes the risk of infection but is not a practicable procedure for the types of animal producer for which salmonellosis is a major problem – the calf-rearer and the commercial pig fattener. For such producers the following rules apply:

- Introduce the animals directly from the farm of origin. Avoid auction marts, saleyards and public transport, all of which are likely to be sources of infection. Insure that the farm of origin is free of salmonellosis
- If possible, purchase animals when they are older, such as 6 weeks of age for calves, to provide an opportunity for specific and nonspecific immunity to develop. Animals from vaccinated herds are desirable
- The premises of dealers, saleyards and transport vehicles must be under close surveillance and the need for frequent vigorous disinfection must be stressed. The infection rate in calves delivered to calf-dealers' yards in the UK was less than 1% but the infection rate increased to 36% if the calves were kept on the premises over the weekend
- Introduce only those animals likely not to be carriers. Unfortunately the detection of carriers is inaccurate and expensive. To have any confidence in the results, fecal samples for culture must be submitted on at least three occasions. Even then, occasional carriers with lesions in the gallbladder or tonsils will escape the net and be capable of reviving the disease on the farm or transferring it to another one.

For the control of multiple drug-resistant *S. typhimurium* DT104 in cattle herds, the risk factors over which the farmer can exert a level of control and that are effective in reducing the incidence of disease include purchasing replacement stock from direct sources rather than dealers, quarantine of purchased cattle for a 4-week period, housing sick animals in dedicated isolation areas and preventing wild bird access to cattle feed supplies.

Management practices to reduce the risk of *S. brandenburg* on a sheep farm include reducing stocking density; avoiding strip grazing; maintaining adequate nutrition; minimizing yarding of ewes and the time spent in yards; dampening down yards prior to yarding; providing stock with a fresh clean source of drinking water; avoiding the purchase and/or grazing of stock from known affected farms, as they may contain carrier animals; preventing dogs from scavenging; and preventing scavenging by black-backed gulls by removing and burying aborted fetuses frequently during the lambing season.[40]

Limitation of spread within a herd

When an outbreak occurs, procedures for limiting spread, as set out below, need to be strictly enforced, and medication of affected groups, and of susceptible groups at high risk, must be carried out. The drugs to be used are those listed under treatment, the choice of the individual drug depending on its efficiency and cost.

- **Identify carrier animals and either cull them or isolate and treat them vigorously.** Treated animals should be resampled subsequently to determine whether a 'clean' status has been achieved
- **The prophylactic use of antimicrobials** such as oxytetracycline in the feed at the rate of 10 g/tonne, or chlortetracycline in the drinking water at the rate of 55 mg/L, is used but not recommended because results are poor and there is a risk of developing resistant strains. Probiotics intended for the prevention of shedding of *Salmonella* in the postoperative period in horses with colic have been evaluated and found to be ineffective[104]
- **Restrict the movement of animals around the farm** and limit the infection to the smallest group. Pasture and permanent buildings are both important, although the major source of infection in most cases is the drinking water
- **The water supply should be provided in troughs that are not susceptible to fecal contamination.** Static drinking water or pasture may remain infected for as long as 7 months
- **Rigorous disinfection of buildings is important.** An all-in/all-out policy should be adopted and steam cleaning and chemical sterilization performed after each batch of animals. Piglets can be reared free of *Salmonella* infections up to 6 weeks of age by removing the piglets from infected herds to isolation facilities when they are weaned at 10–21 days of age. The movement of pigs either at weaning, from the nursery, or from the grower unit to newly built or rigorously cleaned and disinfected finishing units with known history of *Salmonella* infection is highly successful.[102] If economics permit, individual pens for calves are beneficial. Where calves are reared indoors they are common and economical. Pig houses need especially careful treatment. Dirt yards present a problem, especially those used for sheep and calves, but, provided they can be kept dry and empty, two sprayings, 1 month apart, with 5% formalin is recommended
- **The control of salmonellosis in veterinary clinics and veterinary teaching hospitals** requires special attention to the possible sources of infection and containing and preventing the spread of infection. Following the diagnosis of the disease in a clinic, an environmental survey should be carried out using bacteriological culturing of stalls, wall padding, stomach pumps, nasogastric tubes, alleyways, water drains, and other equipment used routinely.[105] This is followed by a thorough cleaning and disinfection of the entire animal-holding premises. A power water sprayer is used, followed by application of 10% solution of hypochlorite for at least 15 minutes. The surfaces are then recultured to determine the presence of residual contamination. Medical and surgical equipment are cleaned and gas-sterilized. Traffic flow patterns in the clinic are reviewed and modified accordingly. Use of disposable gloves

and thorough washing of hands after handling suspect animals are recommended. Stalls in which horses with salmonellosis were housed should only be used to accommodate newly hospitalized horses after sample (collected after two cycles of cleaning and disinfection) from stall drains, cracks and corners yield negative results on bacteriological culture.[105] Using PCR assay for *Salmonella* DNA, samples from floor drains and drainpipes yield the greatest proportion of positive results. The PCR results should be confirmed by bacteriological culture because a positive PCR in itself is not considered to pose a risk of salmonellosis to hospitalized horses. When a hospitalized horse leaves its stall permanently, it should be cleaned of organic matter using a cold water hose and scrubbed with a steel wool mop. This is followed by an application of generic bleach solution. This is then followed 24 hours later by another cleaning and disinfection with a peroxygen solution (Virkon) and allowed to dry. Virkon is a balanced stabilized blend of peroxygen compounds, surfactants, organic acids, and inorganic buffer system. Active ingredients are potassium peroxymonosulfate, sodium chloride, and other ingredients. It is effective against a wide range of bacteria, virus, and fungi, including: *Streptococcus pyogenes*, *Campylobacter pyloridis*, *Klebsiella pneumoniae*, *E. coli*, and *S. typhimurium*

- **Suitable construction of housing is important.** Impervious walls to stop spread from pen to pen, pen design to permit feeding without entering the pen, avoidance of any communal activity and slatted floors to provide escape routes for manure all assist in limiting the spread of enteric diseases. Deep litter systems are satisfactory provided they are kept dry and plenty of bedding is available. With pigs the opportunity for oral–fecal cycling of the organism and buildup and spread of infection within and between groups must be kept to a minimum. Pen design and the environment should be such as to encourage proper eliminative behavior and good pen hygiene. Drinkers should be sited at one end of the pen, preferably on a narrow end with oblong pens, to encourage defecation in this area. Wet or damp areas of the floor in other parts of the pen will encourage defecation and urination there and should be eliminated. Drinkers of the nipple type rather than bowls are preferable for hygienic reasons. Communal dunging alleys increase the possibility of spread, especially during the cleaning procedure, and the trend is towards slatted or meshed areas over a channel. A totally slatted or mesh floor for pigs from weaning until 10–12 weeks of age will markedly reduce the opportunity of oral–fecal cycling of organisms in this age group, which is especially susceptible to enteric disease. Feeders should allow the ingress of the pig's head and should be constructed to avoid fecal and other contamination of feed. Pigs need to be grouped according to size, and overcrowding, which may result in improper pen hygiene, must be avoided. Space requirements vary according to pen and housing design but generally fall in the region of 0.3 m^2 for recently weaned piglets to 0.6–1 m^2 for market-size pigs. In conventionally floored or partially slatted floored pens, approximately two-sevenths of the area should be available for the dunging area. The construction of the pen should allow for easy and efficient cleaning. In problem herds an especial vigilance for the occurrence of enteric disease is needed following the breakdown of pen hygiene on very hot days
- **Heat treatment of feed** is an effective procedure for pigs. Heating during pelleting greatly reduces the bacterial content of feed and special treatment is worthwhile because of the very high proportion of animal-derived feeds that are infected. The availability of such feeds guaranteed to be *Salmonella*-free would be an advantage
- **Disposal of infective material should be done with care.** Carcasses should be burned or, better still, sent to an institution for diagnosis, rather than to a rendering plant to be converted into still more contaminated bone meal. Slurry and manure for disposal should be placed on crops rather than on pasture. Slurry does not constitute a danger via hay, and salmonellas do not survive silage making. When slurry is used on pasture it should be stored for at least a month beforehand and even longer if silo effluent is included. Slurried pasture should not be grazed for 1 month, and for young animals a 6-month delay is recommended. Pig slurry is most dangerous and should always be avoided
- **All persons working on infected premises should be warned of the hazards to their own health.** Other peripatetic species, especially dogs, should be kept under close restraint.

Principles of infectious disease control for prevention of nosocomial gastrointestinal and respiratory diseases in large-animal hospitals

The principles of an infectious disease control (IDC) program for the prevention of gastrointestinal and respiratory diseases in a large-animal hospital have been described and are applicable to the control of salmonellosis.[106] The three basic strategies are reducing exposure to pathogens, avoiding increasing susceptibility to pathogens, and monitoring effectiveness of the IDC program. The major procedures are summarized here.

Reducing exposure to pathogens
- Promoting appropriate personal hygiene
- Using effective methods for cleaning and disinfection
- Controlling the flow of human and animal traffic
- Implementing protocols for prompt identification of patients with signs of contagious disease
- Controlling birds, rodents, and flies.

Avoiding increasing susceptibility to pathogens
- Controlling ambient temperature
- Using antimicrobials appropriately
- Aiding in establishing normal intestinal or rumen flora
- Controlling endotoxemia.

Monitoring effectiveness of the infectious disease control program
- Bacterial culture of fecal samples of animals admitted to the hospital
- Regular culture of environmental samples.

Recommended steps in developing an effective infectious disease control program (IDC) for a large-animal hospital

An effective IDC program is necessary for all large-animal veterinary teaching hospitals and private veterinary clinics. The recommended steps are outlined here.[106]

- Have all clinicians work together to develop and approve the IDC program, as grassroots buy-in is vital
- Develop a specific, written IDC program and disseminate it widely among staff members
- Identify a veterinarian who is active in the large-animal hospital to serve as the IDC officer; this individual will oversee the IDC program and should report to the hospital director and practice partners
- Provide the resources, both human and monetary, needed for the IDC officer to effectively carry out the

approved IDC program; prevention costs less than the alternatives
- Make students, residents, and staff aware of the key points of the IDC program and the importance that clinicians place on compliance
- Teach the barn crew, particularly those actually responsible for cleaning, disinfecting and feeding, about the goals of the IDC program and the methods to be used
- Monitor the effectiveness of cleaning and sanitation by means of bacterial culture of environmental samples and give regular feedback to the barn crew, staff, students, and clinicians
- Hold a seminar at least yearly to distribute written information about the IDC program and results of monitoring.

Animals being transported

These are a special case. They should be unloaded or exercised at least once every 24 hours and given water and feed, the feed being provided first and at least 2 hours before watering. Hay or chopped hay is preferred to succulent feeds. All railroad cars and feeding and watering troughs should be properly cleaned and disinfected between shipments. Horses that are to be transported should be yarded and hand-fed on hard feed for 4–5 days beforehand. If the disease is likely to occur, prophylactic feeding with sulfonamides or antimicrobials has been shown to decrease the incidence in all species. Apart from the risk that this practice will produce resistant bacteria, there has been a suggestion that it may so change the normal bacterial flora of the gut as to encourage the proliferation of salmonellas and lead to the development of the clinical disease.

Immunization

Salmonella vaccinology

The literature on *Salmonella* vaccines has been reviewed.[58] Host resistance to *Salmonella* relies initially on the production of inflammatory cytokines leading to the infiltration of activated inflammatory cells in the tissues. Thereafter, T- and B-cell-dependent specific immunity develops, allowing the clearance of *Salmonella* from the tissues and the establishment of long-lasting acquired immunity to reinfection. The increased resistance that develops after primary infection or vaccination requires T cells, cytokines such as interferon gamma, tumor necrosis factor and interleukin 2, in addition to opsonizing antibody. Seroconversion and/or the presence of detectable T-cell memory do not always correlate with the development of acquired resistance to infection.

Immunization with live salmonellas induces early resistance rechallenge with virulent organisms that appears 1 day after infection or vaccination with live but not killed organisms. Early protection is nonspecific and effective against different *Salmonella* serotypes. Long-term immunity using live attenuated vaccines is serotype-specific and involves the recall of immunological immunity. Killed vaccines induce strong antibody responses but trigger insufficient T helper 1 (Th1)-cell responses.

Vaccination can decrease the number of bacteria shed in feces and the number of blood-culture-positive calves, thus decreasing the number of carriers and reducing environmental contamination. Many types of vaccine have been developed and tested in cattle and pigs. If vaccination is combined with the hygienic precautions described, the vaccines are an aid to management. Killed bacterins and live attenuated vaccines are available. Either can be used as a prenatal vaccine to provide passive immunization of the newborn. It is now generally accepted that live *Salmonella* vaccines are more effective immunogens in calves than are killed vaccines.

Cattle

In cattle, *S. dublin* is the infection likely to be endemic in a herd and a commercial vaccine, to be effective, must have a strong *S. dublin* component. Live organisms are better able to stimulate antilipopolysaccharide antibodies and to stimulate cell-mediated immunity. Calves vaccinated at 1–3 weeks of age with a modified-live aromatic-dependent *S. dublin* bacterin have detectable antilipopolysaccharide immunoglobulins after immunization. Safe live oral vaccines against *S. typhimurium* and *S. dublin* have been constructed and shown to confer protection against experimental infection with virulent wild-type strains of the organism. Vaccination of calves orally with a genetically altered stable nonreverting aro-*S. dublin* as a modified-live vaccine provided a measurable systemic immune response but the vaccine volume makes it unlikely to be practical for field use. Vaccinated calves responded with increases in humoral-mediated immunity and cell-mediated immunity, as measured by ELISA and skin testing. It is claimed that the combination of humoral immunity and cell-mediated immunity stimulated by live-organism vaccines provides superior protection. Other genetically altered vaccines consisting of hybrid strains derived from *S. dublin* and *S. typhimurium* are being evaluated. An avirulent live *S. choleraesuis* vaccine is efficacious experimentally against salmonellosis due to *S. dublin* infection in calves.

The vaccine strain 51, produced in the UK from a rough variant strain of this organism, has been found to be efficient and safe, and provides good protection against *S. typhimurium* as well as *S. dublin*. It has the disadvantages of a living vaccine but calves can be vaccinated successfully at 2–4 weeks of age. In limited experiments other living, attenuated and killed, adjuvanted vaccines have given calves protection, and a comprehensive program of vaccination, hygiene, and adoption of a closed herd policy has been successful in controlling the disease. Reports on killed *S. typhimurium* vaccines used in calves indicated good results provided the antigenic mass in the vaccine is kept high, but commercial killed vaccines are of doubtful value.

Attenuated *S. typhimurium* (strain SL1479) given orally or intramuscularly has shown good efficiency, and attenuated *S. dublin* (strain SL1438) has been similarly effective. The *S. typhimurium* vaccine also gives some protection against *S. dublin*.

The autogenous bacterin, which must be precipitated on aluminum hydroxide to have any significant effect, is given as two injections 2 weeks apart. Good immunity is produced but calves and pigs less than 6 weeks of age are refractory, and anaphylactic reactions may cause the loss of a significant number of animals. To protect young calves the best program is to vaccinate the cows during late pregnancy. This will give passive protection to the calves for 6 weeks, provided they take sufficient colostrum, and the calves can be vaccinated at that time if danger still exists. Vaccination of pregnant cattle with a formalin-killed *S. typhimurium* vaccine approximately 7 and 2 weeks before parturition protected their calves against experimental infection. Reports of results have not been enthusiastic but if proper attention is given to the detail of the program it has been sufficient, in our hands, to provide almost complete protection. A similar observation has been made with respect to vaccination of calves against *S. typhimurium*.

Pigs

A commercial vaccine containing living, attenuated *S. choleraesuis* has also been shown to protect neonatal pigs after vaccination of sows and weaned pigs. Because of the early age at which pigs need to be immune, it is recommended that sows be vaccinated three times at 7–14-day intervals. The young pigs are vaccinated at 3 weeks of age. A live avirulent *S. choleraesuis* vaccine has been developed and evaluated for protection against experimental challenge. Vaccinated pigs were able to maintain normal body weight gains during a 4-week observation period following challenge inoculation with a high dose of a virulent strain. It has

consistently been safe and efficacious in pigs as young as 3 weeks and provides protection for at least 20 weeks.

Most cases of salmonellosis in pigs are subclinical and due to *S. typhimurium*. The ideal vaccine against *S. typhimurium* would prevent colonization, shedding of the organism in the environment, development of carriers and clinical salmonellosis, and promote elimination of the organism from infected animals.[107] Live vaccine strains are considered to provide superior protection compared to inactivated vaccines.

Horses

In horses, a similar regimen with a booster dose for all mares in late pregnancy appears to be effective. In foals, an autogenous *S. typhimurium* bacterin has been used in several bad field situations and has been credited with preventing further clinical cases and with reducing environmental contamination, in spite of continued poor hygiene and management practices.

Sheep

Results in sheep have been unconvincing. Some live *S. typhimurium* vaccines are being evaluated for their efficacy against salmonellosis in sheep.

Nationwide surveillance and control programs

In 1993, the Ministry of Food, Agriculture and Fisheries of Denmark and the Danish Bacon and Meat Council initiated an ambitious program to eliminate pork as an important source of human salmonellosis. In the early 1990s pork had become recognized as an increasingly important source of human salmonellosis in Denmark. In Denmark, the proportion of human salmonellosis attributable to pork was estimated to be 10–15% in 1997 and 1998.[108] In the Netherlands, it was estimated that approximately 15% of human cases of salmonellosis were associated with the consumption of contaminated pork.

The Danish Salmonella Surveillance and Control Program for pigs operates at all stages of the production chain and has been applied nationally since 1995.[108] As a result of the program the level of *Salmonella* in Danish pork declined from 3.5% in 1993 to 0.7% in 2000. Simultaneously, the number of human cases of salmonellosis due to pork declined from approximately 1444 in 1993 to 166 in 2000.[109]

The control program is integrated from 'feed to food'. It is based on routine testing and classification of slaughter pig herds and subsequent slaughter of pigs according to the inherent risk, as measured by the continual test program.[109]

Basically, the level of *Salmonella* is controlled at various stages.

Feedstuffs

Compounded feeds are heat treated at 81°C to eliminate *Salmonella*. The national program requires mandatory *Salmonella* testing in all plants producing animal feeds. In 2000, the level of *Salmonella* spp. in final products was only 0.3%.

Breeder and multiplier herds

Each month all herds are blood sampled and examined for *Salmonella* antibodies.[110] Based on the level of antibodies, a *Salmonella* index is calculated. If the index exceeds 5, pen fecal samples must be taken and examined for the presence of *Salmonella* spp. When the index exceeds 15, a sales ban on breeding pigs is imposed until the index has declined below 15 again.

Weaner producers

If a sow herd sells weaners to a *Salmonella* level 2 or 3 finishing herd, pen fecal samples must be taken and examined for *Salmonella*.

Slaughter pigs

Slaughter herd pigs are monitored continuously by serological testing of 'meat juice'. Meat samples are frozen, and meat juice (harvested after thawing) is examined for specific antibodies against *S. enterica* using an ELISA.[111] The ELISA combines several *S. enterica* O antigens and allows detection of antibody response after a variety of serovar infections. The meat samples for testing are collected at the slaughter line, and the number of samples and frequency of sampling are determined by the size of the herd. Herds sending fewer than 200 pigs to slaughter per year are not examined, which amounts to 1.6% of slaughter pigs not examined. The herds are categorized in four levels based on the proportion of seropositive meat juice samples during the previous 3 months. Based on the optical density per cent (OD%) of the ELISA test, the herds are classified into:

Level 0: Herds having only seronegative over 3 months or more
Level 1: Herds with acceptable low *Salmonella* prevalence
Level 2: Herds with moderate *Salmonella* prevalence
Level 3: Herds with unacceptable high *Salmonella* prevalence.

A herd categorized as level 2 or 3 must receive an advisory visit by a practicing veterinarian and a local extension specialist, and certain management precautions must be adopted. In a herd with level 3, the finishing pigs must be slaughtered under special hygiene conditions.

The proportion of serologically positive meat-juice samples collected during 1995 ranged from a mean of 2.9% in small herds to 6.1% in large herds.

Danish National Surveillance Program for *Salmonella dublin*

A national surveillance program for *S. dublin* in dairy cattle was begun in 2002 by initiative of both the Danish Veterinary and Food Administration and the Danish Cattle Federation. The short-term goal was to screen both dairy and beef cattle herds for *S. dublin* infection, and to classify the herds according to the estimated level of infection in order to provide a control scheme. The long-term goal was to reduce the prevalence of *S. dublin* in Danish cattle and reduce the risk of human infection associated with the consumption of meat and milk from Danish cattle.[112] All Danish cattle herds are screened by the use of ELISA assay of bulk tank milk collected from dairy herds every 3 months and of three yearly blood samples from other herds.

ABORTION IN MARES AND SEPTICEMIA IN FOALS ASSOCIATED WITH *SALMONELLA ABORTUSEQUI (ABORTIVOEQUINA)* (EQUINE PARATYPHOID)

This is a specific disease of Equidae characterized by abortion in females, testicular lesions in males and septicemia in the newborn.

ETIOLOGY

Salmonella abortusequi (*abortivoequina*) (also known as *Salmonella enterica* serovar *abortusequi*) is a host-adapted serovar causing abortion in mares and donkeys.[1,2] *S. abortusequi* strains vary in virulence, with more virulent strains having greater in vitro cytotoxigenicity.[3] It is possible to determine the origin and progression of outbreaks of the disease by determining pulsed-field gel electrophoretic patterns of *S. abortusequi*.[2]

EPIDEMIOLOGY

The infection appears to be limited to horses and donkeys.[2,4] Although widely reported in the early 1900s, this disease is rarely encountered nowadays and is one of the less common causes of either abortion or septicemia in horses.[5,6] Recent reports of the disease are from Austria, Brazil, Croatia, Japan, and India, although the disease occurs in other countries. However, in the early 1990s, an outbreak of abortion occurred in a herd of 38 horses, in which 21 mares aborted between 5 and 10 months of gestation.[1]

Natural infection may be due to the ingestion of foodstuffs contaminated by uterine discharges from carriers or mares that have recently aborted. Transmission from the stallion at the time of service is also thought to occur. The infection may persist in the uterus and cause repeated abortion or infection of subsequent foals. Transmission from a female donkey to mares is reported with abortion a result in both species.[2]

PATHOGENESIS

When infection occurs by ingestion, a transient bacteremia without marked systemic signs is followed by localization in the placenta, resulting in placentitis and abortion. Foals that are carried to term probably become infected in utero or soon after birth by ingestion from the contaminated teat surface or through the umbilicus.

CLINICAL FINDINGS

Abortion usually occurs at about the seventh or eighth month of pregnancy. The mare can show signs of impending abortion followed by difficult parturition but other evidence of illness is usually lacking. Retention of the placenta and metritis are common sequels and may cause serious illness, but subsequent sterility is unusual. A foal that is carried to term by an infected mare may develop an acute septicemia during the first few days of life or survive to develop polyarthritis 7–14 days later. Polyarthritis has also been observed in foals from vaccinated mares that showed no signs of the disease.[7]

Infection in the stallion has also been reported, clinical signs including fever, edematous swelling of the prepuce and scrotum, and arthritis. Hydrocele, epididymitis, and inflammation of the tunica vaginalis are followed by orchitis and testicular atrophy.

CLINICAL PATHOLOGY

The organism can be isolated from the placenta, the uterine discharge, the aborted foal, and the joints of foals with polyarthritis. A high titer of *Salmonella* agglutinins in the mare develops about 2 weeks after abortion. Vaccinated mares will give a positive reaction for up to a year.

NECROPSY FINDINGS

The placenta of the aborted foal is edematous and hemorrhagic and may have areas of necrosis. The nonspecific changes of acute septicemia will be manifested in foals dying soon after birth; polyarthritis is found in those dying at a later stage.

Samples for confirmation of diagnosis

- Bacteriology – placenta, fetal stomach content, lung, culture swabs of joints (CULT)
- Histology – formalin-fixed placenta, various fetal tissues including lung, liver (LM).

TREATMENT

The antimicrobials recommended in the treatment of salmonellosis should also be effective in this disease.

CONTROL

Careful hygiene, including isolation of infected mares and disposal of aborted material, should be practiced to avoid spread of the infection. Infected stallions should not be used for breeding. In the past, when this disease was much more common than it is now, great reliance was placed on vaccination as a control measure. An autogenous or commercial bacterin, composed of killed *S. abortivoequina* organisms, was injected on three occasions at weekly intervals to all mares on farms where the disease was enzootic, commencing 2–3 months after the close of the breeding season. A smaller dose (5 mL) of vaccine of higher concentration is as effective as a larger dose (20 mL) of vaccine of lower concentration.[8] A formol-killed, alum-precipitated vaccine is considered to be superior to a heat-killed, phenolized vaccine.[9] In China a virulent strain vaccine is credited with effective protection after two injections 6 months apart.[5] The widespread use of vaccines and hyperimmune sera is credited with the almost complete eradication of the disease in developed countries.

ABORTION IN EWES ASSOCIATED WITH *SALMONELLA ABORTUSOVIS*

Salmonella abortusovis (*S. enterica* serovar *abortusovis*) is a relatively uncommon cause of abortion in ewes but appears to be enzootic in particular areas. Spread of the disease may occur after the introduction of carrier animals. The reservoir of infection is infected animals that do not abort. The organisms persist in internal organs of the carriers for up to 6 months, and are excreted in the feces and vaginal mucus for periods up to 4 months.[1] Ingestion is thought to be the main mode of infection. The experimental disease induced by the conjunctival route has been examined.[2] Venereal spread has been postulated, and rams certainly become infected, but all the evidence is against spread at coitus. Experimental induction of the disease in ewes is more successful after the third month of pregnancy.[3] Intrapreputial inoculation results in infection of rams and the passage of infected semen for up to 15 days. Abortion 'storms', with up to 10% of ewes aborting, occur about 6 weeks before lambing, and septic metritis and peritonitis subsequently cause a few deaths among the ewes. Mortality in lambs is common due either to death of weak lambs or to the development of acute pneumonia in previously healthy lambs up to 2 weeks old.

Identification of the disease depends upon isolation of the organism, which is present in large numbers in the fetus, placenta and uterine discharges, and the presence of a strong positive agglutination test in the ewe for 8–10 weeks after abortion. An ELISA test detects antibody to *S. abortusovis* in a greater proportion of sheep than does a microagglutination test.[4] The disease can be diagnosed in fetuses by use of a coagulation test on fetal stomach contents. The test had a sensitivity and specificity of 100% and 90% in a small number of samples.[5] Use of PCR to identify *S. abortusovis* is feasible because the organism has an IS200 element in a distinct chromosomal location. The resulting PCR assay has high specificity for *S. abortusovis*, effectively discriminating it from other *S. enterica* serovars.[6]

The clinical and serological findings in *S. dublin* infections in ewes are very similar,[7] and infection has become more important as a cause of abortion in ewes in the UK than *S. abortusovis*. A strong immunity develops after an attack and an autogenous vaccine has given good results in the control of the disease. The results of vaccination need to be very carefully appraised because flock immunity develops readily and the disease tends to subside naturally in the second year.

Salmonella ruiru has also been recorded as a cause of abortion in ewes, and ewes with salmonellosis associated with *S. typhimurium* may also lose their lambs. *S. brandenburg* is a cause of illness and abortion in sheep, horses, calves, goats, and humans in New Zealand.[8] Spread of the disease is strongly associated with presence of aborting ewes and subsequent heavy environmental contamination.[8]

The administration of broad-spectrum antibiotics might aid in controlling an outbreak but available reports are not generally encouraging. Chloramphenicol, and trimethoprim and sulfadiazine combination are considered effective for treatment but use of chloramphenicol in animals intended for us as human food is not permitted in many countries. A live *S. typhimurium* vaccine with optimal level of attenuation for sheep constructed by means of 'metabolic drift' mutations was highly effective in preventing *S. abortusovis*-induced abortions under field trial conditions.[9] Subcutaneous and conjunctival vaccination with a live attenuated strain of *S. abortusovis* confers immunity for at least three lambing periods. More recent vaccines, including those containing plasmid-cured strains of *S. abortusovis*, are effective in preventing pregnancy loss in response to experimental challenge with wild-type *S. abortusovis*.[10]

Diseases associated with *Pasteurella* species

Pasteurellas occur in many animal diseases and, although in some instances they act as primary causes, the number of conditions in which they appear to play only a secondary role is gradually increasing. However, their importance is not insignificant. A primary viral pneumonia may be an insignificant disease until the intervention of a secondary pasteurellosis converts it into an outbreak of pneumonia of major economic importance. The common diseases in which *Pasteurella* spp. play an important etiological role are described in this section with due regard to their possible secondary nature. Mastitis associated with *Pasteurella* spp. is dealt with in the section on mastitis. There is now general agreement that atrophic rhinitis in pigs is associated with toxigenic strains of *Pasteurella multocida*.

The bovine strains of *P. multocida* have been characterized and compared with isolates of avian, ovine, and porcine origin.[1] *P. multocida* is a heterogeneous species of Gram-negative bacteria and is a commensal of the upper respiratory tract of many animal species. Under certain predisposing conditions the organism is the etiological agent of a wide range of economically important infections in domesticated animals. The pathogen consists of five capsular subgroups, A, B, D, E, and F, and there is a relationship between the capsular subgroup and disease predilection. *P. multocida* is responsible for two major disease conditions of cattle: hemorrhagic septicemia and pneumonic pasteurellosis. **Hemorrhagic septicemia** occurs almost exclusively in cattle and water buffalo in Asia and Africa and is associated with *P. multocida* strains of capsular serogroups B and E. In contrast, **pneumonic pasteurellosis** is an important infectious disease of cattle in Europe and North America and, in addition to *Mannheimia haemolytica*, is associated mainly with *P. multocida* strains of capsular serogroup A. *P. multocida* is also occasionally the cause of mastitis, abortion and localized infections in cattle such as otitis externa.

There is a limited degree of strain diversity among bovine disease isolates of *P. multocida*.[1] Comparison of the outer membrane profiles of bovine isolates with those of avian, ovine, and porcine strains indicate that a high proportion of the respiratory tract infections in each of these species are associated with different strains. However, the presence of small numbers of closely related strains in more than one host species suggests that transmission of bacteria between different host species is also a factor in the population biology of *P. multocida*.

Other isolated instances of disease associated with *P. multocida* are meningoencephalitis of calves[2] and yearling cattle,[3] manifested by muscle tremor, opisthotonos, rotation of the eyeballs, collapse, coma and death within a few hours; and lymphadenitis in lambs, which show enlargement of the submandibular, cranial, cervical, and prescapular lymph nodes.[4] An epidemic of meningoencephalitis in horses, donkeys, and mules has been reported from Mexico. The causative agent was *Mannheimia haemolytica*. Clinical findings included incoordination, paralysis of the tongue, tremor, and blindness. Death occurred 1–7 days after the commencement of the illness.[5] There is also a report of a fatal septicemia in horses and donkeys in India in which *P. multocida* appeared to be implicated as a causative agent.[6] *M. haemolytica* is one of several bacterial pathogens causing otitis externa in cattle.[7]

Pasteurella (*Yersinia*) *pseudotuberculosis* is a common cause of epizootic disease in birds and rodents and occasionally causes disease in domestic animals. It is described under a separate heading in this chapter. The literature of the molecular biology of *P. multocida* has been reviewed.[8]

PASTEURELLOSIS

The nomenclature of the diseases associated with infections with *Pasteurella* spp. in farm animals has been indefinite and confusing. A suggested nomenclature is set out below, which is based on the clinical findings and on the bacteria that are commonly associated with each entity.

- **Septicemic pasteurellosis of cattle** (hemorrhagic septicemia or barbone), commonly associated with infection by *P. multocida* type 1 or B, is the classical disease of southern Asia characterized by a peracute septicemia and a high mortality rate
- **Pneumonic pasteurellosis of cattle**, commonly associated with infection by *Mannheimia* (formerly *Pasteurella*) *haemolytica* biotype A serotype 1, and *P. multocida* biotype A, is a common disease in Europe and the western hemisphere. *M. haemolytica* tends to cause a fulminating fibrinous lobar pneumonia, and *P. multocida* causes a fibrinopurulent bronchopneumonia. Coagulation necrosis sharply demarcated by leukocytes is considered to be the pathognomonic lesion associated with *M. haemolytica*. There is a lack of multifocal coagulation necrosis in pneumonia associated with *P. multocida*
- **Pasteurellosis of pigs, sheep, and goats**. In pigs this is usually associated with infection by *P. multocida* and is mainly pneumonic in form. Pasteurellosis of sheep and goats is usually associated with infection by *M. haemolytica* and, although it is often pneumonic in form, a septicemic form of the disease is not unusual, especially in lambs.

There are a number of immunologically distinct types of the common causative organism, *P. multocida*. These have been classified as types 1 (or B), 2 (or A), 3 (or C), and 4 (or D) and there is a loose relationship between the serotype and the host species. There is also some relationship between the serotype and the disease produced. Septicemic pasteurellosis is caused only by type 1 and, as this type does not occur in the UK and is uncommon in North America, it is not surprising to find that this form of the disease does not occur there.

The position with *M. haemolytica* is more obscure but preliminary work suggests that a number of serotypes occur and that there may be biological differences in virulence between them.

SEPTICEMIC PASTEURELLOSIS OF CATTLE (HEMORRHAGIC SEPTICEMIA, BARBONE)

ETIOLOGY

Hemorrhagic septicemia is associated with two specific serotypes of *P. multocida*. The Asian serotype is designated B:2, 5 and the African serotype is E:2 by the Carter–Heddlestone system, corresponding to 6:B and 6:E by the Namioka–Carter system. The electrophoretic profiles of *P. multocida* isolates from animals with hemorrhagic septicemia can be placed in two distinct groups on the basis of their country of origin. Antibodies against *P. multocida* capsular types B and E were demonstrated in a high percentage of serum samples from a group of domestic feeder calves in the USA. Since capsular E organisms have been isolated only in Africa and there is only one report of capsular B isolation from cattle in the USA, these organisms were not considered

likely sources of the antigenic stimulation that provoked production of these antibodies.

EPIDEMIOLOGY

Hemorrhagic septicemia occurs in cattle, yaks, camels, and water buffalo and, to a much smaller extent, pigs and horses. It is considered economically important in southern Europe, Russia, Africa, the Near East, Middle East, South Africa, India, and southern and south-east Asia, including Indonesia, Malaysia, Thailand, and the Philippines, where it causes heavy death losses, particularly in low-lying areas and when the animals are exposed to wet, chilly weather or exhausted by heavy work.[1] It is also recorded in bison and cattle in the USA and the causative bacterium and its endotoxin have been used to produce the disease experimentally. Animals of all ages are susceptible but the most susceptible age group is 6 months to 2 years of age. There is no difference in susceptibility between breeds. The incidence of disease is reduced significantly in areas where the vaccine is used. Both morbidity and case-fatality rates vary between 50% and 100%, and animals that recover require a long convalescence. Morbidity will depend on the immune status of the herd, either acquired naturally or induced by vaccination. The greater the percentage of immune to nonimmune animals, the lower will be the morbidity. In endemic areas, adult animals develop a naturally acquired immunity and large outbreaks no longer occur in these areas. The overall mean case fatality rate for buffaloes is nearly three times as high as in cattle.

Outbreaks of the disease are often associated with wet humid weather during the rainy season. During intervening periods the causative organism persists on the tonsillar and nasopharyngeal mucosae of carrier animals. Approximately 45% of healthy cattle in herds associated with the disease harbor the organism, in comparison to 3–5% in cattle from herds unassociated with the disease. Spread occurs by the ingestion of contaminated foodstuffs, the infection originating from clinically normal carriers or clinical cases, or possibly from ticks and biting insects. The saliva of affected animals contains large numbers of *Pasteurella* during the early stages of the disease. Although infection occurs by ingestion, the organism does not survive on pasture for more than 24 hours. The epidemiology of hemorrhagic septicemia in India has been described.

PATHOGENESIS

The portal of entry of infection is thought to be the tonsils. A fulminating septicemia occurs, which is associated with the capsular material of the organism. The effects of the septicemia are most severe in the respiratory tract, heart, and gastrointestinal tract. In cattle and buffalo there is rapid translocation of bacteria from the respiratory tract to the blood, liver, and spleen, suggesting that the bacteria are able to invade via the mucosal epithelial layers.[2] Colostral immunity of calves from cows vaccinated against hemorrhagic septicemia peaks at 8–16 weeks of age and then declines.[3]

CLINICAL FINDINGS

The disease is an acute septicemia and is clinically characterized by a sudden onset of fever (41–42°C, 106–107°F), profuse salivation, submucosal petechiation, severe depression and death in about 24 hours. On range lands, animals may be found dead without any clinical signs having been observed. Localization may occur in subcutaneous tissue, resulting in the development of warm, painful swellings about the throat, dewlap, brisket or perineum, and severe dyspnea may occur if the respiration is obstructed. In the later stages of an outbreak, some affected animals develop signs of pulmonary or alimentary involvement. *Pasteurella* may be isolated from the saliva and the bloodstream. The disease in pigs is identical with that in cattle.

CLINICAL PATHOLOGY

Culture and detection of bacteria

Laboratory diagnosis is by isolation and identification of the causative agent. The organism can be cultured from blood or a nasal swab from an animal within a few hours of death. Blood or a nasal swab during the clinical phase of the disease is not reliable because the septicemia is a terminal event. From older carcasses, a long bone is used for culture from the bone marrow. Samples of blood are injected into mice, which will die in 24–36 hours. Smears made from the mouse blood or cultures of mouse blood will reveal the organisms.

Serology

A rapid ELISA is now available for the identification of the specific serotypes of *P. multocida* responsible for hemorrhagic septicemia.

NECROPSY FINDINGS

At necropsy, the gross findings are usually limited to generalized petechial hemorrhages, particularly under the serosae, and edema of the lungs and lymph nodes. Subcutaneous infiltrations of gelatinous fluid may be present and in a few animals there are lesions of early pneumonia and a hemorrhagic gastroenteritis. Varying degrees of lung involvement range from generalized congestion to patchy or extensive consolidation. Thickening of the interlobular septa may be prominent. Lymph nodes in the thoracic region are enlarged and hemorrhagic. Isolation of the causative bacteria is best attempted from heart, blood, and spleen.

TREATMENT

The disease occurs chiefly in areas where veterinary assistance is not readily available, and no detailed reports of the efficiency of various forms of treatment have been published. Oxytetracycline has been shown to be highly effective in pigs and sulfadimidine in cattle and the other treatments listed under pneumonic pasteurellosis of cattle should also be effective in this disease.

CONTROL

The literature on hemorrhagic septicemic vaccines has been reviewed.[4] Vaccines have been used for many years to protect cattle during the dangerous periods but the method was only moderately effective until the recent introduction of a stable vaccine composed of killed organisms in an adjuvant base containing paraffin and lanolin. This vaccine has been highly effective, especially when used prophylactically, although vaccination in the face of an outbreak may also reduce losses.[1] Immunity after vaccination appears to be solid for at least 12 months and the only apparent disadvantage is the development of persistent subcutaneous swellings when the vaccine is improperly administered. Anaphylactic shock may occur in up to 1% of animals after the injection of some batches of vaccine. A potential refinement in the vaccine used is suggested by the finding that endotoxin-free capsular antigen of *P. multocida* types B and E is capable of immunizing cattle against challenge.

Plain broth bacterins, or alum-precipitated and aluminum hydroxide gel vaccines are administered twice a year since these vaccines offer immunity of 4–6 months.[4] Many countries use oil adjuvant vaccine (OAV), which gives both a higher degree and a longer duration of immunity, up to 1 year. A double emulsion and a multiple emulsion vaccine of a thin viscosity have also been experimentally developed that provide immunity parallel to the OAV.

A live streptomycin-dependent mutant *P. multocida* vaccine provides good protection. A live vaccine containing *P. multocida* serotype B:3,4 isolated from a fallow deer in England has been developed and in preliminary field trials provided good protection.[4,5] It protects cattle and buffaloes against B:2,5 challenge.[5] Although the subcutaneous inoculation of the vaccine in buffalo calves under 5 months of age caused severe reactions and mortality, intranasal aerosol application is safe and has been used in immunizing cattle and buffaloes over 6 months of age.[5] It has the advantages of

apparent absence of anaphylactoid shock, protection for up to 1 year, easy preparation and a relatively small dose, and when lyophilized has prolonged viability. Freeze drying would be necessary for large-scale production of the live vaccine.[5]

The Food and Agriculture Organization has reviewed development and use of the vaccine in Myanmar, has commended the intranasal use of live B:3,4 vaccine as safe and potent, and has suggested that the technology be transferred to other countries.

The *aroA* derivatives of the *P. multocida* B:2 strains are being examined as possible antigens for a live attenuated vaccine.[2] The safety and efficacy of these strains have been demonstrated in a mouse model of infection.[6]

The safety, efficacy, and duration of immunity of an improved oil-adjuvant vaccine containing inactivated cells of *P. multocida* serotype B:2,5 have been tested in young buffalo calves.[7] Protection was satisfactory. To test for cross-protection against the heterologous serotypes E:2,5 and B:3,4, groups of mice were vaccinated once or left unvaccinated. Four weeks later, the vaccinated and control groups were challenged with a dilution series of the different challenge cultures. The vaccine appeared to induce protection against challenge with different strains of serotypes B:2,5 and E:2,5 but not against strains of serotype B:3,4.

The safety, efficacy and cross-protectivity of a live attenuated aerosol hemorrhagic septicemia vaccine containing *P. multocida* serotype B:3,4 has been tested in young cattle and buffaloes in Myanmar, where more than 1.5 million animals were inoculated with the vaccine between 1989 and 1999.[8] A recommended dose of 2×10^7 viable organisms was used for the efficacy test. The administration of 100 times the recommended dose to 50 cattle and 39 buffalo calves was innocuous. Three of three buffaloes were protected 7 months after they were vaccinated, and 12 months after they were vaccinated, three of four buffaloes were protected against a subcutaneous challenge with serotype B:2, which killed three of three unvaccinated buffaloes, while 12 months after they were vaccinated, eight of eight cattle survived a serotype B:2 challenge that killed four of four unvaccinated controls. The vaccinated cattle had developed serum antibodies detectable by the passive mouse protection test. Indirect hemagglutination tests on sera taken from cattle 10 days and 5 weeks after they were vaccinated showed high titers on antibodies, The serum of vaccinated cattle cross-protected passively immunized mice against infection with *P. multocida* serotypes E:2, F:3,4, and A:3,4.

The intranasal aerosol vaccination is safe, even at very high dose levels, and does not induce anaphylactic shock even after repeated vaccinations. The freeze-dried live vaccine is stable for at least 3 years at room temperatures of 30–36°C, and thus a 'cold chain', which is impracticable for many hemorrhagic-septicemia-endemic areas, is not necessary for the storage and transport of the vaccine.

BOVINE RESPIRATORY DISEASE: ACUTE UNDIFFERENTIATED BOVINE RESPIRATORY DISEASE

DEFINITION OF THE PROBLEM

A major problem which large animal clinicians commonly encounter is a group of cattle that are affected with an acute respiratory disease of uncertain diagnosis.

Acute undifferentiated bovine respiratory disease (UBRD) is characterized clinically by dyspnea, coughing, nasal discharge, varying degrees of depression, inappetence to anorexia, a fever ranging from 40–41°C, evidence of pneumonia on auscultation of the lungs, and a variable response to treatment. Some unexpected deaths may have occurred as the initial indication of the problem.

In most cases, pneumonia is the cause of the disease but determining the etiology is the formidable diagnostic problem. If lesions typical of any of the common diseases of the respiratory tract of cattle can be recognized clinically, like those of infectious bovine rhinotracheitis, then on a clinical basis a specific diagnosis can be made.

The affected group may be recently weaned beef calves in a farm feedlot; weaned beef calves or yearlings that have recently arrived in a feedlot; cattle that have been in the feedlot for varying periods of time; young growing cattle on summer pasture or mature cows that have recently been placed on a lush pasture; yearling or mature lactating dairy cattle; or a group of veal calves.

The morbidity rate can range from 10–50% depending on the age of animals affected, the immune status of the animals, the nature of the stressors involved and the nature of the disease. In a study of mortality ratios among US feedlots over a 5-year period (1994–1999), the relative risk of death attributable to respiratory tract diseases increased during most years of the study.[1] Cattle entering the feedlots during 1999 had a significantly increased risk (relative risk, 1.46) of dying of respiratory tract diseases, compared with cattle entering in 1994. Respiratory tract diseases accounted for 57.1% of all deaths. Dairy cattle had a significantly increased risk of death of any cause, compared with beef steers, and beef heifers had a significantly increased risk of dying of respiratory tract diseases compared with steers.

In general, bovine respiratory disease accounts for 65–79% of the morbidity and 44–72% of mortality in feedlot cattle. In addition to direct costs associated with death loss and medical treatment, losses attributable to decreased growth performance associated with the incidence of bovine respiratory disease may also occur. Cattle with detectable lung lesions at slaughter had a reduced (0.08 kg/d) growth rate compared with cattle without lesions. Also, 68% of cattle with lung lesions at slaughter were never treated for bovine respiratory disease, suggesting that current methods of diagnosing bovine respiratory disease based on visual appraisal by feedlot pen riders may not always effectively identify sick animals. In general, medical treatment is more effective the earlier in the process it can be initiated. The limitations of identifying clinically affected animals that need therapy was a major factor in the development of metaphylactic use of antimicrobials.[2]

The primary goal of the clinician is to make the most accurate clinical diagnosis as rapidly as possible, based on the clinical and epidemiological findings that are identifiable on the farm, preferably when examining the animals on the first visit. Giving a prognosis and the formulation of rational and economic treatment that will minimize morbidity and mortality are the next goals. The outbreak may involve a herd of lactating dairy cows, and the selection of antimicrobials used can have a major impact on the length of time the milk from treated cows must be discarded. In any group situation, mass medication of each in-contact animal is a major consideration that will increase costs and must be balanced against the economic losses that might occur if all animals are not treated prophylactically. The clinical management of the outbreak, which includes treatment of the obvious cases and the prevention of new cases if possible, is dependent in part on the diagnosis. However, differentiation between the diseases based on clinical findings can be unreliable and it is usually

necessary to begin antimicrobial therapy that will be effective against the bacterial pathogens most likely to be present. The specific cause may or may not be determined by laboratory examination or further clinical and epidemiological examination. Even after intensive clinical and laboratory investigation, the specific etiology will often not be determined and the clinician is left with a diagnosis of '**acute undifferentiated respiratory disease of cattle**' or **bovine respiratory disease**.

The salient clinical and epidemiological findings of the diseases included in the complex of bovine respiratory disease are summarized in Table 18.5. The common diseases of the respiratory tract of cattle can be broadly divided into those affecting the lower respiratory tract and those affecting the upper respiratory tract. Diseases of the lungs associated with either viruses or bacteria alone or in combination are difficult to distinguish from each other on the basis of clinical findings alone. Thus in a group of cattle with pulmonary disease it may be difficult to distinguish between pneumonic pasteurellosis, *Haemophilus* pleuropneumonia and the viral interstitial pneumonias with or without secondary bacterial infection. The presence of toxemia, which causes depression and anorexia in bacterial pneumonias, is a useful guide in categorizing the common diseases when making a differential diagnosis list. Cattle affected with uncomplicated viral diseases of the respiratory tract are usually not depressed and anorexic because bacterial toxemia is absent.

Table 18.5 Differential diagnosis of bovine respiratory disease

Disease	Epidemiology	Clinical and laboratory findings	Response to treatment
Pneumonic pasteurellosis (shipping fever)	Common disease in North America. Young cattle recently stressed by weaning or transportation, mixing from many different sources, many animals affected, some found dead, common in feedlots. Epidemics occur 7–10 days after arrival in the lot but cattle may be sick on arrival or within a few days after arrival	Acute toxemic bronchopneumonia, moderate dyspnea, fever, increased breath sounds over ventral aspects of lungs, moist crackles, cough, pleuritis. Leukopenia and neutropenia in severe cases	Good response to treatment in early stages. Failure to respond due to advanced lesions, pleuritis, abscesses, inadequate dosage, and incorrect diagnosis
Viral interstitial pneumonia (parinfluenza-3 virus, bovine respiratory syncytial virus (BRSV))	Yearling and adult cattle indoors or outdoors, young cows in closed dairy herd, may occur following addition to herd, high morbidity, low mortality	Sudden onset of acute pneumonia, moderate dyspnea and toxemia, loud breath sounds and wheezes due to bronchiolitis, no moist crackles unless secondary pneumonia. Leukopenia and lymphopenia	Gradual recovery occurs in 3–5 days. Treat secondary complication with antimicrobials
Enzootic pneumonia of calves	Common disease in housed dairy calves, occasionally in pastured beef calves 2–6 months of age	Acute, subacute, and chronic pneumonia, moderate fever, loud breath sounds ventrally, crackles and wheezes	Respond favorably to treatment for uncomplicated secondary bacterial bronchopneumonia
Bovine respiratory syncytial virus infection	Young cattle 6–8 months of age, adult dairy cattle, herd outbreaks are characteristic; case fatality rate varies from 1–30%. Maternal antibody in calves is not protective	Inappetence, fever, coughing, dyspnea, and abnormal lung sounds suggestive of interstitial pneumonia. Death common in those with severe respiratory distress. Fourfold or greater seroconversion to BRSV. Immunofluorescence of nasopharyngeal smears and virus isolation. Acute bronchiolitis and alveolitis	Treat secondary complications with antimicrobials for 3–5 days
Histophilus somni (formerly *Haemophilus somnus*) pneumonia, pleuritis, and myocardial abscesses	Common in feedlot calves, 6–8 months of age; mean fatal disease onset for pneumonia is 12 days after animal in the lot, and day 22 for myocarditis and pleuritis	Toxemic suppurative pleuropneumonia, dyspnea, mouth breathing. Persistent fever for several days. Concurrent myocarditis may cause sudden death	Inadequate response to treatment
Infectious bovine rhinotracheitis	Common disease. All age groups but mostly young feedlot cattle, outbreaks common, occurrence unpredictable. Most common in unvaccinated herds	Acute rhinotracheitis with discrete nasal lesions, inspiratory dyspnea, explosive loud coughing, ocular and nasal discharge, high fever 3–5 days. 1% die of secondary bacterial pneumonia. Virus isolation from nasal swabs. Acute and convalescent serology	Gradual recovery occurs in 3–5 days in spite of treatment. Treat secondary pneumonia
Mycoplasma bovis pneumonia	Feedlot cattle with history of respiratory disease. Dairy calves with enzootic pneumonia. Mastitis in lactating dairy cows	Acute to chronic bronchopneumonia, anorexia, fever, polyarthritis, otitis. Exudative bronchopneumonia, extensive foci of coagulative necrosis. Nasal swabs, joint fluid, lung tissue	No response to antibiotic therapy
Epidemic acute interstitial pneumonia (acute pulmonary emphysema and edema, fog fever)	Occurs 4–10 days after adult cattle turned into lush autumn pasture. Outbreaks usual, sudden onset, high case fatality. Common in beef cattle in North America	Sudden and rapid death, severe loud dyspnea with grunting expiration, loud breath sounds over ventral aspects, crackles, subcutaneous emphysema, severe cases die, laboratory data not helpful, confirm at necropsy	Most severe cases die, moderate to mild cases recover, treatment difficult to evaluate. Can be prevented with monensin in the feed for a few days before and after change of pasture

Table 13.5 (*Cont'd*) Differential diagnosis of bovine respiratory disease

Disease	Epidemiology	Clinical and laboratory findings	Response to treatment
Acute or chronic interstitial pneumonia (bovine farmer's lung)	Extrinsic allergic alveolitis. Not common. Mature cattle housed during winter months and exposed to moldy or dusty feeds. Several animals over period of time	Chronic coughing, dyspnea, weight loss, reduced milk yield, loud breath sounds, crackles, dull but not toxemic, abnormal nasal discharge	No response to treatment
Chronic interstitial pneumonia (diffuse fibrosing alveolitis)	Single animals only. May be chronic form of epidemic acute interstitial pneumonia	Chronic onset of coughing, dyspnea, weight loss, reduced milk yield, decreased breath sounds, no toxemia, cor pulmonale	No response to treatment
Verminous pneumonia (*Dictyocaulus viviparus*)	All ages susceptible, usually young cattle 6–12 months on pasture, wet warm seasons, outbreaks common, enzootic area	Moderate to severe dyspnea, coughing, fever, loud breath sounds, crackles over **dorsal half of lung**, eosinophilia may occur, larvae in feces 3 weeks after infection	No response to antimicrobials. Responds to anthelmintics
Ascaris suis pneumonia	Not common. All ages. On pasture previously occupied by pigs	Sudden onset, severe dyspnea, rapid deaths, loud breath sounds, crackles over entire lung. Will recover gradually if not too severe	No specific treatment response
Allergic rhinitis (summer sniffles)	Mostly late summer, autumn when pasture in flower. Sporadic cases. Mostly Channel Island breeds. Cows may have disease each year	Sudden onset, dyspnea, inspiratory wheezing, mucopurulent then caseous yellow to orange nasal discharge. Sneeze, rub muzzle in bushes, twigs up nose, bleed	Into housing, antihistamines, excellent response if early. In cases of long duration, wheezing persists until nasal mucosa sloughs
Pulmonary abscess	Single animal. History of pneumonia with no response to treatment. Occasionally, several cases in feedlot	Chronic coughing with epistaxis and hemoptysis, chronic toxemia, mild fever, crackles and wheezes distributed randomly. Neutrophilia	Nil
Calf diphtheria	Young calves, dirty conditions or on rough dry pasture. Usually only few affected	Acute toxemia, fever, inspiratory stridor and stertor, necrotic lesions visible in larynx and oral cavity	Responds to antimicrobials and topical treatment
Embolic pneumonia due to ruptured vena caval abscess	1–8 years of age. History of respiratory disease with hemoptysis and epistaxis and poor response to treatment	Dullness, polypnea, hyperpnea, thoracic pain, frequent coughing with hemoptysis, epistaxis, temperature variable, anemia. Common, widespread foci of crackles and wheezes with increased breath sounds. May die rapidly from massive hemorrhage. Hepatomegaly and congestive heart failure. Neutrophilia and hypergammaglobulinemia	No response to treatment. Slaughter for salvage
Aspiration pneumonia	History is important. Following faulty drenching techniques or regurgitation and aspiration in weak cows (i.e. milk fever)	Acute bronchopneumonia with toxemia. 24–48 hours following aspiration. Loud breath sounds ventral half, moist crackles. Marked leukopenia and neutropenia	May respond to treatment if treated early
Dusty feed rhinotracheitis	Few days following introduction of finely chopped dry feed. Feed contains high concentrations of 'fines'	Outbreak of coughing, rhinitis with copious serous nasal discharge, conjunctivitis and ocular discharge. Bright and alert	Recover in few days following removal of dusty feed
Enzootic nasal granuloma	In enzootic area up to 30% morbidity in a herd, up to 75% of herd. Coastal regions, autumn is worst, Channel Island breeds most affected. Loss is due to continuous loss of production. A chronic debilitating disease. All ages, mostly adults	May be acute 'summer sniffles' early. Then chronic dyspnea with stertor, eat indifferently, lose condition, have to be culled. Chronic nasal discharge. Smear nodules on nasal cavity mucosa palpable through nostril	Nil
Contagious bovine pleuropneumonia	Outbreak in susceptible cattle – morbidity up to 100%, mortality up to 50% if cattle stressed, traveling. Aerogenous spread, no mediate contagion. Outbreaks due to introduction of cattle often inapparent 'carriers' that are detectable by CF test. Incubation period 3–6 weeks	Acute fibrinous pneumonia and pleurisy. Dyspnea, fever 40.5°C (104.5°F), deep cough, shallow, fast, elbows out, grunting respiration. Pain on chest percussion. Pleuritic friction rub early, moist crackles. Course 3 days to 3 weeks	Not to be treated. Eradication is urgent. Is treated in enzootic areas where control is not attempted

ETIOLOGY

The major etiological agents which cause or may be associated with acute UBRD include the following:

- Viruses
  - Bovine herpesvirus-1
  - Bovine respiratory syncytial virus
  - Parainfluenza-3 virus
  - Bovine virus diarrhea virus
  - Bovine coronavirus
- Bacteria
  - *Mannheimia haemolytica*
  - *Pasteurella multocida*
  - *Histophilus somni (formerly Haemophilus somnus)*
- *Mycoplasma* spp.
  - *Mycoplasma bovis*
  - Contagious bovine pleuropneumonia
- Uncertain or unknown etiology
  - Acute interstitial pneumonia
- Verminous
  - *Dictyocaulus viviparus.*

Role of etiological agents

The role of the etiological agents in the cause of acute undifferentiated respiratory disease in cattle has been controversial and often uncertain because the major pathogens of bovine respiratory disease are ubiquitous in clinically normal animals. The disease is considered to be the result of the effects of stressors causing immunosuppression, which allows colonization of the respiratory tract by opportunistic pathogens. The spectrum of the immune status of the animals is also a major factor. Animals vaccinated well before natural infection will usually be immune to specific pathogens. Animals that have had the natural infection and have adequate humoral immunity, or cell-mediated immunity in the case of some infections, will be immune to clinical disease.

Many epidemiological studies of bovine respiratory disease have attempted to correlate the level of serum antibodies in feedlot calves on arrival at the feedlot and over the first 30–50 days of the feeding period with morbidity and mortality due to bovine respiratory disease. A low level of antibody to a specific pathogen on arrival followed by significant seroconversion in animals that develop bovine respiratory disease in the first few weeks of the feeding period suggest that the pathogen was an important pathogen in the cause of cases of the disease. Conversely, those animals with a high level of antibody on arrival that do not develop bovine respiratory disease are considered immune. However, some animals with low levels of antibody may remain normal and seroconvert during the early part of the feeding period.

Feedlot cattle commonly seroconvert to the viruses of infectious bovine rhinotracheitis (IBRV), parainfluenza-3 virus (PI-3V), bovine virus diarrhea virus (BVDV), and bovine respiratory syncytial virus (BRSV),[3] and to *Mycoplasma bovis* and *Mycoplasma dispar*, within the first month after arrival.[4] Seroconversion to these pathogens occurs both in animals that develop respiratory disease and those that remain normal within the same group, but the relative importance of each agent and their causative nature is controversial. Seroconversion to *M. haemolytica* cytotoxin, BRSV and BVDV were predictive of approximately 70% of all respiratory disease cases in Ontario feedlots.[3] Calves arriving in Ontario feedlots with high serum antibody levels to *Histophilus somni* (formerly *Haemophilus somnus*) had less bovine respiratory disease than calves with lower levels.[5]

Many respiratory pathogens that could cause disease are present in both individuals and groups of feedlot cattle after they are mixed and during outbreaks of bovine respiratory disease.[3] Which ones are most important and causing disease is a major question. It has been suggested that undifferentiated bovine respiratory disease in weaned beef calves entering a feedlot is not a contagious disease and that, while respiratory pathogens may be necessary causes of the disease, they are not sufficient causes.[3] This suggests that groups of animals experiencing a high incidence of bovine respiratory disease have been highly stressed and that it may be more important to identify and prevent the environmental and managemental risk factors.

The relationships between bacterial and viral antibody titers and undifferentiated fever and mortality in recently weaned beef calves in western Canada were examined.[6] Feedlot calves are commonly exposed to *M. haemolytica*, *H. somni*, bovine herpesvirus (BHV)-1 G-IV glycoprotein, BVDV, *M. bovis*, and *Mycoplasma alkalescens* in the early feeding period.[6] Seroconversion to *M. haemolytica* antileukotoxin was associated with a decreased risk of undifferentiated fever. Higher arrival BVDV antibody titer was associated with a decreased risk of undifferentiated fever. Higher arrival *H. somni* antibody titer and increases in *H. somni* antibody titer after arrival were both associated with a decreased risk of undifferentiated fever. The odds of overall mortality (OR 5.09) and hemophilosis mortality (OR 11.31) in clinical cases were higher than in the controls. In summary, protective immunity to *M. haemolytica* antileukotoxin *H. somni*, BHV-1 G-IV glycoprotein, BVDV, and *Mycoplasma* spp. may be necessary to reduce the occurrence of undifferentiated fever.

The association between exposure to *H. somni* and *M. haemolytica* and the risk of acute UBRD was examined using serological evidence of exposure and a vaccine field trial.[7] Vaccination with *H. somni* in combination with *M. haemolytica* and with *M. haemolytica* alone reduced the risk of UBRD. There was no association between serological evidence of concurrent exposure to *M. haemolytica* and UBRD occurrence. Treated animals tend to have lower titers to *H. somni* compared to untreated animals.

Chronic, antibiotic-resistant pneumonia, sometimes with polyarthritis, occurs in feedlot cattle in western Canada.[8,9] *M. bovis*, BVDV, and *H. somni* are commonly found in the tissues at necropsy. This coinfection suggests the possibility of synergism between the BVDV and *M. bovis* in the pneumonia with the arthritis syndrome.

BVDV has been identified as a contributor to respiratory disease in feedlot calves. On arrival in feedlots, 39% of animals were seropositive for BVDV, and those animals treated for UBRD had larger titer increases to the virus than nontreated animals.[10] The virus has been demonstrated by experimental infections of the respiratory tract, isolation of the virus and/or identification of BVDV antigen in tissues and demonstration of active infection through seroconversion in groups of cattle with bovine respiratory disease. BVDV-1b strains have been associated with acute pneumonia in commingled calves that were not vaccinated with BVDV vaccines, and in which *M. haemolytica* and *P. multocida* were also present in the pneumonic lesions.[11] Experimental infection of seronegative and immunocompetent calves with BVDV type resulted in primary respiratory disease.[12]

Bovine coronavirus (BCV) has been implicated as a cause of UBRD based largely on the isolation of the virus from the nasal cavities of cattle with respiratory disease. However, based on seroepidemiology of BCV titers in feedlot cattle, although higher antibody titers to the virus were associated with a decreased subsequent risk of treatment for UBRD, there was no association between evidence of recent infection (titer increase) and the occurrence of UBRD.[13] Other studies have shown that BCV infections are not associated with an increased risk of treatment for UBRD.[10]

BCV is widespread in the cattle population and can be isolated from nasal swabs from cattle with bovine respiratory disease. The virus can be found in the feces and nasal swabs of recently arrived feedlot cattle and calves with and without clinical signs of bovine respiratory disease.[14] Exposure to BCV prior to arrival in the feedlot is common, with 90% of animals

being seropositive on arrival.[10] BCV can be isolated from feedlot cattle in many different locations and most cattle seroconvert to the virus during the first 28 days after arrival in the feedlot.[15] Cattle shedding the virus from the nasal cavity and developing an antibody response to the virus were 1.6 times more likely to require treatment for respiratory disease than cattle that did not shed the virus or develop an immune response. Cattle that shed the virus from the nasal cavity were 2.2 times more likely to have pulmonary lesions at slaughter than cattle that did not shed the virus.[16] In natural outbreaks of shipping fever, more than 80% of affected cattle shed BCV at the beginning of the epidemic when the *M. haemolytica* infection rate was low.[17]

Intranasal vaccination of backgrounded feedlot cattle with a BCV vaccine reduced the risk of bovine respiratory disease.[18] Vaccination had the greatest effect on calves with intranasal BCV, and on those with antibody titers less than 20, on entry.

The role of BCV in epidemics of shipping fever pneumonia in cattle was examined by the collection of nasal swabs and serum samples prior to the onset of the epidemic, during the course of the illness and after death when necropsies were done and samples of lung tissues were examined.[19] Respiratory BCV (RBCV) was isolated from the nasal secretions before and after transport, from lung tissues of those cattle that died early in the epidemic but not later. *Pasteurella* spp. were isolated from all cattle that had severe pneumonia. All cattle were immunologically naive to both infectious agents at the onset of the epidemic but those that died after day 7 had rising antibody titers to RBCV and *M. haemolytica*. In contrast, the 18 clinically normal and RBCV isolation-negative cattle had high HAI antibody titers to RBCV from the beginning, while their antibody responses to *M. haemolytica* were delayed. Application of Evan's criteria for causation were applied to the findings identified RBCV as the primary inciting cause in the epidemics. Because of the multifactorial nature of bovine respiratory disease, the criteria used are as follows.

Evan's criteria for causation

1. The virus infects the mucosa of respiratory tract passages and lungs of affected cattle
2. The virus can be isolated in cell cultures at high rates from respiratory secretions and lung samples during the pathogenesis of bovine respiratory disease
3. Virus-specific immune responses are observed in cattle that recover from bovine respiratory disease. Rising titers of HAI antibodies against RBCV were detected in all surviving calves that had RBCV infections on days 0, 5 and later. They developed typical primary antibody responses to RBCV infections characterized by rises in IgG1 and IgG2. In contrast, the RBCV isolation-positive cattle with fatal outcomes had no or low titers of HAI antibodies against RBCV in the early stages of the epidemics. These cattle developed only initial IgM responses to RBCV infections before they died
4. Viruses isolated from cattle with bovine respiratory disease are not isolated from clinically normal cattle but they may be detected in the pathogenesis of other respiratory tract diseases
5. Cattle with significant antibody titers against the virus do not develop bovine respiratory disease, which occurs in cattle without such immune protection
6. Elimination of the virus factor prevents or decreases the severity of bovine respiratory disease
7. The whole thing should make biological and epidemiological sense.

CLINICAL CASE DEFINITION AND EPIDEMIOLOGY

Clinical case definition

The most important part of the clinical and epidemiological examination is to determine the case definition, which includes the following questions.

What is the clinical disease that is present in the affected animals?

- Which body system is affected and where in that body system is the lesion?
- Do the animals have pneumonia, rhinitis, laryngitis, tracheitis, bronchitis or combinations of these abnormalities?

The clinician should attempt to make a clinical diagnosis by closely examining several typically affected animals and determine if the lesions are in the lower or upper respiratory tract. The presence of toxemia, depression, fever, anorexia, and agalactia in lactating dairy cattle indicates a primary or secondary bacterial infection. The presence of loud breath sounds (consolidation) and abnormal lung sounds (crackles and wheezes) indicates the presence of pneumonia. Diseases of the upper respiratory tract are characterized by inspiratory dyspnea, stridor, loud coughing, sneezing, wheezing, and lesions of the nasal mucosa. When a single animal is involved, such as a dairy cow, or a group of dairy cows, a close physical examination, including auscultation of the lungs and inspection of the nasal mucosae and the larynx, is usually done.

In commercial feedlots, where large numbers of clinically affected animals are processed daily, and time is an economically important factor, the clinical examination of affected animals may be cursory and limited to taking the rectal temperature of animals that have been identified as sick based on recognition of depression and the absence of clinical findings suggestive of disease of some body system other than the respiratory tract. In such instances, if depressed animals have a rectal temperature above a predetermined level of, for example, 40°C, they are considered to have bovine respiratory disease if no other clinical findings are detectable that are referable to organ systems other than the respiratory system. In such cases, a diagnosis of **acute undifferentiated fever of feedlot cattle** has been suggested.[20] In most cases, the thorax of these animals is not auscultated for evidence of pneumonia. As a result it is probable that the number of animals with respiratory disease is overestimated. Undoubtedly, some sick feedlot animals have a fever of undetermined origin unassociated with respiratory disease or any other inflammatory lesion. In a pen of recently arrived cattle in a feedlot, many animals that appear normal will have rectal temperatures above the critical temperature without any clinical evidence of bacterial infection that requires treatment. The elevated temperatures of these animals will return to within normal ranges within a few days.

The subjective clinical findings of distant examination that have been used by animal attendants in commercial feedlots to identify sick animals that need to be closely examined include: degree of ruminal fill (1, normal; 2, slightly gaunt; 3, moderately gaunt; 4, excessively gaunt), attitude (1, normal; 2, slight lethargy; 3, severe lethargy; 4, nonambulatory), ocular discharge (1, none; 2, slight; 3, moderate; 4, abundant), nasal discharge (1, none; 2, slight; 3, moderate; 4, abundant).

The sounds heard on auscultation of the lungs at three sites along a line extending from the cranioventral to caudodorsal lung fields (1, normal; 2, slightly harsh; 3, moderately harsh; 4, severely harsh).

The feeding and watering behavior of healthy and sick animals in a commercial feedlot has been examined using radiofrequency technology to record individual animal behaviors.[21] Eating and drinking behaviors are associated with clinical signs of bovine respiratory disease but there is no obvious predictive association between signs of bovine respiratory disease in recently arrived weaned beef calves and eating and drinking behavior.[22]

Calves that were sick had greater frequency and duration of drinking 4–5 days after arrival than calves that were not sick. Sick calves had significantly lower frequency and duration of eating and drinking 11–27 days after arrival but had greater frequency of eating 28–57 days after arrival than calves that were not sick. Calves at slaughter that had a higher percentage of lung tissue with lesions had lower frequency and duration of eating 11–27 days after arrival but had greater frequency and duration of eating 28–57 days after arrival. Agreement of calves being sick and having pulmonary lesions at slaughter was adequate. Agreement for calves being removed and having pulmonary lesions at slaughter was low. Experimentally, the electronic acquisition of feeding behavior data for feedlot cattle, when analyzed using cumulative sums (CUSUM) procedures, offers the potential for predicting morbidity before conventional visual methods of appraisal. The feeding behavior during the first 30 days cattle are in a receiving pen may be used to detect animal morbidity approximately 4.1 days earlier than conventional methods typically employed in commercial feedlots.[23] Overall accuracy, positive predictive value and sensitivity of the CUSUM prediction method were 87, 91, and 90%, respectively.[23]

There is a need to improve our clinical diagnostic techniques and to develop new ones that can be applied to making a rapid and accurate diagnosis beside the animal in the field situation. To base a diagnosis of acute respiratory disease on the presence of depression, which has a component of observer subjectivity, and a fever results in the unnecessary treatment of many animals, which is uneconomic and potentially promotes undesirable antimicrobial resistance and residues in milk and meat.

Who is affected?

This includes age of animals affected, a single animal or group of animals, and vaccination history. Recently arrived feedlot cattle mixed from many different origins are susceptible to fibrinous pneumonia associated with *M. haemolytica.*

Where are the affected animals?

Are they in the feedlot, on pasture, or housed in a barn with what quality of ventilation?

When were the animals affected?

- How soon after arrival in the feedlot did the animals become affected?
- What stressors may have recently preceded the outbreak?
- What risk factors could have predisposed to this outbreak?
- Have the animals been recently shipped and mixed with animals from another source?

Consideration of the clinical and epidemiological findings can then be correlated, and hypotheses formulated and tested to determine **why** the disease occurred.

Occurrence

Bovine respiratory disease occurs under many different situations, including all age groups, feedlot animals kept outdoors, housed dairy calves, nursing and recently weaned beef calves, dairy and beef cattle heifers, and adult lactating dairy cows. Epidemics of acute respiratory disease have been described in dairy calves from birth to 6 months of age.[24,25] Outbreaks of BRSV can occur in dairy cattle heifers and adult dairy cattle.[26]

Pneumonic pasteurellosis is most common in recently arrived feedlot calves. In calves 3–5 weeks after arrival in the feedlot, *H. somni* pleuropneumonia may be more likely. Acute interstitial pneumonia (pasture-induced) is the most likely diagnosis when confronted with an outbreak of acute respiratory disease in mature beef cattle that have been moved from a summer pasture to a lush autumn pasture within the last 4–10 days. Acute pulmonary disease in a few head of feedlot animals several weeks or months after arrival in the lot is probably an acute interstitial pneumonia, which may be associated with 3-methlyindole (3MI) metabolites.[27]

Risk factors

The risk factors that have been identified in outbreaks of respiratory disease in feedlot cattle include the purchase of cattle from auction markets, whereby cattle arrive at the feedlot over an extended period of time, and mixing of cattle from many different sources.[3] An epidemiological study of fatal fibrinous pneumonia in auction-market-derived feedlot calves in western Canada revealed that peak mortality occurred approximately 16 days after arrival at the feedlot.[28] The risk of fatal fibrinous pneumonia was consistently greater for calves entering the feedlot in November, shortly after the auction sales had peaked, when the feedlot was reaching capacity.[29] Mixing of calves from different farms was considerable, with a median of two calves per farm on truckloads arriving at the feedlot. Increased mixing at the auction markets was associated with increased fatal disease risk. The distance calves were transported by truck from the auction markets to the feedlot was not associated with fatal disease risk.[3] When the incidence of fatal fibrinous pneumonia was high, the disease clustered within truckloads or pens. Risk factors positively associated with disease clustering included increased mixing of calves from different farms at the auction markets, month of purchase, number of calves passing through the auction markets, and weather conditions at arrival.[28–31]

Transportation of feedlot calves increases serum concentration of oxidative stress biomarkers, which are related to episodes of bovine respiratory disease.[32] Transportation stress significantly decreases serum total antioxidant capacity and increases malondialdehyde concentrations in steer calves.[33] It is proposed that stressors such as marketing (through an auction barn) and transportation to the feedlot precipitate oxidative stress, which reduces the antioxidant defense capacity and increases total body lipid peroxidation, resulting in increased susceptibility to bovine respiratory disease. These biomarkers may be useful to measure the oxidative stress of transported cattle. There is some experimental evidence that acidogenic diets and ketoacidosis may affect lymphocyte function, which may affect vaccine efficacy.[34]

The literature on how the adequacy of diets of recently arrived feedlot cattle may affect their health and immunity has been reviewed.[35] Diets for newly arrived stressed beef cattle must be formulated to compensate for decreased feed intake and known nutrient deficiencies.

The literature on the risk factors for bovine respiratory disease in dairy heifers and the effect of the disease on productivity has been reviewed with relevance to commercial dairy farming in the Netherlands.[26] Bovine respiratory disease in dairy heifers increases the risk of mortality directly after the disease episode by up to six times, reduces growth during the first 6 months of life by up to 10 kg, and increases the likelihood of dystocia after first calving. Both herd size and other diseases in dairy heifers are clearly associated with the risk of bovine respiratory disease. Season and colostrum feeding are important. The most important risk factors for mild and severe pneumonia in dairy calves aged birth to 3 months were inadequate air circulation and the purchase of cattle.[24]

An epidemic of acute respiratory disease associated with BRSV occurred during the winter and spring of 1995 in Norway.[36] Data from 431 cattle herds were collected. The risk of acute respiratory disease occurring in cattle was related to herd size and type of production and an expressed interaction between these two variables. The risk of a herd outbreak in a mixed herd of 20 animals was estimated to be 1.7 times greater than in a dairy herd, and 3.3 times greater than in a beef herd of

comparable size. On increasing herd size to 50 animals, the risk increased 1.3-fold for a mixed herd, 3.3-fold for a dairy herd and 2.1-fold for a beef herd, compared to a risk for a corresponding type of herd of 20 animals. The disease spread initially from one location to another during the first 6–9 weeks; the rate of transmission between neighboring farms seemed to be higher than for the other districts included in the study. It was hypothesized that one common source of infection was involved in the outbreak and the case herds were clustered in time as well as spatially.[37] The average daily milk loss was estimated to be 0.70 kg per cow for 7 days after a herd outbreak compared with the period one week before.[38]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The clinician is limited in most situations to correlating clinical, epidemiological and necropsy findings in making a diagnosis. Diagnostic laboratories may not be readily available and their resources for microbiological and serological investigations may be much less than is needed for an accurate determination of causes. In the past, investigations of outbreaks of bovine respiratory disease have been incomplete and the interpretation of the findings almost impossible because one or more pieces of information were missing.

A number of important factors contribute to the difficulty of unraveling the etiologies in field outbreaks of respiratory disease. A review of the literature on the morbidity and mortality rates and disease occurrence in North American feedlots found differences in the definition of the terms used that makes the reports difficult to compare.[39] In addition, the case definition or the clinical diagnosis is invariably inadequately defined. In feedlots, the morbidity rate will range from 15–45% of cattle within 3 weeks after arrival and the population mortality rate varies from 1–5%. Respiratory diseases account for about 75% of the diseases. Three important items are to be considered:

- Case definitions should be clearly stated
- The population at risk should be precisely measured
- The period of observation must be stated.

A systematic method of data collection from the customized records of large feedlots has been developed and validated for use in the National Animal Health Monitoring System. The current collection of data from large feedlots provides an acceptable level of sensitivity and specificity for the program but it is important that the veterinarian makes regular clinical observations to validate the data.

The course of the disease, especially when animals have been treated, alters the gross and microscopic appearance of tissues and the microbiological (bacteriological, virological) and serological findings so that the animal's status is impossible to determine.

CLINICAL PATHOLOGY

Bacterial culture and antimicrobial sensitivity

Nasal swabs taken from clinical cases before treatment often yield a pure culture of pasteurellas but *M. haemolytica* biotype A serotype 1 is the most common isolate obtained from cattle with acute pneumonic pasteurellosis. The same serotype can usually be isolated from in-contact and apparently healthy calves. The antimicrobial sensitivity of the pasteurellas isolated can be done, but interpretation of the results is often difficult because it is not known whether the isolates from nasal swabs represent the organisms causing the lesions. Significant differences may exist between the antimicrobial sensitivities of isolates from nasopharyngeal swabs and those from the lung tissues. Thus it is not yet possible to recommend routine culturing and antimicrobial sensitivity determination of pasteurellas from nasal cavity or nasopharyngeal mucus from cattle with acute bovine respiratory disease. At the individual animal level, nasopharyngeal swabs and bronchoalveolar lavage reveal only moderate agreement; at the group level the isolation rates of various organisms are similar. In healthy calves monitored from the farm to the feedlot there was no relationship between the nasal flora and pulmonary lesions. The results of antimicrobial susceptibilities of bacterial pathogens isolated from the lung tissues of cattle with pneumonia over a period of years may provide some indication of trends in antimicrobial sensitivities but the results are not useful in making decisions about the selection of antimicrobial-affected animals.[40]

The literature on the principles of antimicrobial susceptibility testing of bacterial pathogens associated with bovine respiratory disease has been reviewed.[41] Two different methods are used. The Kirby–Bauer method is the traditional in vitro test of bacterial susceptibility or resistance to antimicrobials, which uses a disk containing a standardized concentration of an antimicrobial. Bacteria grow or fail to grow surrounding the disk, and results are interpreted as resistance or susceptibility of the bacteria to certain antimicrobials. The serial-dilution testing uses a broth or agar medium with selected dilutions of antimicrobials in 1:2 dilution steps. Results are expressed as susceptible, intermediate susceptibility or resistant and also as minimum inhibitory concentrations (MICs), which are considered more reliable. The MIC is defined as 'the lowest concentration of an antimicrobial that prevents visible growth of a microorganism in agar or broth dilution susceptibility test'.

It is important to adhere to standards set by the National Committee on Clinical Laboratory Standards/Veterinary Antimicrobial Susceptibility Testing Subcommittee (NCCLS/VASTS). Veterinary-specific breakpoints are determined by the NCCLS/VASTS through a consensus process based on reviewing pharmacokinetic, MIC, zone-diameter scattergram and clinical trial data relating to an antimicrobial application. The subcommittee selects MIC breakpoints and zone-interpretative criteria that best fit the definitions of susceptible, intermediate susceptibility and resistant.[41]

The most veterinary-specific breakpoints for pathogens in bovine respiratory disease have been determined for five antibiotics: ceftiofur, enrofloxacin, florfenicol, spectinomycin, and tilmicosin.[41] The breakpoints for oxytetracycline and chlortetracycline are adapted from human breakpoints developed for tetracycline.[41]

Virus isolation or detection

Nasal swabs may be submitted for isolation or detection of viruses such BVH-1, BRSV, bovine coronavirus.

Serology

Serum samples may be submitted for determination of the levels of specific antibody to suspected viral causes of the bovine respiratory disease. Paired acute and convalescent serum samples from both affected and normal animals in the herd are desirable. In a group of animals in a feedlot, or dairy or beef cattle herd, serology for a specific etiological agent may be followed over a period of time to determine seroconversion and its relationship to occurrence or absence of clinical disease.

Hematology

Plasma fibrinogen concentrations are elevated, paralleling the increase in body temperature, and are a more reliable indication of the presence of the lesion than clinical assessment. Young cattle with clinical signs of acute respiratory disease, a fibrinogen concentration greater than 0.7 g/dL, and a temperature greater than 40°C (104°F) are likely to have pneumonic pasteurellosis. Leukocyte counts are of little value, as a leukocytosis and neutrophilia occur in some animals but in others there may be a neutropenia

or no significant change. Acute phase proteins are increased within 24 hours following experimental intratracheal inoculation of *M. haemolytica* into calves. The availability of a rapid test for acute-phase proteins could assist in the field diagnosis of the disease and its possible differentiation from similar diseases.

NECROPSY FINDINGS

Necropsies should be done on all animals that die with the disease. In feedlots this is a means of obtaining daily information on the occurrence of specific diseases and on the efficacy of the animal health management program. The most common pathological finding is fibrinous pneumonia and coagulation necrosis, with varying degrees of the common complications such as pleuritis and pulmonary abscesses. One of the major problems in the diagnosis of feedlot pneumonia has been to assess the age of the lesions. Determining the age of a bacterial pneumonia with some accuracy would help the health management to assess whether or not the pneumonia was already present in the animal on arrival or whether a treatment failure resulted from late detection or from inadequate drug therapy. An attempt to age the lesions of bacterial pneumonia of feedlot cattle indicated that the degree and extent of necrosis and fibrosis offers the best opportunity to age the pneumonia. In acute interstitial pneumonia, the lungs are diffusely red-tan, enlarged, and do not collapse. All lobes are rubbery, wet, and heavy. Emphysema is present mainly in the diaphragmatic lobes and there is white froth in the trachea. In fibrinous pleuritis there are thick sheets of fibrin over the visceral and parietal pleura. The thorax contains fibrin and straw-colored fluid. In caudal vena caval thrombosis, the lungs contain pulmonary arterial aneurysms and abscesses. Blood clots are present in the airways and the liver has an abscess near the vena cava that contains a thrombus.

Tissue samples are submitted for histopathology and bacteriological and virological examination depending on the specific disease suspected. However, the length of time usually required to do the diagnostic work and interpret the results means that the procedure is expensive and to an extent inconclusive because the results are available only when the outbreak is over.

A method has been described of recording pulmonary lesions of beef calves at slaughter and the association of lesions with average daily gain.[42] Computer imaging technology can be employed to facilitate the capture of feedlot necropsy data.[25] A digital camera is used to capture necropsy findings and the images are electronically transferred to a central reference laboratory for veterinary interpretation and diagnosis.

Interpretation of results of clinical pathology and necropsy findings

A large body of information has been generated on the microbiology, and more recently molecular microbiology, of specific pathogens associated with bovine respiratory disease but only a small amount is applicable clinically. Insufficient effort has been directed towards integrating the information and applying it to the effective control of respiratory disease on the farm. Ideally, investigations of outbreaks of bovine respiratory disease should consist of in-depth examinations of a representative sample of the affected group and normal in-contact animals using a multidisciplinary approach involving clinical, epidemiological, and laboratory investigation. These procedures, especially those requiring detailed virological and serological examinations, are expensive and in the light of the economic status of cattle industries not likely to be lightly borne. But it will only be when such a multidisciplinary approach is brought to bear on bovine respiratory disease that we will improve our position with respect to knowing what actually occurs in outbreaks of the disease. Of paramount importance is the identification of risk factors, which, if valid, gives the clinician a powerful clinical tool for the clinical management and control of respiratory disease in cattle. Of even greater importance is the necessity for the clinician to visit the farm and conduct those clinical and epidemiological investigations that are necessary to solve the problem and to monitor the problem and the herd until recovery occurs.

TREATMENT

The principles of the clinical management of outbreaks of acute undifferentiated bovine respiratory diseases are:

- The clinician must visit the farm and do the clinical and epidemiological investigations necessary to solve the problem, to assist the owner or the animal attendants with the clinical management of the disease, and to monitor the problem and the herd until recovery occurs. Simply dispensing antimicrobials to the owner without clinical examination of the animals is inadequate and contradicts the intention of the veterinarian–client relationship. The veterinarian is professionally obliged to provide explicit instructions about medication of affected animals and the drug withdrawal requirements, and to keep adequate records of affected animals, treatments given and the results of laboratory examinations. A final report should be prepared by the veterinarian and sent to the owner
- Unless otherwise determined, when toxemia and fever are present it is assumed that a primary bacterial pneumonia is present or, if a viral interstitial pneumonia is suspected, then a secondary bacterial pneumonia may occur. Therefore, antimicrobial therapy is of prime importance
- New cases must be identified as soon as possible. This will require increased surveillance of the group to detect affected animals as soon as clinical abnormalities such as depression, nasal discharge, and dyspnea are noticeable
- New cases must be treated as soon as they are detected. Each treated animal should be suitably identified and a record kept of the initial body temperature and the treatment administered. If the outbreak is due to pneumonic pasteurellosis, failure to respond favorably to antimicrobial therapy or relapse that occurs a few days after an initial apparent recovery is usually due to late treatment. Delaying treatment until 48 hours after an experimental aerosol infection of *M. haemolytica* can prolong the course of the disease and increase mortality
- Any of the common antimicrobials must be administered parenterally daily for at least 3 days. Oxytetracycline at 10 mg/kg BW intramuscularly, procaine penicillin G at 30 000–45 000 IU/kg BW intramuscularly, or trimethoprim–sulfadoxine at 3 mL/45 kg BW intramuscularly are effective when given early in the course of the disease. Tilmicosin at a dose of 10 mg/kg BW subcutaneously is also effective. Florfenicol at 20 mg/kg BW intramuscularly and repeated 48 h later is also highly effective.[20] Florfenicol and tilmicosin are comparable for treatment of undifferentiated bovine respiratory disease in western Canada.[43] Florfenicol is superior to tilmicosin for the treatment of undifferentiated fever in feedlot calves that have previously received metaphylactic tilmicosin upon arrival in the feedlot in western Canada.[44] Enrofloxacin at 2.5–5.0 mg/kg BW intramuscularly daily for 3–5 days or a single dose of 7.5–12.5 mg/kg BW is effective for the treatment of bovine respiratory disease.[45]

In lactating dairy cows, antimicrobials with the shortest milk withdrawal times commensurate with effectiveness should

be used. Ceftiofur with no withdrawal period is now available for use in lactating dairy cattle. Milk from treated cows must be kept from the bulk milk supply until the stated withdrawal time has elapsed. Other antimicrobials that have been evaluated for the treatment of acute undifferentiated bovine respiratory disease include sulbactam–ampicillin and the fluoroquinolones.

A beneficial response to therapy should be apparent within 12–24 hours. The body temperature should decline significantly and the appearance of the animal and its appetite should be improved.

The response to treatment, or lack of it, is valuable information in making a final decision on cause. Animals that do not respond to treatment and die should be submitted to intensive necropsy examination and culture of affected lungs. One of the emerging problems inherent in such broad policies in treatment is public health concern with the amount of antibiotic residue in meat. Pressure is now being applied to use antimicrobials only when necessary, which necessitates a more accurate diagnosis. A good example of this problem is when cattle are treated with antibiotics for bovine respiratory disease but the diagnosis is then refined in a day or two to interstitial pneumonia and emergency slaughter is then the appropriate course of action. The cattle cannot be slaughtered until the withdrawal period for the specific antibody used has expired, by which time many of the cattle will have died anyway. The regular use of a particular antimicrobial in feedlots may increase the level of resistance to *M. haemolytica*.

When confronted with an outbreak, one of the major decisions to be made is whether or not to recommend mass medication of the water or feed supplies for several days or to administer an antimicrobial to all in-contact animals in an attempt to treat cases in the preclinical stage. Veterinarians commonly recommend the use of medicated water supplies as an aid in the treatment of outbreaks of acute respiratory disease, and field observations claim beneficial results. However, there is no validated information available to support a recommendation for a medicated water supply for treatment or prophylaxis in the face of an outbreak. Depending on the water supply system it can be difficult to deliver and maintain a constant concentration of a drug in the water supply; palatability of certain drugs can also be a problem. The medication of the water or feed supplies can also create a false sense of security in the animal attendants, who may not be as efficient in the selection of affected animals in the early stages of the disease.

There are no validated reports of the use of medicated feed as an aid to treatment for outbreaks of acute respiratory disease in cattle.

In an outbreak of acute respiratory disease in feedlot cattle when the daily morbidity rate reaches 6–10% the parenteral administration of long-acting oxytetracycline to all in-contact cattle at a dose of 20 mg/kg BW intramuscularly is recommended. Tilmicosin at 10 mg/kg BW subcutaneously is also effective in reducing the morbidity rate when given to beef calves on arrival in the feedlot or 72 hours later.[3] The intramuscular injection of two different formulations of oxytetracycline to high-risk feedlot calves on arrival can reduce the morbidity rate due to respiratory disease during the first 2 weeks on feed and for the entire feeding period by 15–19% and the mortality rate from fatal fibrinous pneumonia by 67–84%. Meta-analysis of field trials of antimicrobial mass medication for prophylaxis of bovine respiratory disease in feedlot cattle indicated that prophylactic parenteral mass medication of calves with long-acting oxytetracycline or tilmicosin on arrival at the feedlot would reduce morbidity rates.

CONTROL

The control of outbreaks of acute bovine respiratory disease will depend on mass medication or metaphylaxis, minimizing the effects of the risk factors and enhancing immunity by the judicious use of vaccines.

Mass medication or metaphylaxis

The parenteral administration of antimicrobials to each animal as a form of mass medication may assist in the reduction of morbidity and mortality rates due to respiratory disease. The use of long-acting oxytetracycline at a dose of 20 mg/kg BW intramuscularly to feedlot cattle on arrival significantly reduced morbidity and mortality rates. The combined use of long-acting oxytetracycline at a dose of 20 mg/kg BW intramuscularly on arrival followed by the oral administration of 25 g of sustained-release sulfadimethoxine on day 3 resulted in a 90% reduction in treatment days per calf purchased. Tilmicosin, given at a dose of 10 mg/kg body weight subcutaneously to calves on arrival in the feedlot or 72 hours later, can significantly reduce the morbidity rate due to respiratory disease and improve the rate of gain.[46]

A formulation of long-acting oxytetracycline (300 mg/mL) at a dose of 30 mg/kg BW intramuscularly is superior to the standard formulation of long-acting oxytetracycline (200 mg/mL) given at 20 mg/kg BW.[47] The 300 mg/mL preparation of oxytetracycline is also more cost-effective than tilmicosin.[48]

Mass medication of cattle on entry into feedlots in Australia with tilmicosin at 10 mg/kg BW grew 0.08 kg/d faster than cattle medicated with oxytetracycline at 20 mg/kg BW and nonmedicated cattle.[49] There was no significant difference in growth rate between oxytetracycline-medicated cattle and those not medicated on entry into the feedlot. Cattle medicated with tilmicosin had fewer treatments for all illnesses compared with cattle not given an antibiotic on entry to the feedlot and compared with cattle mass-medicated with oxytetracycline. Tilmicosin induces apoptosis in pulmonary neutrophils, leading to a reduction in leukotriene B4 synthesis, thereby reducing further amplification of the inflammatory injury of bovine respiratory disease. Preshipment medication with tilmicosin are not more effective than mass medication on arrival.[50]

The mass medication of feed supplies of newly arrived feedlot cattle has been investigated as a method of reducing the morbidity and mortality due to respiratory disease. The provision of chlortetracycline in the feed at a rate of 1, 2, or 4 g per head daily during the 2-week period after arrival reduced the number of calves that required treatment for respiratory disease.

Management of risk factors

As a general outline for the control of bovine respiratory disease the following factors are considered as contributing to disease and their effects must be minimized with suitable management and disease prevention techniques.

- Young growing cattle are more susceptible than mature cattle because of a lack of sufficient immunity. The mixing of young cattle of different origins requires increased surveillance to detect evidence of disease. Vaccination of calves at strategic times may be necessary
- Cattle purchased from various sources and mingled in a feedlot are more likely to develop bovine respiratory disease than cattle that have originated from one source. Some cattle will be highly susceptible and others relatively resistant because of differences in nasal flora and immunological, genetic, and nutritional backgrounds. A high level of management and constant surveillance are necessary to recognize, isolate, and treat clinical cases early in order to minimize morbidity and case mortality
- Rapid fluctuations in environmental temperatures and relative humidity, not only during the fall and winter months but also during warm seasons, will commonly precede outbreaks of respiratory diseases.

Every practical and economical management technique must be used to provide as much comfort as possible and to avoid overcrowding
- Inadequate ventilation is a major predisposing cause of respiratory disease of cattle raised indoors. This is of major importance in dairy herds during the winter months in temperate climates
- The weaning of beef calves during inclement weather may exacerbate the stress of weaning and commonly results in an outbreak of respiratory disease
- The stress associated with the marketing of cattle is a major factor. The movement of cattle through saleyards – where they may be overcrowded, mixed with cattle of many different origins, temporarily deprived of adequate feed and water, handled roughly while being sorted, weighed, tagged, blood sampled, vaccinated or injected with antibiotics and/or vitamins and then loaded on to uncomfortable vehicles and transported long distances without adequate rest stops – is stressful. The practice of preconditioning cattle before they enter the feedlot must continue to be examined to determine which aspects are most profitable.

Presale vaccination programs are designed to establish an effective immune response to common respiratory tract pathogens well in advance of any natural exposure that may occur while calves travel through the auction market or after they arrive in the feedlot. These programs usually require calves to be castrated, dehorned, and vaccinated against IBRV, PI-3V, BRSV, and BVDV. Some programs also require vaccination against *H. somni* and *M. haemolytica*. Presale conditioning programs involve these procedures but also include weaning and nutritional components. Most such conditioning programs require calves to be weaned and adjusted to a roughage and concentrate diet for at least 30 days prior to sale.

Presale vaccination and conditioning programs have increased and decreased in popularity since their introduction in the 1970s. Producers tend to be reluctant to adopt these practices, because there is no assurance they will be rewarded, in terms of price premiums, for their efforts. However, the establishment of special auctions in Ontario that feature large numbers of vaccinated or conditioned calves resulted in an increased interest in these management practices. Producers selling lots of vaccinated or conditioned feeder calves through special auctions received a premium sale price compared with lots of feeder calves sold through conventional auctions.[51] Vaccinated and conditioned calves were less likely to receive treatment for bovine respiratory disease during the first 28 days in the feedlot; but there was no difference in mortality.[52] Calves that received antimicrobials on arrival at the feedlot had a reduced risk of treatment for bovine respiratory disease compared with calves that did not.

Vaccines

While vaccines are available for the control of acute respiratory disease associated with IBRV, PI-3V, and *Pasteurella* spp., there are almost no reports available of their efficacy determined under scientifically designed field trials. Based on current immunological technology, efficacious vaccines are considered to be feasible. The vaccines have been evaluated by experimental challenge of vaccinated animals with specific pathogens in a laboratory environment. However, there is little scientific evidence available that the vaccines are protective against acute UBRD as it occurs in the 'real world' situation. Preshipment vaccination of beef calves 3 weeks prior to weaning with vaccines containing IBRV, PI-3V, *Pasteurella* spp., and *H. somni* did not reduce the incidence of UBRD compared to those unvaccinated.

***Pasteurella* bacterins and respiratory viral vaccines** have been used extensively in an attempt to control bovine respiratory disease. Many veterinarians and feedlot owners maintain that vaccination against respiratory disease is an essential component in their disease prevention programs, both to prevent specific disease of the respiratory tract such as clinical infectious bovine rhinotracheitis and to reduce losses due to respiratory disease in the first few weeks after arrival. However, a review of the literature on the efficacy of the vaccines available for the control of bovine respiratory disease concluded that there are few documented data to support the use of vaccines against respiratory disease under feedlot conditions. Efficacy refers to the ability of the vaccine to reduce overall treatment rate and/or increase weight gains economically.

In North America a large number of bacterial and viral vaccines are available for the control of bovine respiratory disease. There are single antigen or multiple antigen vaccines, modified live virus or inactivated virus vaccines containing one or more of the following antigens: *M. haemolytica*, *H. somni*, IBRV, PI-3V, BRSV, and BVDV. There are many multiple antigen vaccines containing combinations of the respiratory viruses, BVDV, *H. somni*, and *M. haemolytica*. In western Canada, it is more cost-effective to vaccinate auction-market-derived, fall-placed feedlot calves with a multivalent viral vaccine containing IBR, PI-3, BVD, and BRS viruses than a single univalent viral vaccine containing IBRV only.[53]

Selection of vaccines

The selection of which vaccine to recommend for the control of UBRD in feedlot cattle is currently not possible based on the efficacy information which is available to the veterinarian. The vaccines are used widely and many anecdotal claims for their effectiveness are made but there is little scientific evidence based on properly designed field trials that the vaccines are effective and economical in reducing the incidence or the consequences of respiratory disease such as suboptimal weight gain. The major problem has been that vaccine manufacturers have not conducted a sufficient number of well-designed field trials to evaluate the efficacy of the vaccine against naturally occurring disease in the field with vaccinated animals and unvaccinated animals as concurrent controls. In most cases the vaccines were approved for sale on the basis of tests for safety in animals, and the potency measured by a serological response to the vaccine or experimental challenge in animals under laboratory conditions.

The information available about the commercial vaccines currently used in Canada for protection against bovine respiratory disease has been reviewed.[54] The available vaccines offer protection against only IBRV, BVDV, BRSV, PI-3V, *M. haemolytica*, and *H. somni*. Various combination vaccines containing modified live virus, killed virus, bacterins, and/or bacterial culture supernatants/surface extracts are available.

Efficacy of vaccines

Meaningful field trials to evaluate vaccines for the control of bovine respiratory disease are difficult to achieve. The case definition of what is a 'case of respiratory disease' has been very general, such as the presence of anorexia, depression, and a fever. Therefore, when testing a vaccine for the control of pneumonic pasteurellosis, the conclusions reached may be questionable if the cause of the sick animals in either the vaccinated or control group is not known – thus the importance of case definition. In contrast to field trials, the measures used by the manufacturer in the laboratory challenge of the vaccine have been specific. In a field trial, the control group and the vaccinated groups must be comparable. Where more than one vaccine is used to control

respiratory disease in vaccinates and controls it is difficult to evaluate one of the vaccines or the components of a multiple antigen vaccine unless large numbers of animals are used. Another problem is the difficulty of having the controls and the vaccinates experience approximately the same risk of being affected with respiratory disease.

Field trials for bovine respiratory disease vaccines are often unsatisfactory because of inadequate planning, unsatisfactory experimental design and lack of monitoring. A check list of key elements to consider when assessing the clinical research published for a particular vaccine has been suggested. The following items should be considered:

- Has the vaccine been laboratory and field tested in randomized controlled field trials? If so, how many trials, and, in each case:
  - Were the control groups concurrent or historical?
  - How were the trial animals challenged?
  - Was the measure of outcome meaningful?
  - Were the biology and epidemiology of the disease considered?
  - Was the vaccine assigned randomly?
  - Were blinding techniques used to reduce bias?
  - What other potentially important biases are evident?
  - How likely is it that the result was a chance finding?
  - What are the differences between the trial animals and animals in your practice? Are these differences important with respect to the vaccine?

A field trial was conducted to compare the serological responses in weaned beef calves 6–8 months of age vaccinated against IBRV, PI-3V, BRSV, and BVDV. There were significant differences in serological responses among the various commercial vaccines. Antibody titers to IBRV were higher in calves vaccinated with modified-live virus IBRV vaccines than when the inactivated vaccine was used. Following double vaccination with modified-live virus IBRV and PI-3V vaccines, seroconversion rates and antibody titers were higher in calves vaccinated intramuscularly than in those vaccinated by the intranasal route. It is not known if these differences reflect differences in vaccine efficacy under field conditions. The effect of using multiple antigens in the same vaccine on the serological responses is not clear. In some cases, vaccines containing the BRSV antigen resulted in lower titers to BVDV and PI-3V than vaccines that did not contain the BRSV.

The following comments on the use of vaccines as an aid in the control of acute undifferentiated respiratory disease in feedlot cattle are based on the current information available.

Pasteurella *vaccines*

Because fibrinous pneumonia associated with *M. haemolytica* is the most common lesion associated with bovine respiratory disease in feedlot cattle, much of the emphasis has been on the development of effective vaccines for bovine pneumonic pasteurellosis. Based on the immunological and microbiological observations of both naturally occurring and experimentally induced pneumonic pasteurellosis it appears that effective artificial immunization of cattle is possible. High levels of naturally acquired antibody to *M. haemolytica* have been associated with protection against the disease.

Calves that recover from experimentally induced pneumonic pasteurellosis possess increased resistance to subsequent experimental challenge. Calves that were naturally exposed to *M. haemolytica* or exposed by vaccination subcutaneously or intradermally to the live organisms developed some resistance to experimental challenge and developed antibodies to all surface antigens and cytotoxin. Resistance to experimental challenge with the organism correlated directly with serum cytotoxin neutralizing titers. This supports the hypothesis that protection against experimental challenge with *M. haemolytica* may require an immune response to cytotoxin. This is supported by the observation that cattle that died from fibrinous pneumonia due to *M. haemolytica* had lower cytotoxin neutralizing activity in their sera than cattle from the same group that died from other causes.

Antibodies to leukotoxin and certain bacterial surface components appear to be important for resistance to disease. The basis of a recently introduced pasteurella vaccine is that vaccination of calves with a leukotoxic culture supernatant from pathogenic *M. haemolytica* provided some protection against experimental challenge with the organism. The vaccine has been evaluated in field trials in feedlots in Canada with variable results. In one trial, the vaccine was used on arrival in fall-placed calves and reduced the pull rate by 4%, the first relapse rate by 11.9% and the second relapse rate by 18.7%. There was an 8.2% decrease in the mean number of treatment days. Overall mortality was decreased by 49% and mortality rate due to fibrinous pneumonia was reduced by 50%. It appeared that vaccinated animals also responded more favorably than non-vaccinated animals. Vaccination of recently shipped nonpreconditioned calves with the vaccine in Ontario resulted in a slight decrease in morbidity, slight improvement in response rates and perhaps an important reduction in relapse rates. When the vaccine was combined with an intramuscular modified-live IBR/PI-3 virus vaccine, the morbidity rate was increased, the response rate was decreased and the mortality rate was increased in some groups. It appears that the use of modified-live virus vaccines in recently arrived calves is contraindicated; this is consistent with earlier observations in the Bruce County Project, where fall-placed calves were vaccinated on arrival with a modified-live virus vaccine.

The *Pasteurella* vaccine has also been evaluated in a field trial that compared its efficacy in calves vaccinated at the ranch 3 weeks prior to shipping to the feedlot, vaccination of ranch calves on arrival in the feedlot, and auction mart calves assigned to either receive or not receive the vaccine on arrival at the feedlot. The vaccine did not effect a change in morbidity rates or weight gain. Total mortality rates were increased significantly, and mortality rates from respiratory disease tended to be increased in ranch calves that were vaccinated at the ranch. In auction-mart-derived calves, the relapse rates were significantly lower in vaccinated calves. The source of calves was a major factor affecting the incidence and/or effects of bovine respiratory disease. Calves moved directly from the ranches to feedlots, regardless of vaccination status, had lower morbidity and mortality, and better weight gains, than calves purchased from auction marts.

Histophilus somni (*formerly* Haemophilus somnus) *vaccine*

A *H. somni* bacterin evaluated in a large number of feedlot cattle had no effect on the overall crude mortality rate; however, vaccination appeared to reduce the incidence rate of fatal disease and the mortality rate during the first 2 months in the feedlot, when risk of fatal disease onset was highest. The incidence of fatal disease onset was highest during the first week after arrival, which suggests that inclusion of a *H. somni* bacterin in a cow–calf preimmunization program might reduce the proportion of disease that occurs during the first week in the feedlot. Crude mortality and incidence of fatal disease onset during the second week were reduced significantly in the vaccinated steers. It was concluded that about 17% of fatal respiratory disease in the unvaccinated

steers could have been prevented by vaccination with the *H. somni* bacterin. Fibrinous pneumonia was the most common pathological diagnosis. Vaccinating calves twice with a killed whole-cell *H. somni* bacterin reduced the clinical and pathological effects of experimentally induced *H. somni* pneumonia.

Viral vaccines

Because prior infection of the respiratory tract with either IBRV or PI-3V may predispose to pneumonic pasteurellosis, the vaccination of beef calves 2–3 weeks before weaning and feedlot cattle 2 weeks before shipment to a feedlot has been recommended as part of a preconditioning program. The results are variable, but vaccination of calves at 3-6 months of age with an intranasal modified-live IBR and PI-3 virus vaccine has provided protection against experimental pneumonic pasteurellosis induced by aerosol challenge with IBRV followed 4 days later by an aerosol of *M. haemolytica*. It is important to vaccinate the calves at least 2 weeks before they are weaned, stressed, or transported to a feedlot.

A modified-live virus BRSV vaccine given to beef calves prior to weaning, at weaning or immediately after arrival in the feedlot was associated with a significant reduction in the treatment rate in one of three groups immunized prior to weaning and in calves immunized after arrival in the feedlot.[25] There was no significant effect of the vaccine on treatment rate in calves immunized at weaning, in calves immunized after arrival in a bull test station, or in yearlings immunized after arrival in the feedlot. It would appear that the vaccine did provide some protection but the small reduction may not justify the cost of the vaccination program.

Some feedlot veterinarians recommend that feedlot cattle be vaccinated on arrival with an *M. haemolytica* vaccine, the IBRV and PI-3V vaccine, an *H. somni* vaccine, and the BRSV vaccine. In some cases the BVDV vaccine is also used because some veterinarians feel that the virus is part of the respiratory disease complex. It is expected that control will be achieved if the animals are vaccinated against all the common pathogens that contribute to lesions of bovine respiratory disease. However, there is little, if any, published evidence based on controlled field trials that such blanket recommendations are justifiable.

PNEUMONIC PASTEURELLOSIS OF CATTLE (SHIPPING FEVER PNEUMONIA)

Synopsis

Etiology *Mannheimia (Pasteurella) haemolytica* biotype A serotype 1. *Pasteurella multocida* biotype A:3
Epidemiology Young growing cattle, especially recently weaned beef calves placed in feedlot. Can occur in nursing calves and mature cows. Stressors include transportation, mixing animals from many different sources, ineffective ventilation of housed animals
Signs Sudden deaths, acute bacterial bronchopneumonia, fever, toxemia, anorexia, abnormal lung sounds; respond to treatment with antimicrobials
Lesions Acute fibrinohemorrhagic pneumonia with pleuritis
Clinical pathology Culture organism from nasal swabs. Hemogram indicates severe infection and increase in fibrinogen
Diagnostic confirmation Culture organism from lung and histopathology of lung
Treatment Antimicrobials
Control Preconditioning programs. Management strategies to reduce stressors. Mass medication with antimicrobials of individual animals on arrival in the feedlot. Vaccines containing antigens of *M. haemolytica*

Differential diagnosis list
- Acute interstitial pneumonia due to BRSV
- Epidemic acute interstitial pneumonia (fog fever)
- Contagious bovine pleuropneumonia
- Enzootic pneumonia of calves
- *Haemophilus* pleuropneumonia of feedlot cattle
- Infectious bovine rhinotracheitis
- Verminous pneumonia (*Dictyocaulus viviparus*)
- Aspiration pneumonia

ETIOLOGY

Mannheimia (Pasteurella) haemolytica biotype A serotype 1 is the most common cause of the pneumonia.[1] Eleven serotypes have been demonstrated within *M. haemolytica*.[2] *M. haemolytica* serotypes 6, 2, 9, and 11 and untypable serotypes have been found in lesions of pneumonic pasteurellosis.[3] *M. haemolytica*-like bacteria have been isolated from cases of bovine pneumonia, and a careful characterization of such isolates is necessary for a proper identification.[4]

Biotype T strains have been isolated from cases of pneumonic pasteurellosis and *P. multocida* is isolated occasionally. *P. multocida* serotypes A3 and D can cause severe bronchopneumonia in calves.[5] The *Pasteurella* spp. are the final cause of the pneumonia but the mechanisms by which the bacteria enter and colonize the lung

and produce the lesions are complex and unclear. Viruses or mycoplasmas may act synergistically to allow the bacteria to be pathogenic. There is often a history of stressors such as:

- Transportation
- Mixing of groups of cattle from different sources
- Confinement of cattle
- Ineffective housing and ventilation.

EPIDEMIOLOGY

Occurrence

Pneumonic pasteurellosis is a common disease of young growing cattle in Europe, the UK, and North America. In Canada and the USA the disease occurs most commonly in recently weaned beef calves 6–8 months of age shortly after being placed into feedlots in the fall of the year. Nursing beef calves, yearlings, and mature dairy and beef cows may also be affected, but less frequently. Pneumonic pasteurellosis, also known as **shipping fever**, is an entity within the bovine respiratory disease complex, characterized clinically by acute bronchopneumonia with toxemia and pathologically by lobar, anteroventrally distributed, exudative pneumonia in which fibrin is usually a prominent part of the exudate and fibrinous pleuritis is common.

Morbidity and mortality

The morbidity may reach 35%, the case-fatality rate may range from 5–10%, and the population mortality rate may vary from 0.75–1%. However, these morbidity and mortality data may not be reliable because of wide variations in the methods used to calculate disease incidence and prevalence. A review of the literature of morbidity and mortality rates and disease occurrence in feedlot cattle in North America found deficiencies in the epidemiological data available from feedlots.[6] Case definitions of clinical cases are often poorly defined. A summary of 14 comparable studies containing disease incidence rates in calves in the first few weeks following arrival in feedlots found wide variations in how the disease definitions and statistics were used. The incidence of morbidity ranged from 0–69% with most reports between 15% and 45%. The population mortality rate ranged from 0–15% with most reports between 1% and 5%. The peak incidence of disease occurs within the first 3 weeks after arrival of the calves in the feedlot. The most common clinical and pathological diagnosis was respiratory disease, often described as shipping fever.

In order to make valid assessments of morbidity and mortality rates, it is imperative that case definitions are stated clearly, the population at risk is precisely measured and the period of observation is stated or incorporated into the rate.[7] The morbidity rates quoted for bovine respiratory disease are actually treatment rates based on treatment of animals that appear depressed, have a fever and have no signs to suggest disease of a body system other than the respiratory tract. Systematic methods of data collection from the customized records of large feedlots are now available[8] and have been validated by the National Animal Health Monitoring System.[9]

An observational study of the epidemiology of fatal fibrinous pneumonia in feedlot calves purchased from auction marts in western Canada and placed in a commercial feedlot between September 1 and December 31 over a 4-year period identified some valid information.[1] Peak fibrinous pneumonia occurred approximately 16 days after arrival at the feedlot; the median number of days between arrival and the first treatment of fatal fibrinous pneumonia cases varied from 3–8 days. The fatal fibrinous pneumonia mortality varied 11-fold (0.25–2.73%) between years. The fatal fibrinous pneumonia proportionate mortality varied from 10–57%. Fully 75% of the calves that died of fibrinous pneumonia already were sick within 2 weeks after arrival.[1] When the incidence of fatal fibrinous pneumonia was high (greater than 2%), the disease clustered, either within certain truckload groups of calves or within certain pens, or within both.[10] Clustering could have been due to contagious factors, noncontagious factors, or both.

Economic importance

Pneumonic pasteurellosis is a major cause of economic loss in the feedlot industry. It is responsible for the largest cause of mortality in feedlots in North America. In addition to the death losses, the costs of treatment (which include the personnel involved in the detection and actual treatment, the drugs used and the vaccines) are considerable. While it has been assumed that there is a loss of production following the illness, this has not been documented. In fact, because of compensatory regrowth in animals that have recovered there may be no correlation between average daily gain, feed conversion and treatment.

Risk factors

Animal risk factors

The disease occurs most commonly in young growing cattle from 6 months to 2 years of age but all age groups are susceptible. Calves that are nonimmune to *M. haemolytica* are considered to be more susceptible to the disease than calves that have serum neutralizing antibodies to the organism and its cytotoxin. Calves that have recovered from the experimental disease are resistant to naturally occurring disease. In western Canada, auction market calves that originate from many different farms and are mixed at the market are at high risk. The calves may develop the disease before weaning if subjected to the stress of an early snowstorm in the late fall in Canada. Similar observations in single-suckled calves have been made in the UK.

The disease occurs commonly in outbreaks 7–10 days after cattle have arrived in the feedlot following stressful transportation. This forms a major part of the 'shipping fever' complex, which is a major hazard in the practice of rearing beef cattle on range country and then transporting them long distances to other centers for growing and finishing. However, in a western Canadian study, the distance that calves were transported by truck from the auction markets to the feedlot was not associated with an increased risk of fatal fibrinous pneumonia.[11] The risk of fatal fibrinous pneumonia was just as high for calves arriving from nearby markets as for calves transported much greater distances.

Although the disease occurs most commonly in young beef cattle soon after their introduction to feedlots it is not uncommon in dairy herds, especially when recent introductions have been made or cattle are returned to their home farms after summer grazing on community pastures or exhibition at fairs. Herd outbreaks of peracute pleuropneumonia due to *M. haemolytica* have been reported in adult dairy cattle.[12] Only adults were affected, many animals were affected, a high proportion of affected cows were in the immediate postcalving period, and all farms had purchased cows and/or heifers within the last 12 months. There was no history of transportation or movement of affected animals. Mature beef cows are also susceptible to pneumonic pasteurellosis if they are subjected to stressors during the summer months or in the fall of the year, usually associated with moving large groups to or from pasture during inclement weather.

Environmental and management risk factors

The mixing of cattle from different sources is an important risk factor. Mixing of recently weaned beef calves from different sources at auction markets was associated with an increased risk of fatal fibrinous pneumonia in calves moved to feedlots in western Canada, especially in November, shortly after auction sales had

peaked and when the feedlot was reaching capacity.[13,14]

The role of stress as a risk factor in shipping fever pneumonia has been examined experimentally. Experimental transportation and handling to mimic stress, followed by an aerosol of *M. haemolytica*, did not result in significant lesions of pneumonia but did make the animals susceptible to BHV-1. The effects of transportation and assembling of yearling beef calves can result in an increase in the levels of plasma fibrinogen, which is an indication of some stress. Deprivation of feed and water followed by confinement in unfamiliar surroundings also results in an increase in fibrinogen. The response of the animals was also dependent upon the previous environment and management applied to them before assembly and transportation.

Confinement in drafty or humid and poorly ventilated barns, exposure to inclement weather, transport, fatigue and deprivation from feed and water are commonly followed by outbreaks of the disease in cattle. An increase in virulence of the bacteria is often evident after animal passage; at the commencement of an outbreak only those animals that have been subjected to devitalizing influences are affected but the disease may subsequently spread to other animals in the group. There is little tendency for the disease to become an area problem, sporadic outbreaks occurring with the appearance of conditions favorable to the development of the disease.

Pathogen risk factors

The frequency of isolation of *Pasteurella* spp. from the nasal passages of normal healthy unstressed calves is low but increases as the animals are moved to an auction mart and then to a feedlot.[15] Normally, it is difficult to establish long-term colonization of the nasal cavities of healthy, nonstressed calves with *M. haemolytica*. When calves are inoculated intranasally with IBRV or PI-3V, the nasal passages become much more susceptible to colonization with *M. haemolytica* even in the presence of antibodies to the organism in the serum and nasal secretion. The prevalence of *M. haemolytica* biotype A serotype 1 in the nasal cavity and trachea can be low in beef calves from a closed herd that is maintained on range pastures, and serum antibody levels are also low. Over time there may be an increase in the frequency of isolation of the bacteria from healthy calves that were moved to pens, held in low population densities and maintained under low stress conditions. In some cases, serotype 2 predominates while the calves are on the farm, and serotype 1 predominates when the calves are in the feedlot and affected with pneumonia.

There also are relationships between the numbers of bacteria in the nasopharynx and the ambient temperature and humidity. In calves kept at a constant temperature of 16°C (60°F), the bacterial populations in the nasopharynx were at a minimum between 65% and 75% relative humidity and tended to rise at humidities outside that range.

The possibility that infection with several different viruses and mycoplasma may predispose to pneumonic pasteurellosis has been a subject of intense research activity and is presented in more detail under Pathogenesis. Seroepidemiological surveys of cattle in feedlots reveal that IBRV, PI-3C, BVDV, and BRSV were present, active, and associated with respiratory disease.[16] The presence of antibody indicates current or recent exposure to the virus but does not indicate resistance. Cattle with low titers to IBRV and/or BRSV were at increased risk of subsequent treatment for bovine respiratory disease. Treated cattle also had greater increases to PI-3V and/or BVDV than control calves. While there is evidence that BVDV can experimentally affect certain immune mechanisms, there is little direct evidence that the virus is a major predisposing factor in the causation of naturally occurring pneumonic pasteurellosis. Seroepidemiological surveys indicate that seroconversion to BVDV is related to increased risk of respiratory disease at both individual and group levels. Serologically there is also evidence of a high prevalence of *M. bovis* and *M. dispar* in feedlot calves.[17] But the relative importance of these pathogens as a cause and effect relationship is controversial.

Bovine coronavirus has been associated with some natural outbreaks of shipping fever in feedlot cattle. Up to 80% of affected animals shed bovine coronavirus from their nasal cavities when the infection rate with *Pasteurella* spp. was low.[18]

The virulence factors of *M. haemolytica* include fimbriae, polysaccharide capsule, outer membrane proteins, endotoxin (lipopolysaccharide), and leukotoxin, which are described later under pathogenesis. The genes that code for the various virulence factors of *M. haemolytica* have been cloned for detailed characterization.[19] Fibrinogen-binding proteins may be present in the culture supernatants of *M. haemolytica* serotype 1 and *Pasteurella trehalosi* serotype 10.[20] These bacteria may contribute directly to fibrin formation and the development of fibrinous pneumonia.

M. haemolytica serotypes A1 and A2 can survive for long periods of time in relatively low-nutrient in vivo fluids. Both strains survived for at least 244 days in ovine and 156 days in bovine tracheobronchial washings, respectively.[21] This may provide an explanation for the long survival of the organism in the nasopharynx of ruminants.

Tetracycline resistance (*tet*) genes have been found in isolates of *P. multocida*, *M. haemolytica*, *Mannheimia glucosida*, and *Mannheimia varigena* from cases of respiratory diseases in cattle and pigs in Germany.[22] Tetracycline resistance in *P. multocida* and *M. haemolytica* is mediated by at least three different *tet* genes, most of which are located on the chromosomes. A new *tet* (H)-carrying plasmid has been identified, and *tet* (B) has been detected in *P. multocida*, and *tet* (G) in *M. haemolytica*.

Immune mechanisms

Calves that have recovered from the experimental disease are resistant to naturally occurring disease. Numerous *M. haemolytica* antigens may stimulate the immune response and resistance to disease. These antigens include capsular polysaccharide, leukotoxin, and surface antigens, including iron-regulated proteins,[23] a serotype-specific outer membrane protein, and several other antigens that are less well defined. High antibody responses to *M. haemolytica* surface extract proteins are correlated with resistance to experimental pneumonic pasteurellosis. Resistance to experimental challenge with the organism correlates directly with serum cytotoxin neutralizing titers. Cattle dying from pneumonic pasteurellosis may have lower levels of cytotoxin neutralizing antibody than animals from the same group dying from other causes. Aerosol exposure of calves with *M. haemolytica* results in the development of toxin neutralizing antibodies in pulmonary lavage samples and an accompanying increase in serum neutralizing titer. Since aerosol exposure of calves to viable *M. haemolytica* elicits a protective immune response characterized by enhanced clearance of the organism from the lung and by protection against fibrinous pneumonia, it is possible that the presence of pre-existing antibodies to the leukotoxin in the lungs may provide immunity by protecting phagocytic leukocytes from the leukotoxin and by promoting phagocytosis and intracellular killing of the organism.

Passive immunization with antibodies to whole *M. haemolytica* or leukotoxin-containing supernatants provides protection against experimentally induced pneumonic pasteurellosis similar to the protection provided by active immunization with these antigens.[24] In contrast, antibodies to lipopolysaccharide provided little protection against challenge.

Cattle exposed to live organisms produce antibodies to both cell surface antigens and cytotoxin, whereas exposure to the killed vaccine results in the production of antibodies primarily to cell surface antigens.

The experimental lung challenge of calves with formalin-killed *P. multocida* does not provide subsequent protection to challenge with live *P. multocida*.[25]

Method of transmission

Transmission of pasteurellas probably occurs by the inhalation of infected droplets coughed up or exhaled by infected animals, which may be clinical cases or recovered carriers in which the infection persists in the upper respiratory tract. *M. haemolytica* and *P. multocida* are highly susceptible to environmental influences and it is unlikely that mediate contagion is an important factor in the spread of the disease. When conditions are optimal, particularly when cattle are closely confined in inadequately ventilated barns, or when overcrowded in trucks and trains, or held for long periods in holding pens in feedlots, the disease may spread very quickly and affect a high proportion of the herd within 48 hours. In animals at pasture, the rate of spread may be much slower.

PATHOGENESIS

The literature on pathogenesis, including the extensive experimental work done on the role of the virulence factors, has been reviewed.[23,26]

Colonization of upper and lower respiratory tracts

Considerable research has centered on determining how the pasteurellas, which are part of the normal flora of the upper respiratory tract, colonize first the upper respiratory tract then the lower respiratory tract. Under normal conditions the bovine lung is relatively free of pasteurellas because of an effective lung clearance mechanism. The current hypothesis is that a combination of a viral infection of the respiratory tract and/or devitalizing influences from transportation, temporary starvation, weaning, rapid fluctuations in ambient temperature, the mixing of cattle from different origins and the excessive handling of cattle after arrival in a feedlot can all collectively promote an increase in the total numbers and virulence of pasteurellas in the nasopharynx, which then enter the lung. In clinically normal cattle, *M. haemolytica* are present in low numbers in the tonsil and nasal passages and those that are isolated are predominantly biotype A serotype 2 which is rarely associated with shipping fever. Exposure of healthy cattle to stressors such as viral infection, change in management practices and environmental changes leads to an explosive growth and selective colonization by *M. haemolytica* A 1 in the upper respiratory tract.

The experimental intranasal exposure of calves to a leukotoxin-deficient *M. haemolytica* elicits an increase in the serum antibody titers against the organism and decreased colonization of the nasopharynx by wild-type *M. haemolytica*.[27] This could allow an immune response to develop before transportation and offer protection from nasopharyngeal colonization and pneumonia by wild-type *M. haemolytica*.

Under normal conditions, alveolar macrophages will effectively clear pasteurellas from the alveoli by phagocytic mechanisms. When the large numbers of organisms enter and colonize the lung they interact with alveolar macrophages. Neutrophils enter the lung within the first few hours after bacterial inoculation.

Bovine alveolar macrophages release superoxide anion when exposed to *M. haemolytica* and the response is dependent on the presence of opsonizing antibody and the quantity of organisms presented to the phagocyte.[28] This may have a major role in the pathogenesis of the acute lung injury associated with pneumonic pasteurellosis. It is an important mechanism by which this phagocyte can initiate microbicidal activity and may provide clues to further study of the defense mechanisms of the lung.

Virulence factors and cellular and humoral reactions

The lung injury caused by the organisms after entry into the lung is dependent on important virulence factors.

Four virulence factors have been associated with *M. haemolytica*:

- **Fimbriae**
- **A polysaccharide capsule**
- **Endotoxin (lipopolysaccharide)**
- **Leukotoxin.**

The interactions of these virulence factors contribute to the pathogenesis of the disease.[23,26] **Fimbriae** enhance the colonization of the upper respiratory tract. The **polysaccharide capsule** of the organism inhibits complement-mediated serum killing as well as phagocytosis and intracellular killing of the organism. The capsule also enhances neutrophil-directed migration and adhesion of the organism to alveolar epithelium. The **lipopolysaccharide** or **endotoxin** can alter bovine leukocyte functions and is directly toxic to bovine endothelium. It also modifies cardiopulmonary hemodynamics and elevates circulatory prostanoids, serotonin, cAMP, and cGMP. The organism induces morphological alterations in bovine pulmonary endothelial cells, the effects of which can be partially inhibited by indomethacin.[29] Tissue factor is involved in intra-alveolar fibrin deposition and coagulopathy associated with pneumonic pasteurellosis in cattle.[30]

The migration and activation of neutrophils in inflamed tissue are regulated by a complex network of interactions among cytokines, leukocytes, vascular endothelium, cellular adhesion molecules, and soluble chemotactic factors.[26] The inflammatory cytokines tumor necrosis factor alpha, interleukin (IL)-1 beta, and IL-8 play a central role in the initiation and orchestration of these interactions.[23,26] IL-8 is the dominant cytokine expressed within the lungs during the acute phase of pneumonic pasteurellosis.[31]

Neutrophil-mediated inflammation in cattle with pneumonic pasteurellosis contributes to the development of severe disease rather than effective clearing of invading *M. haemolytica*. Leukotoxin is one of the major virulence factors of *M. haemolytica* responsible for impaired function of neutrophils.

The **lipopolysaccharide** or **endotoxin** of *M. haemolytica* is capable of causing direct injury to bovine pulmonary arterial endothelial cells, which may be a contributing pathogenetic mechanism. Endotoxin interacts with numerous cell types and humoral mediator systems, resulting in widespread injury to the lung. Endotoxin can readily cross the alveolar wall either from the air or blood and interact with cells and humoral mediators. The endotoxin can be found in the neutrophils in the alveolus, interstitial tissue, and capillary lumen; in intravascular, interstitial, and alveolar macrophages; in endothelial cells; and on alveolar epithelial cell surfaces.[23] The interaction of endotoxin with cells leads to cell activation and death.

Leukotoxin is produced by all known serotypes and is a heat-labile protein exotoxin, a pore-forming cytolysin that affects ruminant leukocytes and platelets. The bacterium produces the leukotoxin, with maximum production occurring during the log phase of growth, peaking after 6 hours of incubation. Following the inhalation of *M. haemolytica* into the lung there is an accumulation of neutrophils that, when destroyed by leukotoxin, result in the release of proteolytic enzymes, oxidant products, and basic proteins, which degrade cellular membranes, increasing capillary permeability, which results in fluid accumulation in the interstitium of the alveolar wall, alveolar wall necrosis, and pulmonary edema. Leukotoxin also induces histamine release from bovine mast cells.[32] The importance of the neutrophil is supported

by experimental evidence that depletion of blood neutrophils in calves made the animals much less susceptible to pulmonary injury following intratracheal inoculation of *M. haemolytica*.

Exposure to low concentrations of *M. haemolytica* leukotoxin in vitro induces apoptosis in bovine leukocytes.[33] Apoptosis is a process of cell death distinguished from necrosis by various morphological and biochemical criteria. These include chromatin collapse with subsequent chromatin margination in crescent-shaped masses around the periphery of the nucleus, blebbing of the cytoplasmic membrane, and internucleosomal cleavage of DNA into nucleosome-sized fragments. This may represent an important mechanism by which *M. haemolytica* overwhelms host defenses.

Tilmicosin, a very effective antibiotic for the treatment of pneumonic pasteurellosis, induces apoptosis in neutrophils, which results in reduced levels of the potent proinflammatory mediator leukotriene B_4 in lung fields of infected calves treated with tilmicosin. The tilmicosin-induced apoptosis in neutrophils directly enhances phagocytic removal of these cells by macrophages.[33,34]

Supernatants of the organism can also cause rapid cytolysis of platelets. The genes that code for the synthesis and secretion of the leukotoxin have been cloned. It is a highly immunogenic protein that is produced by all 15 serotypes of *M. haemolytica*. Antiserum raised to the 105 kDa protein neutralizes its leukotoxic activity. Cattle with high leukotoxin antibody titers have higher survival rates in natural and experimental cases of pneumonic pasteurellosis than animals with low antibody titers. The development of efficacious vaccines will probably depend on using leukotoxin antigens and bacterial surface components to elicit maximum resistance against pneumonic pasteurellosis. Assay tests for determination of cytotoxin neutralizing antibody titers in cattle sera are described. There is positive correlation between ELISA titers to cytotoxin and protection to experimental pneumonic pasteurellosis.

Experimental pneumonic pasteurellosis

In an attempt to understand the pathogenesis of shipping fever pneumonia the experimental disease has been reproduced using several different methods: the most commonly used is the sequential aerosol infection of calves with either the PI-3 virus or the IBR virus followed by an aerosol of *M. haemolytica* 3 days or more later.[35,36] Exposure of calves to aerosols of PI-3V followed by *M. haemolytica* at intervals of 3–13 days later results in a purulent bronchopneumonia. The virus interferes with the lung clearance of *M. haemolytica* when an aerosol of the bacteria is given 7 days following the viral infection. There is little interference after only 3 days and a moderate degree at 11 days.

Pneumonic pasteurellosis similar to the naturally occurring disease can be reproduced experimentally by exposing calves sequentially to aerosols of BHV-1 and *M. haemolytica* 4 days apart.[35,36] The virus infection partly destroys the clearance mechanism of the respiratory tract epithelium and exacerbates the subsequent *M. haemolytica* infection.[35] Both antigens can be detected by immunohistochemical methods in the bronchoalveolar fluid cells.

The viral–bacterial synergism is associated with the release of cytokines, which attract more leukocytes and increase leukocyte expression of CD11a/CD18. In this experimental model, vaccination of the animal against the virus before challenge with the viral–bacterial aerosol sequence is protective. The interaction between the IBR virus and *M. haemolytica* can persist for up to 30 days after infection with the virus. A sequential aerosol infection of IBRV and *P. multocida*, or *P. multocida* alone, can also result in pneumonia. Experimental in vitro studies indicate that IBRV infection does not have a direct effect on the ability of neutrophils to phagocytose *M. haemolytica* but rather that there is an indirect effect, perhaps through the release of mediators that have an effect on phagocyte function. Large amounts of interferon are produced throughout the course of IBRV infection, which reduces chemotaxis and elevates oxidase activity by bovine neutrophils.

Pneumonic pasteurellosis can also be reproduced by transthoracic intrapulmonic infection of unstressed, conventional calves with only *M. haemolytica* or *P. multocida*, endobronchial inoculation intratracheal challenge, or intranasal inoculation of calves with the organism without a preceding viral infection. The intratracheal injection of *P. multocida* biotype A:3 into 8-week-old calves results in clinical and pathophysiological findings characteristic of bovine pneumonic pasteurellosis and gross pathological and microscopic changes similar to field cases.[5] Concentrations of the acute phase proteins haptoglobin, serum amyloid-A and alpha-1 acid glycoprotein increased, suggesting a role for these proteins as markers of the onset of and progress of the disease.

The intratracheal instillation of live *M. haemolytica* into conscious calves results in acute cardiovascular changes consisting of two systemic hypodynamic and pulmonary vasoconstrictive phases.[37] Injection of metrenperone (a $5HT_2$ receptor antagonist) 2 hours after inoculation abolishes the late increases in pulmonary arterial pressure and pulmonary vascular resistance.[28]

Synergism between pathogens

Experimentally, synergism may occur between *M. haemolytica* and *M. bovis* in producing pneumonia in gnotobiotic calves and not in conventional calves.

The role of BVDV in outbreaks of pneumonic pasteurellosis is uncertain. In one study the virus did not impair the pulmonary clearance of *M. haemolytica*. In a different study the endobronchial inoculation of calves with the virus and *M. haemolytica* sequentially 5 days apart resulted in a severe fibrinopurulent bronchopneumonia and pleuritis involving up to 75% of the total lung volume. Endobronchial inoculation of the organism only caused a localized noninvasive lesion in the lungs.

In summary, pneumonic pasteurellosis can be reproduced experimentally without a preceding virus infection, and it is likely that the naturally occurring disease can also occur without a preceding viral infection.

The terminal lesion is an acute fibrinous pleuropneumonia. The ventral aspects of the apical and cardiac lobes of the lungs are most commonly affected; in advanced cases a greater portion of the lung becomes affected and other lobes of the lung become involved. Consolidation of affected lobes results in loud breath sounds, and the exudative nature of the lesion causes crackles. The pleuritis causes thoracic pain and pleuritic function rubs. Death is due to hypoxemia and toxemia. Complications include pulmonary abscessation, chronic pleuritis with or without pleural effusion, bronchiectasis, pericarditis and, rarely, congestive heart failure due to cor pulmonale.

CLINICAL FINDINGS

The spectrum of clinical findings depends in part on whether the disease is occurring in groups of young cattle in a large commercial feedlot, in a small farm feedlot or in individual animals such as lactating dairy cows, in which illness is more easily recognized based on milk production and feed intake. In the feedlot situation, affected animals must be identified primarily by visual observation followed by closer physical examination.

Feedlot

In the feedlot, the disease usually occurs within 10–14 days after the animals have been stressed or have arrived in the feedlot. It may occur within 1 day after arrival if the animals have been incubating

the disease prior to arrival. Animals found dead without any previous warning signs may be the first indication of an outbreak in which many weaned beef calves are obviously affected and some are in the incubation stages of the disease.

When viewed from a distance, affected cattle are depressed and their respirations are rapid and shallow. There may be a weak protective cough, which becomes more pronounced and frequent if they are urged to walk. Those that have been ill for a few days will appear gaunt because of anorexia. A mucopurulent nasal discharge, a crusty nose, and an ocular discharge are common. Although affected cattle are anorexic, they may continue to drink maintenance amounts of water, which may be useful in mass medication of the water supplies.

When the disease has been diagnosed in a group or pen of animals, and new cases are occurring daily, those that are in the earliest stages of the disease are not obviously ill when examined from a distance. If the entire group of animals is put through a chute and examined closely, up to 20%, or even more, of apparently normal animals may have a fever ranging from 40–41°C (104–106°F) and no other obvious clinical abnormalities. Auscultation of the thorax of some of these subclinical cases will reveal rapid shallow respirations and an increase in the loudness of the breath sounds. These animals respond remarkably well to treatment. If not treated at this stage, they may progress to clinical cases within a few days or they may recover uneventfully.

Not all animals that appear depressed have significant lung disease that requires treatment. When the presence of a fever of 40°C, or higher, in animals which are depressed, is used to decide whether or not the animal has pneumonia and requires treatment, some animals are treated unnecessarily. This is a problem in large feedlots that process many 'sick' animals daily based on the clinical findings of depression and fever. Using depression and a fever, the sensitivity of detection of sick animals is high but the specificity is low and therefore more animals are treated than is necessary. Improvement of the accuracy of both the diagnosis and the selection of those animals that require treatment will require improvement in the accuracy of the identification of affected animals by visual observation, and the use of rapid and reliable clinical examination techniques of individual animals that can identify animals with evidence of pulmonary disease. Close physical examination techniques, such as auscultation of the lungs, have not been routinely used in feedlots because of the time required to examine individual animals and the perceived inaccuracy of the examination in making a clinical diagnosis.

Outbreaks of the disease in feedlots may last for 2–3 weeks or longer after the first **index case**, depending on the health status of the cattle when first affected. Outbreaks can be prolonged in feedlots that add groups of newly arrived cattle to an existing pen of cattle every few days in order to fill the pen to optimum capacity. The disease then occurs in each new group of cattle and may spread to previously resident cattle, perpetuating the disease for several weeks.

The origin of the cattle also influences the severity and length of outbreaks. In well-nourished cattle originating from one ranch and maintained as a single group the morbidity may be less than 5% and the mortality nil. The outbreak will last only a few days and the cattle return to normal quickly. In cattle that have originated from a variety of sources and moved through saleyards and then commingled in the feedlot, the disease may persist for several weeks. In these situations, many animals are sick with the disease when they arrive at the feedlot. Some cattle will develop complications, never fully recover and are culled later.

Close physical examination

The relationships between clinical and pathological findings of disease in calves experimentally infected with *M. haemolytica* type A1 indicated that the respiratory rate, rectal temperature and clinical scores are significantly correlated with the extent of consolidation of the lungs.[38] The respiratory rate increased from 30 per minute up to 70 per minute as the percentage of lung consolidation increased from 10% to 50%.

The typical case of pneumonic pasteurellosis reveals a fever of 40–41°C (104–106°F), bilateral mucopurulent nasal discharge, gaunt abdomen with rumen atony, coughing, varying degrees of polypnea and dyspnea, and evidence of bronchopneumonia. In the early stages there are loud breath sounds audible over the anterior and ventral parts of the lungs. As the disease progresses these breath sounds become louder and extend over a greater area; crackles become audible, followed by wheezes in a few days, especially in chronic cases. Pleuritic friction rubs may be audible, although their absence does not preclude the presence of extensive adherent pleuritis. In severe cases or those of several days' duration the dyspnea is marked, commonly with an expiratory grunt, although the respiratory rate may not be elevated.

The course of the disease is only 2–4 days. If treated early, affected cattle recover in 24–48 hours but severe cases and those that have been ill for a few days before being treated may die or become chronically affected in spite of prolonged therapy. Some cattle recover spontaneously without treatment.

A mild diarrhea may be present in some cases but is usually of no consequence. On an affected farm, calves may be affected with pneumonia and young calves may die of septicemia without having shown previous signs of illness.

CLINICAL PATHOLOGY

Bacterial culture

Nasal swabs taken from clinical cases before treatment often yield a pure culture of pasteurellas, but *M. haemolytica* biotype A serotype 1 is the most common isolate obtained from cattle with acute pneumonic pasteurellosis. The same serotype can usually be isolated from in-contact and apparently healthy calves. The antimicrobial sensitivity of the pasteurellas isolated can be determined, but interpretation of the results is often difficult because it is not known whether the isolates from nasal swabs represent those causing the lesions. Significant differences may exist between the antimicrobial sensitivities of isolates from nasopharyngeal swabs and those from the lung tissues. Thus it is not yet possible to recommend routine culturing and antimicrobial sensitivity determination of pasteurellas from nasal cavity or nasopharyngeal mucus from cattle with acute shipping fever pneumonia. At the individual animal level, nasopharyngeal swabs and bronchoalveolar lavage reveal only moderate agreement; at the group level the isolation rates of various organisms are similar. In healthy calves monitored from the farm to the feedlot there was no relationship between the nasal flora and pulmonary lesions. There is some evidence that antimicrobial resistance is emerging among field isolates of *M. haemolytica*, and plasmid-mediated antimicrobial resistance is now known to occur.

Hematology

Plasma fibrinogen concentrations are elevated, paralleling the increase in body temperature, and are a more reliable indication of the presence of the lesion than clinical assessment. Young cattle with clinical signs of acute respiratory disease, a fibrinogen concentration greater than 0.7 g/dL and a temperature greater than 40°C (104°F) are likely to have pneumonic pasteurellosis. Leukocyte counts are of little value, as a leukocytosis and neutrophilia occur in some animals but in others there may be a neutropenia or no significant change. Acute phase proteins are increased within 24 hours following experimental intratracheal inoculation of *M. haemolytica* into calves. The availability

of a rapid test for acute phase proteins could assist in the field diagnosis of the disease and its possible differentiation from similar diseases.

NECROPSY FINDINGS

There is marked pulmonary consolidation, usually involving at least the anteroventral third of the lungs. The stage of pneumonia varies within the affected tissue, commencing with congestion and edema and passing through various stages of airway consolidation with serofibrinous exudation in the interlobular spaces. A catarrhal bronchitis and bronchiolitis, and a fibrinous pleuritis are usually present and may be accompanied by a fibrinous pericarditis. The lung is firm and the cut surface usually reveals an irregular, variegated pattern of red, white, and gray tissue due to hemorrhage, necrosis, and consolidation. Coagulation necrosis of pneumonic lungs is the most characteristic lesion in pneumonic pasteurellosis. In chronic cases there are residual lesions of bronchopneumonia with overlying pleural adhesions. Occasionally, sequestra of necrotic lung tissue are found. *P. multocida* causes a fibrinopurulent bronchopneumonia without the multifocal coagulation necrosis that is characteristic of the fibrinous lobar pneumonia associated with *M. haemolytica*.

The sequential gross and microscopic lesions of experimental bovine pneumonic pasteurellosis have been described and may provide guidelines for aging the lesions in naturally occurring cases.[39] On days 2–3 after infection the lesion is characterized by soft gray-purple consolidation; on day 6 the affected areas are firm and nodular; on days 9–10 the nodular lesions are more prominent and fibrous tissue encapsulates the lesions and becomes obvious. The initial microscopic changes consist of flooding of the alveoli with edema, fibrin, and hemorrhage. Large numbers of neutrophils and macrophages move into the alveoli by day 2. The classical lesion is visible by day 4 and consists of necrotic tissue surrounded by a dark zone of inflammatory cells. The elongate, 'oat-cell' profile of some of these leukocytes is a useful marker in culture-negative cases. In nonfatal cases a walling-off reaction by fibrous tissue isolates the necrotic tissue. Determination of the age of the lesions by gross and/or microscopic examination may assist in correlating the occurrence of the disease with specific health management procedures in the herd.[39] In feedlot cattle, determining the age of bacterial pneumonia can help to assess whether or not the pneumonia was present in the animal on arrival or if treatment failure resulted from late detection or from inadequate drug therapy. The degree of necrosis and fibrosis are the main lesions used to age pneumonia.[39]

In general, *M. haemolytica* causes a fibrinous pleuropneumonia with extensive thrombosis of interstitial lymph vessels and limited evidence of bronchitis and bronchiolitis. In contrast, bronchopneumonia due to *P. multocida* is associated with a suppurative bronchitis, minor thrombosis of interstitial lymph vessels and considerably less exudation of fibrin.

The organism is easily cultured from acute, untreated cases but other species of bacteria, including anaerobes, are often found in more chronic cases. More sophisticated tests such as PCR and immunoperoxidase techniques are available for the detection of *M. haemolytica* but are seldom required in diagnostic cases.

Samples for confirmation of diagnosis

- Bacteriology – lung, bronchial lymph node (CULT)
- Histology – formalin-fixed lung (LM).

DIFFERENTIAL DIAGNOSIS

The differential clinical diagnosis of pneumonic pasteurellosis is summarized in Table 18.5.

As a general guideline the common pneumonias of cattle may be divided into bronchial, interstitial, and hematogenous.

- The **bronchial pneumonias** include pneumonic pasteurellosis and other less common bacterial pneumonias characterized by toxemia and shallow respiration and a good response to early treatment
- The **interstitial pneumonias** include the viral and parasitic pneumonias, and acute interstitial pneumonias characterized by **marked** respiratory distress and a slow response or no response to treatment. In viral pneumonias the animals may die acutely in a few days or recover over a period of several days
- The **hematogenous pneumonias** are associated with vena caval thrombosis and pulmonary aneurysm and are characterized by acute respiratory distress and hemoptysis and no response to treatment.

Pneumonic pasteurellosis of cattle is an acute, toxemic bronchopneumonia with a high fever and a good response to treatment in the early stages. Depression and anorexia are common. The disease is most common in young beef calves that have been recently stressed following weaning or mixed in auction markets and shipped to feedlots. The disease can also occur in mature cattle as a primary or secondary pneumonia.

In **viral interstitial pneumonia** of calves, young and adult cattle there is characteristic dyspnea, a moderate fever, only a mild toxemia, loud breath sounds over the ventral aspects of the lungs followed by crackles and wheezes in a few days, and recovery may take several days. Pneumonia due to BRSV may be mild with uneventful recovery or severe with dyspnea and subcutaneous emphysema and a high case-fatality rate.

Lungworm pneumonia occurs most commonly in young pastured cattle and is characterized by dyspnea, coughing, only mild toxemia and a moderate or normal temperature; the course may last several days. Usually many cattle are affected. Crackles and wheezes are usually audible over the dorsal aspects of the lungs and the response to treatment is usually favorable if treatment is initiated early when signs are first noticed.

Less common causes of acute pneumonia in calves and young cattle include infection with *Klebsiella pneumoniae*, *Streptococcus* spp., and *Fusobacterium necrophorum*, all of which are characterized by a bronchopneumonia indistinguishable clinically from pneumonic pasteurellosis.

Epidemic acute interstitial pneumonia (fog fever) usually occurs in outbreaks in pastured cattle that have been moved from dry to lush pasture (or just a different species of pasture or on to a recently harvested cereal grain field); the onset is sudden, some cattle may be found dead, while others are in severe respiratory distress with an expiratory grunt.

Infectious bovine rhinotracheitis is characterized by rhinitis, usually with discrete lesions in the nares, tracheitis, loud coughing, high fever and no toxemia unless secondary bacterial pneumonia is present. Recovery usually occurs gradually over 4–7 days.

Contagious bovine pleuropneumonia resembles pneumonic pasteurellosis but occurs in plague form; there is severe, painful, toxemic pleuropneumonia and the case fatality rate is high.

TREATMENT

Antimicrobial therapy

The recommendations for the treatment of bovine pneumonic pasteurellosis are based on clinical experience and the results of clinical field trials.

About 85–90% of affected cattle recover within 24 hours if treated with antimicrobials such as oxytetracycline, tilmicosin, trimethoprim–sulfadoxine, the sulfonamides, and penicillin. Broad-spectrum antimicrobials are used most commonly. One treatment is usually adequate and most economical for most cases but severely affected cattle or those that relapse require treatment daily, or even two to three times daily, depending upon the drug used, for up to 3–5 days.

Choice of antimicrobial

This will depend on the cost, availability, expected efficacy based on previous experience with the antimicrobial in a

particular area, ease of administration, frequency of administration required, concentrations of the antimicrobial that can be achieved in the lung tissues of affected animals, and length of the withdrawal period required before slaughter or withholding of milk in lactating dairy cattle. The choice of antimicrobial also depends on the concentrations that can be achieved in the lung tissues of affected animals. The concentrations of oxytetracyclines are higher in pneumonic lung than in normal lung. Pharmacokinetic studies of oxytetracycline in experimental pneumonic pasteurellosis indicates the need for observance of 12-hour dose intervals.[40]

The antimicrobials and their dosage schedule in Table 18.6 are recommended as a guideline.

The efficacies of **oxytetracycline, penicillin, and trimethoprim–sulfadoxine** are not significantly different for the treatment of undifferentiated bovine respiratory disease in cattle within the first 28 days after arrival in the feedlot.[41] The response, relapse, and case fatality rates overall were 85.7%, 14.8%, and 1.4%, respectively. In some studies, the use of trimethoprim–sulfadoxine resulted in fewer days of treatment compared to penicillin and oxytetracycline.

Tilmicosin, a semisynthetic macrolide antimicrobial, is highly effective as a single subcutaneous injection at 10 mg/kg BW.[42] Tilmicosin is effective in treating experimentally induced pneumonic pasteurellosis as measured by alleviation of clinical signs, reduction in extent of lesions at necropsy and the presence of viable bacteria from the lung.[43] Concentrations substantially above MIC for *M. haemolytica* were present in the lung tissue even at 72 hours following a single subcutaneous injection of 10 mg/kg BW.[43] Tilmicosin rapidly accumulates in lung tissue and significantly higher concentrations are found in infected pulmonary tissue than in normal lung. Uniquely, tilmicosin effectively controls *M. haemolytica* infection, induces neutrophil apoptosis, reduces pulmonary inflammation and does not affect neutrophil infiltration or function.[42] Tilmicosin-induced peripheral neutrophil apoptosis occurs regardless of the presence or absence of live *M. haemolytica*, exhibits at least some degree of drug specificity and promotes phagocytic clearance of dying inflammatory cells.[34]

Tilmicosin is also effective in reducing the population of *M. haemolytica* colonizing the nasal cavities of calves with respiratory disease.[44] By reducing colonization, prophylactic use of tilmicosin before transportation or at the time of arrival at a feedlot is likely to reduce the incidence of acute respiratory disease in animals during the first several days after arrival.[45] Tilmicosin and danofloxacin did not differ in their effect on mean body temperature of beef calves with experimental pneumonic pasteurellosis.[46] Some studies have shown that tilmicosin has no effect on neutrophil function or apoptosis.[47]

Tilmicosin was highly effective as a single-dose treatment of bacterial pneumonia secondary to severe BRSV pneumonia in weaned beef calves.[48]

Florfenicol, an analog of **thiamphenicol**, is highly effective for the treatment of acute undifferentiated respiratory disease of feedlot cattle and its use will become widespread.[49] Florfenicol and tilmicosin are comparable in the treatment of undifferentiated bovine respiratory disease in western Canada.[50]

Enrofloxacin at a dose of 2.5–5.0 mg/kg BW subcutaneously daily for 3–5 days or 7.5–12.5 mg/kg BW subcutaneously is effective.[51] Difloxacin and enrofloxacin are equally effective for treatment of the experimental disease.[52] Danofloxacin is rapidly distributed to the lungs and high tissue concentrations are achieved in the pneumonic lung, including areas of consolidation.[53] In calves with experimental pneumonic pasteurellosis, a single dose intravenously is more effective than the same dose administered by continuous infusion.

Ceftiofur preparations are being evaluated. Ceftiofur crystalline-free acid sterile suspension (CCFA-SS), a long-acting ceftiofur at 4.4–6.6 mg ceftiofur equivalents/kg administered subcutaneously in the middle third of the posterior aspect of the ear is effective, safe and practical for the treatment of experimental pneumonic pasteurellosis and the control and treatment of bovine respiratory disease in feedlot cattle.[54]

A rapidly disintegrating bolus formulation of **baquiloprim** (an antifolate compound) and **sulfadimidine** was effective for the treatment of experimental pneumonic pasteurellosis.[55] The baquiloprim is absorbed effectively and is synergistic with sulfonamides.

Antimicrobial sensitivity

The antimicrobial sensitivity of *M. haemolytica* varies, depending on the geographical origin of the animals and the previous use of the drug in the herd or the feedlot. Most isolates of *M. haemolytica* have some degree of multiple antimicrobial resistance, associated with continued use.

A 4-year survey of antimicrobial sensitivity trends for pathogens isolated from cattle with respiratory disease in North America based on MIC determinations using a broth microdilution method, indicated that, overall, resistance to ampicillin, tetracycline, erythromycin, and sulfamethazine was frequently encountered among isolates of *M. haemolytica* and *P. multocida*.[56] There was widespread resistance to erythromycin, which, because of cross-resistance, may account for the wide variation in sensitivity to tilmicosin. Ceftiofur was very active against the pathogens.

Ampicillin- and tetracycline-resistant *Pasteurella* isolates from dairy cattle (dairy herds and calf ranches) with pneumonia were spatially clustered within certain geographical areas in California.[57] The percentage of *M. haemolytica* isolates resistant to ampicillin was 21.3%; to *P. multocida*, 12.3%. The percentage of *M. haemolytica* isolates resistant to

Table 18.6 Antimicrobials for treatment and prevention of bovine pneumonic pasteurellosis

Antimicrobial Individual treatment	Dosage and route of administration
Oxytetracycline	10 mg/kg BW, IV or IM daily for 3 d; can also use long-acting at 20 mg/kg
Florfenicol (analog of thiamphenicol)	20 mg/kg BW, IM; repeat in 48 h
Trimethoprim–sulfadoxine (40 mg trimethoprim/200 mg sulfadoxine/mL)	20 mg/kg BW, IM; repeat in 48 h 3–5 mL/45 kg BW, IV or IM daily for 3 d
Penicillin	20 000–30 000 IU/kg BW IM or SC daily for 3 d
Sulfamethazine (sustained-release bolus)	250 mg/kg BW/72 h; severely affected cattle need to be treated parenterally initially with a rapidly acting sulfonamide because of rumen stasis due to toxemia
Tilmicosin	10 mg/kg BW SC and repeat 72 h later if necessary
Enrofloxacin	2.5 mg/kg BW IM daily 3–5 d; or single dose of 7.5–12.5 mg/kg
Mass medication (feed and water)	
Sulfamethazine	100 mg/kg BW in drinking water daily for 5–7 d
Oxytetracycline	3–5 mg/kg BW in feed for 7 d
Mass medication (individual)	
Long-acting oxytetracycline	20 mg/kg BW, IM to all in-contact animals
Tilmicosin	10 mg/kg BW SC on arrival and/or 72 h after arrival

BW, body weight; IM, intramuscularly; IV, intravenously; SC, subcutaneously.

tetracycline was 37%; to *P. multocida*, 52.5%. This reinforces the need to establish regional estimates of percentages of bacterial isolates which are susceptible to commonly used antimicrobials.

Early identification of affected animals in feedlots

Where large numbers of cattle are involved, early identification is crucial to successful therapy. Affected animals should be removed from their pen, examined, treated, identified with a suitable tag for reference purposes and placed in a hospital pen until recovered. This avoids confusion in deciding which animal requires treatment the next day. The duration of treatment will depend on the severity of the individual case, the response achieved in the first few days, the economic worth of the animal, the extent of complications that may be present, such as pleurisy, pulmonary abscesses, and bronchiectasis, and the results that the veterinarian may expect from prolonged therapy in difficult cases.

Animal identification

Identification of every animal in the feedlot with a unique eartag when it arrives in the lot, and the use of a chute-side computerized records system allows the collection and collation of animal health reports on individual animals, and on pens or groups of animals. Large commercial feedlots now have computerized records systems, which have replaced the manual card system. The case abstract of each animal will include the number of times it has been examined and treated, its body temperature and diagnosis. The abstract is useful when doing a necropsy on animals that have been treated and died. The epidemic curve can be calculated from the number of animals identified each day from each pen. From the cumulative treatment data, the computer can provide information on the diagnostic capability of identifying sick animals based on their body temperature when they were examined the first time, the treatment response, relapses and when they occurred, and mortality rates.

Medication of feed and water supplies

There is much interest in mass medication of the drinking water or feed supply or both. The rationale is that the medication of the feed or water would successfully abort an outbreak by treating those animals incubating the disease, provide convalescent therapy to those that have already been treated individually, and deal with mild cases before they become acutely ill and need individual treatment. However, there are problems. The amount of water that cattle drink is directly proportional to feed consumption. If they are inappetent or anorexic, water consumption will decline to only maintenance requirements and therapeutic levels of drug will not be achieved if the concentration in the water is provided at a level for normal consumption. The other major problem is the provision of a uniform concentration of drug in the water supply, either through automatic water proportioners in the waterline or placing the drug directly into water tanks. Both can be unreliable. There is a need for the development of reliable methods of mass medication of the feed and water supplies of cattle.

Mass medication of individual animals

The individual treatment of all in-contact animals in an affected group may be useful in controlling an outbreak of the disease. If the rate of new cases each day ranges from 5–10% of the group, each animal in the remainder of the group may be treated with a long-acting preparation of oxytetracycline at the rate of 20 mg/kg BW intramuscularly. Tilmicosin at 10 mg/kg BW subcutaneously is also effective for mass medication of individual animals. This form of group medication will treat cases during the subclinical stages and may prevent new infections. Long-acting oxytetracycline at the same dose rate is also effective for the treatment of clinical cases and reduces the labor and the stress of handling associated with daily treatment, which may be required in severe cases.

Anti-inflammatory agents

Corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs) are used by some veterinarians as an ancillary treatment for severe cases. The rationale is their anti-inflammatory effect but no data are available to support the field experience of some veterinarians that they are efficacious and economical.

Failure to respond

The causes of failure to respond to therapy include:

- **Advanced pneumonia before treatment is initiated**
- **Presence of viral or interstitial pneumonia or some other pneumonia that is not responsive to antimicrobials**
- **Inadequate dose of antimicrobials**
- **Antimicrobial resistance of the bacteria**
- **Complications such as pulmonary abscess, bronchiectasis, and pleuritis.**

CONTROL

Satisfactory economical control of the disease depends on the successful integration of management and perhaps the use of vaccines and antimicrobials prophylactically. It is unrealistic to depend on a vaccine, an antimicrobial or a single management technique to control the disease. Successful control begins with the adoption of effective management techniques when beef calves are still on the range, the judicious use of efficacious vaccines, and care in handling and transportation of cattle.

Management strategies

Preconditioning programs

Because of the common occurrence of the disease at the time of shipment from the range to the feedlot, much attention has been given to reducing the incidence of disease at this time. This led to the development in North America of the concept of preconditioning. The objective of preconditioning was to prepare the weaned calf for the feedlot environment by vaccinating it for all the commonly anticipated diseases before weaning and distributing all stressful procedures such as castration, dehorning, branding, and deworming over a period of time rather than concentrating these at weaning time. Weaning at least 2 weeks before shipment was also considered a desirable practice. This was to result in a weaned calf that could be moved into a feedlot in which the feed bunks and water bowls would not be strange but familiar and the calf would adjust quickly. The most common vaccinations were for IBRV, PI-3V, BVDV, and clostridial disease. In some situations, calves were also vaccinated for *H. somni* and BRSV, and against pneumonic pasteurellosis.

Preconditioning has not been widely accepted because its economic value has not been proven. Nevertheless, the procedures involved promote health and can be recommended even though their economic value remains to be determined. Some reports claim that preconditioning can benefit both cow–calf producers and the buyers of preconditioned calves. Heavier calves at sale, low cost of average daily gain, and the price differential have the greatest impact on increased net return. Preconditioning programs have motivated cow–calf producers to examine preconditioning as a method to improve the marketability of their calves and to develop a reputation for a high-quality product. Calves perform better in the feedlot if the stresses from dehorning, castration, and vaccination occur at the same time, but before the stress of weaning occurs.

Weaning procedures

Beef calves should be weaned well in advance of anticipated inclement weather. This is especially true in North America, where the fall months can be cold and windy, and snowstorms can occur. A

common successful practice is to begin feeding hay and providing water to calves at least 2 weeks before weaning in the same corral or paddock into which they will subsequently be weaned. Following such a weaning program the calves require only a minimum of adjustment: the only adjustment necessary should be the loss of their dams. Recently weaned calves should be observed at least twice daily for evidence of respiratory disease and treated promptly if necessary. They should not be transported long distances until they appear to be healthy and are eating liberal quantities of hay and drinking water normally. During transportation liberal quantities of bedding are necessary and cattle should not be without feed and water for more than 24–30 hours. For long trips, calves should be rested for 8–12 hours and fed water and hay at intervals of 24 hours. This will minimize the considerable loss of body weight due to shrinkage and the effects of temporary starvation.

Creep feeding

The use of creep feed for calves for several weeks prior to weaning has been successful but may not always be economical. A high-energy ration containing cereal grains, a protein supplement and the necessary vitamins and minerals is provided for the calves in a creep arrangement to which the dams do not have access. At weaning time the dams are removed from the calves and the stress on the calves is minimal. This program has been very successful for purebred herds, where it may be economic, but in commercial herds it is only economic when the market value of the calves warrants it.

Conditioning programs

In the absence of preconditioning programs, conditioning programs have become the usual procedure for preparing beef calves or yearlings for the feedlot. This begins with movement of the animals from their farm source to the feedlot. The ideal situation would be to avoid public saleyards and move the cattle directly from the ranch to the feedlot. This avoids the stress of handling, overcrowding, temporary starvation, exposure to aerosol infection from other cattle, and the unnecessary delays associated with buying and selling cattle. However, large intensified feedlots are unable to buy cattle directly from the herd of origin according to their needs at a particular time and thus inevitably purchase large groups of cattle of different backgrounds. This has necessitated the development of **conditioning procedures** or processing procedures in which, after arrival, the cattle are individually identified, injected with a mixture of vitamins A, D, and E, treated with a residual insecticide, perhaps given an anthelmintic, injected with a long-acting antimicrobial and vaccinated for clostridial and respiratory diseases. The issue of whether the cattle should be processed immediately after arrival or after a rest period of 2–3 weeks remains unresolved because there are few data to support one time over the other. However, the feedlot industry feels that processing immediately after arrival is most economical.

Feeding newly arrived cattle

The feeding and nutritional status of newly arrived cattle is important but there are few scientific data to formulate a sound economic feeding program that will promote rapid recovery from shipping stress. Good results can be achieved when stressed calves are fed a receiving ration consisting of 50–75% concentrate with good-quality hay in a total mixed ration for the 2–3 weeks until the cattle have become adapted to their new environment.

Vaccines

General comments

Pasteurella vaccines and respiratory viral vaccines have been used extensively in an attempt to control pneumonic pasteurellosis in cattle. A review of the literature in 1997 on the efficacy of the vaccines available for the control of bovine respiratory disease concluded that there were few documented data to support the use of vaccines against respiratory disease under feedlot conditions.[58] Since that time progress has been made in understanding immunity to pneumonic pasteurellosis, and some vaccines with varying degrees of efficacy have been developed. The development of experimental models to reproduce the disease with *M. haemolytica* has provided a challenge method for evaluating the efficacy of the vaccines.

Various commercial vaccines induce differences in the rapidity and intensity of serum antibody responses to *M. haemolytica* whole cells and leukotoxin.[59] However, well-controlled field trials are necessary to compare efficacy under naturally occurring conditions.

Pasteurella vaccines

Based on the immunological and microbiological observations of both the naturally occurring and experimental disease it appears that immunization of cattle is possible. Calves that recover from experimentally induced pneumonic pasteurellosis possess increased resistance to subsequent experimental challenge. Cattle that have recovered from the natural disease are resistant to the disease. High levels of naturally acquired antibody to *M. haemolytica* leukotoxin have been associated with protection against the disease.[59]

The challenge in the development of an efficacious vaccine against pneumonic pasteurellosis has been to determine the most effective protective antigens of the organism.

Several different *Pasteurella* vaccines have been developed based on the virulence factors, including exotoxic leukotoxin, lipopolysaccharide with endotoxic activity, capsular polysaccharide, and iron-regulated outer membrane proteins. Each of the vaccines produced may provide some protection against experimental and naturally occurring disease but none provides a high degree of protection.

Several outer membrane proteins of *P. multocida* type A:3, which occasionally causes a severe bronchopneumonia in cattle, may be important for immunity to the organism.[60] A vaccine made of the outer membrane protein fraction of *M. haemolytica* induces a protective response in calves against intrathoracic challenge exposure with the homologous serovar.[61] A tissue-culture-derived *M. haemolytica* serotype 1 vaccine elicits a serotype-specific inhibition of nasal and tonsillar colonization by the homologous serotype under field conditions.[15]

Calves naturally exposed to *M. haemolytica* or vaccinated subcutaneously or intradermally with the whole cell live organisms are resistant to experimental challenge and develop antibodies to all surface antigens and leukotoxin antibody titer. This supports the hypothesis that protection against experimental challenge with *M. haemolytica* may require an immune response to leukotoxin. Cattle that have died from pneumonic pasteurellosis have lower leukotoxin neutralizing activity in their sera than cattle from the same group that died from other causes. This important observation was followed by vaccination of calves with a leukotoxic culture supernatant from pathogenic *M. haemolytica*, which provided some protection against experimental challenge with *M. haemolytica* A1.[59] One vaccination of cattle with a *M. haemolytica* leukotoxin extract vaccine was as effective in enhancing protection against experimental challenge as two vaccinations.[62]

The use of modified-live *M. haemolytica* and *P. multocida* vaccine in dairy calves between 14 and 20 days of age was effective in increasing titers of antibodies against *M. haemolytica* but did not improve calf health or performance.[63] Vaccination of colostrum-deprived calves at 2 and 4 weeks of age with a *M. haemolytica* A1 culture supernatant vaccine resulted in high titers of IgM antibodies to capsular polysaccharide

within 1 week of vaccination.[64] All vaccinated calves seroconverted with leukotoxin-neutralizing antibodies but peak antibody levels were low. Following experimental challenge, vaccinated calves had considerable lung injury but survival rate, clinical scores, and amount of lung involvement were better than those of control calves.

Leukotoxin extract vaccine

Resistance to pneumonic pasteurellosis correlates well with high serum antibody levels to various antigens of *M. haemolytica*, such as leukotoxin and various capsular antigens, and has led to the use of these components in the development of vaccines.[59] High leukotoxin neutralizing antibody titers induced by natural infections have been associated with reduced susceptibility to pneumonic pasteurellosis. Vaccination of calves with a leukotoxic culture supernatant from pathogenic *M. haemolytica* provides some protection against experimental challenge with the organism.

The efficacy of the leukotoxin extract vaccine has been evaluated in clinical field trials against naturally occurring bovine respiratory disease in weaned beef calves 6–8 months of age entering feedlots in Ontario and Alberta.[58] In an initial field trial in Alberta, auction-market-derived calves were given two doses of the vaccine within 1–5 days of arrival. Mortality from all causes was significantly lower in vaccinated calves (4.2% vs 2.1%) and mortality due to fibrinous pneumonia was lower (2.2% vs 1.1%).[58] In a trial in Ontario feedlots, recently shipped non-preconditioned calves were vaccinated within 24 hours after arrival.[58] The vaccine resulted in a slight decrease in morbidity, slight improvement in treatment response rates and a reduction in relapse rates. When the vaccine was combined with a modified live virus vaccine containing the IBR and PI-3 viruses, the mortality rate increased. However, the number of calves in each group was insufficient to adequately evaluate the differences. In another trial in Alberta, calves were assigned to one of four groups:

- Vaccinated on the ranch of origin 3 weeks prior to shipment to the feedlot
- Vaccinated only on arrival at the feedlot
- Vaccinated at both locations
- Not vaccinated at either location.[58]

The vaccine did not result in a change in morbidity or weight gain. Total mortality rates were increased significantly, and mortality rates from respiratory disease tended to be increased in ranch calves vaccinated at the ranch. However, calves moved directly from ranches to feedlots, regardless of vaccination status, had lower morbidity and mortality, and better weight gains, than calves purchased from auction markets. In summary, there were no major benefits from vaccination. One of the problems may be the timing of the vaccination. Ideally, calves should be vaccinated at least 2 weeks prior to arrival at the feedlot; this is consistent with the temporal design of the laboratory studies, in which the first vaccination was given 42–51 days before challenge.

A single vaccination of a *M. haemolytica* bacterin-toxoid given to calves on arrival in the feedlot reduced overall crude mortality but there were no differences between vaccinates and nonvaccinates in bovine respiratory disease-specific mortality, morbidity, and/or average daily gain.[65] Vaccination of seronegative persistently infected BVDV calves with a *M. haemolytica* bacterin-toxoid does not result in increased *M. haemolytica* antibodies compared to BVDV negative calves receiving the same vaccine.[66]

Vaccination of feedlot cattle prior to transport to the feedlot with a *M. haemolytica* bacterin-toxoid elicited an antibody response but did not have any effect on *M. haemolytica* colonization of the nasopharynx.[67] Florfenicol given on arrival reduced the incidence of respiratory disease, delayed the interval before onset of disease and reduced the incidence of colonization of the nasopharynx by *M. haemolytica*.

Vaccination of calves after arrival in the feedlot with a genetically attenuated leukotoxin of *M. haemolytica* combined with bacterial extracts of *M. haemolytica* and *H. somni* reduced morbidity due to bovine respiratory disease.[68] The same vaccine, along with a modified-live BRSV vaccine, has been used to aid in the control of enzootic pneumonia in beef calves vaccinated at 3–5 weeks of age.[69] Vaccination of feedlot calves after arrival with the genetically attenuated leukotoxin of *M. haemolytica* combined with bacterial extracts of *M. haemolytica* alone reduced the risk of UBRD.[70]

Whole cell vaccine

Experimental vaccination of calves with live *M. haemolytica* or *P. multocida* by aerosol or subcutaneous route effectively reduces the severity of subsequent experimental disease.[71] Vaccinated calves develop high serum antibody titers to the somatic antigens of the homologous organism.

Passive immunity to *Mannheimia haemolytica*

Vaccination of pregnant dairy cows at 6 and 3 weeks before parturition with a leukotoxin extract vaccine induced leukotoxin-neutralizing serum antibody titers in the cows, increased titers in colostrum and increased passive leukotoxin colostral antibody titers in the calves.[72,73] Vaccination was also associated with increased indirect agglutinating serum antibody titers in the cows. The protective effect of the antibodies against naturally occurring disease in the calves was not determined.

Vaccination of beef cows with a combined genetically attenuated leukotoxin *M. haemolytica* vaccine and a *H. somni* vaccine once at 4 weeks prepartum increases passive antibody titers to both organisms in their calves.[74] Double vaccination of the calves with pre-existing maternal antibodies at 1 and 2 months of age will increase antibody titers to both organisms until 6 months of age. Vaccination of beef calves with low levels of pre-existing antibody at 3 and 4 months of age will increase antibody titers to *H. somni* until 6 months of age and to *M. haemolytica* until 5 months of age.[74] Thus prepartum vaccination may be an effective measure for the control of pneumonia in calves under 2 months of age, and vaccination of the calves at 3 and 4 months of age may provide additional protection until the calves are 6 months of age.

Evaluation of efficacy of *Mannheimia haemolytica* vaccines

Meta-analysis of the published literature on the efficacy of the various vaccines against pneumonic pasteurellosis of cattle indicates that culture supernatants and/or potassium-thiocyanate-extracted outer membrane protein vaccines perform as well as live vaccines.[75] Live vaccines are considered to be the best in terms of protective immunity induced against pneumonic pasteurellosis because they replicate at the site of injection and produce the important immunogens that stimulate a protective immune response. However, live vaccines are associated with side-effects such as fever, local abscessation, and lameness.

Commercial vaccines have been evaluated by measuring antibodies in 4–6-week-old calves vaccinated against leukotoxin, capsular polysaccharide, whole cell antigens, and iron-regulated outer membrane proteins.[76] A bacterin-toxoid, a leukotoxin culture supernatant, a modified-live *M. haemolytica* and *P. multocida* vaccine, and an outer membrane extract of the organism were evaluated. All vaccines induced antibodies to the antigens but there were wide variations between the vaccines: some vaccines demonstrated little if any antibody to leukotoxin or outer membrane proteins. The highest leukotoxin antibody

titer did not reach its peak until 14 days after the booster dose of vaccine, which suggests that a second dose of vaccine is necessary for protection.

The efficacy of three commercial vaccines was evaluated against experimental pneumonic pasteurellosis.[77] Protective immunity was evaluated by assessment of clinical scores and lung lesions after endobronchial challenge with virulent *M. haemolytica*. There was significant correlation between lung and serum antibody levels against leukotoxin, capsular polysaccharide and outer membrane proteins. The vaccines did not provide optimal protection but the bacterin-toxoid vaccine was superior to the others. The culture supernatant containing leukotoxin, lipopolysaccharide, and capsular polysaccharide provided the best protection against experimental disease compared to a sodium salicylate extract containing outer membrane proteins, lipopolysaccharide, and capsular polysaccharide, and a combination of the above two. Leukotoxin is an important virulence factor in the disease and its use in vaccines provides significant protection. Muramyl dipeptide analogs may increase the humoral and protective response of calves to capsular polysaccharide.[78]

Adverse vaccine reactions

Some adverse reactions are associated with live vaccines. Systemic infection due to *M. haemolytica* occurred 2–18 days following vaccination with an avirulent live culture of *M. haemolytica*.[75] Lesions included injection site inflammation, purulent meningitis, and polyarthritis. Abscess formation at injection sites after vaccination with modified live *M. haemolytica* vaccines is also possible.[75] The purified capsular polysaccharide of *M. haemolytica* used in combination with other antigens did not provide protection but rather caused a high incidence of anaphylaxis.

Viral vaccines

Because prior infection of the respiratory tract with either IBRV or PI-3V may predispose to pneumonic pasteurellosis, the vaccination of beef calves 2–3 weeks before weaning and feedlot cattle 2 weeks before shipment to a feedlot has been recommended as part of a preconditioning program. Vaccination of calves at 3–6 months of age with an intranasal modified live IBRV and PI-3V vaccine provides protection against experimental pneumonic pasteurellosis induced by aerosol challenge with IBRV followed 4 days later by an aerosol of *M. haemolytica*. Using this principle of control it would be necessary to vaccinate the calves at least 2 weeks before they are weaned, stressed, or transported to a feedlot. Vaccination on arrival with modified-live virus vaccines, while commonly done, may be associated with increased mortality. The development of viral vaccines that contain viral glycoproteins and inactivated whole-virion IBRV, which are immunogenic but do not cause disease, may show some promise.

Vaccination programs

Feedlot cattle

Under ideal conditions, feedlot cattle should be vaccinated twice at a 14-day interval with the *M. haemolytica* bacterial extract and genetically attenuated leukotoxin vaccine, with the second dose at least 14 days before arrival in the feedlot. However, in commercial feedlots, cattle are usually vaccinated only once after arrival. The second dose is not given because most cases of shipping fever occur within 2 weeks after arrival. Experimentally, one vaccination is as effective as two vaccinations.[62] The presence of the organism as a natural commensal in the upper respiratory tract can effectively prime the animal and allow it to respond in an anamnestic mode to only one vaccination.

Beef breeding herds

The breeding herd is vaccinated annually with the *M. haemolytica* bacterial extract and genetically attenuated leukotoxin vaccine at 4 and 7 weeks prepartum to boost specific colostral antibody levels.

Nursing beef calves

Calves are vaccinated at 3–4 months of age, twice, at a 14-day interval with the *M. haemolytica* bacterial extract and genetically attenuated leukotoxin vaccine.

Dairy cattle herds

Pregnant dairy cattle are vaccinated with the *M. haemolytica* bacterial extract and genetically attenuated leukotoxin vaccine at 4 and 7 weeks prepartum to boost specific colostral antibody levels. Dairy calves are vaccinated beginning at 4–6 months of age as part of a calfhood vaccination program.

Chemoprophylaxis

Antimicrobials are used for the control of pneumonic pasteurellosis, particularly in cattle that have just been introduced into a feedlot.

Mass medication of individual animals

The early onset of pneumonic pasteurellosis in cattle within a few days after arrival in the feedlot requires consideration of mass medication of all animals in a group as part of a health management program. Field trials indicate that administration of antimicrobials to calves at varying times on arrival in the feedlot can reduce subsequent morbidity and mortality from respiratory disease. The administration of antimicrobials to high-risk calves immediately after arrival is particularly effective under commercial feedlot conditions. Meta-analysis of the literature on mass medication for bovine respiratory disease indicates that prophylactic parenteral mass medication of calves with long-acting oxytetracycline or tilmicosin on arrival at the feedlot will reduce bovine respiratory disease morbidity rates.[79]

The injection of trimethoprim–sulfadoxine or oxytetracyclines on arrival reduced morbidity and mortality from respiratory disease in high-risk calves. The administration of a long-acting preparation of oxytetracycline at a dose rate of 20 mg/kg BW intramuscularly to feedlot cattle on arrival can reduce the morbidity and mortality from respiratory disease. Both the intramuscular and subcutaneous administration of oxytetracycline formulation are comparable to the intramuscular administration of currently available oxytetracycline formulations after arrival in the feedlot. Tilmicosin, at 10 mg/kg BW subcutaneously, given to calves immediately after arrival significantly reduced the treatment rate for bovine respiratory disease during the first 5 days as well as during the first month of the feeding period. The relapse rate and the treatment rate for all diseases during the first month were also reduced. The administration of tilmicosin to calves either upon arrival at the feedlot, or 3 days later, reduced the treatment rate for respiratory disease in the first 30 days. The average daily gain was also improved in the treated group compared to the controls, and the feed conversion efficiency over the first 60 days of the feeding period was superior in the medicated group compared to the nonmedicated animals.

Mass medication of feed and water supplies

Medication of the feed and water supplies has given variable results because of the difficulties in obtaining adequate levels of antimicrobials in those cattle that most need them. In normal weaned beef calves 6–8 months of age blood levels of sulfamethazine of 5 mg/dL or greater can be achieved in 15–24 hours by providing medicated water at a dose rate of approximately 150 mg/kg BW; at 75 mg/kg BW the same blood levels are achieved by 72–84 hours. A standard recommendation is to provide 150 mg/kg BW for the first 24 hours and reduce the level to 75 mg/kg BW for the duration of the medication period, which may last 5–10 days. A feed additive containing 700 mg/d per head of chlortetracycline and sulfamethazine from the day of arrival at the feedlot to day 56 of the feeding period improved average daily gain and feed conversion

and reduced the incidence of bovine respiratory disease for days 0–28 and 0–56, the rate of relapses and mortality for days 0–56 and the incidence of chronic respiratory disease for days 0–28 and 0–56.[80] Performance and health improvements attributed to the feed additive were cost-effective.

Medication of the feed and water supplies can result in a false sense of security and the number of advanced cases of disease can actually increase.

PASTEURELLOSIS OF SHEEP AND GOATS

Mannheimia (Pasteurella) haemolytica is the cause of pasteurellosis in sheep and goats. In the old classification system of *M. haemolytica* there were two biotypes, A and T, which were further subdivided into serotypes based on antigenic differences in capsular polysaccharide.

- The serotypes within biotype A are now classified as *Mannheimia haemolytica* with the exception of serotype A11, which is recognized as a separate species, *Mannheimia glucosida*. *M. haemolytica* is associated with enzootic pneumonia in sheep and goats and with septicemic disease in young suckling lambs
- *M. glucosida* comprises a heterogeneous group of organisms that have low virulence and are mainly opportunistic pathogens of sheep
- Biotype T, containing four serotypes, is now classified as *Pasteurella trehalosi*. *P. trehalosi* is primarily associated with septicemic disease in weaned sheep
- Population genetics show that bovine and ovine strains of *M. haemolytica* represent genetically distinct subpopulations that are specifically adapted to, and elicit disease in, either cattle or sheep
- The most common manifestation in sheep is pneumonic pasteurellosis, which occurs in all ages
- *M. haemolytica* is a secondary invader, and a cause of death, in chronic enzootic pneumonia in sheep associated with *Mycoplasma ovipneumoniae*
- Other manifestations of *M. haemolytica* infections in sheep include septicemic pasteurellosis in very young lambs, which often occurs in association with pneumonic pasteurellosis in the same flocks, and mastitis in ewes
- *P. multocida* is an uncommon respiratory pathogen in sheep in temperate areas but may be of greater importance in tropical areas.

Septicemic pasteurellosis of suckling lambs

This is a disease of **young lambs** associated with *M. haemolytica* biotype A. It occurs in lambs from 2 days to 2 months of age but presents most commonly at 2–3 weeks of age. The young lamb is highly susceptible to biotype A infections, which progress rapidly to a **fatal septicemia**. The organism is also a primary pathogen in goat kids. Septicemic pasteurellosis in suckling lambs may occur as an isolated disease but more commonly occurs in conjunction with pneumonic pasteurellosis, younger lambs succumbing to the former and ewes and older lambs to the latter. This disease probably does not warrant a separate classification but is kept separate because some outbreaks are manifest only with this septicemia in lambs.

There is a significant difference in the incidence of death from septicemic pasteurellosis in lambs between flocks that are infested with *Ixodes ricinus* and flocks that are *Ixodes*-free. It is believed that tick-borne fever can predispose to septicemic pasteurellosis[1] and lambs that die are usually 4–8 weeks of age.

A single intramuscular injection of 10 mg/kg tilmicosin or 20 mg/kg oxytetracycline is effective in preventing disease.[2]

P. multocida is a rare cause of septicemic disease in neonatal lambs but can occur with a high morbidity and high case fatality rate.[3] Clinically, it presents with a syndrome resembling watery mouth with marked salivation, abdominal distension and a short clinical course. On postmortem examination there is excess peritoneal and pleural pericardial fluid. Prophylactic long-acting tetracycline at a dose of 100 mg per lamb has prevented further cases.

Mastitis

M. haemolytica is recorded as a major cause of mastitis in ewes in Britain. It has been isolated from the udder of 20% of ewes with subclinical mastitis and from 40% of cases of acute mastitis.[4] A variety of typed and untyped strains within biotype A are isolated and serotype A2 is commonly isolated from acute mastitis. The epidemiology of the disease is unclear. Infection may occur from the organism on bedding[5] but the source of infection is more probably from the nose and mouth of the suckling lamb, which is supported by the observation that the prevalence of mastitis associated with this organism is less in dairy sheep than in conventional flocks.[6] Experimental challenge studies show that strains vary in their pathogenicity for the udder.[6]

Pneumonic pasteurellosis affecting wildlife

Pasteurella and *Mannheimia* spp. have been isolated from a number of different species of wildlife but there has been particular concern with outbreaks of acute fatal pneumonic pasteurellosis that have occurred in Rocky Mountain and desert bighorn sheep (*Ovis canadensis*) following commingling with domestic sheep or feral goats.[7] *M. haemolytica*, *P. trehalosi*, and *P. multocida* have been isolated. *P. trehalosi* serotypes are carried in the tonsils of healthy bighorn sheep[8] but bighorn sheep are believed to be particularly susceptible to pathogenic biotype A strains acquired as a result of commingling with domestic sheep on range coupled with the stress of high densities and food shortage.[9,10] This association has raised environmentalist concerns for practices of communal grazing of domestic sheep with wildlife species. As with sheep, disease associated with these bacterial species in wildlife has not been prevented by vaccination with current vaccines.[11]

PNEUMONIC PASTEURELLOSIS OF SHEEP AND GOATS

Synopsis

Etiology *Mannheimia haemolytica* (*Pasteurella haemolytica* biotype A)
Epidemiology Organism carried in oropharynx and tonsils of healthy sheep and goats. Carrier prevalence rate increases in late spring/early summer and again in early autumn, which coincides with an increased prevalence of disease. Disease occurs in ewes and young lambs in late spring and early summer and feeder lambs late summer. Commonly there is a history of stress. In pastured sheep outbreaks often associated with changes in climate or management. Outbreaks in housed sheep associated with poor ventilation
Clinical findings Rapid onset and short course. Outbreaks often heralded by sudden death. Fever, cough, respiratory distress, dyspnea. Sheep that recover have persisting ill health
Necropsy findings Fibrinous pleuritis, pericarditis, and bronchopneumonia
Diagnostic confirmation Lesions found on necropsy. Culture, biotyping, and serotyping
Treatment Antibiotics
Control Antibiotics. Long-acting tetracyclines in the face of an outbreak. Avoidance of stress. Vaccination may be of value

ETIOLOGY

Pneumonic pasteurellosis in sheep and goats is associated with biotype A of *Mannheimia (Pasteurella) haemolytica*. Serotype A2 is the most prevalent serotype isolated from pneumonic lungs in both sheep and goats. Less common but important serotypes in sheep are A1, A6 to A9, A11, and A12, and in goats A1 and A6, although there is some regional variation.[1-6] Some experimental challenge studies suggest that there is a difference in virulence between serotypes, with serotypes A1, A2, A7, and A9 having greater virulence.[6] Untypable serotypes can account for approximately 10% of isolates from pneumonic lungs.

Infection with PI-3V or *Bordetella parapertussis* may predispose to pneumonic pasteurellosis.[7]

M. haemolytica is a **normal inhabitant** of the upper respiratory tract of sheep. Colonization of the nasopharynx and the tonsil occurs very shortly following birth, mainly from the ewe but also from the environment, and carriage persists through adult life. *M. haemolytica* has been isolated from 95% of the tonsils and 64–75% of nasopharyngeal swabs from normal adult sheep.[1,8] In healthy flocks there is considerable sheep-to-sheep variation in the biotype and serotype present in the nasopharynx and there are cyclical changes in carrier rate with time and changes in the predominant serotypes that are present. When compared to healthy flocks the prevalence of carriers is higher in flocks that are experiencing disease and there is more decisive prominence of a particular serotype. The carrier prevalence rate also increases in late spring and early summer and again in early fall, which coincides with an increased prevalence of disease.

M. haemolytica is also present on grass and in water in grazing areas and in the bedding of sheep pens; survival in these environments is prolonged in cooler, wet conditions.[9]

EPIDEMIOLOGY

Occurrence

The disease occurs in sheep of all ages and causes losses in sheep in most parts of the world, through both death and depression of weight gain. The seasonal prevalence varies regionally. In the northern hemisphere, outbreaks, as opposed to sporadic disease, are more prevalent in the late spring and early summer. In contrast, in New Zealand and Australia the disease is more prevalent in the late summer and fall, occurring in lambs associated with mustering or transport in hot weather.[10]

Lambs are most susceptible during the first few months of life and ewes are most susceptible at lambing.[4] Outbreaks in lambs can have attack rates up to 40% and a population mortality up to 5%. Both ewes and lambs can be affected in the same outbreak. Outbreaks often start with sudden death in lambs from septicemic pasteurellosis and progress to pneumonic pasteurellosis in the ewes and also in the lambs as they get older. The loss of 400 of 1200 ewes from this disease over a 3-year period is recorded[11] and a mean flock population mortality of 2.49% has been calculated from 450 outbreaks in Britain.[4]

In **housed lambs** the majority of deaths occur over a 2-week period, 3–6 weeks after entry;[12] death losses in feeder and housed lambs are usually of the order of 5%[10] but may be as high as 20%.

High mortality has occurred in **goats** kept in confined quarters after collection from a number of centers.

Experimental reproduction

Pneumonic pasteurellosis can be experimentally reproduced by challenge of specific-pathogen-free lambs with aerosols of *M. haemolytica*, either given alone or

preceded by PI-3V or *B. parapertussis* challenge[5] and by intratracheal inoculation.[6]

Environmental and pathogen risk factors

In **sheep at pasture**, the disease tends to spread slowly and the population mortality rate is lower than in feeder lambs maintained in small areas. Outbreaks in flocks at pasture are frequently associated with changes in climate or management and deleterious changes in environment. In range sheep, confinement for shearing, mating or supplementary feeding may precipitate an outbreak, and severe parasitism or rain and windchill, exposure to bad weather or sudden change in weather may also increase susceptibility,[6,13] with deaths starting within 2 weeks of the stress factor.

In **housed sheep**, risk factors for disease include commingling of animals from different sources, taking sheep to show fairs, drafty or poorly ventilated barns, transport and malnutrition.[3,14]

Feedlot dust contains significant endotoxin and it has been postulated that inhalation of dust may be a predisposing factor in feedlot sheep. However, an experimental challenge study found no effect.[15]

PI-3V appears to be an important predisposing factor to pneumonic pasteurellosis in some outbreaks, based on serological evidence of concurrent infection with PI-3V during outbreaks of pasteurellosis in sheep.[8,16] Adenovirus may also predispose to naturally occurring and experimentally produced pneumonic pasteurellosis.[17,18]

PATHOGENESIS

The development of pneumonic pasteurellosis in sheep and goats is in general the same as in pneumonic pasteurellosis of cattle. *M. haemolytica* is a **primary pathogen** in very young lambs but older lambs are more resistant and predisposing factors are required for the production of disease. Infection with **PI-3V** impairs the bactericidal activity of ovine neutrophils and the clearance of *M. haemolytica* by the ovine lung,[19] and PI-3V has been incriminated in some outbreaks.[16] Experimental infection of specific-pathogen-free lambs with this virus, followed 4 or 7 days later by challenge with *M. haemolytica*, results in pneumonic pasteurellosis that resembles the naturally occurring disease.

Organisms such as *Mycoplasma ovipneumoniae* and *B. parapertussis* colonize the lower respiratory tract in large numbers and attach to cilia, reducing pulmonary clearance of other organisms, which may explain the predisposition of chronic progressive pneumonia to secondary infection with *M. haemolytica* under stress situations.[4,7]

M. haemolytica itself has cell-wall-associated components that may help it to become established during an infection and that are putative virulence determinants. It produces a **leukotoxin** (cytotoxin) that is considered to be an important virulence factor in the pathogenesis of ovine pneumonic pasteurellosis and promotes bacterial proliferation by killing or incapacitating ruminant neutrophils and pulmonary macrophages.[20,21] It is a member of the RTX family of Gram-negative bacterial pore-forming cytotoxins. It is specific for ruminant lymphoid cells. Leukotoxin binding occurs via a high-affinity species-specific mechanism and beta-2 integrins are the putative leukotoxin receptor on leukocytes.

Two other components, **capsular polysaccharide** and **lipopolysaccharide**, attach to alveolar and bronchial epithelium. Capsular polysaccharide precipitates pulmonary surfactant and *M. haemolytica* may attach to this surfactant layer in the alveolus by the lectin reaction of its capsular polysaccharide, thus promoting its establishment and colonization in the lung.[22]

Intraspecific variation in virulence determinants may be responsible for observed differences in host specificity.[21] As in cattle, the endotoxic activities of the bacterial lipopolysaccharide are believed to be critical to the development of the pulmonary lesions, and lipopolysaccharide deposited directly into the lung produces lesions similar to those seen in the lung of natural cases.[22]

In New Zealand, slaughterhouse data consistently show a higher prevalence of lesions of pleurisy and pneumonia in sheep from the warmer areas of the country and this, coupled with the late summer occurrence of clinical disease, suggests heat stress as a predisposing factor, possibly acting through the bypassing of nasal defense mechanisms by open-mouthed breathing.[10]

CLINICAL FINDINGS

Outbreaks often commence with **sudden deaths** in the absence of premonitory clinical signs. In groups of lambs this occurrence of sudden death without prior illness may continue throughout the outbreak but some older sheep will show signs of **respiratory distress**, which can be accentuated by driving. As the outbreak progresses, respiratory involvement becomes more evident, signs including dyspnea, slight frothing at the mouth, cough, and nasal discharge. Affected sheep have fever from 40.4–42.0°C (105–107°F) and are depressed and anorectic. In more chronic cases an increase in intensity of air-flow sounds with an increase in pitch is heard over the area of the bronchial hilus, often with fluid sounds. Death may occur as soon as 12 hours after the first signs of illness but the course in most cases is about 3 days. Sheep that recover have evidence of chronic pneumonia and are often culled because of **persisting ill-health and poor thrift**. In cases produced experimentally, arthritis, pericarditis, and meningitis occur in lambs that survive the acute stages of the disease, but these are not often observed in natural cases.

CLINICAL PATHOLOGY

Most outbreaks are heralded by dead sheep and the diagnosis is established by postmortem examination. There is little information concerning the clinical pathology or the cellular findings in tracheobronchial aspirates in natural case. The organism can survive considerable periods in tracheobronchial washings.[23] Nasal swabs for culture are of little value because of the high carriage rate by healthy sheep of the organism in the nasopharynx.

NECROPSY FINDINGS

With pneumonic pasteurellosis, petechial and ecchymotic hemorrhages are present throughout the body but the salient findings are in the thoracic cavity. In sheep that have died from peracute pneumonic pasteurellosis there is a greenish gelatinous exudate over the pericardium and large quantities of straw-colored **pleural exudate**. The lungs are enlarged, edematous, and hemorrhagic. With less acute cases there is **consolidation** of the lung, usually the apical and cardiac lobes but occasionally in the diaphragmatic lobe. The affected lung is solid and clearly demarcated. Histologically, there is diffuse alveolar necrosis, edema of interlobular septa, and sloughing of bronchial mucosa, and in sheep that survive the peracute phase of the disease there are so-called 'oat cells' in zones surrounding the necrotic alveoli. The organism can be cultured in large numbers in lung lesions and exudates.

Samples for confirmation of diagnosis

- Bacteriology – lung, bronchial node, retropharyngeal node, spleen (CULT)
- Histology – formalin-fixed lung, liver, kidney (LM).

DIFFERENTIAL DIAGNOSIS

When deaths occur in lambs without prior clinical illness the primary differentials are:

- Septicemia associated with *Histophilus somni* (formerly *Haemophilus somnus*)
- Enterotoxemia associated with *Clostridium perfringens* type D
- Other causes of sudden death.

Parasitic pneumonia, jaagsiekte, chronic nonprogressive pneumonia, and chronic progressive pneumonia (maedi) are the common chronic clinical pneumonias of sheep, but these should not be confused with pasteurellosis because of their longer course and distinctive features.

TREATMENT

Where possible, treatment should be based on sensitivity testing of the isolate associated with the outbreak. Penicillin has commonly been used. Not all strains of biotype A are sensitive to penicillin, but almost all strains are sensitive to oxytetracycline, which may be the drug of choice with the availability of long-acting preparations requiring less handling of the sheep. A commercially available combination of amoxicillin and clavulanic acid has shown good efficacy against the experimental disease.[24] Alternate therapies include florfenicol or ceftiofur. Medication of the water supplies with oxytetracycline for 7–10 days may be beneficial.

CONTROL

Environmental and managerial factors that may precipitate outbreaks of the disease should be controlled where possible.

Antibiotics

The use of long-acting tetracycline in the face of an outbreak is a common approach to control. At-risk animals are given the drug intramuscularly at a dose rate of 20 mg/kg BW. The treatment may be repeated at 4-day intervals. A controlled field trial of this procedure has shown it to be efficacious.[25] The feeding of broad-spectrum antibiotics, especially tetracyclines, to lambs in feedlots is a common method of preventing pneumonia in recently weaned lambs. However, there is no documented evidence of its efficiency.

Vaccination

There has been considerable activity in the development of vaccines for the control of pasteurellosis in sheep and goats; however, the development of an effective vaccine has proved elusive. Early studies showed that sheep that had recovered from infection were resistant to subsequent homologous challenge. Also, immune serum will protect against experimental challenge in specific-pathogen-free lambs.[26] Because *M. haemolytica* A2 is the most common isolate from pneumonic lungs of sheep and goats throughout the world, most research on vaccines for sheep and goats has focused on incorporating either a suitable isolate of *M. haemolytica* A2 or suitable antigens extracted from the serotype. Different antigen preparations have been used and, whereas most studies have shown that vaccination can give protection against homologous challenge, there is variable protection against challenge with other serotypes of *M. haemolytica*.[27] The approach has thus been to incorporate other serotypes in the vaccine, usually the ones that are common in the region of vaccine manufacture. However, despite the fact that vaccines against experimental challenge with *H. haemolytica* in sheep and goats, they are not always effective in natural outbreaks and several studies show limited or no protection against natural disease in the field.[16,27–30] This may be because the relevant serotype is not in the vaccine formulation. There have been few controlled field studies of vaccination.[30] Vaccines containing concentrated components of organisms such as outer membrane proteins show potential for cross-serotype protection with experimental infections but remain to be proved in the field.[31]

Vaccines containing various serotypes of *M. haemolytica* stimulate antibody production in pregnant ewes and the lambs receive colostral antibody, which does interfere with the production of antibody by the lambs if they are vaccinated at an early age.

Another approach to control is the vaccination of lambs with PI-3V vaccines in addition to *Pasteurella* vaccination in an attempt to immunize lambs against challenge exposure with both this virus and *H. haemolytica*. The experimental vaccination of specific-pathogen-free lambs with an inactivated PI-3V vaccine provides protection against the combined effect of an experimental challenge with PI-3V and *H. haemolytica*, and field reports suggest that this vaccination is of value.[32,33]

SEPTICEMIC PASTEURELLOSIS IN WEANED SHEEP

Synopsis

Etiology *Pasteurella trehalosi* (*Pasteurella haemolytica* biotype T)
Epidemiology *P. trehalosi* is carried in oropharynx and tonsils of healthy sheep and goats. Carrier prevalence rate increases in late spring/early summer and again in early autumn, which coincides with an increased prevalence of disease. Septicemic pasteurellosis in weaned lambs commonly follows stress such as transport, marketing, shearing, coupled with a change to better feed
Clinical findings Clinical disease seldom seen, as clinical course is very short. Affected sheep are dull, rapidly become prostrate and toxemic, with frothy bloody nasal discharge in the terminal stages
Necropsy findings Pulmonary congestion and edema. Necrotic ulcers of abomasum. Multifocal hepatitis
Diagnostic confirmation Necropsy lesions. Culture, biotyping, and serotyping
Treatment Antibiotics
Control Antibiotics. Long-acting tetracyclines in the face of an outbreak. Avoidance of stress. Vaccination may be of value

ETIOLOGY

The disease is associated with septicemic infection with *Pasteurella trehalosi*, which occurs most commonly following stress. *P. trehalosi* is a common inhabitant in the upper respiratory tract and tonsils of healthy sheep.[1] The organism was previously known as *P. haemolytica* biotype T and all four serotypes within this biotype have been incriminated in the disease.[2,3]

EPIDEMIOLOGY

Occurrence

This is an important disease in regions of Britain; it occurs in Europe and the USA. While recorded as occurring in Australia or New Zealand it is not a significant disease in these countries.[4] The disease occurs predominantly in **weaned lambs** 5–12 months of age. It occurs following some form of **stress** such as transport, marketing, or shearing; or coupled with a

movement to better feed, which is often to turnips, rape, or alfalfa and crop aftermath grazing. In Britain it is a disease of sheep moved from hill and upland farms to lowland farms for fattening.

In North America it is a disease of feedlot lambs and occurs following a change from roughage to concentrate feeding.

In affected groups a population mortality up to 9% is recorded[4] and in some areas septicemic pasteurellosis is the most common cause of death in lambs of this age group.[3]

Experimental reproduction

The disease has been reproduced by oral inoculation coupled either with rapid change in feed from 100% roughage to 90% concentrate or with drugs eliciting immunosuppression.[5]

PATHOGENESIS

P. trehalosi colonizes the tonsil and in affected sheep necrotic lesions are consistently found in the tonsils and the pharyngeal mucosa and sometimes in the abomasal mucosa.[3] It is postulated that bacteria invade from these lesions and enter the bloodstream via venous and lymphatic routes to produce embolic pneumonia with hematogenous spread of the organism to other internal organs.[3] The organism proliferates in these areas to produce a fatal bacterial **endotoxemia**.

CLINICAL FINDINGS

Septicemic pasteurellosis

Clinical disease is seldom seen as the clinical course is often less than 6 hours and affected sheep are **found dead**. Affected sheep are dull, rapidly become prostrate, are toxemic, and may have a frothy bloody nasal discharge in the terminal stages.

CLINICAL PATHOLOGY

Most outbreaks are heralded by dead sheep and the diagnosis is established by the typical lesions at postmortem examination. There is little information concerning the clinical pathology. Nasal swabs for culture are of little value because of the high carriage rate in healthy sheep of the organism in the nasopharynx.

NECROPSY FINDINGS

The principal lesions are in the upper alimentary tract, thorax, and liver. Subcutaneous hemorrhages over the neck and thorax are common. The trachea and bronchi contain blood-stained froth, the lungs are congested and edematous, there are subpleural ecchymoses, but there is **no pneumonia** on gross examination, although an embolic pneumonia is evident histologically. The tonsils and pharyngeal lymph nodes are enlarged and there is ulceration and necrosis of the pharynx and esophagus. There is also hemorrhage, and small **necrotic ulcers** are present on the tips of the folds of the abomasal mucosa.

Histologically there is acute inflammation and emboli in small arterioles and capillaries. The organism can be isolated in large numbers from the tonsils, lungs, liver, and mucosal lesions of the pharynx and esophagus.

Samples for confirmation of diagnosis

- Bacteriology – lung, spleen (CULT)
- Histology – formalin-fixed lung, upper alimentary tract ulcers, liver, kidney (LM).

DIFFERENTIAL DIAGNOSIS

When deaths occur in lambs without prior clinical illness the primary differentials are:

- Septicemia associated with *Histophilus somni* (formerly *Haemophilus somnus*)
- Enterotoxemia associated with *Clostridium perfringens* type D
- White muscle disease
- Toxicities.

TREATMENT

Where possible, treatment should be based on sensitivity testing of the isolate associated with the outbreak. Isolates of *P. trehalosi* are often resistant to penicillin and oxytetracyclines. Florfenicol or ceftiofur should be considered if the sensitivity is unknown. The whole group should be treated prophylactically by injection or, if there is an appropriate antimicrobial, in the feed or water.

CONTROL

Environmental and managerial factors that may precipitate outbreaks of the disease should be controlled where possible.

Vaccination

Immune serum will protect against experimental challenge in specific-pathogen-free lambs.[6] However, despite the fact that vaccines have been developed that engender protection against experimental challenge, they are not always effective in natural outbreaks and several studies show limited or no protection against natural disease in the field.[6–8]

PASTEURELLOSIS OF SWINE

Pasteurella multocida is an important pathogen of pigs. Toxigenic strains, in conjunction with *Bordetella bronchiseptica*, are recognized as the etiological agents of atrophic rhinitis described under that heading. Pneumonic pasteurellosis and septicemic pasteurellosis are also manifestations of infection with *P. multocida* in pigs. It has recently been shown that *P. multocida* capsular type A can cause not only pneumonia in growing pigs but also septicemia and arthritis[1] as well as being associated with the presence of skin lesions in sporadic cases of porcine dermatitis and nephropathy syndrome.[2,3]

PNEUMONIC PASTEURELLOSIS

ETIOLOGY

P. multocida is commonly isolated from the lungs of pigs with chronic pneumonia, purulent bronchopneumonia, and pleuritis.[4,5] Isolates are predominantly capsular serotype A strains with some serotype D strains.[6,7] It is possible to serotype *P. multocida*[8] and of the 16 serotypes, serotypes 3 and 5 are the predominant isolates. In most herds there is a single isolate and this is usually A3.[9] In a recent study 88% of the lung strains were type A (OMP strains 1:1, 2:1, 3:1, 5:1, and type 6:1).[10] These authors suggest that the agent may be a primary pathogen with a relatively high degree of virulence and furthermore there has been a considerable transfer of capsular biosynthesis and *tox*A genes between the strains representing subpopulations of both type A and type D strains. It has recently been suggested that most *P. multocida* strains have the *tox*A gene.[11] This is further evidence of a trend reported earlier,[12] when it was suggested that there was widespread genetic diversity in the capsular type A strains and that a single clone might be more predominant in a particular pig population. For many years it was thought that toxigenic strains were not found in the lung but in three surveys 25–90% of the pneumonic strains were toxigenic.[13–15] The largest and most recent study[15] looked at 230 isolates from 250 pigs and found that 200 (88%) were A, 4% were D and 9% could not be identified. The *tox*A gene was found in 13%, of which 11%

belonged to A, 1% to D and 1% could not be typed. Serotype D strains were specifically associated with abscesses in the lung.

P. multocida is a common secondary infection in the lungs of pigs with enzootic pneumonia associated with *Mycoplasma hyopneumoniae*. The pneumonic lesions from which both organisms are recovered are more severe than those associated with *M. hyopneumoniae* alone.[16] The organism is also a common secondary infection in pneumonia associated with *Actinobacillus pleuropneumoniae*.

EPIDEMIOLOGY

Although found in other species it is generally assumed that there is little interspecies transfer.

It is generally considered that *P. multocida* is not a primary pathogen of the lower respiratory tract and that its involvement in pneumonia is secondary to infection with other respiratory pathogens. A large-scale survey in Germany[17] of 6560 postmortem examinations found that pneumonia was present in 24.4% of cases. In 49.3% of these *P. multocida* was found and with increasing age there was an increasing rate of recovery of *P. multocida*. Most of the lung cultures (54.2%) showed multiple infections. Pneumonic pasteurellosis cannot be reproduced by the intranasal or intratracheal challenge of healthy pigs with *P. multocida* but can be reproduced by challenge to pigs whose pulmonary clearance mechanisms have been compromised by infections with *Mycoplasma hyopneumoniae*,[18] pseudorabies virus,[19] or by anesthesia[20] and also lungworms. Although atmospheric ammonia may predispose to nasal attachment of *P. multocida* type D it seems unlikely that this applies to pulmonary infection.[21] It has been reproduced when nontoxigenic strains are given repeatedly by intrabronchial injection following *A. pleuropneumoniae* or *M. hyopneumoniae* infections.[22] Strains vary in their ability to produce secondary pneumonia and pleuritis in these experimental models, suggesting the existence of specific pneumotropic and pleurotropic strains,[19] which is supported by epidemiological studies that have found that a single strain predominates in problem herds.[23] The organism is carried in the nasal cavity and tonsils of pigs, and carriage rates are higher in herds with a history of chronic respiratory disease.[23]

Transmission is by aerosol and more probably by direct nose-to-nose contact and thence by inhalation or ingestion. The bacterium has a short-term survival in aerosols, particularly of low humidity (less than 1 h), but survives for longer at high humidity and lower temperature. Heating to 60°C will kill it, but it can survive for up to 14 days in water, 6 days in slurry and up to 7 weeks in nasal washings at room temperature. There is always the feeling that the condition is most common under conditions of poor husbandry, notably overcrowding, and poor hygiene and where environmental stress is high. As a result it is often seen after transport, mixing or moving groups of pigs. The virulence mechanisms are not known but it is known that some may adhere to mucus and some have pili or fimbriae for attachment.[24] Serotype A strains are resistant to phagocytosis, which has been attributed to the presence of capsular hyaluronic acid and might allow their colonization of lung lesions.[9] Isolates from lung lesions are not invariably toxigenic. A recent study has shown that there is a change in the functional capabilities of the blood cells with oxygen radicle formation and phagocytosing neutrophils elevated after infection.[25]

CLINICAL FINDINGS

There is a possibility of a hyperacute condition in which the only sign is sudden death.

Pneumonic pasteurellosis is a common cause of sporadic cases of acute bronchopneumonia in grower–finisher pigs. Affected pigs have fever of up to 41°C (106°F), are anorectic and disinclined to move (lethargic), and show significant respiratory distress with labored respiration and increased lung sounds, often breathing through the mouth. Cyanosis may occur. Without treatment, death is common after a clinical course of 4–7 days. There is a marked tendency for the disease to become chronic, resulting in reduced weight gain and frequent relapses, and real recovery seldom occurs. Although pneumonic pasteurellosis is secondary to other underlying respiratory disease it can occur as an outbreak, spreading to affect several pigs within a group. The first indication of disease within a group and of an impending outbreak may be the finding of a pig dead with a peracute infection. In an intermediate stage there may be fever, coughing and poor growth rate for about 3–5 weeks before recovery. The disease may also exist in chronic form within pigs in a herd as part of the swine pneumonia complex with little evidence of overt clinical disease but with an effect on growth rate and food conversion efficiency.

NECROPSY FINDINGS

At necropsy the lesions are considered to be typical of what is normally called enzootic pneumonia – a chronic bronchopneumonia with abscessation. Pleuritis is common and there may also be pericarditis. In some instances there may be carcass congestion and the trachea may be full of frothy fluid. Experimental infections have caused between 15.5% and 39.4% of lung tissue to be affected with pneumonia.[25] Histologically, the airways are filled with degenerate leukocytes but the overall lung pathology is often complicated by other pathogens. Peracute fatalities show an acute necrotizing and fibrinous bronchopneumonia reminiscent of bovine pneumonic pasteurellosis. There is edema, congestion, and hemorrhage with bronchiolar exudation containing bacteria, neutrophils, and macrophages, which are also present in the alveoli. Small bronchi and bronchioles may be completely occluded by the exudates.

DIAGNOSIS

Diagnosis is through the clinical signs (fever, dyspnea, cyanosis, sudden death), lesions at gross post-mortem, histopathology, and isolation of *P. multocida*.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other causes of respiratory disease in pigs.

Enzootic pneumonia of pigs, unless accompanied by pasteurellosis, is not manifested by a marked systemic or pulmonary involvement.

Dyspnea is a prominent sign in **Glasser's disease** but there is obvious arthritis and at necropsy the disease is characterized by arthritis, a general serositis and meningitis.

Pleuropneumonia associated with *A. pleuropneumoniae* causes a severe pneumonia with rapid death, and differentiation from pasteurellosis is necessary at necropsy.

The septicemic and acute enteric forms of salmonellosis in pigs are often accompanied by pulmonary involvement but these are usually overshadowed by signs of septicemia or enteritis. Chronic pasteurellosis has to be differentiated from lungworm infestations and ascariasis.

TREATMENT

The animals are usually severely ill so therefore treatment is firstly by parenteral injection and then by water medication and once they start to eat medication should continue with in-feed antibiotics.

Treatment is with antibiotics, commonly with tetracyclines.[26,27] There is also a case for using ceftiofur, penicillin, streptomycin, trimethoprim/sulfonamides, ampicillin, spiramycin, and spectinomycin for 3–5 days. Tilmicosin and telithromycin would also be suitable antibiotics. There is significant variation in the antibiotic sensitivity of isolates[28] and the choice of antibiotic should be based on a sensitivity established for the organism for that farm. In a recent survey in the UK, 15% of

P. multocida isolates were resistant to tetracyclines and it was also reported that resistance to trimethoprim/sulfonamides, apramycin, and neomycin was found in some isolates.[29] A German survey showed that 55% were resistant to sulfonamides.[17]

CONTROL

Vaccination is ineffective, although autogenous vaccines have been produced that are effective (need to be certain that you have the strain causing the problem). Control depends on management of the risk factors, which are described under enzootic pneumonia of swine, since pasteurellosis is often secondary to that condition. In particular all-in/all-out management with vaccination for enzootic pneumonia is essential. Tiamulin at 40 ppm in the feed has also been used strategically at the time of stress, for example over mixing and moving.

SEPTICEMIC PASTEURELLOSIS

Septicemic disease with death occurring within 12 hours and without signs of pneumonia is occasionally observed in neonatal pigs. Septicemic disease is also recorded in India in association with infection with capsular serotype B.[30,31] The disease occurs in all ages of pigs including adults and is manifest with fever, dyspnea, and edema of the throat and lower jaw. A population mortality of 40% in a group of pigs is recorded.[30] Acute septicemic disease in grower pigs aged 14–22 weeks and associated with serotype D has been recorded in Australia.[18] Recently,[32] an outbreak of hemorrhagic septicemia was reported from Australia associated with *P. multocida* subsp. *gallicida* in a large pig herd. Affected pigs were found dead with swelling of the pharyngeal region and blue discoloration of the ventral abdomen and ears.

On gross postmortem there was hemorrhage and congestion on serosal surfaces. Histological examination of the viscera showed widespread vascular damage with thrombus formation and intravascular colonies of bacteria.

Samples for confirmation of diagnosis

- Bacteriology – lung, bronchial node (plus liver, spleen, kidney for septicemic form). Culture produces large mucoid colonies 3–5 mm in diameter on blood agar. In the past the recovered organisms were rarely toxigenic. Some isolates did have fimbriae. On a smear Gram-negative coccobacilli may be seen. In early cases aerobic cultures of heart blood and lung lesions will give a pure culture. Anaerobic cultures often yield *Bacteroides* spp. as well and if *Haemophilus* cultures are used as well these will also often prove positive. Further identification using electrophoretic typing may be necessary, as in the case of secondary infection in sporadic cases of porcine dermatitis and nephropathy syndrome.[2,3] Here a high proportion had a single electrophoretic type (01) isolated from a range of tissues. In the septicemic form[1] the organism was readily cultured from the liver, spleen, and lymph nodes
- Histology – formalin-fixed lung (variety of organs for septicemic form) (LM).

TULAREMIA

Tularemia is a highly contagious disease occurring principally in wild animals but it may transmit to farm animals, causing septicemia and high mortality.

Synopsis

Etiology *Francisella tularensis* biovar *tularensis* in North America is tick-transmitted. *Francisella tularensis* biovar *holarctica* in Asia, Europe, and North America is transmitted by ticks and mosquitoes
Epidemiology Livestock disease mainly reported from North America; seasonal, associated with heavy tick infestation. Majority of reports in livestock are historical. Zoonosis
Clinical findings Tick infestation. Fever, stiffness of gait, diarrhea, weight loss, recumbency. Wool break
Clinical pathology Culture. Agglutination and intradermal test but not specific
Necropsy findings Subcutaneous swellings at site of tick attachment, lymphadenitis, and septicemia in sheep. Pigs have pleuritis, pneumonia, and abscessation of submaxillary and parotid lymph nodes
Diagnostic confirmation Culture or indirect fluorescent antibody staining

ETIOLOGY

Francisella tularensis is the causative organism. It is Gram-negative, does not form spores and gives partial cross-agglutination with *Brucella* spp. Isolates are antigenically similar but they can be divided into **two types** on biochemical and epidemiological features and virulence tests. **Type A**, *Francisella tularensis* biovar *tularensis*, is prevalent in North America. **Type B**, *Francisella tularensis* biovar *holarctica* (*palaearctica*), is found in Asia, Europe and North America. Type A is associated with tick-borne tularemia in rabbits and type B is associated with mosquitoes and with water-borne disease in aquatic rodents. Type A is the more pathogenic of the two types and the more virulent for humans.[1–3] Type B rarely causes disease in higher mammals.

EPIDEMIOLOGY

Occurrence

Tularemia is primarily restricted in its occurrence to countries in the **northern hemisphere** and occurs in most of them. In North America the disease is most prevalent in farm animals in the north-western states of the USA and the adjoining areas of Canada, although in these areas it is rare and the majority of reports in livestock are historical.

Risk factors

Animal risk factors

F. tularensis has a wide host range and is recorded in over 100 species of bird and wild and domestic animal. Disease is recorded among farm animals, most commonly in **sheep and pigs** and to a lesser extent in calves, which appear more resistant but can be infected in association with heavy tick infestation.[4] Sheep and pigs of all ages are susceptible but most losses occur in lambs, and in pigs clinical illness occurs only in piglets. There is a sharp seasonal incidence, the bulk of cases occurring during the spring months. The morbidity rate in affected flocks of sheep is usually about 20% but may be as high as 40%, and the mortality rate may reach 50%, especially in young animals.

Transmission

The **major reservoirs** and transmitters of the infection are rabbits, hares, wild rodents, **ticks**, and flies and the principal mammalian target host in North America is the cottontail rabbit (*Sylvilagus* spp.). With sheep, transmission occurs chiefly by the bites of the wood tick, *Dermacentor andersoni*, and from *Haemaphysalis otophila*, the ticks becoming infected in the early part of their life cycle when they feed on rodents.[5] In Europe *Ixodes ricinus* and *Dermacentor reticulatus* are vectors.[6]

Trans-stadial and **transovarial transmission** occurs in the tick. The adult ticks infest sheep, and pastures bearing low shrubs and brush are particularly favorable to infestation. The ticks are found in greatest numbers on the sheep around the base of the ears, the top of the neck, the throat, axillae, and udder. It is assumed that sheep are relatively resistant to tularemia but become clinically affected when the infection is massive and continuous. Transmission to pigs and horses is thought to occur chiefly by tick bites but **mechanical transmission** to laboratory animals does occur with tabanid and blackflies.[7]

Pathogen risk factors

There is little information concerning virulence mechanisms of *F. tularensis*. The capsule appears to be a necessary component for expression of full virulence and protects against serum-mediated lysis. The lipopolysaccharide has unusual biological and structural properties and low toxicity in vitro and in vivo.[3] The organism can persist in dry straw for 6 months, persists for at least 16 months in **mud and water** and may proliferate in these media.[8,9] It does not appear to survive in carcasses for long periods unless they are frozen, when it may persist for 60–120 days.

Zoonotic implications

F. tularensis biovar *tularensis* has remarkable invasive powers and infection in humans can occur through the **unbroken skin**. Most exposures appear to result from the handling of infected rabbits and other wildlife but infections can arise from **bites** of ticks and the deer fly (*Chrysops discalis*), from the **ingestion** of contaminated meat and water, and from the bite or scratch of infected cats.[10–12] The disease is an occupational hazard to workers in the sheep industry in areas where the disease occurs. Spread of the disease to humans may also occur in abattoir workers who handle infected sheep carcasses. **Shearers** are susceptible because outbreaks often occur at shearing time. The inhalation or intradermal injection of as few as 10 organisms can establish infection in humans,[1,3] and appropriate precautions should be taken in the clinical and postmortem examination of suspect cases. The organism is identified as a potential agent of bioterrorism.[13]

PATHOGENESIS

Tularemia is an acute septicemia but localization occurs, mainly in the parenchymatous organs, with the production of granulomatous lesions.

CLINICAL FINDINGS

Sheep

The incubation period has not been determined. A heavy tick infestation is usually evident.

The **onset** of the disease is slow with a gradually increasing stiffness of gait, dorsiflexion of the head and a hunching of the hindquarters; affected animals lag behind the group. The pulse and respiratory rates are increased, the temperature is elevated up to 42°C (107°F), and a cough may develop. There is diarrhea, the feces being dark and fetid, and urination occurs frequently with the passage of small amounts of urine. Body weight is lost rapidly, and progressive weakness and recumbency develop after several days, but there is no evidence of paralysis, the animal continuing to struggle while down. Death occurs usually within a few days but a fatal course may be as long as 2 weeks. Animals that recover commonly shed part or all of the fleece but are solidly immune for long periods.

Pigs

The disease is latent in adult pigs but young piglets show fever up to 42°C (107°F), accompanied by depression, profuse sweating, and dyspnea. The course of the disease is about 7–10 days.

Horses

In horses, fever (up to 42°C, 107°F) and stiffness and edema of the limbs occur. Foals are more seriously affected and may show dyspnea and incoordination in addition to the above signs.

CLINICAL PATHOLOGY

An agglutination test is available for the diagnosis of tularemia, a titer of 1:50 being regarded as a positive test in pigs. Serum from pigs affected with brucellosis does not agglutinate tularemia antigen, but serum from pigs affected with tularemia agglutinates brucellosis antigen. Cross-agglutination between *F. tularensis* and *Brucella abortus* is less common in sheep and an accurate diagnosis can be made on serological grounds because of the much greater agglutination that occurs with the homologous organism. Titers of agglutinins in affected sheep range from 1:640 to 1:5000 and may persist at levels of 1:320 for up to 7 months. A titer of 1:200 is classed as positive in sheep. In horses the titers revert to normal levels in 14–21 days.

An intradermal sensitivity test using 'tularin' has been suggested as being more reliable as a diagnostic aid in pigs than the agglutination test, but is unreliable in sheep.[5]

NECROPSY FINDINGS

In sheep, large numbers of ticks may be present on the hides of fresh carcasses. In animals that have been dead for some time, dark red subcutaneous areas of congestion up to 3 cm in diameter are found and may be accompanied by local swelling or necrosis of tissues. These lesions mark the attachment sites of ticks. Enlargement and congestion of the lymph nodes draining the sites of heaviest tick infestation are often noted. Pulmonary edema, congestion, or consolidation are inconstant findings.

In pigs the characteristic lesions are pleuritis, pneumonia, and abscessation of submaxillary and parotid lymph nodes. The organisms can be isolated from the lymph nodes and spleen, and from infected ticks. Isolation can also be effected by experimental transmission to guinea pigs. Techniques such as immunoperoxidase staining of fixed specimens and PCR of fresh tissues can circumvent the need for culture of this zoonotic agent.

Samples for confirmation of diagnosis

- Bacteriology – lung, lymph node, spleen (CULT – requires cystine-enriched media, PCR)
- Histology – above tissues plus liver, fixed in formalin (LM, IHC).

Note the zoonotic potential of this organism when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The occurrence of a highly fatal septicemia in sheep during spring months when the sheep are heavily infested with *Dermacentor andersoni* should suggest the possibility of tularemia, especially if the outbreak occurs in an enzootic area.

- **Tick paralysis**. This occurs in the same area and at the same time of the year as tularemia but is not accompanied by fever and there is marked flaccid paralysis. Recovery from tick paralysis occurs commonly if the ticks are removed
- **Other septicemias** include *P. trehalosi* in sheep and *Haemophilus* spp. in sheep and cattle. These are unusual in the age group in which tularemia occurs and are not associated with tick infestation. In pigs, local lesions can resemble tuberculosis
- **Anthrax.**

TREATMENT

Streptomycin, gentamicin, the tetracyclines, and chloramphenicol are effective treatments in humans and companion animals.[10] Oxytetracycline (6–10 mg/kg BW) has been highly effective in the treatment of lambs and much more effective than penicillin and streptomycin.[5]

CONTROL

An outbreak of tularemia in sheep can be rapidly halted by spraying or dipping with an insecticide to kill the vector ticks. In areas where ticks are enzootic, sheep should be kept away from shrubby, infested pasture or sprayed regularly during the months when the tick population is greatest. An experimental live attenuated vaccine has been developed but there is no routine vaccination of livestock.

YERSINIOSIS

Synopsis

Etiology *Yersinia pseudotuberculosis* and *Yersinia enterocolitica* cause occasional disease in farm animals under special circumstances. These organisms also are increasingly recognized as a cause of disease in humans and this is their main importance

Epidemiology Subclinical and clinical disease in ruminants associated with either organism in animals that are debilitated from other influences. Enterocolitis is an emerging form of infection. Pigs carry *Y. enterocolitica* in the tonsils, pharynx, and intestine but the epidemiology of infection is poorly established

Clinical findings Ruminants: chronic ill-thrift and in a wasted condition with or without diarrhea

Diagnostic confirmation Culture. PCR

ETIOLOGY

There are pathogenic and nonpathogenic strains of *Yersinia pseudotuberculosis* and *Yersinia enterocolitica*. The **pathogenic strains** of both organisms possess chromosomal and plasmid-mediated virulence determinants.[1]

Y. pseudotuberculosis can be divided into 15 major serogroups, based on O-antigens, some of which can be further divided into subgroups on the basis of type-specific somatic and flagellar antigens. There is variation in animal and human pathogenicity between the serogroups.

Y. enterocolitica is divided into five biovars. It is serologically heterogeneous and 27 serotypes have been identified on the basis of somatic and flagellar antigens with further subdivisions. Bioserotypes may be host-specific. Serotypes O:2, O:3, O:5, O:8, and O:9 have been associated with infection in farm animals and humans, whereas other serotypes appear to be nonpathogenic. Serotype O:9 is antigenically very similar to *Brucella* spp., and infection with this serotype is a cause of false-positive reactions to *Brucella* agglutination and complement fixation tests.

EPIDEMIOLOGY

Occurrence

Yersiniosis has **worldwide** occurrence, although there appear to be regional differences in the species of animal infected, the **prevalence** of disease and the organism involved. *Y. pseudotuberculosis* has historically been associated with **sporadic pyemic disease** in sheep manifest with extensive abscessation of internal organs such as liver and spleen. More recently it, and *Y. enterocolitica*, have been associated with **enterocolitis** occurring in cattle,[2–4] sheep, pigs and goats,[3,5] buffalo,[6] and farmed and feral deer.[7–9] Enteric disease in ruminants has been particularly reported in recent years from Australia and New Zealand.

Yersinia pseudotuberculosis

Y. pseudotuberculosis is a common inhabitant of the **intestine** in a wide variety of domestic and wild mammals. Wild birds and rodents are also **reservoirs** of the organism, and fecal–oral spread on pastures and in water is a major method of transmission. Spring migratory birds can spread pathogenic types over long distances.[10]

There may be differences in the **host specificity** of different serotypes and strains. Rodents and birds may be the major reservoirs for serotypes I and II, which infect deer and goats,[9] whereas sheep and cattle may be a maintenance host for serotype III.

In an Australian study *Y. pseudotuberculosis* serotype III was isolated from the feces of healthy **sheep** in 5% of flocks examined and the prevalence was probably much higher as only a small number of sheep were sampled in each flock. Infection was more common in young sheep, occurred during the winter and spring months, and excretion of the organism persisted for 1–14 weeks.[2]

In **cattle** the organism has been found without disease in 26% of normal cattle and on 84% of farms tested.[11] The fecal excretion that occurs in clinically normal sheep and cattle possibly results from a subclinical infection of the intestine, as experimental challenge of ruminants can result in the establishment of the organism in the intestine with the presence of microscopic abscessation in the lamina propria and serological conversion in the absence of clinical disease.[2,5]

Enteric disease associated with this organism in both cattle and sheep appears to occur as the result of a heavy **infection pressure** in animals that are **debilitated** from other influences. These include cold wet weather, inanition and starvation, trace element deficiency, change of diet, management procedures such as marking and, in farmed deer, procedures such as capture, yarding, and recent transport.[2–5,12]

In sheep, attack rates in the flock for clinical disease have ranged from 1–90% with a mean of 18% and a population mortality varying from 0–6.7%.[13] *Y. pseudotuberculosis* may also cause sporadic **abortion** in cattle and sheep.[11,14] In sheep, abortion rates of 1–9% of pregnant sheep are recorded, abortion occurring in the latter part of pregnancy and without clinical illness in the ewes.[11] The organism is the cause of occasional cases of bovine caprine mastitis,[15,16] epididymitis, and orchitis in rams, and it may be found in sporadic cases of abscessation and lymphangitis in ruminants.

Yersinia enterocolitica

Y. enterocolitica is not commonly associated with clinical disease in farm animals. Diarrhea associated with this organism can occur in sheep, and the organism can be isolated from affected lambs. However pathogenic strains of *Y. enterocolitica* are less pathogenic to sheep and goats than pathogenic strains of *Y. pseudotuberculosis*.

Enterocolitis is recorded in **sheep and goats**.[3,13,17,18] Biotype 5, serotype O:2,3 has been isolated from some of these.[18] In an Australian survey this organism was detected in 17% of flocks and was isolated from young sheep at all seasons of the year.[2] Clinical disease appears to be predisposed by the same **stress factors** as apply with disease associated with *Y. pseudotuberculosis*. Disease is recorded in sheep under 1 year

of age with an attack rate that varied from 2–55% and a population mortality that ranged from 0.3–16.7%.[13,17] *Y. enterocolitica* is also an occasional cause of abortion in sheep and this has been reproduced experimentally.[19]

Whereas *Y. enterocolitica* is commonly isolated from **pigs**, and pigs are a major reservoir for human disease, it is a rare cause of clinical disease in conventional pigs,[20] although clinical enteric disease can be produced by experimental challenge of colostrum-deprived pigs.[21] Conventional pigs challenged with serotype O:3 excreted the organism in feces but were fecal-culture-negative 10 weeks after challenge and at slaughter, even though the organism could be isolated from the tonsils at slaughter. Pigs seroconverted at day 19 postchallenge and remained seropositive until slaughter 70 days later.[20]

Zoonotic implications

Yersinia pseudotuberculosis

Human infection with *Y. pseudotuberculosis* is primarily manifest with septicemia, and renal failure is a sequel. In addition to food-borne infection the consumption of water contaminated by animal feces appears to be a major risk factor. Raw milk consumption is also a risk.[22]

Yersinia enterocolitica

Gastrointestinal disease associated with *Y. enterocolitica* appears to have **increasing prevalence** in humans and can be associated with a reactive arthritis as a sequel. Septicemia does occur but is largely limited to those with other underlying disease. Serotypes O:3, O:5, O:8, and O:9 are incriminated. **Pigs are a major reservoir** for *Y. enterocolitica*, and pork and pork products are sources for human infection. Serotype O:3, in particular, is commonly isolated from the tonsils and pharynx of pigs at slaughter and less commonly from feces. The rate of isolation varies geographically and with farm source and it has been suggested that pathogen-free breeding is a method for control.[23]

In contrast to Australia and New Zealand, it is believed that in Europe the pig is the only domestic animal consumed by humans that regularly harbors pathogenic *Yersinia*.[24] There is an apparent increasing prevalence of O:3 infections in humans in the northern hemisphere and pigs and pork products are considered to be important sources.[23,25] A survey in Great Britain comparing isolates of *Y. enterocolitica* from cattle, sheep, and pigs with those from humans over a 2-year period did not find a strong correlation between pathogenic serotypes isolated from the two groups, with the exception of isolates from pigs.[26] The importation of meat products has been incriminated as the vehicle of introduction of pathogenic serotypes into Japan.[27] There would appear to be an increased risk for infection in humans handling pigs at slaughter and in veterinarians in pig practice.

PATHOGENESIS

Invasion of the intestinal epithelium is followed by inflammation in the mucosa and the formation of microabscesses in the lamina propria and mesenteric lymph nodes. Ulcers and disruption of the intestinal mucosa lead to loss of fluid and function. The intestinal lesions are accompanied by villous atrophy and lead to malabsorption and ill-thrift, diarrhea or a combination of the two.[13]

CLINICAL FINDINGS

Affected animals may present with a syndrome of chronic ill-thrift and in a wasted condition with or without diarrhea. Where diarrhea is present the feces are watery, foul-smelling, and black in color, but occasionally they also contain mucus and blood. Diarrhea persists for 2–3 weeks in an individual animal and may require yarding and dagging as control procedures to avoid fly strike.

CLINICAL PATHOLOGY

There is a neutrophilia with a left shift. Affected animals are often hypoproteinemic and anemic, although this may be a reflection of the underlying malnutrition. In experimental infections antibody develops by 9–19 days postinfection and may be an aid to diagnosis.[5,20] The organism can be isolated from the feces. A multiplex PCR is capable of detecting 10 pathogenic serobiotypes of *Y. enterocolitica*[28] and PCR has been developed to discriminate pathogenic *Y. enterocolitica* from other members of this genus.[29]

NECROPSY FINDINGS

There are liquid intestinal contents but usually no gross findings. Some sheep may have thickening of the mucosa of the small intestine and the cecum and colon, and the mesenteric lymph nodes may be enlarged and edematous.

The characteristic findings on histopathology consist of a segmental suppurative erosive enterocolitis.[13] Microabscesses, consisting of aggregations of neutrophils with prominent colonies of Gram-negative coccobacilli, are present in the mucosa. Lesions are most prevalent in the jejunum and ileum and are accompanied by atrophy of villi and hyperplasia of cryptal epithelium. Microabscesses may coalesce to produce extensive erosions and there may be microabscesses in the liver.

The placenta from sheep that have aborted in association with *Y. pseudotuberculosis* is thickened and edematous with necrotic debris in the intercotyledonary zone and must be differentiated from enzootic abortion.[14]

Samples for confirmation of diagnosis

- Bacteriology – jejunum, ileum, colon, mesenteric lymph node (CULT – sometimes requires cold enrichment)
- Histology – formalin-fixed jejunum, ileum (several sections), colon, mesenteric node (LM).

Note the zoonotic potential of this organism when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The major differential is the syndrome of weaner ill-thrift.

TREATMENT AND CONTROL

Isolates vary in their sensitivity to antibiotics and a sensitivity test is advisable. Most isolates show in vitro sensitivity to the aminoglycosides, to tetracyclines and to sulfonamides or a combination of sulfonamides and trimethoprim.[13,23,30] Sulfonamides and trimethoprim are reported not to be effective in the treatment of yersiniosis in cattle; long-acting tetracyclines are recommended for the treatment of both infections, in combination with supportive therapy.[31]

There is no specific control but the maintenance of good nutrition is believed to be an important factor in avoiding clinical disease.

PROGRESSIVE ATROPHIC RHINITIS (TURBINATE ATROPHY OF SWINE)

Atrophic rhinitis is a disease affecting primarily young pigs but causing anatomical lesions which may persist for life. The term nonprogressive atrophic rhinitis is used for the slight to severe rhinitis and usually transient turbinate atrophy in which no toxigenic *P. multocida* are found, when there are no clinical signs and no obvious growth retardation. This mild form is probably as a result of infection with *Bordetella bronchiseptica* and/or nontoxigenic *P. multocida*. The term progressive atrophic rhinitis is proposed for the infection with toxigenic *P. multocida* (capsular serotype D and A strains) characterized by shortening or distortion of the snout, sneezing, nasal discharge, and epistaxis. Progressive atrophic rhinitis is often accompanied by reduced growth rates in severe cases.

Synopsis

Etiology Toxigenic strains of *Bordetella bronchiseptica* and *Past. multocida*
Epidemiology Young growing pigs. High percentage of pigs reared under intensive conditions may have some degree of atrophic rhinitis. Infection widespread and transmitted by carrier sow to piglet. Housing and ventilation risk factors. Immunity develops in herd. Major economic importance because may affect growth rate and predispose to pneumonia
Signs Initially sneezing when piglets 3–9 weeks of age. Nasal discharge. Deformity of face with nasal bones (twisted snout). Growth rate may be decreased
Clinical pathology Culture organism from nasal swabs. PCR
Lesions Varying degrees of severity of atrophic rhinitis
Diagnostic confirmation Necropsy examinations of snouts

Differential diagnosis list
- Inclusion body rhinitis
- Necrotic rhinitis
- Inherited prognathia

Treatment Antimicrobials in early stages; nothing later
Control Eliminating toxigenic strains of *Past. multocida*. Depopulation and repopulation. Reduction of infection. Mass medication. Medicated early weaning. Vaccination

ETIOLOGY

Infection of the nasal cavities with *B. bronchiseptica* followed by toxigenic strains of *P. multocida* – primarily capsular type D[1–4] and occasionally type A – results in progressive turbinate atrophy.[5] *P. multocida* type A strains were formerly thought to be associated entirely with lung infections but there is increasing evidence that some strains of *P. multocida* type A are increasingly toxin producers and may be involved in atrophic rhinitis.[6,7] Toxin production appears to be independent of serotype. The strains of *P. multocida* isolated from the lungs are usually nontoxigenic and of capsular type A[8] but a small proportion are toxigenic and/or possess capsular type D.[8,9] A complex study of the porcine strains from progressive atrophic rhinitis and pneumonia has been completed.[10] Eighteen groups of strains were identified on the basis of specific combinations of capsular type, *tox*A status and outer membrane protein (OMP) type. The majority (88%) of cases of pneumonia were associated exclusively with nontoxigenic capsular type A strains of OMP types 1.1, 2.1, 3.1, and 5.1 and capsular type D isolates of OMP6.1. They are primary pathogens with a relatively high degree of virulence.[10] In contrast the majority (76%) of cases of progressive atrophic rhinitis were associated with *tox*A-containing capsular type D strains of OMP4.1 and capsular type A and D strains of OMP6.1. They further found that toxigenic capsular type A strains associated with progressive atrophic rhinitis and nontoxigenic strains of capsular type A associated with pneumonia represented separate populations of *P. multocida* recognizable by their OMP types.[10] The results of this analysis led the authors[10] to conclude that horizontal transfer of capsular biosynthesis and *tox*A genes has occurred between certain strains of *P. multocida*.

EPIDEMIOLOGY

Occurrence

Atrophic rhinitis occurs worldwide where pigs are reared under intensive conditions. It has, however, become much less important with the onset of vaccination, improvement in resistance by pig breeding companies and general attention to the environment in the farrowing house. It is one of the most common diseases in pigs in the midwestern USA. Some surveys have shown that 50% of finished pigs and sows at slaughter have lesions of atrophic rhinitis. The incidence of clinical disease varies from 5–30%, which in part depends on the method of detection of the gross lesions. Abattoir surveys of the snouts of slaughtered pigs indicate that the incidence of gross lesions ranges from 14–50%. However, the incidence of gross lesions in abattoir surveys is biased by the source of the pigs; the incidence may be low in pigs from herds that have attempted to control the disease and high in some commercial herds with no control program. In pigs slaughtered from pig testing stations the incidence of lesions may be uniform over a long period.[3] The published data on the incidence of gross lesions are also variable because of the lack of a uniform method of evaluating and quantifying the lesions. However, major improvements in the development of uniform and repeatable methods of evaluating lesions have occurred in recent years.

The incidence and severity of the lesions may vary with the season and the type of facility in which pigs are reared. In a slaughter survey of the snouts and lungs of pigs from 21 pig herds over one winter and one summer the lesions of atrophic rhinitis were more severe among pigs slaughtered in the summer, whereas lesions of pneumonia were more severe among pigs slaughtered in the winter.[11] Lesions of atrophic rhinitis were also more severe in pigs farrowed in central, enclosed farrowing houses and finished in enclosed, mechanically ventilated buildings than in pigs farrowed individually in sow huts and finished on dirt lots. It is possible that the incidence and severity of the lesions at slaughter may be a reflection of the condition of the housing facilities when the animals were piglets several months previously, but many other factors could have been involved.

Prevalence of infection

B. bronchiseptica readily colonizes the ciliated mucosa of the respiratory tract of pigs and infection of the nasal cavities of pigs is present in almost every pig herd, with the prevalence of infection in pigs in commercial herds varying from 25–50%. Serological surveys of individual herds have found that up to 90% of the pigs are positive, which indicates that there is no reliable correlation between the frequency of isolation of the organism and the percentage of animals with antibody. The prevalence of infection is just as high in specific-pathogen-free herds as in non-specific-pathogen-free herds.

The prevalence of infection of toxigenic *P. multocida* type D is higher in herds with clinical disease. The organism can be present in 50–80% of weaned pigs in a herd with clinical disease in the finishing pigs. Toxigenic type D *P. multocida* was first detected in New South Wales, Australia, in 1986; in all herds examined, the introduction of pigs from an infected herd in South Australia was associated

with an increased risk of infection.[12] Toxigenic *P. multocida* type D has been isolated rarely from herds free of atrophic rhinitis.[13]

Whereas *B. bronchiseptica* is eliminated from the respiratory tract of most infected pigs, leaving only a few infected at slaughter, *P. multocida* often persists.

Method of transmission

Direct contact and droplet infection are presumed to be the most likely methods of transmission. The reservoir of infection is the infected sow, and litters of piglets become infected at an early age. Colonization of the tonsil by *P. multocida* in conventionally reared pigs is common.[14] In the Netherlands it has been recognized that infection is usually by one of four possibilities.[15] These are artificial insemination centers, laborers, neighborhood infection by direct aerosol or indirect local contact, and the presence of carrier animals and birds.

The infection is usually introduced into a herd by the purchase of infected pigs. Spread between piglets is probably enhanced after weaning when mixing of litters occurs and 70–80% of a large weaned group become infected. Infection persists for up to several weeks and months, followed by a gradual reduction in the intensity and rate of infection. In herds where *B. bronchiseptica* is the initiating agent, up to 90% of pigs 4–10 weeks of age will have nasal infection, but this infection rate falls to approximately 15% by 12 months of age and the proportion of carrier pigs within the breeding herd decreases with increasing age of sow. The prevalence of infection is also much higher during the period from October to March than at other times of the year, and the prevalence of serologically positive animals is highest from July to December. This is most probably a result of the winter housing conditions, with few air changes per hour, fluctuating temperatures, and high humidity.

The epidemiology of toxigenic strains of *P. multocida* as a causative agent of atrophic rhinitis is not as well understood. The organism colonizes the tonsils of clinically normal pigs. In contrast to *B. bronchiseptica*, which is ubiquitous in pig herds the toxigenic isolates of *P. multocida* appear to be restricted to herds affected with progressive atrophic rhinitis.[5] The organism is invariably present in herds with progressive atrophic rhinitis but may also be present in about 5% of the pigs in a herd with no clinical history of atrophic rhinitis. The main source of toxigenic isolates of *P. multocida* for young pigs appears to be the pharyngeal tissues of the breeding stock. About 10–15% of sows in farrowing houses may be infected with toxigenic isolates and piglets become infected within a week after birth. In contrast to *B. bronchiseptica*, infection of piglets at 12–16 weeks of age with toxigenic *P. multocida* will still result in varying degrees of severity of lesions.

It is possible for growing pigs to develop lesions of atrophic rhinitis well beyond the age of 3 weeks if they are exposed to pigs affected with disease and infected with *P. multocida* and *B. bronchiseptica*.

Risk factors

Animal risk factors

The age at which piglets first become infected with *B. bronchiseptica* has an important effect on the development of lesions. The most severe lesions occur in nonimmune animals infected during the first week of life. Animals infected at 4 weeks of age develop less severe lesions, while those infected at 10 weeks do not develop significant lesions.

Immune mechanisms

The level of immunity in the young pigs will influence the level of infection and the incidence of clinical disease. Colostral immunity from sows serologically positive to *B. bronchiseptica* is transferred to piglets and provides protection for 2–5 weeks. Clinical disease does not occur in piglets with high levels of passive antibody. Older pigs from 10–12 weeks of age may become infected but are less likely to develop severe turbinate atrophy and may develop inapparent infection and become carriers.

Vaccination of the sow before parturition to increase colostral immunity or vaccination of the young pig will increase the rate of clearance of the organism from the nasal cavity and reduce the incidence of clinical disease. In chronically affected herds a level of immunity develops with increasing age of the breeding herd.

Pathogen factors

The virulence characteristics of *B. bronchiseptica* and the toxigenic isolates of *P. multocida* are important risk factors. Both organisms are required to produce lesions similar to the naturally occurring progressive disease. The virulence of *B. bronchiseptica* is dependent on the ability to produce heavy, persistent colonization in the nasal cavity and the production of a heat-labile toxin. Bordetellas produce several virulence factors and toxins, which are regulated by a two-component sensory transduction system encoded by the *bvg* locus.[16,17] These virulence factors include adhesins such as filamentous agglutinin, pertactin, and fimbriae, and the adenylate cyclase–hemolysin toxin and the dermonecrotic toxin. In cell cultures the dermonecrotic toxin stimulates DNA and protein synthesis and assembly of actin stress fibers while inhibiting cell division, resulting in polynucleation of cells.[18,19] It mediates these through the modification and activation of the small guanosine 5′-triphosphate (GTP)-binding protein Rho.[20,21]

There are both toxigenic and nontoxigenic strains of *B. bronchiseptica*.[22] Colonization of the nose was greater with the dermonecrotic-toxin-positive strains than with the dermonecrotic-toxin-negative mutant strains.[23] This was maintained for the first, second, and third weeks postinoculation but by the fourth week the position had changed to the opposite. All dermonecrotic-toxin-positive pigs had pneumonia but the dermonecrotic-toxin-negative animals were able to colonize the lung more freely. There is an outer membrane protein P68 perlactin (*B. bronchiseptica* perlactin gene (*prn*)) that is an adhesin, which may play a part in the protective immunity[24] and may be extremely variable.[25] The most important experiment is one that shows that *P. multocida* mutant strains without the capacity to produce *P. multocida* type D toxin did not produce turbinate atrophy.[26] Only certain porcine phase 1 cultures possess both properties. However, even the most virulent of 10 isolates of *B. bronchiseptica* did not cause progressive turbinate atrophy or significant snout deformation in experimental infections. The severe lesions of atrophic rhinitis cannot be attributed to this organism alone. Experimental inoculation of specific-pathogen-free or gnotobiotic pigs with the organism results in a nonprogressive moderately severe turbinate atrophy 2–4 weeks after infection, followed frequently by regeneration of the turbinates. These virulence characteristics of *B. bronchiseptica* are consistent with the observations that in herds where the organism is common it can provoke sneezing and coughing but no evidence of clinical turbinate atrophy. Examination of the turbinates within 2 weeks after the sneezing will reveal some mild lesions but no lesions will be evident when the pigs are examined at slaughter. It may be that the adhesins left over in the nasal cavity from an infection of *B. bronchiseptica* are subsequently available for the attachment of other bacteria.[27]

Toxigenic isolates of *P. multocida* colonize the nasal cavities, elaborate several toxins, and produce progressive lesions of the turbinate bones and snout. Toxigenic *P. multocida* can colonize the upper respiratory tract of pigs[28] and the presence of the capsule is a virulence factor.[29] The presence of *B. bronchiseptica* can enhance the colonization of

P. multocida, particularly the toxigenic type D strains isolated from pigs. The cytotoxin of *B. bronchiseptica* is required for optimum growth by toxigenic *P. multocida*; other products of phase 1 *B. bronchiseptica* growth assist colonization by *P. multocida*, and the degree of atrophy of the turbinates in these mixed infections is related to the numbers of toxigenic *P. multocida* in the nasal cavity.[30] Severe turbinate damage and shortening of the snout can be reproduced in specific-pathogen-free and gnotobiotic pigs by combined infection with *B. bronchiseptica* and certain strains of *P. multocida*. Following experimental infection both organisms may persist in the nasal cavities for up to 64 days. The cell envelope proteins and lipopolysaccharides of *P. multocida* strains associated with atrophic rhinitis have been characterized and compared. At least three protein patterns and six lipopolysaccharide patterns can be distinguished, which can be used to predict the pathogenic character of some of the strains. This will obviate the need to use the guinea-pig skin test to distinguish those strains that are associated with atrophic rhinitis and those that are not.

The gene for the osteolytic toxin of *P. multocida* has been cloned and expressed in *E. coli*; the protein expressed has been shown to have the same properties as the native toxin. The toxin is the main colonization factor produced by toxigenic strains of the organism and antitoxin made from the toxin is protective experimentally and cross-protective between toxins from different capsule types.[31] The toxin can produce turbinate atrophy when injected intranasally and also when given intramuscularly, intraperitoneally, intravenously, or intradermally.[32] Fingerprinting techniques have been used to show that outbreaks of atrophic rhinitis since 1985 in Australia have been associated primarily with a single strain of toxigenic type D *P. multocida*.[12]

Environmental factors

The effects of housing, population density and adequacy of ventilation on the prevalence of infection of *B. bronchiseptica* and toxigenic isolates of *P. multocida*, and on the incidence and severity of atrophic rhinitis, have not been examined in detail. Atmospheric ammonia, dust, and microbial concentrations in the farrowing house and dust in weaner barns have a significant role in the severity of atrophic rhinitis.[33,34] The mean daily gain of gilts with atrophic rhinitis exposed to ammonia may be smaller than that of those not affected.[35] Undocumented field observations suggest that the disease is more common and severe when pigs are confined, overcrowded and housed in poorly ventilated unsanitary barns, all of which promote the spread of infection.

There is no effect of high levels of ammonia on the severity of turbinate atrophy. It has been shown that high levels of ammonia have no effect on the disease progression of atrophic rhinitis and pneumonia but do enhance the colonization of the nasal turbinates by toxigenic *P. multocida*.[36] A recent experiment has shown[34] that higher numbers of *P. multocida* bacteria were isolated from the tonsil than the nasal membranes per gram of tissue. Aerial pollutants contribute to the severity of lesions associated with atrophic rhinitis by facilitating colonization of the upper respiratory tract by *P. multocida*.

Management factors such as confinement farrowing and the use of continual throughput farrowing houses and weaner houses are also considered to be important risk factors. Adverse climatic conditions (below thermoneutrality with drafty periods) can result in a lower amount of energy available for production because of increased maintenance requirements,[37] which results in growth retardation associated with lowered feed intake.

Economic importance

Historically, it was accepted as dogma that atrophic rhinitis was an important cause of economic loss in pig herds because of decreased growth rate, less than optimal feed efficiency and the fact that it was a major risk factor in enzootic swine pneumonia. A number of field studies have found an association between atrophic rhinitis and reduced growth rate in some herds, whereas other observations were unable to show an association between the presence of the disease and growth rate. The lack of a standard system for evaluation of conchal lesions may be a factor in the variable results between observations.[38]

Some field studies have failed to show that the disease has an effect on growth rate in finishing pigs or that there is a cause and effect relationship between atrophic rhinitis and pneumonia. The presence of pneumonia in pigs from a test station reduced mean daily weight gains by 33% for each 10% of affected lung, but atrophic rhinitis did not affect daily gain and there was no association between the development of atrophic rhinitis and the development of pneumonia. Pigs vaccinated against *B. bronchiseptica* had turbinate atrophy scores or mean daily gains no different from those of unvaccinated pigs. In another study there was a low positive correlation between the herd mean turbinate atrophy score and the herd mean percentage pneumonia score. A recent report from Illinois indicates that the prevalence of clinical atrophic rhinitis in farrow-to-finish herds ranged from 0–20% and in pigs from those herds examined at the abattoir the incidence of turbinate lesions ranged from 5–92%. In some of the herds the mean daily weight gain was 15–18% higher than in herds where pigs had severe turbinate lesions. In an Australian report there was no correlation between the severity of atrophic rhinitis and growth rate or back fat thickness.

In one study of three commercial pig herds, the snouts and lungs of individual pigs were examined and scored at slaughter and the results were correlated with growth indicators for each pig (average daily gain during the growing and finishing phases, and days to reach market). Scores for lung lesions were also correlated to scores for snout lesions. Contrary to findings in many other studies, pigs that reached market weight at the youngest age did not have the lowest score for lung lesions, nor the lowest grade for snout lesions, nor the least extensive or severe lesions.[39] It was concluded that lung lesions and grades for snout lesions in pigs at slaughter are not valid indicators for determining the economic effect of either pneumonia or atrophic rhinitis on growth performance of pigs.

PATHOGENESIS

Following infection of the nasal cavity, *B. bronchiseptica* becomes closely associated with the ciliated epithelium of the respiratory tract. The organism produces a heat-labile toxin that results in a non-progressive, moderately severe turbinate atrophy that is apparent within 2–4 weeks after infection, followed frequently by regeneration of the conchae. There is, initially, ciliary loss and ciliary stasis, followed by reduction in mucociliary clearance followed by hyperplasia and metaplasia of the nasal epithelium, fibrosis in the lamina propria, and resorption and replacement fibrosis of the osseous core. Experimental infection with *B. bronchiseptica* alone does not result in severe persistent conchal atrophy or twisting or shortening of the snout. The strains of *B. bronchiseptica* that produce cytotoxin may predispose to the colonization of *P. multocida* in the nasal cavities.

Infection and colonization of the nasal cavities with the toxigenic strains of *P. multocida* results in the elaboration of a toxin that causes progressive conchal atrophy. The toxin is thermolabile and dermonecrotic and is called the dermonecrotic toxin of *P. multocida*. The inoculation of a toxin from a toxigenic strain of type D *P. multocida* into the nasal cavities of gnotobiotic pigs results in

severe bilateral atrophy of the conchae. Atrophy of the ventral conchae can be produced experimentally with pathogenic *B. bronchiseptica* in piglets at 6 weeks of age and with toxigenic *P. multocida* strains in piglets as old as 16 weeks of age.

The toxin enhances osteoclastic resorption and impairs osteoblastic synthesis of the conchal osseous core; irreversible changes can occur within a few days.[40] The toxin is able to subvert cell cycle progression and cell–cell signaling systems in osteoblasts and osteoclasts.[41,42] The toxin is the sole agent responsible for the conchal atrophy and the effect appears to be related to the total exposure to the toxin, i.e. dose-dependent.[43] More importantly, this also appears to have an immunomodulatory effect. There is an inverse relationship between the number of *P. multocida* and the total concentration of immunoglobulin.[44] This may in part be one of the reasons that local changes in the nose produce such adverse growth effects, and they may be due to the fact that the *P. multocida* type D toxin has in fact changed the immune functions and that the *P. multocida* may have predisposed to many other agents.[43] These authors' conclusion is that *P. multocida* significantly suppresses the antigen-specific IgG immune responses of pigs to parenteral antigen challenge.[43] The epithelium and the submucosa undergo secondary atrophy and the conchae may disappear almost completely within 10–14 days. These lesions can persist until the animal is 90 kg in body weight. The conchal atrophy is not accompanied by an inflammatory reaction. The effect of the *P. multocida* toxin is restricted to the nasal cavity; this is supported by the intriguing observation that the parenteral injection of the toxin into gnotobiotic piglets results in turbinate lesions and shortening and twisting of the snout. The parenteral injection of the dermonecrotoxin of *P. multocida* capsular type D into specific-pathogen-free adult pigs will result in moderate conchal atrophy.[45] In piglets 7 days of age, the intramuscular injection of the purified dermonecrotoxin will result in severe atrophy of the conchae.[45] The culture filtrate of a non-atrophic-rhinitis pathogenic *P. multocida* will not cause lesions after intramuscular injection. The disappearance of the conchae and the involvement of the bones of the face lead to deformity of the facial bones with the appearance of dishing and bulging of the face and, if the lesion is unilateral, to lateral deviation of the snout.

The effect on growth rate, if any, may be due to the chronic irritation and interference with prehension. Experimentally, atrophic rhinitis suppressed the health of pigs, reducing their activity and feed intake.[46] Experimentally, parenteral injections of the toxin decrease physeal area and reduce chondrocyte proliferation in long bones, in addition to conchal atrophy.[47]

Reliable experimental models of atrophic rhinitis in gnotobiotic pigs are now available and are useful for studying the pathogenesis of the disease and testing vaccine strategies. A sterile sonicate of a toxigenic strain of *B. bronchiseptica* is instilled into the nasal cavities of piglets at 5 days of age followed by intranasal inoculation of toxigenic strains of *P. multocida* at 7 days of age.[48]

CLINICAL FINDINGS

The clinical findings of atrophic rhinitis depend on the stage of the lesions. In acute cases in piglets 3–9 weeks of age, irritation of the nasal mucosa causes sneezing, some coughing, small amounts of serous or mucopurulent nasal discharge, and transient unilateral or bilateral epistaxis. The frequency of sneezing may be a measure of the incidence and severity of the disease. In piglets born from sows vaccinated with *B. bronchiseptica* and *P. multocida* vaccine before farrowing, followed by two vaccinations within 3 weeks of age, the frequency of sneezing at 3–9 weeks of age was much less than in piglets given only *B. bronchiseptica* vaccine. There may be rubbing of the nose against objects or on the ground. A watery ocular discharge usually accompanies this and may result in the appearance of dried streaks of dirt below the medial canthus of the eyes. There may be a decrease in growth rate. In infection with *B. bronchiseptica* these clinical signs will disappear spontaneously in a few weeks, when the pigs will appear normal. In severe cases, respiratory obstruction may increase to the point of dyspnea and cyanosis, and sucking pigs may have great difficulty in nursing. The nasal secretions become thicker and nasal bleeding may also occur.

In the more chronic stages, inspissated material may be expelled during paroxysms of sneezing. During this chronic stage, there is often pronounced deformity of the face due to arrested development of the bones, especially the conchae, and the accumulation of necrotic material in the nasal cavities. The nasal bones and premaxillae turn upwards and interfere with approximation of the incisor and, to a lesser extent, the molar teeth. There are varying degrees of brachygnathia superior and protrusion of the lower incisor teeth. Prehension and mastication become difficult, with a resulting loss of body condition. Facial distortion in the final stages takes the form of severe 'dishing' of the face with wrinkling of the overlying skin. If the condition is unilateral, the upper jaw may be twisted to one side. These visible facial deformities develop most commonly in pigs 8–10 weeks old within 3–4 weeks after infection, but they may occur in younger pigs.

The most serious effects of the advanced disease are depression of growth rate and unthriftiness. The appetite may be unaffected but much feed is lost by spillage and feed efficiency may be reduced in some instances.

CLINICAL PATHOLOGY

Culture and detection of bacteria

It is important to be able to detect infected animals in a herd, especially the carrier animal. Nasal swabs are used to detect the bacteria and to determine their drug sensitivity. The collection of the nasal swabs must be done carefully and requires a special transport medium to insure a high recovery rate. A sampling technique and a special culture medium to facilitate the isolation and recognition of *B. bronchiseptica* are described.[49] The external nares are cleaned with alcohol and a cotton-tipped flexible wire is pushed into the nasal cavity (of each side in turn) until it reaches a point midway between the nostril and the level of the medial canthus of the eye. On removal, the cotton tip is cut off into 0.5 mL of an ice-cold sterile transport medium comprising phosphate-buffered saline (PBS, pH 7.3) with fetal calf serum (5% v/v). The samples are then placed on special media, preferably within 4 hours. Normally the organism grows well on conventional culture media, especially when younger pigs are sampled. However, in the carrier pig the organism may be sparse and the selective medium is recommended.

The nasal culturing procedure has been used as an aid in the control of atrophic rhinitis associated with *B. bronchiseptica*. A series of three nasal swabs from each animal is considered to be about 77% efficient in detecting infected animals for possible culling and elimination from the herd. However, in some studies there may be no marked difference in the prevalence of *B. bronchiseptica* or *P. multocida* in pig herds with or without clinical atrophic rhinitis.[49]

Toxigenic *P. multocida* grow readily in the laboratory but are difficult to isolate from nasal swabs because they are frequently overgrown by commensal flora. Selective laboratory media containing antimicrobial agents have been developed to promote the isolation of *P. multocida* from nasal swabs. Inoculation of cotton swabs to selective medium on the same day as the sampling provides the best isolation of toxigenic *P. multocida*.

Immersion of pigs at slaughter in the scalding tank can result in a marked reduction in the isolation of toxigenic *P. multocida*.

A cell culture assay using embryonic bovine lung cell cultures is available and is a sensitive *in vitro* test for the differentiation of toxigenic from nontoxigenic isolates of *P. multocida*. This test can replace the lethal tests in mice or the dermonecrotic tests in guinea-pigs.

Serology

Agglutination tests and an ELISA test are available for the detection of pigs infected with *B. bronchiseptica*, especially carrier animals. Serology is of value in the assessment of the response of pigs vaccinated with the *B. bronchiseptica* vaccines. There are currently no reliable serological tests for *Pasteurella*.

Antigen detection

A PCR method originally described in 1996[50] for the enhanced detection of toxigenic *P. multocida* directly from nasal swabs has been described and upgraded.[51] This was shown to be 10 times more sensitive than *P. multocida* type D toxin (PMT) ELISA and five times more sensitive than clinical bacteriology with subsequent use of PMT ELISA. A nested PCR has also been described.[52] Similarly, a PCR method for the detection of *B. bronchiseptica* has been described[53] that produces 78% more positives than culture, particularly with swabs with a high mixed bacterial load. Recently a nested-PCR has been described that was reported to be more specific and sensitive than the other PCR methods previously described.[54] It does not require culture, it is less laborious and the results can be provided within 24 hours. The authors concluded that this test was suitable for breeding company evaluations and for eradication schemes.

Radiography

Some aids to the clinical diagnosis have been examined but are not highly accurate. Radiography of the nose is not reliable in detecting the severity of conchal atrophy.

NECROPSY FINDINGS

The typical lesions of atrophic rhinitis are restricted to the nasal cavities, although concurrent diseases, especially virus pneumonia of pigs, may produce lesions elsewhere. In the early stages there is acute inflammation, sometimes with the accumulation of pus, but in the later stages, there is evidence only of atrophy of the mucosa, and decalcification and atrophy of the conchae and ethmoid bones, which may have completely disappeared in severe cases. The inflammatory and atrophic processes may extend to involve the facial sinuses. There is no evidence of interference with the vascular supply to the affected bones. The changes in the nasal cavities are most readily seen if the head is split in the sagittal plane but for accurate diagnosis the degree of conchal symmetry, volume and atrophy and medial septum deviation should be assessed by inspection of a vertical cross-section of the skull made at the level of the second premolar tooth.

The clinical diagnosis is confirmed and the severity of the lesions is assessed by the postmortem examination of a cross-section of the snout. The snout must be sectioned at the level of the second premolar tooth because the size of the conchal bone reduces anteriorly and may give a false-positive result if the section is taken too far forward. Quantification of the severity of the lesions has been of value for monitoring the incidence and severity of the disease in a herd. Several systems have been used for grading the severity of lesions of the snout. Most of them have used a subjective visual scoring system in which snouts are grade 0 (complete normality) to 5 (complete conchal atrophy). Reasonable agreement among observers recording morphological changes of nasal conchae is achievable with some training.[49]

The standards for each grade are as follows:[55]

Grade 0: No deviation from absolute normality, with nasal septum straight and conchae symmetrical and filling nasal cavities

Grade 1: Slight irregularity, asymmetry or distortion of the nasal structures without atrophy

Grade 2: Marked distortion of nasal structure but without marked atrophy

Grade 3: Definite atrophy of the conchae with or without distortion

Grade 4: More severe atrophy with severe atrophy of one or more conchae

Grade 5: Very severe atrophy in which all conchae have virtually disappeared.

Such a discontinuous grading system does not provide a direct quantitative relationship. Regular examination of the snouts from heads of pigs sent to slaughter can be used to assess the level of conchal atrophy in the herd. Morphometric methods, using either point counting or semi-automated planimetry applied to photographic or impression prints of sections of the snout to measure the extent of conchal atrophy on a continuous scale as a morphometric index, are now available. Cross-sections of the snout are photographed or used to make impression prints, which are then measured.[56] A morphometric index is determined, which is the ratio of free space to total cross-sectional area of the nasal cavity. The system correlates well with the visual grading system of 0–5 but is labor-intensive and relatively expensive. The conchal perimeter ratio may be a more reliable morphometric measure of atrophic rhinitis and also provides parametric data suitable for quantitative analysis.[57] A morphometric analysis using conchal area ratio is the best method for quantifying gross morphological turbinate changes.[58] Descriptions of the methods for making snout impressions are available.[59,60] Computed tomography has been described.[61]

A major limitation of the grading system is that conchal atrophy occurs as a continuous spectrum and it is difficult to decide, for example, if a pig with a grade 3 lesion represents the more severe manifestation of *B. bronchiseptica* infection, which may not progress further, or an early manifestation of infection with toxigenic *P. multocida*, which could develop into a severe herd problem.

Samples for confirmation of diagnosis

- Bacteriology – nasal swabs
- Histology – formalin-fixed cross-section of snout at level of second premolar
- Antigen detection – nasal swabs.

DIFFERENTIAL DIAGNOSIS

The occurrence of sneezing in the early stages and of facial deformity in the later stages are characteristic of this disease.

Inclusion body rhinitis due to a cytomegalovirus is a common infection in young piglets in which there is sneezing and conjunctivitis. However, by itself it does not progress to produce turbinate atrophy and facial distortion. Under good hygienic conditions the course of the disease is about 2 weeks and the economic effects are minimal. In the early acute stages, atrophic rhinitis may be mistaken for swine influenza which, however, usually occurs as an outbreak affecting older pigs and accompanied by a severe systemic reaction without subsequent involvement of facial bones.

Necrotic rhinitis is manifested by external lesions affecting the face, and virus pneumonia of pigs is characterized by coughing rather than sneezing.

The inherited prognathic jaw of some breeds of pigs has been mistaken for the chronic stage of atrophic rhinitis; protrusion of the lower jaw is quite common in adult intensively housed pigs and has been attributed to behavioral problems of pushing the snout against fixed equipment such as bars and nipple drinkers.

TREATMENT

Treatment early in the course of the disease will reduce the severity of its effects, but it

is of little value in chronically affected pigs, and these pigs are best culled at an early age because of their persistent poor growth rate and high food conversion.

Tylosin at 20 mg/kg BW, oxytetracycline at 20 mg/kg BW, or trimethoprim–sulfadoxine (40 mg/200 mg/mL) at 0.1 mL/kg BW may be given parenterally or the creep feed may be medicated with sulfamethazine and/or tylosin at 200 and 100 mg/kg of feed respectively. Parenteral injections need to be repeated every 3–7 days for at least three injections and feed medication should be given for 3–5 weeks. The problem with early creep medication is in obtaining adequate intakes of the antibacterial. This is seldom achieved before 2 weeks of age and parenteral antibiotics may be required if significant infection occurs before this stage.

The parenteral administration of antimicrobial agents to individual piglets at 3–7-day intervals beginning at 3 days of age for a total of three to five injections per piglet has been recommended for the treatment and control of atrophic rhinitis. However, in a large herd such a treatment regimen would be a major task and, until a cost–benefit analysis indicates a beneficial effect over other methods, we cannot recommend such a practice.

The treatment of experimental *B. bronchiseptica* infection in young pigs has been successful with the use of trimethoprim–sulfadiazine in the drinking water at levels of 13.3 and 77.6 μg/mL respectively, for 3 weeks. This method would remove the necessity to inject pigs repeatedly.

Tilmicosin has proved useful;[62,63] fed continuously over 6 weeks at concentrations of 200 g per ton of feed it controlled transmission of atrophic rhinitis, weight gains were positively affected, and fewer nasal swabs were positive for *P. multocida* at the end of the study period.[64]

CONTROL

Effective control depends on developing methods of eliminating or controlling the prevalence of toxigenic isolates of *P. multocida*, which cause progressive atrophic rhinitis if they become established in the nasal cavity. Previous infection of the nasal cavity with *B. bronchiseptica* can enhance the establishment of toxigenic *P. multocida* and result in progressive atrophic rhinitis.

While there is considerable information available on the ecology of *B. bronchiseptica* and the methods by which it might be eliminated or controlled in a herd, there is little documented information available on methods that can be used for control of the toxigenic isolates of *P. multocida* associated with atrophic rhinitis.

Control of atrophic rhinitis can be attempted in at least four ways:

- Total eradication
- Reduction of infection pressure
- Mass medication with antimicrobials to reduce the severity and adverse effects of infection
- Vaccination.

Regardless of the method employed, any effective control program must have a system for monitoring the incidence of clinical disease in the herd and the incidence and severity of conchal lesions of the pigs sent to slaughter. Accurate and reliable methods for monitoring clinical disease are not available but the incidence of acute rhinitis and facial deformities could be recorded regularly. At slaughter, snouts can be examined for lesions of conchal atrophy and for assessing a mean snout score for each group of pigs slaughtered.

Eradication

Total eradication can only be achieved with confidence by complete depopulation for a 4-week period and repopulation with primary or purchased specific-pathogen-free stock. This approach has the added advantage of also eliminating enzootic pneumonia, which may be a significant contributing factor to the economic importance of this disease. However, this method of control is extremely costly and the economic importance of the disease would need to be carefully evaluated in relation to this cost before this method was instituted. Other techniques of obtaining pigs free of atrophic rhinitis, such as the isolated farrowing of older and presumed non-carrier sows with subsequent clinical and postmortem examinations of a proportion of the litters, have had a significant failure rate in the field and are not recommended. Eradication by repopulation with cesarean-derived stock may be essential in breeding nucleus herds where a high generation turnover results in a low herd sow age and a low herd level of immunity. The breakdown rate of herds established by this method can be significant, presumably because the initiating organisms are not solely confined to pigs.

A pilot control scheme was initiated in Britain in which a herd had to meet the following conditions:

- It must be inspected by a veterinarian every 6 months over a period of 2 years, over which time there must be no clinical evidence of atrophic rhinitis
- The herd owner must certify that atrophic rhinitis has not been suspected over the same time period
- Cross-sections of snouts taken from at least 30% of marketed pigs must be examined regularly by a veterinarian, and over a 2-year probationary period the average 6-monthly snout score must not exceed 0.5
- There must be no vaccination or treatment for atrophic rhinitis
- New breeding stock can be introduced only from other qualified herds or herds derived by hysterectomy, artificial insemination, or embryo transfer techniques.

Over a 5-year period 45 herds qualified at some stage, and 34 were still qualified at the end of 5 years. As of 1988, some herds had exceeded the snout score limit of 0.5, with their average scores increasing to 2.24.[65] In these herds, there was no clinical, epidemiological, or bacteriological evidence that they were at risk of developing severe atrophic rhinitis. It is suggested that the higher scores were associated with a group of recurrent husbandry factors, especially overstocking and unsatisfactory conditions in the weaner barns. These increased scores suggested the possibility that the upper limit for the snout scores in qualifying herds could be raised and allow bacteriological testing to be confined to more doubtful herds.

Eradication in the Netherlands was based on the fact that they thought that there were four main possibilities for the spread of toxigenic *P. multocida*: artificial insemination centers, laborers, neighborhood infection either by aerosol or by local spread, and carrier animals or birds. They assumed that most herds were closed or buying certified stock and that the major source of infection was therefore the boar.[26] In this study they tested boars; in herds with less than 50 boars they tested all and in those with more than 50 they tested 50 as the minimum. They took nasal and tonsil samples,[66,67] which were placed in cold transport medium[68] and sent to the laboratory within 24 hours under cooled conditions for overnight culture followed by PCR.[69]

Reduction of infection

Reduction of infection pressure can be attempted. Infection of piglets occurs primarily either from carrier sows or from other infected piglets in the immediate environment and severe atrophic rhinitis generally results from infection of piglets under 3 weeks of age. If these factors can be minimized the incidence and severity of the disease can be reduced.[70] An all-in/all-out pig flow is one of the most effective methods of control of atrophic rhinitis. Changing to an all-in/all-out pig flow from continuous flow management can improve snout scores by 50%, lung

scores by 55%, average daily gain by 0.14 lb and days to market by 13 days.[71]

Since severe lesions depend upon infection of the piglet under 3 weeks of age, every attempt should be made to minimize the severity of the challenge to young piglets. It is a common observation that the effects of atrophic rhinitis are minimal under good systems of management and adequate ventilation, nondusty conditions and good hygiene. The use of continual-throughput farrowing houses and weaner houses allows a buildup of infection with the presence of actively infected pigs that can provide a high infection pressure on piglets born into or introduced into these areas. The use of all-in/all-out systems of management in these areas is recommended and young piglets should be kept in a separate area from older pigs.

Mass medication

The prophylactic use of antimicrobials is frequently employed to reduce the incidence of the disease within the herd. Antimicrobials are used both within the breeding herd to reduce the prevalence of carriers and in young suckling and weaner pigs to reduce the severity of the infection. The medication is begun about 2 weeks before farrowing, continued throughout lactation and incorporated in the creep feed for the sucking pigs and the starter feeds for the weaned pigs. In this way there is continuous medication of the sow and the piglets during the most susceptible period. For the breeding herd, sulfamethazine at levels of 450–1000 mg/kg feed, with the higher levels being given to dry sows on restricted feeding, has been recommended. Sulfonamide resistance has proved a problem in some countries but beneficial results may still be achieved with these levels. It is recommended that medication be continued for a 4–6-week period. Carbadox at a level of 55 ppm in combination with sulfamethazine at 110 ppm is reported to be effective in clearing experimentally induced *B. bronchiseptica* infection, and when used alone improved growth rate and feed efficiency in pigs with naturally occurring atrophic rhinitis. In the starter period, carbadox fed alone or in combination with sulfamethazine improved average daily gain in piglets from herds with naturally occurring atrophic rhinitis.[72] Use of the medication, however, did not result in a reduction of mean nasal lesion scores due to atrophic rhinitis. Sulfamethazine at 110 mg/kg of feed is more effective than sulfathiazole at the same concentration for the control of experimentally induced atrophic rhinitis due to *B. bronchiseptica*. Sulfamethazine may also be incorporated in creep rations and the use of tetracyclines (200 mg/kg), tylosin (50–100 mg/kg), and penicillin (200 mg/kg) have also been suggested.

Medicated early weaning is recommended to obtain pigs free from pathogens, including *B. bronchiseptica*, that are endemic in the herd of origin. The sows are fed medicated feed from 5 days before to 5 days after weaning and the piglets are dosed from birth to 10 days of age.

Vaccination

There has been considerable interest in the development of vaccines for the control and prevention of atrophic rhinitis due to *B. bronchiseptica*. Inactivated vaccines have been used to vaccinate the pregnant sow 4–6 weeks before farrowing, and in some cases, followed by vaccination of the piglets at 7 and 28 days of age. In general, the use of the vaccine in pregnant sows in herds where the disease has been endemic has reduced the incidence of clinical atrophic rhinitis. However, the results from one study to another have been highly variable. Vaccination of the pregnant sow results in an increase in colostral antibody titer, which does improve the clearance rate of *B. bronchiseptica* in the piglets. However, it has been difficult to evaluate the efficacy of the *B. bronchiseptica* used alone because the turbinate atrophy **associated with** infection of piglets with *B. bronchiseptica* experimentally or naturally heals and regenerates completely when they are reared to about 70–90 kg BW in good housing conditions.

Vaccination with both components (*B. bronchiseptica* and *P. multocida*) in a vaccine reduces lesions considerably when compared with a placebo and a group with only *P. multocida* type D toxin in the vaccine[73] but neither vaccine eliminated toxigenic *P. multocida* from the upper respiratory tract.

Experimentally, piglets born from sows vaccinated with *P. multocida* are protected from a challenge with atrophic rhinitis toxin. This indicates that artificial immunization for atrophic rhinitis should be possible. Vaccination of sows at least three times before farrowing for the first time and during each subsequent pregnancy with a vaccine containing *B. bronchiseptica* and *P. multocida* was highly successful in reducing the incidence of atrophic rhinitis in the pigs. The incidence in affected herds was reduced from 7.5% to about 2%. Experimentally, the vaccine provides good protection against challenge in piglets from vaccinated sows.[72]

A recombinant *P. multocida* toxin derivative vaccine given to gilts 4–5 weeks before farrowing and again 2–3 weeks later provided excellent protection in their piglets against experimental challenge with *B. bronchiseptica* and toxigenic *P. multocida*.[74] This indicates the excellent immunoprotective properties of the nontoxic derivative of the *P. multocida* toxin. In five field trials a single component vaccine containing a nontoxic but highly immunogenic protein, the d0-protein, as the antigen, provided much better protection than the control vaccine containing killed *P. multocida* and killed *B. bronchiseptica*.[75]

Experimental infection and vaccination of pregnant minimum-disease sows with *B. bronchiseptica* resulted in much higher agglutinins in serum and colostrum than in sows only vaccinated or control animals, and the piglets were provided with protection against experimental disease. Vaccination of pregnant gilts with purified inactivated *P. multocida* toxin resulted in a high degree of protection of their progeny against progressive atrophic rhinitis.[76]

A new vaccine has been described[77] using a truncated *P. multocida* type D toxin that is immunogenic and nontoxic, a toxoid for *B. bronchiseptica* and an adjuvant. Sows were vaccinated at 8–6 weeks and 4–2 weeks before farrowing. The vaccinated animals had fewer organisms.

Diseases associated with *Brucella* species

INTRODUCTION

The species of *Brucella* and their principal farm animal hosts are *Brucella abortus* (cattle), *Brucella melitensis* (goats), *Brucella suis* (pigs), and *Brucella ovis* (sheep). In general, the principal manifestations of brucellosis are reproductive failure, such as abortion or birth of unthrifty newborn in the female, and orchitis and epididymitis with frequent sterility in the male. Persistent (lifelong) infection is a characteristic of this facultative intracellular organism, with shedding in reproductive and mammary secretions. Brucellosis is also an important zoonosis causing debilitating disease in humans. Because of the major economic impact on animal health and the risk of human disease, most countries have attempted to provide the resources to eradicate the disease from the domestic animal population.

Control programs have employed two principal methods: vaccination of young or mature animals and the slaughter of infected and exposed animals, usually on the basis of a reaction to a serological test.

Brucellosis has been eradicated from cattle in several regions of the world and is nearly eradicated in others. However, it is still widespread and is an economically important agricultural disease in many countries. There are still many cases of human brucellosis reported each year in regions where the disease has not been eliminated in farm livestock.

In 2002, an entire issue of the journal *Veterinary Microbiology*, vol 90, pp 1–603, was devoted to brucellosis. Several review articles on various aspects of brucellosis from that special issue are listed below under Review literature.

The history of brucellosis is fascinating.[1] In 1884, Captain David Bruce and several others working on Mediterranean fever isolated an agent they called *Micrococcus melitensis* from human spleens. Hospital patients were fed raw goat's milk for many illnesses and this was an early example of a nosocomial infection. The ship SS *Joshua Nicholson*, when anchored in Malta in 1905, took on board 65 goats bound for Washington. The Bureau of Animal Industry of the USDA had decided to import Maltese goats to encourage goat husbandry among peasant immigrants from Southern Europe. Nearly all the ship's crew drank the raw milk and, within weeks, were ill. The goats were never shipped to the USA, on the recommendation of Bruce. Goat's milk was banned from the military garrison in 1906, essentially ending the problem among naval forces, but the controversy about goats persisted for many years: The goat had a special niche in Maltese culture and was taken door to door providing fresh milk. A pasteurization commission was formed in 1938 and but not enforced until 1959. Even as late as 1955, over 200 human cases of brucellosis were **associated with** ingestion of a special cheese. Human brucellosis exists worldwide and is spread mainly by ingestion of unpasteurized dairy products. An overview of the literature on human brucellosis is available.[2]

In 1985, Professor L.F. Benhard Bang, Danish veterinary pathologist and bacteriologist, described a different causative organism isolated from cattle, called *Bacillus abortus*. The first recognized human case of brucellosis in the USA was in 1898 in an army officer who contracted the disease in Puerto Rico. In the early 20th century contagious abortion of cattle and tuberculosis were recognized as major causes of economic loss. By 1922, several states had passed laws and regulations in an attempt to prevent introduction of the disease in cattle purchased from other states. In 1930, concerns were raised about the relationship between the disease in animals and humans. The American Veterinary Medical Association recommended a field trial of a vaccine, which was developed from a strain of lower virulence named *Brucella abortus* strain 19. This vaccine has been used several decades as the most common immunizing agent for control of bovine brucellosis.

In 1934, a cooperative State Federal Brucellosis Eradication program was launched on a nationwide scale in the USA. A uniform plan provided for blood tests, slaughter of seropositive cattle and federal indemnities. In 1941, strain 19 was introduced and used in most states. All vaccinated cattle had to be properly identified. In 1934/35, the reactor rate in cattle tested was 11.5%. In 1954, the US Congress appropriated funds for a comprehensive national effort to eradicate brucellosis. The brucellosis eradication program was designed as a cooperative effort between the federal government, the states, and livestock producers. In 1957, shortly after the inception of the program, there were almost 124 000 infected herds identified. As of December 2004, there were no brucellosis-affected cattle herds in the USA; truly a success story in veterinary medicine.[3] When brucellosis can be identified, contained

and eliminated before spread occurs, eradication can be achieved.

The evolution of the *Brucella* spp. and its taxonomy have been described in detail.[4] In 2002, the genomes for *B. melitensis* were published, and *B. suis* and *B. abortus* are in their final stages.[5] The proteomes of selected *Brucella* spp. have been extensively analyzed, all of which will provide opportunities to understand the complete biology of different *Brucella* species.[6] The major outer membrane proteins of *Brucella* spp. have also been determined.[7] The lipopolysaccharide of *Brucella* is unique and considered as a virulence factor that helps bacterial survival by circumventing the immune response.[8] The pathology of brucellosis reflects the outcome of a battle between the host genome and the *Brucella* genome.[9]

In addition to brucellosis occurring in terrestrial wildlife, *Brucella* spp. have been isolated from some marine mammals of North America[10] and there is serological evidence of *Brucella* spp. infection from several species of marine mammal from both hemispheres.[11] Serological evidence of *Brucella* spp. has been found in odontoceles (suborder of toothed whales, including sperm whales, porpoises, grampuses, dolphins, beaked whales, bottle-nosed whales, and narwhals) from the south Pacific and the Mediterranean.[11]

Status of brucellosis in regions of the world and countries

The status of brucellosis in regions of the world and countries varies considerably. The following is a summary of the status of brucellosis in various regions of the world as of 2002.

Romania

Romania, like many other developed countries, eradicated *B. abortus* from cattle in 1969.[12] The incidence of brucellosis in sheep and pigs is rare and *B. melitensis* has never been reported. Vaccination against brucellosis is prohibited.

Countries in central and south-east Europe

In Macedonia and Greece, brucellosis occurs in sheep, goats, and humans, **associated with** *B. melitensis*.[13] In Greece, cows are infected with *B. abortus* or *B. melitensis*. In Croatia, *B. suis* biovar 2 is found in pigs. In Yugoslavia, brucellosis is endemic in some regions. A financially well-supported control and eradication program such as that sponsored by the European Union is needed.

Kosovo

The overall serological prevalence of infection is 6.26% in sheep, 7.24% in goats and 0.58% in cattle.[14] *B. melitensis* predominates as the cause of brucellosis in ruminants in Kosovo.

Sub-Saharan Africa

Brucellosis is an important disease among livestock and humans in sub-Saharan Africa.[15] The disease in cattle is prevalent and widespread and is caused primarily by *B. abortus*; *B. melitensis* and *B. suis* have been suspected. In sheep and goats, *B. melitensis* is common and the prevalence of infection is high. Brucellosis has occurred in pigs in these countries but information is limited. Brucellosis due to *B. abortus* is one of the most important diseases of camels in the arid and semi-arid pastoralist areas of central, east, and west Africa.

Eritrea

Seroepidemiological surveys for brucellosis in Eritrea found a prevalence of 8.2% in dairy cattle, with a herd prevalence of 35.9%.[16,17] The prevalence in sheep and goats was variable depending on the geographical area. In camels, the seroprevalence was 3.1%.

Near East

In the near East region, animal brucellosis affects almost all domestic animals, particularly cattle, sheep, and goats.[18] Brucellosis occurs in camels in Saudi Arabia, Kuwait, Oman, Iraq, Iran, Sudan, Egypt, Libya, and Somalia. In Egypt, brucellosis occurs in cattle, buffaloes, horses, and pigs. *B. melitensis* biovar 3 is the most commonly isolated species from animals in Egypt, Jordan, Israel, Tunisia, and Turkey. The highest incidence of human brucellosis occurs in Saudi Arabia, Iran, Palestinian Authority, Syria, Jordan, and Oman. Bahrain has none. Most human cases are **associated with** *B. melitensis*, biovar 3 but *B. abortus* is increasingly being reported in humans. The control of brucellosis in these countries is very controversial, with varying emphases on different aspects of control. The most commonly used vaccines are *B. abortus* strain 19, *B. melitensis* Rev. 1, and *B. abortus* RB 51.

Sri Lanka

B. abortus is a major cause of abortion among cattle and buffaloes.[19] The incidence of the disease is low and the small size of the country would facilitate an effective disease control program.

India

Brucellosis was first recognized in India in 1942 and is endemic throughout the country.[20] The disease occurs in cattle, buffalo, sheep, goats, pigs, dogs, and humans. *B. abortus* biotype 1 in cattle and buffaloes and *B. melitensis* biotype 1 in sheep, goats, and humans are the predominant infective biotypes. Economic losses are considerable in an agrarian country such as India. There is no organized and effective brucellosis control program. Plans for a large-scale control program, including calfhood vaccination, are underway.

A major constraint of a control program is that all slaughter of cows is banned and that segregation of seropositive cows until their death will therefore be necessary, but very costly.

China

Before the 1980s, human and animal brucellosis was severe. *B. melitensis* is most common in outbreaks.[21] Sheep, cattle, and pigs are the main sources of infection for humans. Beginning in 1950, control programs have been in place and progress is being made towards control and eradication.

Brazil

Bovine brucellosis due to *B. abortus* is the most prevalent *Brucella* infection in Brazil, followed by *B. suis* in pigs. *B. melitensis* and *Brucella neotomae* have not been isolated. The prevalence of bovine brucellosis ranged from 4–5% in the period of 1989–1998. The disease is considered endemic, with a higher incidence in regions with a higher cattle density.[22] In 2001, a New National Program was launched, including compulsory vaccination of heifers aged 3–8 months, voluntary accreditation of free herds, voluntary monitoring of beef herds based on periodic sampling, regulatory tests for breeding stock prior to interstate movement and entrance into livestock fairs and exhibitions, compulsory slaughter of cattle testing positive, and standardization of testing procedures through short courses for accredited veterinarians.

Paraguay

Brucellosis has existed in the country for many years. Most reports are on *B. abortus* in cattle, but *B. melitensis* and *B. suis* have been identified. In 2000, it was estimated that the prevalence of *B. abortus* in the cattle population was 3.15%.[23] A national campaign for the control and eradication of brucellosis was begun in 1978. The program is based on vaccination of calves at 3–8 months of age, testing and culling of seropositive animals, declaration of *Brucella*-free areas, and promotion of *Brucella*-free Herd Certification Programs in dairy herds. For beef herds there is mandatory vaccination, control of movement of animals intended for breeding, including testing for those imported, destined to fairs and auctions.

Venezuela

Brucellosis continues to be a serious disease for animal and human health in Venezuela.[24] *B. abortus* is the most common biovar, causing high rates of abortion in cattle and buffalo. Based on the rapid agglutination plate test, the positive reactor rate ranges from 0.8–1.2%; using

the ELISA the prevalence is 10.5%. A control program, in effect since 1968, consists of vaccination of calves with strain 19 vaccine, and test and slaughter of positive reactors. Improved testing methods and vaccination of all female calves between 3 and 8 months of age, and revaccination at 10–15 months of age and adult cattle in high prevalence areas.

Central America (Guatemala, Belize, Honduras, El Salvador, Nicaragua, Costa Rica, and Panama)

B. abortus and *B. suis* infections occur in all Central American countries, and sheep and goat brucellosis **associated with** *B. melitensis* occurs in Guatemala.[25] The estimated prevalence of bovine brucellosis ranges from 4–8% with a herd prevalence (dairy herds) of 10–25%.[25]

A national control program based on vaccination of calves and test and slaughter of reactors has been unsuccessful. Possible reasons include inadequate economical support for vaccination and test and slaughter programs, and the high density of *Brucella* infections.

Argentina

Brucellosis has been recognized in Argentina since the 19th century.[26] In 2000, the individual cow prevalence was 5% and the herd prevalence 10–15%.[26] In dairy cattle, the prevalence is estimated at 2–2.5%. The annual economic losses due to the disease in cattle have been estimated at US$60 000 000. A control program began in 1932 and successive changes have been issued since then. The current program mandates vaccination of all females with *B. abortus* strain 19 between 3 and 8 months of age, and test and slaughter of positive animals. However, the compensation paid for reactors is inadequate and producers commonly retain the reactors in the herd. The program has been most successful in dairy herds, which receive incentive payments if the prevalence of infection is low. The disease has been found in pigs, goats, sheep, and dogs. Human brucellosis is an important disease in Argentina. Federal financial support is needed to assist the livestock industry to eradicate the disease.

Mexico

Brucellosis is an important disease in Mexico.[27] Five of the seven known *Brucella* species have been isolated, including *B. melitensis* biovars 1–3; *B. abortus* biovars 1, 2, 4–6; *B. suis* biovar 1; *Brucella canis* and *B. ovis*. Brucellosis is endemic in the cattle, sheep, and goat populations. The disease is a trade barrier. Each year Mexico exports 1.2 million steers and heifers to the USA. The heifers must be spayed to minimize the risk of brucellosis transmission. A control program has been in effect since 1942 but vaccination was voluntary and the disposition of reactors inconsistent. Brucellosis is a significant public health problem in Mexico because 35% of the milk and cheeses consumed are unpasteurized. As of 2002, about 3500 cases of human brucellosis are reported annually and it is estimated this figure represents only one-third of the actual cases. About 98% of cases are due to ingestion of contaminated dairy products (mainly goat cheeses). About 93% of human cases are infected with *B. melitensis* of goat origin. In 1993, a control program was reinforced with the creation of the National Commission for Bovine Tuberculosis and Brucellosis Eradication. In high-risk areas, massive vaccination programs of goats with *B. melitensis* Rev. 1 strain in adults and young females are being implemented, along with a Sanitary Package to improve goat and sheep health. In 1997, the use of *B. abortus* RB 51 vaccine was officially approved. Mexico is one of the few countries authorized to produce this live attenuated vaccine. To reduce abortions, a reduced dose is commercially produced for adult females. As of 2000, almost 1 million beef and dairy cattle, and 1 million goats are vaccinated annually; almost 97% of the dairy cattle population is vaccinated.

Canada and the USA

The status of bovine brucellosis in Canada and the USA is presented below under Bovine brucellosis **associated with** *Brucella abortus*.

European Union

Bovine brucellosis

Austria, Denmark, Finland, Germany, the Province Bolanzo (Italy), Luxembourg, Norway, Sweden, the Netherlands, and Great Britain have gained the status of being officially brucellosis free.[28] Countries not officially brucellosis-free are France, Greece, Ireland, Italy, Portugal, and Spain. The prevalence of infection in countries not free of brucellosis is extremely diverse. The highest numbers of infected herds occurred in southern Europe: Greece, Spain, Italy, and, Portugal. The prevalence of infection has increased in both the Republic of Ireland and Northern Ireland.

Both *B. abortus* and *B. melitensis* have been isolated from cattle; *B. melitensis* may be isolated from cattle in contact with sheep and goats. *B. melitensis* may cause isolated cases of abortion in cattle rather than outbreaks of abortion.

Great Britain has been free from brucellosis since 1993 and is required by the European Union regulations to test 20% or more of both beef and dairy cattle below 24 months of age routinely.

Ovine and caprine brucellosis

Belgium, Denmark, Finland, Germany, the Netherlands, Ireland, Austria, Luxembourg, Norway, Sweden, the UK, Spain, and France are officially free of ovine and caprine brucellosis. Greece, Italy, and Portugal are not officially free. Ovine and caprine brucellosis is a significant problem for both public health and animal production in Greece, and a control program consists of vaccination of lambs and kids, and test and slaughter policy. European co-financed eradication programs for sheep and goat brucellosis are in place in France, Greece, Italy, Portugal, and Spain.[28]

Brucellosis in pigs

Brucellosis in pigs, especially outdoor-raised pigs, has re-emerged as a result of infection from the wild boar brucellosis (*B. suis* biovar 2) reservoir. In all EU countries and Norway, boars are subject to pre-entry testing and regular testing every 18 months at artificial insemination stations.

BRUCELLOSIS ASSOCIATED WITH *BRUCELLA ABORTUS* (BANG'S DISEASE)

Synopsis

Etiology *Brucella abortus*
Epidemiology Major cause of abortion in cattle in countries without a national control program. Undulant fever in humans an important zoonosis. Sexually mature animals susceptible; outbreaks occur in first-calf heifers, older cows infected but do not abort. Transmitted directly from infected animal to susceptible animal by uterine discharges. Congenital infection occurs. Infection in wildlife species but significance to domestic animals unknown. Infection introduced into herd by unknown infected carrier animal. Natural infection and vaccination result in immunity to abortion but not infection, and infected animals remain serologically positive for a long time
Signs Abortion epidemics in first-calf unvaccinated heifers after fifth month of pregnancy. Subsequent pregnancies carried to term. Orchitis and epididymitis in bulls. Synovitis (hygromas) occurs. Fistulous withers in horses
Clinical pathology Serology. Serum agglutination test is standard test. Rose Bengal test (rapid screening test). Complement fixation test. ELISA test. Milk ring test. False-positive reactors are major problem
Lesions Necrotizing placentitis, inflammatory changes in fetus
Diagnostic confirmation Culture organism from fetus. Positive serological test in unvaccinated animal
Differential diagnosis list Other causes of abortion (see Table 18.7)
Treatment No treatment
Control Test and reduce reservoir of infection. Quarantine. Depopulation. Vaccination to reduce incidence of abortion and percentage of infected animals. Eradication on herd and area basis by test and slaughter

ETIOLOGY

Brucella abortus is the causative organism and at least nine biotypes have been recognized including a number of strain variants. Approximately 5% of infections are from biotype 1. Biotype 2 was isolated in an outbreak of brucellosis in cattle in Canada in 1986. In the USA biotypes 1–4 are found.

EPIDEMIOLOGY

Occurrence and prevalence of infection

Brucellosis is an important disease of cattle and an important zoonosis worldwide. It is of major economic importance in developing countries that have not had a national brucellosis eradication program (see Introduction, above). The prevalence of infection varies considerably among herds, areas, and countries. Many countries have made considerable progress with their eradication programs and some have eradicated the disease. However, in other countries brucellosis is still a serious disease problem facing the veterinary and medical professions. In Argentina, for example, the prevalence of infection in cattle is more than 10% and it is estimated that 20 000 new cases of human brucellosis occur annually.

Cattle

Infection occurs in cattle of all ages but is most common in sexually mature animals, particularly dairy cattle. **Abortions occur most commonly in outbreaks in unvaccinated heifers after the fifth month of pregnancy.** Bulls are affected with orchitis, epididymitis, and seminal vesiculitis. The infection has been confirmed in cattle and water buffaloes in Trinidad.[1]

Wildlife species

The infection has occurs in bison (*Bison bison*),[2,3] elk (*Cervus elaphus canadensis*),[4] deer, coyotes, wild opossums and raccoons, moose, and other wild and domesticated ruminants, but there is no evidence that these species are a source of infection for cattle. Infection of moose with *B. abortus* biovar 1 is highly fatal and it is likely that the moose is a dead-end host for brucellosis. Experimental inoculation of the organism into badgers results in the development of antibodies and elimination of the organism, which indicates that the badger is relatively resistant to infection and unlikely to be a reservoir of the organism.

Bison and elk are potential reservoirs of brucellosis and, because they are the species of choice for game farming, which is a recent development in North America and elsewhere, they could serve as a source of infection for cattle. Brucellosis **associated with** *B. abortus* was first detected in bison (*Bison bison*) in Yellowstone National Park in 1917 and has been present ever since.[5] Bison can remain latently infected with virulent *B. abortus* until attainment of reproductive age despite extensive use of vaccination and serological testing.[6]

A strain of biotype 1 isolated from bison in Canada is infectious and contagious for cattle. While bovine brucellosis is being effectively eradicated in North America, infected populations of bison, elk, and moose in Canada and the USA are of sufficient size and geographical distribution to create a real and serious threat to the livestock producers in certain areas of both countries.[5] *B. suis* biovar 4 is the cause of rangiferine brucellosis, a disease of reindeer and caribou (*Rangifer tarandus*).[7] Under natural conditions, rangiferine brucellosis is limited to the circumpolar Arctic but translocations to reindeer for game ranching may place traditional livestock species, game-farmed species and non-Arctic wildlife at risk. Naturally infected reindeer can transmit *B. suis* biovar 4 to brucellosis-free cattle.[7] Exposed cattle had a serological response; the organism remained in tissues 60 days after exposure. *B. suis* biovar 4 does not cause clinically important disease in cattle and is not shed in sufficient numbers to maintain infection in cattle populations. Conventional serological tests can be used to detect *B. suis* biovar 4 infection in cattle, but their ability to detect exposed animals varies widely and they cannot discriminate between *B. suis* biovar 4 and *B. abortus* of cattle. Cattle to cattle transmission of *B. suis* biovar 4 is unlikely.[7]

In Canada, the wood bison herd in Wood Buffalo National Park has been infected with *Mycobacterium bovis* and *B. abortus* since 1925.[8] The infected herd poses a potential threat to the nearby MacKenzie Bison Sanctuary, in which these infections are not present.

Horses

In horses the organism is often found in chronic bursal enlargements as a secondary invader rather than a primary pathogen. It is commonly present with *Actinomyces bovis* in fistulous withers and poll evil. It has also been identified as a cause of abortion in mares. A serological survey of horses over a period of 8 years revealed that 8–16% of serum samples were positive. However, experimentally infected horses do not excrete the organism in sufficient numbers to infect susceptible in-contact cattle.

Pigs and sheep

The organism can be recovered from naturally infected pigs and, although not normally pathogenic in this species, may occasionally cause abortion. The disease occurs naturally in sheep exposed to infected cattle, which has significant implications for brucellosis eradication.

Dogs

Naturally acquired *B. abortus* infection can occur in dogs associated with infected cattle.[9] While farm dogs are not generally considered to be a major reservoir of *B. abortus*, the organism has been isolated from dogs on a farm where several cattle were serologically positive for brucellosis and dogs should be included in any investigation and eradication of the disease.

Methods of transmission

Parturition

The **risk posed to susceptible animals** following parturition of infected cattle depends on three factors:

- **The number of organisms excreted**
- **The survival of these organisms under the existing environmental conditions**
- **The probability of susceptible animals being exposed to enough organisms to establish infection.**

The organism achieves its greatest numbers in the contents of the pregnant uterus, the fetus and the fetal membranes, all of which must be considered as major sources of infection. The numbers of organisms in the tissues of two naturally infected cows and their fetuses were as follows: umbilicus $2.4 \times 10^8 - 4.3 \times 10^9$/g – 1.4×10^{13}/g. This illustrates the potentially large numbers of organisms that can be shed and to which other animals and humans are potentially exposed. However, the numbers of organisms decrease when uterine discharges are cultured at sequential parturitions, and a substantial number of uterine samples from infected cows are culture-negative at the second and third parturition following challenge.

Transmission

The disease is transmitted by ingestion, penetration of the intact skin and conjunctiva, and contamination of the udder during milking. The organism does not multiply in the environment but merely persists, and the viability of the organism outside the host is influenced by the existing environmental conditions. Grazing on infected pasture, or consuming other feedstuffs and water supplies contaminated by discharges and fetal membranes from infected cows, and contact with aborted fetuses and infected newborn calves are the most common methods of spread.

Intraherd spread occurs by both vertical and horizontal transmission. **Horizontal transmission is usually by direct contamination** and, although the possibility of introduction of infection by flies, dogs, rats, ticks, infected boots, fodder, and other inanimate objects exists, it is not significant relative to control measures. The organism is ingested by the face fly but is rapidly eliminated and there is no evidence for a role in natural transmission. Evidence exists for horizontal, dog-to-dog, cattle-to-dog, dog-to-cattle and dog-to-human transfer of infection.[9] The most likely and effective means of cattle-to-dog transfer is exposure to aborted fetuses or infected placental membranes, because dogs commonly ingest the products of parturition.

Spread between herds

Movement of an infected animal from an infected herd to a susceptible noninfected herd is a common method of transmission. The rate of spread will depend on the level of surveillance testing.[10] In Great Britain, which is officially brucellosis free, 20% or more of both beef and dairy cattle more than 24 months old are tested routinely. A simulation model indicates that reducing the level of testing would have a major effect on the rate of spread of infection, should it be imported.

Spread between countries (breach of biosecurity)

A quantitative risk assessment model to determine the annual risk of importing brucellosis-infected breeding cattle into Great Britain from Northern Ireland and the Republic of Ireland, which are not brucellosis free, was developed.[11] Predictions estimated that brucellosis could be imported from Northern Ireland every 2.63 years and from the Republic of Ireland every 3.23 years. Following this assessment, the Department of Environment, Food and Rural Affairs introduced postcalving testing for all imported breeding cattle. Under this system, all imported animals are issued a passport that records their age and pregnancy status. This information enables identification of animals that require testing and provides an additional safeguard in maintaining official brucellosis status.

Congenital infection

Congenital infection may occur in calves born from infected dams but its frequency is low. The infection occurs in utero and may remain latent in the calf during its early life; the animal may remain serologically negative until its first parturition, when it then begins to shed the organism. Calves born from reactor dams are serologically positive for up to 4–6 months because of colostral antibodies and later become serologically negative even though a latent infection may exist in a small proportion of these calves. The **frequency of latent infections** is unknown, but may range from 2.5–9%. Latent infections in serologically negative animals are of some concern because they remain unnoticed and can potentially serve as a source of infection later. However, latent infections in calves born from infected cows are infrequent. The organism could not be isolated from any of 150 calves born to infected cows, 135 of which were experiencing their first pregnancy after infection. In one report a heifer from a herd affected with widespread infection with *B. abortus* biotype 2 was moved to a brucellosis-free herd and remained apparently free from brucellosis until 9 years later, when the same animal produced a strongly positive serological reaction and the same biotype was isolated from its milk. Such observations have resulted in the recommendation that calves from seropositive dams should not be used for breeding. Even vaccinated heifers from seropositive dams can harbor a latent infection. There is a risk that 2.5% of heifer calves born from serologically positive dams will react in early adulthood and constitute a threat to a re-established herd.

Survival of organism

The organism can survive on grass for variable periods depending on environmental conditions. In temperate climates, infectivity may persist for 100 days in winter and 30 days in summer. The organism is susceptible to heat, sunlight, and standard disinfectants but freezing permits almost indefinite survival. The activity of several disinfectants against *B. abortus* has been examined, and representatives of the phenolic, halogen, quaternary ammonium, and aldehyde groups of disinfectants at 0.5% or 1.0% concentrations in the absence of serum generally inhibited a high concentration of the organism.

Uterine discharges and milk

A cow's tail heavily contaminated with infected uterine discharges may be a source of infection if it comes in contact with the conjunctiva or the intact skin of other animals. In the same way that the more common forms of mastitis can be spread during milking, *B. abortus* infection can be spread from a cow whose milk contains the organism to an uninfected cow. This may have little significance in terms of causing abortion but it is of particular importance in its effects on agglutination tests on milk and the presence of the organism in milk used for human consumption.

Bulls and semen

Bulls do not usually transmit infection from infected to noninfected cows mechanically. Infected bulls may discharge semen containing organisms but are unlikely to transmit the infection. The risk of spread from the bull is much higher, however, if the semen is used for artificial insemination. Some infected bulls are

negative on serum agglutination tests and their carrier status can only be detected by the isolation of organisms from the semen or agglutination tests on seminal plasma.

Carrier cows

Few infected cows ever recover from infection completely and should be considered as permanent carriers whether or not abortion occurs. Excretion of the organism in the milk is usually intermittent, is more common during late lactation and can persist for several years. In cattle vaccinated before infection the degree of excretion of *B. abortus* in the milk is less than in nonvaccinated animals. Embryo transfer from infected donors may be achieved without transfer of infection and superovulation is unlikely to reactivate the release of *Brucella* into the uterus during the period when embryos are normally collected. Thus embryo transfer is a safe procedure for salvaging genetic material from infected animals.

The herd characteristics and the results of the first herd test may be used as predictors of the potential presence or absence of *B. abortus* in herds with reactors to the tube agglutination test. The presence of only single suspicious reactors on the first test is a reliable predictor of lack of infection. The presence of one or more positive reactors on the first herd test is a reliable predictor of the presence of infection.

Risk factors

The risk factors that influence the initiation, spread, maintenance, and/or control of bovine brucellosis are related to the animal population, management, and the biology of disease.[12] The variables that contribute significantly to seropositive animals are:

- **Size of farm premises**
- **Percentage of animals on a premises that are inseminated artificially**
- **Size of investment in livestock**
- **Number of cows which aborted in the previous year, whether or not dairying is the major agricultural activity of the premises**
- **Policy of the owner with regard to disposal of reactor animals.**

The longer infected animals are in contact with the remainder of the herd, the greater will be the ultimate number of seropositive animals. In a defined geographical area in northern Mexico where a brucellosis control program did not exist, the greatest percentage of seropositive animals was related to larger farms, poor artificial insemination technique, and small financial investment in the farm.

From a practical viewpoint, the factors influencing the transmission of brucellosis in any given geographical region can be classified into two fundamental categories: those associated with the transmission of disease between herds and those influencing the maintenance and spread of infection within herds. Factors influencing interherd transmission include the purchase of infected replacement animals and are in turn influenced by frequency of purchase, source of purchase, and brucellosis test history of purchased animals. The proximity of infected herds to clean herds is an important risk factor. Cattle contacts at fence lines, sharing of pastures and strays of infected animals into clean herds are common methods by which transmission occurs to adjacent herds.

The risk factors associated with spread of the disease within a herd include unvaccinated animals in infected herds, herd size, population density, method of housing, and use of maternity pens. Large herd sizes are often maintained by the purchase of replacement cattle, which may be infected. It is also more difficult to manage large herds, which may lead to managerial mistakes that allow the disease to spread. There is a positive association between population density (number of cattle to land area) and disease prevalence, which is attributed to increased contact between susceptible and infected animals. The use of maternity pens at calving is associated with a decrease in the prevalence of infection, presumably due to decreasing the exposure of infected and susceptible animals.

Animal risk factors

Susceptibility of cattle to *B. abortus* infection is influenced by the age, sex, and reproductive status of the individual animal. **Sexually mature, pregnant cattle are more susceptible to infection with the organism than sexually immature cattle of either sex**. Natural exposure to field strains occurs primarily at the time of parturition of infected cows. The greater the number of infected cows that abort or calve, the greater the exposure risk to the other cattle in the herd. An important application of this observation is that infected cows need to be removed from the herd prior to parturition. Thus the stage of gestation and parturition are more important factors in herd plans than early removal of postparturient infected cows following whole-herd strain-19 vaccination. Young cattle are less susceptible to *B. abortus* than older, sexually mature cattle. Susceptibility appears to be more commonly associated with sexual maturity than age. Young, sexually immature cattle generally do not become infected following exposure, or recover quickly. Susceptibility increases with pregnancy and as the stage of gestation increases.

The probability of isolation of the organism at parturition increased from 0.22 to 0.90 as fetal age at exposure of nonvaccinated heifers increased from 60 to 150 gestation days. The stage of pregnancy at experimental challenge exposure of strain-19 vaccinated heifers is positively associated with the proportion of animals that become infected. Nonvaccinated young cattle are also at high risk of brucellosis if exposed to pathogenic strains of the organism. In cattle vaccinated as yearling heifers, the risk of brucellosis is also related to the number of organisms in the vaccine. The risk of brucellosis in heifers vaccinated with 10^8, 10^9, or 10^{10} of strain 19 was, respectively, one-third, one-seventh, or one-17th that of diluent controls or nonvaccinated heifers.

Management risk factors

The spread of the disease from one herd to another and from one area to another is almost always due to the movement of an infected animal from an infected herd into a noninfected susceptible herd. The unregulated movement of cattle from infected herds or areas to brucellosis-free herds or areas is the major cause of breakdowns in brucellosis eradication programs. A case-control study of brucellosis in Canada indicated that herds located close to other infected herds and those herds whose owners made frequent purchases of cattle had an increased risk of acquiring brucellosis. Once infected, the time required to become free of brucellosis was increased by large herd size, by active abortion and by loose housing.

Pathogen risk factors

B. abortus is a facultative intracellular parasite capable of multiplication and survival within host phagocytes.[13] The organisms are phagocytosed by polymorphonuclear leukocytes in which some survive and multiply. These are then transported to lymphoid tissues and fetal placenta. The inability of the leukocytes to effectively kill virulent *B. abortus* at the primary site of infection is a key factor in the dissemination to regional lymph nodes, other sites such as the reticuloendothelial system, and organs such as the uterus and udder. The organism is able to survive within macrophages because it has the ability to survive phagolysosome. The bacterium possesses an unconventional non-endotoxic lipopolysaccharide, which confers resistance to antimicrobial attacks and modulates the host immune response.[14] These properties make lipopolysaccharide an important virulence factor for *Brucella* survival and replication in the host.

Brucellas are able to survive within host leukocytes and may utilize both neutrophils and macrophages for protection from humoral and cellular bactericidal mechanisms during the periods of hematogenous spread. The placenta is a favored site for replication of the organism. Large numbers of the organism can be found in chorionic trophoblasts, which contain metabolically active cells capable of producing a variety of hormones and secretory proteins that may stimulate the growth of brucellas. The ability to survive in the host may explain both the transitory titers occurring in some animals following isolated episodes of bacteremia and the disappearance of titers in animals with latent infection.

Three major groups of outer membrane proteins have been identified in *Brucella* spp.[15] Certain mutants of *B. abortus* lack a major 25 kDa outer membrane protein (Omp25), which renders them unable to replicate efficiently in bovine phagocytes and chorionic trophoblasts.

Immune mechanisms

Immunity against brucellosis is principally mediated by cellular immune responses since it is an intracellular pathogen. *B. abortus* is an efficient inducer of type 1 cellular immune responses and interferon-gamma is crucial for control of brucellosis.[16] Infections are chronic and often lifelong. The bovine T lymphocyte in brucellosis is a critical component of host defense based on mononuclear phagocyte activation by interferon-gamma. The killing of *Brucella*-infected mononuclear phagocytes and interferon-gamma-mediated activation of mononuclear phagocytes are the major mechanisms of host defenses against brucellosis in cattle.[17]

The antibody response to *B. abortus* in cattle consists of an early IgM isotype response, the timing of which depends on the route of exposure, the dose of the bacteria and the health status of the animal. The IgM response is followed almost immediately by production of IgG1 antibody and later by small amounts of IgG2 and IgA. Most cross-reacting antibody from exposure to other bacteria other than *Brucella* spp. or environmental antigens consists mainly of IgM. Serological tests that measure IgM are therefore not desirable, as false-positive results occur. Since IgG2 and IgA antibodies accumulate later after exposure and are usually present in small and inconsistent amounts, the main isotype for serological testing is IgG1.[18]

Naturally infected animals and those vaccinated as adults with strain 19 remain positive to the serum, and other agglutination tests, for long periods. The serum of infected cattle contains high levels of IgM, IgG_1, IgG_2, and IgA isotypes of antibody. Most animals vaccinated between 4 and 8 months of age return to a negative status to the test within a year. All are considered to have a relative immunity to infection. Calves from cows that are positive reactors to the test are passively immunized via the colostrum. The half-life of colostral antibodies to *B. abortus* in calves that have received colostrum from either vaccinated noninfected or infected dams is about 22 days. It is possible that some calves remain immune sufficiently long to interfere with vaccination. After vaccination of cattle with strain 19 of the organism, IgM antibodies appear after about 5 days, reaching peak values after 13 days. IgG_1 antibodies appear a little later or simultaneously with IgM, and peak values are reached at 28–42 days, after which they decline. The same general pattern follows experimental infection with virulent strains and also in chronic field cases, except that IgM antibody declines to low levels and residual activity resides in IgG_1 and IgG_2 as well as in IgA, which remain at higher levels.

Economic importance

Losses in animal production due to this disease can be of major importance, primarily because of decreased milk production in aborting cows. The common sequel of infertility increases the period between lactations, and in an infected herd the average intercalving period may be prolonged by several months. In addition to the loss of milk production, there is the loss of calves and interference with the breeding program. This is of greatest importance in beef herds, where the calves represent the sole source of income. A high incidence of temporary and permanent infertility results in heavy culling of valuable cows, and some deaths occur as a result of acute metritis following retention of the placenta.

Zoonotic implications

Brucellosis is an important zoonosis causing **undulant fever in humans**.[19] According to the Food and Agriculture Organization, the World Health Organization and the Office International des Epizoöties, brucellosis is still one of the most important and widespread zoonoses in the world. The disease spreads mainly by the ingestion of unpasteurized dairy products.[19] Officially approved methods of commercial pasteurization render naturally *Brucella*-contaminated raw milk safe for consumption. However, most cases in humans are occupational and occur in farmers, veterinarians, and butchers. The organism can be isolated from many organs other than the udder and uterus, and the handling of a carcass of an infected animal may represent severe exposure.

The importance of the disease in humans is an important justification for its eradication. Between the years 1965 and 1974 the incidence of brucellosis in humans in the USA increased. Most cases occur in people employed in the meat processing industry, while other sources include the domestic pig, cattle, and unpasteurized dairy products. A majority of human brucellosis cases in Texas could be prevented by prohibiting the importation of unpasteurized goat's milk cheese. Laboratory-acquired brucellosis in humans constituted 1.7% of the cases of brucellosis reported in the USA between 1964 and 1974.

The cost-effectiveness to human health and the potential net economic benefits of a nationwide mass vaccination program for livestock over a period of 10 years has been evaluated using Mongolia as the model.[20] If the costs of vaccination of livestock against brucellosis were allocated to all sectors in proportion to the benefits, the intervention would be cost-effective and would result in net economic benefits.

PATHOGENESIS

B. abortus has a predilection for the pregnant uterus, udder, testicle and accessory male sex glands, lymph nodes, joint capsules, and bursae. After the initial invasion of the body, localization occurs initially in the lymph nodes draining the area and spreads to other lymphoid tissues, including the spleen and the mammary and iliac lymph nodes.

B. abortus is phagocytized by macrophages and neutrophils in an effort by the host to eliminate the organism. However, once inside the phagocyte, *B. abortus* is able to survive and replicate. The phagocyte migrates via the lymphatic system to the draining lymph node, where *Brucella* infection causes cell lysis and eventual lymph node hemorrhage 2–3 weeks following exposure. Because of vascular injury, some of the bacteria enter the bloodstream and subsequent bacteremia occurs, which disseminates the pathogen throughout the body. If the infected animal is pregnant, *B. abortus* will colonize and replicate to high numbers in the chorionic trophoblasts of the developing fetus. The resulting tissue necrosis of the fetal membranes allows transmission of the bacteria to the fetus. The net effect of chorionic and fetal colonization is abortion during the last trimester of pregnancy.

Sexually immature and other nonpregnant cattle can become infected but lose their humoral antibody to the organism much more quickly than cattle infected while pregnant.

In the adult, nonpregnant cow, localization occurs in the udder, and the uterus, if it becomes gravid, is infected from periodic bacteremic phases originating in the udder. Infected udders are clinically normal but they are important as a source of reinfection of the uterus, as a source of infection for calves or humans drinking the milk, and because they are the basis for the agglutination tests on milk and whey.

Erythritol, a substance produced by the fetus and capable of stimulating the growth of *B. abortus*, occurs naturally in greatest concentration in the placental and fetal fluids and is responsible for localization of the infection in these tissues. Invasion of the gravid uterus results in a severe ulcerative endometritis of the intercotyledonary spaces. The allantochorion, fetal fluids, and placental cotyledons are invaded and the villi are destroyed. The organism has a marked predilection for the ruminant placenta. In acute infections of pregnant cows, up to 85% of the bacteria are in cotyledons, placental membranes, and allantoic fluid.

The successful coexistence of *Brucella* spp. with its preferred host is the outcome of coevolutionary relationships and selection pressures, which result in a stalemate where the pathogen has evolved to survive within the biological system of the host, and the host has evolved innate and acquired immune systems that allow controlled survival of infection by the pathogen, ultimately supporting the survival of the host–pathogen system.[21] In contrast to other pathogens, genes controlling virulence, survival and persistence of *Brucella* spp. have been documented as the dominant feature of its genome.

The host responses at the organ and tissue levels have been described and are summarized here.[21] Lymph nodes draining the sites of the early stages of infection have marked germinal center hyperplasia and hypertrophy, accompanied by acute neutrophilic and eosinophilic lymphadenitis. In the later stages of the infection, lymph nodes draining mammary gland, head, and reproductive tract develop chronic granulomatous lymphadenitis, which is usually associated with cortical and paracortical T-cell-dependent lymphoid depletion, germinal center expansion, and deep histiocytic expansion. The spleen may develop lymphoid hyperplasia and histiocytic and plasmacytic expansion in the germinal centers, and the mammary gland usually has a pronounced interstitial lymphoplasmacytic mastitis. In the uterus, there is usually an endometritis, fibrosing mural lymphocytic metritis, and caruncular necrotizing vasculitis, while the placenta is colonized with *B. abortus* and has extensive desquamation of fetal chorioallantoic trophoblasts with subsequent hematogenous spread to villous trophoblastic epithelium, and necrotizing fibrinopurulent cotyledonary placentitis of the placental arcades accompanied by granulation and intercotyledonary inflammation exudation. The fetal lesions consist of marked fibrinopurulent necrotizing bronchopneumonia, monocytic and neutrophilic alveolitis, thromboembolic necrotizing arteritis and lymphangitis, fibrinopurulent pleuritis, and granulomata of the liver, spleen, kidney, and lymph nodes.

Variable disease expression may occur in the male reproductive tract and musculoskeletal system of either sex. The affected joints usually develop a fibrinous and granulomatous synovitis with proliferative villous projection formation, proliferative tendovaginitis with lymphoplasmacytic nodule formation, and arthritis with articular erosions, which may be associated with suppurative, granulomatous bursitis. In the testes there are uni- or bilateral visceral to parietal tunica adhesions, interstitial lymphocyte orchitis with seminiferous tubular degeneration, necrotizing intratubular orchitis, and acute fibrinopurulent periorchitis with infarction. The ampulla may have a uni- or bilateral granulomatous epididymitis with focally necrotic purulent, calcified sperm granulomata and the seminal vesicles have uni- or bilateral necrotizing fibrinopurulent seminal vesiculitis and interstitial lymphocytic, plasmacytic seminal vesiculitis with necrosis.

In **fetuses naturally and experimentally infected** with *B. abortus* the tissue changes include lymphoid hyperplasia in multiple lymph nodes, lymphoid depletion in the thymic cortex, adrenal cortical hyperplasia and disseminated inflammatory foci composed mainly of large mononuclear leukocytes. The fetal pneumonia is due to localization of perivascular foci in the interlobular septa of the lung, indicative of hematogenous spread in the fetus rather than aspiration of contaminated fetal fluids. Fetuses inoculated with sufficient numbers of *B. abortus* will abort 7–19 days postinoculation. With experimental conjunctival exposure of pregnant heifers with the organism, the numbers of infected animals and the number of tissue samples positive for the organism are increased as fetal age at exposure increases from gestation days less than 127 to more than 157.

Abortion occurs principally in the last 3 months of pregnancy, the incubation period being inversely proportional to the stage of development of the fetus at the time of infection.

Congenital infection can occur in newborn calves as a result of in utero infection and the infection may persist in a small proportion of calves, which may also be serologically negative until after their first parturition or abortion.

CLINICAL FINDINGS

Abortion

The clinical findings are dependent upon the immune status of the herd. In highly susceptible nonvaccinated pregnant cattle, abortion after the 5th month of pregnancy is the typical feature of the disease in cattle. In subsequent pregnancies the fetus is usually carried to full term although second or even third abortions may occur in the same cow. Retention of the placenta and metritis are common sequelae to abortion. Mixed infections are usually the cause of the metritis which may be acute, with septicemia and death following, or chronic, leading to sterility.

The history of the disease in a susceptible herd can usually be traced to the introduction of an infected cow. Less common sources are infected bulls, or horses with fistulous withers. In a susceptible herd it is common for the infection to spread rapidly and for an abortion 'storm' to occur. The 'storm' might last for a year or more, at the end of which time most of the susceptible cows are infected and have aborted and then carry their calves to full term. Retained placentae and metritis could be expected to be common at this time. As the abortion rate subsides, the abortions are largely restricted to first-calf heifers and new additions because other animals of the herd acquire partial resistance.

In recent years, particularly in areas where vaccination is extensively practiced, an insidious form of the disease may develop, which spreads much more slowly and in which abortion is much less common.

Orchitis and epididymitis

In the bull, orchitis and epididymitis occur occasionally. One or both scrotal sacs may be affected, with acute, painful swelling to twice normal size, although the testes may not be grossly enlarged. The swelling persists for a considerable time and the testis undergoes liquefaction necrosis and is eventually destroyed. The seminal vesicles may be affected and their enlargement can be detected on rectal palpation. Affected bulls are usually sterile when the orchitis is acute but may regain normal fertility if one testicle is undamaged. Such bulls are potential spreaders of the disease if they are used for artificial insemination.

Synovitis

B. abortus can often be isolated from the tissues of nonsuppurative synovitis in

cattle. Hygromatous swellings, especially of the knees, should be considered with suspicion. Progressive and erosive non-suppurative arthritis of the stifle joints has occurred in young cattle from brucellosis-free herds that had been vaccinated with strain 19 vaccine. The calves may or may not be serologically positive, but synovial fluid and joint tissue samples contain immunological evidence of strain 19 *B. abortus* antigenic material. The synovitis has been reproduced by intra-articular injection of the vaccine.

Fitulous withers

In horses, the common association of *B. abortus* is with chronic bursal enlargements of the neck and withers, or with the navicular bursa, causing intermittent lameness, and the organism has been isolated from mares that have aborted.[22] When horses are mixed with infected cattle, a relatively high proportion can become infected and develop a positive reaction to the serum agglutination test without showing clinical illness. Some horses appear to suffer a generalized infection with clinical signs including general stiffness, fluctuating temperature, and lethargy.

CLINICAL PATHOLOGY

The major objective in the laboratory diagnosis of brucellosis is to identify animals which are infected and potentially shedding the organism and spreading the disease. Most infected animals are identifiable using the standard serological tests but latent infection occurs in some animals which are serologically negative. Furthermore, vaccinated animals may be serologically positive and uninfected, and transitory titers occur sporadically in a small percentage of animals, for which there is no clear explanation. These diagnostic problems make control and eradication programs difficult to administer and difficult to explain to animal owners.

The collection and submission of samples to the laboratory must be done with care, and careful attention must be given to recording the identity of the animal and the corresponding sample which should be uniquely identified. For blood samples, it is recommended that silicone-coated evacuated glass tubes without additives be used to collect the blood sample, as they insure effective clotting and clot retraction, to provide an easy source of serum without the need for centrifugation. Clotting is also aided by maintaining the sample at 25–37°C for 1–2 hours.

Laboratory tests used in the diagnosis of brucellosis include isolation of the organism and serological tests for the presence of antibodies in blood, milk, whey, vaginal mucus, and seminal plasma. The organism may be present in the cervical mucus, uterine flushings, and udder secretions of experimentally infected cows for up to 36 days after abortion. An ELISA test is available for the detection of the organism in vaginal secretions.

Culture and detection of *Brucella abortus*

Culture

The 'gold standard' diagnostic test continues to be based on isolation and characterization of the organism from the organs and lymph nodes of the fetus, the placenta, milk, vaginal mucus, or uterine exudate. Bacteriological methods have the advantage of detecting the organism directly and thus limit the possibility of false-positive results. Isolation of the organism from the udder secretion of a cow is conclusive evidence of infection. Culture methods are reliable and usually definitive. However, disadvantages are the long time required for definitive identification, usually 2 weeks; the tests are complex and must be done by highly skilled laboratory personnel; and the zoonotic nature of the organism is a potential hazard for laboratory personnel.[23]

Detection by polymerase chain reaction

The PCR-based assays for *Brucella* have been developed and are simple.[23] The PCR has been applied to tissues such as aborted fetuses and associated maternal tissues, blood nasal secretions, semen, and food products such as milk and soft cheeses.[23] The detection of *Brucella* DNA from aborted bovine fetuses by PCR has been compared with microbiological techniques and the estimated concordance calculated by Kappa index was 0.73 which is considered satisfactory.[24]

Brucella spp. can be detected in the milk of naturally infected cattle, sheep, goats, and camels using a PCR assay which is more sensitive than the culture method.[25] The literature on the use of the PCR-assay as a diagnostic method for brucellosis has been reviewed.[23]

Serological tests

In the absence of a positive culture of *B. abortus* a presumptive diagnosis is usually made based on the presence of antibodies in serum, milk, whey, vaginal mucus, or seminal plasma.

The antibody response following infection depends on whether or not the animal is pregnant and on the stage of gestation. On average, the agglutinins and complement fixation antibodies become positive 4 weeks following experimental infection during the fourth to sixth months of gestation and not until about 10 weeks if experimental infection occurs 2 months before or after insemination. The serological diagnosis is considered to be unreliable when applied during the period of 2–3 weeks before and after abortion or calving.

Any of the currently available serological tests or combination of tests measures the response of a single animal at one point in time and does not describe the status of the herd. When the tests are used in the recommended sequence and in combination, along with a consideration of accurate epidemiological data, the limitations of each test can be minimized. None of the tests is absolutely accurate and there are varying degrees of sensitivity. The result has been the development of a very extensive range of tests, each of which has its own special applicability. The details are available.[18] The salient features are as follows.

Agglutination tests

Standard tube agglutination test

This is one of the traditional standard tests which is widely used, but its limitations include the following:

- The test detects nonspecific antibodies as well as specific antibodies from *B. abortus* infection and vaccination
  - During the incubation stage of the disease the test is often the last to reach diagnostically significant levels
  - After abortion due to *B. abortus* it is often the last test to reach diagnostically significant levels
  - In the chronic stage of the disease, the serum agglutinins tend to wane, often becoming negative when the results of some other tests may be positive.

Rose Bengal test (buffered plate antigen or card test)

This is a simple, rapid test that detects early infection and can be used as an initial screening test. 'Overkill' using the test is estimated to vary from 1–3%, depending on the level of infection and vaccination history in the herd. False-positive reactions are due to residual antibody activity from vaccination, colostral antibody in calves, cross-reaction with certain bacteria, and laboratory error. False-negative reactions are observed during early incubation of disease and immediately after abortion. However, the rose Bengal test is an excellent test for the large-scale screening of sera. The application of the rose Bengal test as a screening test, followed by a confirmatory complement fixation test along with the indirect hemolysis test, can markedly increase the proportion of infected cattle which are tested positive. This combination can be useful during the latter stages of an eradication program.

For **beef cattle**, screening of herds can be achieved by collecting blood at abattoirs and submitting it to the **rose Bengal test** or **tube agglutination test**. Reactors are traced back to the herd of origin and the herd is tested. In heavily infected herds it is best to remove all cows positive to the rose Bengal test even though it is highly sensitive and a small percentage of false-positive cows will result. In herds where the prevalence of infection is low and where vaccination has been used, this procedure will eliminate too many false-positive cows. In this situation the sera positive to the rose Bengal test are submitted to a more definite confirmatory test such as the complement fixation test and only those animals reacting to the test are discarded.

Complement fixation test

The complement fixation test (CFT) rarely exhibits nonspecific reactions and is useful in differentiating titers of calfhood vaccination from those due to infection. The reactions to the CFT recede sooner than those to the serum agglutination test after calfhood vaccination with the strain 19 vaccine. The CFT titers do not wane as the disease becomes chronic and often the CFT reaches diagnostic levels sooner than the serum tube agglutination test following natural infection. In addition, recent technical laboratory advances have allowed much greater speed and accuracy in doing the CFT and it is now considered to be the nearest approach to a definitive test for infection.

Primary binding assays

Enzyme-linked immunosorbent assays

Two main types of immunosorbent assay have been used: the indirect and competitive formats.[18] The **indirect ELISA (IELISA)** has been a useful test during an eradication program, after vaccination has ceased, for screening or as a supplementary test to the complement fixation test. Preliminary evaluations of the IELISA test alone, or in combination with the complement fixation test and monoclonal antibodies, indicate some comparative advantages over other serological tests. The IELISA has gained wide acceptance for serological diagnosis of bovine brucellosis because of its ability to detect antibody of all isotopes, unlike the conventional tests.[18] The ELISA can be useful in conjunction with the complement fixation test during the latter stages of an eradication program when it is important to reduce the number of false-negative serological reactions which contribute to the persistence of problem herds. The sensitivity and specificity of indirect ELISA has been excellent but it could not distinguish between the antibody response induced by vaccination with *B. abortus* strain 19 and natural infection with the organism. The **competitive ELISA (CELISA)** can differentiate between the induced antibody responses. An improved competitive enzyme immunoassay (C-ELISA) has a sensitivity of 100% and specificity of 99.7% and is considered a reasonable alternative as a single assay for serological diagnosis of brucellosis.

In a comparison of the IELISA with two screening tests, the rose Bengal and the buffered plate antigen, and with two confirmatory tests, the 2-mercaptoethanol agglutination and the complement fixation tests, the overall diagnostic specificity and sensitivity of the ELISA is comparable, if not superior, to the tests used to confirm buffered plate antigen-positive reactor status.[26] The indirect ELISA kits produced by the Joint Food and Agriculture Organization and the International Atomic Energy Authority (FAO/IAEA) were able to detect residual anti-*B. abortus* strain 19 antibodies in adult cows vaccinated with strain 19 vaccine between 3 and 8 months of age but which were negative to the rose Bengal and Rivanol tests.[27] A 'dipstick' enzyme immunoassay is also available and being evaluated.

Fluorescence polarization assay

This test can be done outside the diagnostic laboratory, allowing for rapid and accurate diagnosis.[18] The fluorescence polarization assay (FPA) can be done almost anywhere using a portable analyzer, which receives power from a laptop computer, using serum, milk, or EDTA anticoagulated blood.[28] The FPA technology has been developed and validated for the serological diagnosis of brucellosis in cattle, pigs, sheep, goats, bison, and cervids. Sufficient cross-reactivity of the common epitopes of *B. abortus*, *B. melitensis*, and *B. suis* O-polysaccharide has allowed for the use of a single antigen for all species of smooth *Brucella* and animals. The FPA was initially developed for testing serum; however, the technology has been extended to testing whole blood and milk from individual animals or bulk tank samples pooled from 2000 or fewer animals. The accuracy results of the FPA equals or exceeds those obtained using other serological tests such as the buffered antigen plate agglutination test, the milk ring test, the CFT, the IELISA, and the CELISA. Validation of studies of the FPA and the CELISA for the detection of antibodies to *B. abortus* in cattle sera and comparison to the standard agglutination test, the complement fixation test and the indirect ELISA, found that the FPA is highly superior.[29] The FPA offers clear advantage due to its ease of use. Full implementation and acceptance of FPA methods for the diagnosis of brucellosis will necessitate the use of an International Standard Serum panel containing at least a low titer positive sample and a negative.[29]

Sensitivity and specificity of serological tests

Serological tests must have high sensitivity to insure that all true serological reactors are detected. However, with a high sensitivity, a high rate of false-positive reactions may be expected and hence the need for the use of a confirmatory test to identify false-positive reactors. Confirmatory tests must therefore demonstrate a high level of diagnostic specificity and yet maintain an effective diagnostic sensitivity.

The sensitivity and specificity of several serological tests for the diagnosis of brucellosis in Canada have been compared.[18] It is recommended that either the buffered plate antigen test or indirect enzyme immunoassay test be used as a screening test. Either the complement fixation test or the indirect enzyme immunoassay is appropriate for use as a confirmatory test in situations requiring a high specificity. In brucellosis-free herds, the specificity of tests was 98.9% for buffered plate antigen test (BPAT), 99.2% and 99.3% for the standard tube and plate agglutination tests (STAT and SPAT), respectively, and 99.8% for the 2-mercaptoethanol test (2-MET). The rose Bengal plate test (RBPT), the card test (CARD), and the CFT correctly classified all sera as negative. On a sample of culture-positive cattle, the sensitivities of the tests were complement fixation 79.0%, buffered plate antigen test 75.4%, rose Bengal plate test 74.9%, card test 74.3%, standard plate agglutination test 73.1%, standard tube agglutination test 68.9%, and 2-mercaptoethanol 59.9%. All tests combined detected only 82% of infected cattle. Analysis of the relative sensitivity of the six agglutination tests gave the following ranking from highest to lowest: BPAT, RBPT, CARD, SPAT, STAT. The 2-MET ranked between BPAT and RBPT or between the RBPT and CARD depending on the analysis used. The BPAT is recommended as a screening test, followed by the CFT.

The relationships between the quantitative serology and infection status of brucellosis in bison in Yellowstone National Park have been evaluated and found to be similar to those in chronically infected cattle.[2]

Antibodies in milk

The **milk ring test** is a satisfactory inexpensive test for the surveillance of dairy herds for brucellosis. A small sample of pooled fresh milk or cream, from no more than 25 cows, is tested and the herd

is classified only as suspicious or negative. Final determination of the status of a suspicious herd and each animal in it is accomplished by blood testing. The more frequently a herd is tested with the milk ring test, the more effective the test becomes as a method to detect early infections and thereby prevent serious outbreaks in susceptible herds. At least three tests done annually are now required by some regulatory agencies. The major limitation of the test is the dilution factor which occurs in large dairy herds where large quantities of milk are stored in bulk tanks.

The Bruc ELISA test is a sensitive, specific, and inexpensive method for screening large numbers of individual or bulk milk samples for antibody to *B. abortus*. An ELISA using potassium chloride extract of the organism used on bulk tank milk samples of dairy herds was highly specific and is considered as a highly reliable test for monitoring brucellosis control programs which are being initiated.[30] An indirect ELISA using polysaccharide as the antigen has a sensitivity of 95% and specificity of 99.95% when compared in milk samples from brucellosis-free and brucellosis-infected herds.[31] The combined use of an ELISA and PCR on milk samples gives a sensitivity of 100%.[32]

False-positive reactors

A major problem in brucellosis eradication programs has been the false positive animals or singleton reactor which may remain persistently suspicious or positive in a herd that is otherwise considered to be free of brucellosis. It is of some concern because of the unnecessary slaughter of uninfected animals.

Cross-reacting antibodies usually result from exposure to antigen(s) that share antigenic determinants with *Brucella* spp. which are found in a large number of bacteria. The most prominent cross reaction is with *Yersinia enterocolitica* O:9, which shares the major O-polysaccharide almost completely with *B. abortus*. Serological cross-reactions have also been demonstrated between smooth *Brucella* spp. and *E. coli* O116:H21 and *E. coli* O157:H7, *Francisella tularensis*, *Salmonella* serotypes of Kauffman–White group N, *Pseudomonas maltophilia*, *Vibrio cholerae*, and *Yersinia enterocolitica* serotype O:9. Only rarely will naturally occurring *E. coli* O157H:7 infections cause false-positive reactions with standard serological tests for bovine brucellosis. The standard serological tests are unreliable in differentiating between *Y. enterocolitica* and *Brucella*-infected cows but both the lymphocyte transformation and brucellin skin tests could be used to differentiate them.

Other causes of false positives include a *B. abortus*-infected animal, strain 19 residual vaccination titer and naturally occurring nonspecific agglutinins, which may occur in some cattle populations. These agglutinins are EDTA-labile and can be differentiated from agglutinating antibodies by the addition of EDTA to the diluent used in the standard serum agglutination test. The serological cross-reactions are of major significance when the prevalence of infection has decreased to a very low level. At this stage it becomes much more important to correctly identify the status of animals reacting to the serological tests for brucellosis.

The incorrect attribution of such reactions to factors other than *Brucella* infection is likely to result in herd breakdowns and failure to control the disease. On the other hand, the misinterpretation of cross-reactions as evidence of brucellosis results in the imposition of unnecessary restrictions and waste of resources. The problem of serological cross-reactions has resulted in considerable research and an investigation to find laboratory tests, which will accurately distinguish positive, infected animals from positive, noninfected animals. Differentiation of cross-reacting antibodies can be difficult to achieve, especially in the case of *Y. enterocolitica* O:9 antigen, but immunodiffusion, immunoelectrophoresis and primary binding tests and cross-absorption procedures are useful. The DNA homology of *B. abortus* strains 19 and 2308 has been examined using restriction enzyme analysis. Strain 19 is the official USDA-attenuated *Brucella* vaccinal strain for cattle, and strain 2038 is a virulent laboratory-adapted strain that is pathogenic to cattle. The DNA differences between the two strains are small and will require analysis at the DNA sequence level.

The serological assay of choice for screening samples for antibody to *B. abortus* is the FPA.[33] It is robust, very rapid and field-adaptable, without subjective results. The CELISA is a useful confirmatory assay. The sera from cattle naturally infected with *B. abortus*, vaccinated with *B. abortus* S19, or immunized with *Y. enterocolitica* O:9 or *E. coli* O157H:7 were compared for antibody content to the same bacteria by IELISA, FPA, and CELISA.[33] The serological assay of choice for screening samples for antibody to *B. abortus* is the FPA. Between the two tests, nearly all reactivity to *E. coli* O157H:7 and more than one-half of the sera with antibody to *Y. enterocolitica* O:9 could be eliminated as *Brucella* reactors. These assays, perhaps in combination with a brucellergen skin test, may be capable of distinguishing virtually all reactions due to *Y. enterocolitica* O:9.[33] A brucellosis skin test was more specific than other tests and may be useful as a herd test for brucellosis in the Office International des Epizoöties *Manual of Standards for Diagnostic Tests and Vaccines* and as an official test in the European Union when monitoring is made difficult by a specific brucellosis serological testing.[34]

NECROPSY FINDINGS

Necrotizing placentitis and disseminated inflammatory reactions in aborted fetal tissues are the characteristic changes. Adult animals are seldom necropsied. Findings in bovine fetuses infected with *B. abortus* usually include serohemorrhagic fluid in the body cavities and subcutis, and a pneumonia. Often granulomatous lesions and focal necrosis are noted in several fetal organs and a granulomatous leptomeningitis may also occur. Pneumonia is not a consistent finding and its character may vary. The placenta is usually edematous. There may be leathery plaques on the external surface of the chorion and there is necrosis of the cotyledons. The key microscopic feature of this inflamed chorioallantois is the presence of **intracytoplasmic coccobacilli within chorionic trophoblasts**. The use of modified Ziehl–Neelsen stains on impression smears from fresh placentas can provide a rapid presumptive diagnosis. The histopathological findings in experimental infections in pregnant goats are similar to those described in infected cows and fetuses.

The distribution of *B. abortus* in experimentally and naturally infected cattle has been examined. In experimentally infected pregnant cows, the most frequently infected specimen was the mammary lymph node; the organism could also be found in other lymph nodes, uterine caruncles, cotyledons, or fetal tissues. In naturally infected heifers the most frequently infected specimen was the mandibular lymph node. In bulls, the most frequently infected tissues were the mandibular, caudal superficial cervical, subiliac, and scrotal lymph nodes.

The lesions in *Brucella*-positive aborted fetuses and placentas in bison are similar to those in experimental infections of *B. abortus* in bison and cattle.[3] Both *B. abortus* biovar 1 and *B. abortus* biovar 2 were isolated from specimens collected from aborted bison fetuses or stillborn calves and their placentas. The infection can also be associated with death in calves at least 2 weeks of age.[3]

The development of PCR tests for *Brucella* spp. antigens may permit more timely confirmation of infection and immunohistochemical tests on formalin-fixed tissues can also improve the detection of this slow-growing organism.

Samples for confirmation of diagnosis

- Bacteriology – maternal caruncle; placenta, stomach content, lung (CULT – has special growth requirements; CYTO – Stamp's or Kosters's stain on placental smears)
- Histology – fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (LM, IHC).

Note the zoonotic potential of this organism when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The diagnosis of the cause of abortion in a single animal or in a group of cattle is difficult because of the multiplicity of causes that may be involved. When an abortion problem is under investigation, a systemic approach should be used. This includes a complete laboratory evaluation and follow-up inquiries into each herd. The following procedure is recommended:

- Ascertain the age of the fetus by inspection and from the breeding records
- Take blood samples for serological tests for brucellosis and leptospirosis
- Examine uterine fluids and the contents of the fetal abomasum at the earliest opportunity for trichomonads, and subsequently by cultural methods for *B. abortus*, *Campylobacter fetus*, trichomonads, *Listeria* spp., and fungi
- Supplement these tests by examination of urine for leptospires, and of the placenta or uterine fluid for bacteria and fungi, especially if the fetus is not available
- Examine placenta fixed in formalin for evidence of placentitis.

It is most important that all examinations be done in all cases because coincident infections with more than one agent are not uncommon.

In the early stages of the investigation, the herd history may be of value in suggesting the possible etiological agent. For example, in brucellosis, abortion at 6 months or later is the major complaint, whereas in trichomoniasis and vibriosis, failure to conceive and prolongation of the diestrual period is the usual history.

A summary of the differential diagnosis of contagious abortion in cattle is provided in Table 18.7. Of special interest is epizootic bovine abortion, a major disease of rangeland cattle in the western USA. A spirochete has been isolated from the soft tick *Ornithodoros coriaceus* and from the blood of fetuses with lesions of epizootic bovine abortion.[35] The disease occurs at a very high level of incidence but only in cattle introduced to a certain area; resident cattle are usually unaffected. Cattle returned to the area each winter are unaffected after the first abortion. The cows are unaffected systemically. Aborted fetuses show characteristic multiple petechiae in the skin, conjunctiva and mucosae, enlargement of lymph nodes, anasarca, and nodular involvement of the liver.

In most countries where brucellosis is well under control and artificial insemination limits the spread of vibriosis and trichomoniasis, leptospirosis may be the commonest cause of abortion in cattle.

However, surveys in such countries reveal that in about two-thirds of the abortions that occur no causative agent is detectable with routine laboratory techniques. In only 35% of cases was the cause determined and brucellosis accounted for less than 1% of the total. In an Australian experience the cause of abortion was determined in only 37% of cases in spite of the submission of the fetus, placenta, and maternal serum. The general procedures for submission of specimens to the laboratory and laboratory methods are available.[36]

Bulls

Infected bulls may be serologically positive or negative, their semen may be culturally positive or negative, but the organism may be isolated at slaughter. Clinical examination may reveal the presence of epididymitis, orchitis, seminal vesiculitis, and ampullitis. All bulls from known infected herds should therefore be considered as suspicious, regardless of their serological status, and not be used for artificial insemination.

TREATMENT

Treatment is unsuccessful because of the intracellular sequestration of the organisms in lymph nodes, the mammary gland, and reproductive organs. *Brucella* spp. are facultative intracellular bacteria that can survive and multiply within the cells of the macrophage system. Treatment failures are considered to be due not to the development of antimicrobial resistance but rather to the inability of the drug to penetrate the cell membrane barrier.

CONTROL AND ERADICATION

Most countries with brucellosis have programs designed to control and ultimately eradicate the infection in cattle to reduce economic losses and protect the public from the disease. These programs usually have several components, and to insure effectiveness each component needs to be scientifically sound and accepted by all concerned.[37] The major components of a control and eradication program are as follows.

Test and reduction of reservoir of infection

All breeding cattle in the herd are tested and those that are positive are culled and sent for slaughter. This removes infected cows from the herd and reduces exposure and transmission within the herd. Of particular importance is the detection and removal of infected cows prior to parturition.

Quarantine

This is a period of time during which cattle movement is restricted and the cattle are tested. This will prevent interherd transmission by infected cattle, especially those that are test-negative and incubating the disease. The quarantine period should be sufficiently long that all cattle have had sufficient time to develop brucellosis and insure that the remaining cattle will not be a source for interherd transmission. The time will usually range from 120 days to 1 year, or until all breeding animals have completed a gestation without test evidence of infection.

Depopulation

Depopulation is slaughter of all cattle in a herd when all animals have been exposed and are capable of becoming infected and acting as a source of new infection.

Vaccination

The strain 19 vaccine of *B. abortus* provides increased resistance against field strain infection following natural exposure. Properly vaccinated cattle are less likely to be infected and, therefore, are not a source of field strains of the organism. As the number of infected cattle in the herd is reduced, the exposure potential should be reduced and, if exposure is reduced, then new cases should be reduced.

Education

All participants in a program must understand and adopt the scientific basis for the program. This includes livestock producers, veterinarians, and regulatory officials.

Guidelines

To be successful, any program needs guidelines and policies, which must be followed and modified to meet the needs of certain areas or herds. In the USA, the Uniform Methods and Rules for brucellosis eradication were developed by Veterinary Services of the US Department of Agriculture in cooperation with the US Animal Health Association. The Uniform Methods and Rules are continually updated as new scientific information is made available, and the document is used as a guide for state programs.

Bovine brucellosis can be controlled with an effective vaccination program or eradicated using a test and slaughter program. Vaccination using strain 19 will markedly reduce the incidence of abortion but the level of infection will not be reduced at a corresponding rate. Even with a widespread vaccination program there will be foci of infection, which are perpetuated indefinitely. Complete eradication is the alternative to control by vaccination; some countries have already achieved this status and others are currently engaged in eradication programs.

Table 16.7 Diagnostic summary of causes of abortion in cattle

Epidemiology				Field examination		Laboratory diagnosis	
Disease	**Clinical features**	**Abortion rate**	**Time of abortion**	**Placenta**	**Fetus**	**Isolation of agent**	**Serology**
Brucellosis (*Brucella abortus*)	Zoonotic disease, chronic infection, abortion, retained placenta and metritis	High, up to 90% in susceptible herds	5 months +	Severe placentitis, thickened placenta with surface exudate	May be pneumonia	Culture of fetal stomach, placenta, uterine fluid, milk, and semen	Serum and blood agglutination test, milk ring test, whole milk plate agglutination test. Whey plate agglutination, semen plasma, and vaginal mucous agglutination test
Trichomonosis (*Tritrichomomas foetus*)	Venereally transmitted disease resulting in early embryonic loss with occasional abortion and pyometra	Moderate, 5–30%	Primarily first 5 months	Flocculent material and clear, serous fluid in uterine exudate	Usually no gross lesions, histologically fetal giant cell pneumonia may occur	Hanging drop or culture examination of fetal stomach and uterine exudate within 24 hours of abortion. Isolation, best source in female pyometra fluid if pyometra exists, best method is InPouch. In male bull's preputial smegma with InPouch	Cervical mucous agglutination test. Serology rarely performed, mucus agglutination or complement fixation hemolytic assay
Neosporosis (*Neospora caninum*)	Worldwide distribution of infection in both dairy and beef cattle, most abortions reported in dairy cattle. In addition to abortion, mummification and birth of full-term infected calves can occur with or without clinical signs. Chronic infection in which congenital transmission commonly occurs during pregnancy, acquired postnatal infection may also occur	Sporadic or outbreaks common (20–40%). Repeat abortions from same cow can occur	3–8 months of gestation (mean 5.5 months)	No characteristic gross lesions in placenta. Parasite may be present	Autolyzed midgestation fetus, widespread histological inflammatory lesions in fetus including nonsuppurative necrotizing encephalitis and myocarditis	Identify parasite in fetal tissues by immuno-histochemistry stain or PCR	Antibodies in fetus and cow. IFAT and ELISA antibodies used for serological detection. Positive result supports infection in cow and/or fetus but is not causal proof; negative result in dam strong evidence that neosporosis not involved in abortion; serological comparison of groups of aborting and nonaborting herdmates useful in establishing the role in herd outbreaks of abortion
Vibriosis (*Campylobacter fetus* subsp. *venerealis*)	Venereally transmitted, resulting in infertility, irregular, moderately prolonged diestrus with occasional abortion. (BB) Epidemiology similar to trichomonosis except for a longer vaginal carrier state (up to 4 months after uterus has cleared organism), significance: her fertility returns but she is still a threat to any uninfected bull	Low, up to 5%, may be up to 20%	46 months	Semi-opaque, little thickening. Petechiae, localized avascularity and edema	Flakes of pus on visceral peritoneum. Fibrin may be present in serosal cavities. Usually associated with suppurative pneumonia in fetus	Culture of fetal stomach, placenta, and uterine exudate. Sporadic abortion, not venereally transmitted, can be associated with *C. fetus* subsp. *fetus* and *Campylobacter jejuni*, which need to be differentiated from *C. fetus* subsp. *venerealis*	Blood agglutination after abortion (at 3 weeks). Cervical mucous agglutination test at 40 days after infected service

Epidemiology				Field examination		Laboratory diagnosis	
Disease	**Clinical features**	**Abortion rate**	**Time of abortion**	**Placenta**	**Fetus**	**Isolation of agent**	**Serology**
Leptospirosis (*Leptospira interrogans* serovar *pomona* and *Leptospira hardjo*) *L. hardjo* is now called *L. interrogans* serovar *hardjo* type *hardjo-prajitno* in Europe and elsewhere and *Leptospira borgpetersenii* serovar *hardjo* type *hardjo-bovis* in North America	Abortion may occur at acute febrile stage, later or unassociated with illness	25–30%	Abortions may occur throughout gestation. Late, 6 months +	Avascular placenta, atonic yellow-brown cotyledons, brown gelatinous edema between allantois and amnion	Fetus usually autolyzed, occasional icterus. Fetal death common	Fluorescent antibody stain of smears of fetal kidney or PCR. Direct examination of urine of cow by darkfield or fluorescent antibody stain	Positive serum agglutination test 14–21 days after febrile illness. Titers usually at or near maximum at time of abortion. Chronically infected *L. hardjo* dams may have low or negative titers
Infectious bovine rhino-tracheitis	Abortion storms in inadequately vaccinated animals	Variable	Most in second half of gestation	No significant gross lesions	Autolyzed fetus, rarely may have pale foci of hepatic necrosis. Histopathology characteristic with disseminated multifocal necrosis	Virus isolation on placenta or fetal tissues. Immunohistochemistry or fluorescent antibody stain on fetal tissues	Acute and convalescent sera
Mycoses (*Aspergillus, Absidia*)	Variable incidence, more common in cooler moist climates, retained placenta may occur	Unknown. 6–7% of all abortions encountered	3–7 months	Necrosis of maternal cotyledon, adherence of necrotic material to chorionic cotyledon causes soft, yellow, cushion-like structure. Small yellow, raised, leathery lesions on intercotyledonary areas	Minority of fetuses have skin lesions May be small raised, gray-buff, soft lesions, or diffuse white areas on skin. Resemble ringworm	Direct examination of cotyledon and fetal stomach for hyphae, suitable cultural examination. Histopathology on placenta	
Listeriosis (*Listeria monocytogenes*)	May be an associated septicemia. (Cows that abort may die of septicemia near term.) Retained placentas and metritis may also occur	Low, rare abortion storms related with poorly fermented silage	About 7 months	–	Autolysis. Foci of necrosis in liver and other organs	Organisms in fetal stomach, liver and throughout fetus placenta and uterine fluid	Agglutination titers higher than 1:400 in contact animals classed as positive

(cont'd)

Table 14.1 (Continued) Diagnostic summary of causes of abortion in cattle

Epidemiology				Field examination		Laboratory diagnosis	
Disease	**Clinical features**	**Abortion rate**	**Time of abortion**	**Placenta**	**Fetus**	**Isolation of agent**	**Serology**
Epizootic bovine abortion	Tick-transmitted bacterial infection, occurs in dry foothill pastures in western USA in which tick vector resides. No clinical signs in aborting cattle. Herd immunity develops. Incubation period ≈3 months after exposure to agent	Abortion storms may occur, usually in heifers and newly introduced cattle. High, 30–40%	Third trimester abortion or birth of premature weak calves	Negative	Fresh fetus with petechiae in mucosa, enlarged lymph nodes and spleen, subcutis edema, ascites, nodular swollen liver	Diagnosis based on typical histological lesions, etiological bacterial agent has been identified by DNA analysis but is not culturable on artificial media. Bacterial rod can be detected with special stains (Steiner silver stain and immunohistochemistry)	No serology test, elevated fetal IgG levels
Bovine virus diarrhea	Variable outcome of fetal infection depending on timing of infection and other factors. Persistent BVDV infection in full-term live calves a significant problem for exposure of other animals	Less than 10%	Any time during gestation; most common in first trimester	No obvious gross lesions	Mummification, variable fetal lesions possible including deformities (cerebellar, pulmonary or renal hypoplasia), myocardial lesions with congestive heart failure, thymic depletion or no lesions	Immunohistochemical or fluorescent antibody examination of tissues to detect virus. Virus isolation or PCR also available. Animals affected early with congenital lesions may no longer be positive for virus at time of abortion	Fetal antibody, evidence of seroconversion in dam and/or herd

***Nutritional**: Ingestion of excessive amounts of performed estrogens in the diet may cause abortion. There are usually accompanying signs due to increased vascularity of the udder and vulva. Possible dietary factor in so-called 'lowlands abortion'.*

Isoimmunization: Has not been observed to occur naturally in cattle. It has been produced experimentally by repeated intravenous injections of blood from the one bull of pregnancy. Intravascular hemolysis occurs in the calves.

***Unknown**: 30–75% of most abortions examined are undiagnosed. The ingestion of large quantities of pine needles is suspected as a cause of abortion in range cattle in the USA. Infection with* Ureaplasma *and* Mycoplasma *spp. are other causes of undetermined relative importance.*

BVDV, bovine virus diarrhea virus; ELISA, enzyme-linked immunosorbent assay; IFAT, indirect fluorescent antibody test; PCR, polymerase chain reaction.

Apart from the question of human exposure to infection, the cost and economic benefits of an eradication program must be assessed against the costs and benefits from a vaccination control program.

Certain basic considerations apply to all programs aimed at the eradication of brucellosis.

- The control programs indigenous to any given area must receive primary recognition, and any plan or plans must be adapted to that area
- Cooperation at all levels of government from the local to the national is essential for the success of a program. This is attained only after an intensive program of education has been carried out. The individual owner of an infected herd must recognize the problem of brucellosis and express a willingness to cooperate. Experience has shown that the owner must be impressed with the hazards of the disease for human health and with the economic losses in the herd
- A reliable and uniform diagnostic procedure must be generally available
- If disease is detected in a herd, established procedures should be available for handling the disease. If immunization is to be used, a standardized and effective vaccine must be readily available. The disposal of infected animals may create a serious economic threat for the owner and the possibilities of financial compensation must be explored
- Finally, and of major importance, the movement of animals from one area to another must be controlled at a high level, since a rigid eradication program in one area may be nullified by neglect in a neighboring area.

Sufficient information exists about bovine brucellosis that it can be eradicated. The disease was considered to have been eradicated from Great Britain in 1981; in 1985, having met certain European Community criteria for national surveillance and with over 99.8% of the cattle herds free from brucellosis, all herds within the country not under restrictions were designated as being officially brucellosis-free for trade purposes. However, small foci of infection persisted, and following the prohibition of the use of *Brucella* vaccines the national herd was becoming fully susceptible to brucellosis. This was followed by outbreaks of brucellosis in south-west England during 1984–1986. The movement of cattle through premises owned by dealers who specialized in the purchase and sale of newly calved cattle was a significant epidemiological feature of these herd breakdowns.

Control by vaccination

The literature on *Brucella* vaccines in the past, present, and future has been reviewed.[38] Because of the serious economic and medical consequences of brucellosis, efforts have been made to prevent the infection through the use of vaccines.

Brucella abortus strain 19 vaccine

B. abortus strain 19 vaccine has been most widely used to prevent bovine brucellosis. The vaccine protects uninfected animals living in a contaminated environment, enabling infected animals to be disposed of gradually. This overcomes the main disadvantage of the test and disposal method of eradication, in which infected animals must be discarded immediately to avoid spread of infection. Vaccination cannot eradicate brucellosis but can be used to lay the groundwork for eradication. Eradication requires that the infected animals be identified and eliminated from the herd as a source of infection.

Strain 19 *B. abortus* has a low virulence and is incapable of causing abortion except in a proportion of cows vaccinated in late pregnancy, although it can cause undulant fever in humans. Its two other weaknesses are its failure to completely prevent infection, especially infection of the udder, and the persistence of vaccinal titers in some animals.

The **optimum age for vaccination is between 4 and 8 months** and there is no significant difference between the immunity conferred at 4 and at 8 months of age. In calves vaccinated between these ages the serum agglutination test returns to negative by the time the animals are of breeding age, except in a small percentage (6%) of cases. The lipopolysaccharide with an O-chain on *B. abortus* strain 19 explains the appearance and persistence of antibodies in serum following vaccination. These antibodies are detectable in the serological assays used for the diagnosis of brucellosis and are the major problem with strain 19 vaccination, since they prevent easy differentiation of vaccinated from infected cattle. The appearance and persistence of these antibodies depends on age, dose, and route of vaccination. This situation makes the continued use of the vaccine incompatible with simultaneous application of test and slaughter procedures for the control of brucellosis.

In brucellosis-free herds where heifers are vaccinated between 4 and 9.5 months of age, positive titers may persist for up to 18 months if they are tested with screening tests such as the rose Bengal test. This supports the official policy in some countries not to test vaccinated heifers before 18 months of age and to retest positive cases with the complement fixation test.

Calves vaccinated with strain 19 at 2 months of age have resistance comparable to those vaccinated at 4–8 months of age. However, in general, calves under 75 days of age are immunologically immature in response to strain 19 vaccine. Vaccination of calves with a single dose at 3–5 weeks of age does not provide protection compared to vaccination at 5 months of age.

In most control programs, vaccination is usually permitted up to 12 months of age, but the proportion of persistent postvaccinal serum and whey reactions increases with increasing age of the vaccinates. Such persistent reactors may have to be culled in an eradication program unless the reaction can be proved to be the result of vaccination and not due to virulent infection.

Vaccination of adult cattle is usually not permitted if an eradication program is contemplated but it may be of value in reducing the effects of an abortion 'storm'.

Vaccination of bulls is of no value in protecting them against infection and has resulted in the development of orchitis and the presence of *B. abortus* strain 19 in the semen. For these reasons the vaccination of bulls is discouraged.

Strain 19 has been isolated from vaccinated cattle; it is estimated that the organism can be recovered from fewer than 1:100 000, excluding hypersensitivity cases.

Efficiency of Brucella abortus *strain 19 vaccine*

Calfhood vaccination

This can be assessed by its effect on both the incidence of abortion and the prevalence of infection as determined by testing. Field tests show a marked reduction in the number of abortions that occur, although the increased resistance to infection, as indicated by the presence of *B. abortus* in milk, may be less marked. Vaccinated animals have a high degree of protection against abortion and 65–75% are resistant to most kinds of exposure. The remaining 25–35% of vaccinated animals may become infected but usually do not abort. Experimentally, 25% of cattle vaccinated with strain 19 will become infected following challenge. Vaccinated animals continually exposed to virulent infection may eventually become infected and act as carriers without showing clinical evidence of the disease.

The breed of cattle does not affect the serologic response to vaccination with strain 19. Vaccination of adult Bali cattle (*Bos javanicus*) with the low dose, and of calves 6–12 months of age, induced protection and the vaccine is an important

aspect in the control of brucellosis in Timor, Indonesia.[39]

In summary, vaccination with a single 5 mL dose of *B. abortus* strain 19 vaccine given subcutaneously at 2–6 months of age confers adequate immunity against abortion for five or more subsequent lactations under conditions of field exposure. Multiple or late vaccinations have no appreciable advantage and increase the incidence of postvaccinal positive agglutination reactions. When breakdowns occur, they are due to excessive exposure to infection and not to enhanced virulence of the organism. In herds quarantined for brucellosis, calfhood vaccination reduces reactor rates, duration of quarantine and the number of herd tests.

Adult vaccination

Vaccination of adult cows with strain 19 vaccine is highly successful in reducing the number of infected cows in large dairy herds in which it is impossible to institute management procedures for the ideal control of brucellosis. The difficulty of eliminating brucellosis from large dairy herds by test and slaughter methods alone is well documented. Large numbers of animals are concentrated in relatively small areas, few or no replacements are raised in the herd, and the number of lactating animals is kept relatively constant by purchase of mature replacements. The infection rate is high and the acutely affected herd experiences abortion and rapidly spreading disease. In the USA this problem resulted in the evaluation and adoption of vaccination of adult cattle with strain 19 *B. abortus* vaccine.

The vaccination of adult cattle with a reduced dose of vaccine is efficacious.[38] The use of about 1/20th of the standard subcutaneous dose of vaccine results in an agglutinin response that declines more rapidly after vaccination than when the full dose is used. The reduced dose also provides protection comparable to the standard dose. The experimental challenge of pregnant adult cattle and sexually mature nonpregnant heifers that had been vaccinated with 1/400 of the standard calf dose of strain 19 revealed that, although immunity was incomplete, the increase in resistance to infection was greater than that achieved by standard calfhood vaccination. The serological response to vaccination was greatly reduced and there was no adverse effect on pregnancy. Vaccination eliminates clinical disease and reduces exposure of infection to susceptible cattle. The reduction of infected adult cattle may vary from 60–80% in 6–9 months following vaccination. The complement fixation test becomes negative sooner than the standard tube agglutination test following vaccination and can be used to distinguish postvaccine titers from culture-positive cows. The use of reduced doses of strain 19 vaccine in adult cows will also help to eliminate the problem of postvaccine titers.

The **subcutaneous and conjunctival routes of vaccination** of adult cattle with strain 19 *B. abortus* vaccine have been compared.[38] The protection provided is the same regardless of the route of administration. However, the subcutaneous route may result in a persistent serological response, which requires complement fixation testing and milk culture to identify infected animals.

The **principal advantages of adult vaccination** include:

- An effective method of control of abortion
- Reduction in the reactor losses in herds
- Reduction of the number of tests required to eliminate brucellosis from infected herds.

The **major disadvantages of adult vaccination** are:

- Residual vaccine titers
- Persistent positive milk ring test
- Persistent strain 19 infection in a small percentage of adult vaccinates
- The stigma attached to adult vaccinates, which identifies them with infected herds, even though brucellosis has been eliminated and the herd released from quarantine.

B. abortus strain 19 has been recovered from the supramammary lymph nodes of cattle at slaughter that were vaccinated with a low dose of the vaccine 9–12 months previously and had persistent titers to the complement fixation test. The stage of gestation affects the immune responses of cattle to strain 19 vaccination. Cattle that are late in the first or early in the second trimester of gestation (84–135 days) at the time of administration of a low dose of strain 19 are at greater risk of being positive by official tests for brucellosis. Vaccination of cattle during the third trimester with a low dose of the vaccine is not as efficacious as when carried out earlier. Although reduced-dose strain 19 vaccination is a possible alternative to the total depopulation of problem herds, its use during pregnancy should be avoided because of the risk of abortion and positive serological titers and positive bulk milk ring tests. It should never be used in uninfected herds.

The results expected following adult vaccination depend on the disease situation. In herds vaccinated in the acute phase of the disease, abortion may continue for 60–90 days but the incidence begins to decline by 45–60 days. A large number of serological reactors will be present for the first 120 days following vaccination and testing is usually not done for the first 60 days. The rate of reactors declines rapidly after 120 days and with good infected herd management most adult vaccinated herds can be free of brucellosis 18–24 months following vaccination.

The prevalence of strain 19 *B. abortus* infection in adult vaccinated cattle is low and is often not permanent. The prevalence is lower among cattle given the reduced dose of the vaccine subcutaneously. Bacteriological examination of the milk and serological examination of the infected cattle are necessary to identify strain 19 infected cattle, which can be retained for milk production because the infections are temporary.

Adult vaccination, even with a low dose, should not be used in uninfected herds because of persistent titers, which may last for more than 12 months in up to 15% of vaccinated animals, and because of the potential for abortion. The illegal or unintentional use of the standard dose of strain 19 vaccine in adult cattle will result in a sudden steep antibody titer response in the CFT, which declines in 6–11 months. In herds where adult vaccination with a reduced dose of vaccine is used, blood samples should be collected about 4 months after vaccination and subsequently at intervals of 2 months. Those positive to the CFT should be culled. In one study of three large dairy herds in California, the CFT at 2 and 4 months after vaccination was used to identify and cull pregnant reactor cows that were at risk of aborting or calving. The prevention of parturition of infected cows is an effective management technique.

Systemic reactions to vaccination with strain 19

These occur rarely in both calves and adults, and may be more severe in Jersey calves than in other breeds. A local swelling occurs, particularly in adult cattle, and there may be a severe systemic reaction manifested by high fever (40.5–42°C, 105–108°F) lasting for 2–3 days, anorexia, listlessness and a temporary drop in milk production. An occasional animal goes completely dry. The swellings are sterile and do not rupture, but a solid, fibrous mass may persist for many months.

Deaths within 48 hours of vaccination have been recorded in calves after the use of lyophilized vaccine.

B. abortus strain 19 vaccine has been associated with lameness in young cattle with synovitis following vaccination. Experimentally, the intra-articular injection of the vaccine strain can produce synovitis

similar to that which occurs following vaccination.

Septicemia due to *B. abortus* may cause some deaths but in most cases the reaction is anaphylactic, and vaccinated calves should be kept under close observation. Immediate treatment with epinephrine hydrochloride (1 mL of 1:1000 solution subcutaneously) or antihistamine drugs is recommended and is effective provided it can be administered in time.

Cows in advanced pregnancy may abort if vaccinated, but the abortion rate is only about 1%; although *B. abortus* strain 19 organisms can be recovered from the fetus and placenta, their virulence is unchanged and they do not cause further spread of infection. Vaccination with strain 19 does not have a deleterious effect on the subsequent conception rate.

Brucella abortus strain RB51 vaccine

Brucella abortus strain RB51 (SRB51) is a live, stable, rough mutant of *B. abortus* strain 2308 that lacks much of the lipopolysaccharide O-side chain.[40,41] The O-side chains are responsible for the development of the diagnostic antibody responses of an animal to brucellosis infection.

Heifer calves vaccinated at 3, 5, and 7 months of age with the SRB51 vaccine were protected when challenged against infection and abortion during their first pregnancy.[42] None of the heifers developed antibodies that reacted in the standard agglutination test, but did react in a dot blot assay using RB51 antigen. In pregnant cattle, SRB51 vaccine has a tropism for the bovine placental trophoblast but when given subcutaneously does not cause placentitis or abortion and the induced humoral and cell-mediated immune response does not interfere with the serological diagnosis of field infections.[43,44] Vaccination of mature sexually intact bulls and pregnant heifers with a standard calfhood dose of SRB51 is not associated with shedding or colonization in tissues, and does not appear to cause any reproductive problems when administered to sexually mature cattle.[45] One study found that *B. abortus* RB51 isolated from the milk of a cow was no different from the RB51 vaccine strain and it is possible that shedding of vaccine strains may be associated with the vaccine.[46] Use of the vaccine in cattle already vaccinated with strain 19 vaccine will not cause positive responses on confirmation tests and does not interfere with brucellosis surveillance.[37,47]

Vaccination with a reduced dosage of SRB51 (reduced dose vaccination) protects adult cattle against abortion or infection caused by exposure to virulent *B. abortus* during the subsequent pregnancy.[48] Revaccination of cows with a reduced dose of SRB51 in endemic zones does not cause abortion and protects 94% of animals against field infection but may cause an atypical response to conventional serological tests.[49]

The summary of studies with strain RB51 vaccine indicate that it is as efficacious as *B. abortus* strain 19 vaccine but is much less abortigenic in cattle. It does not produce any clinical signs of disease after vaccination, nor does it produce a local vaccination reaction at the injection site. The organism is cleared from the blood stream within 3 days and is not present in nasal secretions, saliva, or urine. Immunosuppression does not cause recrudescence and the organism is not spread from vaccinated to nonvaccinated cattle. The vaccine is safe in all cattle over 3 months of age. In case of human exposure, strain RB51 is sensitive to a range of antibiotics used in the treatment of human brucellosis but is resistant to rifampin and penicillin.

In the USA, strain RB51 vaccine was licensed by USDA's Animal and Plant Health Inspection Service (APHIS) in 1996 for use in cattle and was approved for use in the Cooperative State-Federal Brucellosis Eradication Program. Strain RB51 vaccine must be administered by an accredited veterinarian or by a state or federal animal health official. Calves must be vaccinated with the calf dose (10–34 billion organisms) between 4 and 12 months of age. Only animals in high-risk areas should be vaccinated over 12 months of age.

Vaccinates must be identified with the standard metal vaccination eartag and a vaccination tattoo. The tattoo will be the same as with *B. abortus* strain 19 vaccination except the first digit for the quarter of the year will be replaced with an 'R' to distinguish animals vaccinated with RB51 from those vaccinated with strain 19. Recording and reporting are the same as with strain 19 vaccine. *B. abortus* strain 19 vaccine has not been removed from the market in the USA or from the Brucellosis Eradication Program at this time. However, APHIS has been advised that strain 19 vaccine production has ceased, and some states no longer allow vaccination with strain 19.

B. abortus strain RB51 has not yet been approved for general use in bison. Preliminary studies indicate that RB51 is safe and efficacious in bison calves. However, in order for RB51 to be conditionally licensed in bison, additional safety and efficacy trials must be completed.

Bison calves can be vaccinated with strain RB51 as part of a field safety trial evaluation prior to its being licensed. The requirements for participating in the trials are that all abnormal reactions or clinical problems associated with the vaccination be reported to a USDA, APHIS Veterinary Services veterinarian for investigation. Bison vaccinated as part of the field safety trials will be recognized as official vaccinates provided that the proper vaccination charts and identification are completed as required under the Brucellosis Eradication Program Uniform Methods and Rules.

Brucella vaccines in wildlife

The literature on the use of *Brucella* vaccines in wildlife has been reviewed.[50] A reservoir of *B. abortus*-infected bison in the Greater Yellowstone Area of the USA is an obstacle in the effort to eradicate brucellosis from the USA and a source of potential reinfection for livestock in the states of Wyoming, Idaho, and Montana. The free-ranging and infected bison in the area migrate from public land on to private lands and may come into contact with cattle. *Brucella*-induced abortions in bison have occurred under experimental and field conditions, and infected bison can transmit brucellosis under range conditions. Wild and free-ranging bison in parts of western Canada have also been shown to be infected with bovine brucellosis. Therefore, a safe and effective vaccine suitable for delivery to free-ranging bison in the greater Yellowstone area and in Canada is considered useful in reducing the risk of transmission and an aid in the prevention and control of the disease.[50]

Brucella abortus *strain 19 in bison*

The use of strain 19 vaccine has been evaluated in pregnant bison and 10-month-old calves, and the results have been unsatisfactory.[50]

Brucella abortus *strain RB51 in bison*

The literature on the safety and efficacy of the RB51 vaccine in bison has been reviewed.[50] The vaccine is safe for vaccination in herds of naive and previously exposed bison calves, young growing bison, adult males, and adult pregnant and nonpregnant females. Fetal lesions do not appear to be significant with bison cows vaccinated with RB51 in early gestation. Efficacy studies indicate that the amount of protection provided to bison from RB51 has not yet been determined precisely.[50]

Calfhood vaccination of bison with SRB51 is efficacious in protecting against intramammary, intrauterine, and fetal infection following exposure to a virulent strain of *B. abortus* during pregnancy.[51] Calfhood vaccination with SRB51 would be beneficial in a program to reduce the prevalence of *B. abortus* field stains in American bison. To be effective, it would have to be combined with a test and slaughter policy program. As with cattle, SRB51 calfhood vaccination provides a

method to prevent transmission and reduce the numbers of susceptible individuals in a bison herd without interfering with serological identification of *Brucella*-infected animals. The vaccine can also cause placentitis and abortion in pregnant bison.[52] The vaccine can be safely used to booster vaccinate pregnant bison in a *Brucella*-infected herd.[6]

Brucellosis management programs in bison and elk are unlikely to be successful if capture and hand vaccination is necessary. The effect of hand vaccination versus ballistic vaccination for vaccination of bison and elk on the immunological responses to SRB51 has been evaluated.[53] Ballistic delivery may require a greater dose of SRB51 to induce cell-mediated immune responses in bison that are comparable to those induced by hand injection.

Brucella abortus *strain RB51 in elk* (Cervus elaphus canadensis)

Following vaccination with SRB51, elk remain bacteremic for a prolonged period of time, rapidly develop high antibody titers and are slower to develop detectable proliferative responses in peripheral blood mononuclear cells than cattle or bison.[54] The safety and efficacy of a reduced dose of SRB51 to prevent *Brucella*-induced abortion in elk vaccinated as calves has been evaluated.[55] A single dose does not provide significant protection against *B. abortus*-induced abortion in elk.[55] A higher dose also does not prevent abortion.[55] The vaccine is safe in bull elk.[12]

Other wildlife species

A single oral dose of SRB51 is safe in bighorn sheep, pronghorn, mule deer, moose, and coyotes.[22]

Vaccination technique

The vaccine is a living agent and must be handled with care if satisfactory results are to be obtained. Lyophilized vaccine is superior to liquid vaccine because of its greater stability and greater longevity but it must be kept under refrigeration at all times, be reconstituted only when required, and unusual material must be discarded. It must be used in an aseptic manner to avoid contamination with other bacteria. The use of a common needle for vaccination on a given day in a herd of dairy cattle is not an effective means of transmission of bovine leukemia virus infection.

Control programs on a herd basis

The following recommendations are based on the need for flexibility depending on the level of infection that exists and the susceptibility of the herd and the disease regulations in effect at the time.

During an abortion storm

Test and disposal of reactors may be unsatisfactory during an outbreak because spread occurs faster than eradication is possible. Vaccination of all nonreactors is recommended in some countries or, if testing is impracticable, vaccination of all cattle. Strain K45/20A vaccine may be used and must be given in two doses at 6-month intervals. It is preferable to retest the herd before the second vaccination and to cull cows with a threefold rise in agglutination titer. However, strain-19 vaccine is a superior vaccine even for use in adult pregnant cattle, although it may cause abortion in a small percentage of animals.

Heavily infected herds in which few abortions are occurring

These do not present an urgent problem because a degree of herd resistance has been reached. All calves should be vaccinated with strain 19 immediately and positive reactors among the remainder should be culled as soon as possible. Periodic milk ring tests (preferably at 2-month, no more than 3-month, intervals) on individual cows are supplemented by complement fixation and culture tests.

Lightly infected herds

These present a special problem. If they are situated in an area where infection is likely to be introduced, the calves should be vaccinated and positive reactors immediately culled. If eradication is the goal in the area, culling of reactors will suffice, but special market demands for vaccinated cattle may require a calfhood vaccination policy. When a herd is declared free of brucellosis on the basis of serum agglutination tests, its status can be maintained by introducing only negative-reacting animals from brucellosis-free herds, and annual blood testing. In areas where dairying predominates, semi-annual testing by the milk tests may be substituted for blood testing.

In all the above programs the careful laboratory examination of all aborted fetuses is an important and necessary corollary to routine testing. There are many difficulties in the way of achieving control and eventual eradication on a herd basis. These relate mainly to the failure of owners to realize the highly infectious nature of the disease and to cooperate fully in the details of the program. Particularly, they may fail to recognize the recently calved cow as the principal source of infection. In a herd control program such cows should be isolated at calving and blood tested at 14 days, since false-negative reactions are not uncommon prior to that time.

Hygienic measures

These include the isolation or disposal of infected animals, disposal of aborted fetuses, placentas, and uterine discharges, and disinfection of contaminated areas. It is particularly important that infected cows be isolated at parturition. All cattle, horses, and pigs brought on to the farm should be tested, isolated for 30 days, and retested. Introduced cows that are in advanced pregnancy should be kept in isolation until after parturition, since occasional infected cows may not show a positive serum reaction until after calving or abortion. Chlorhexidine gluconate is an effective antiseptic against *B. abortus* and is recommended for washing the arms and hands of animal attendants and veterinarians who come into contact with contaminated tissues and materials.

Eradication on an area basis by test and slaughter and cessation of calfhood vaccination

Following a successful calfhood vaccination program, eradication on an area basis can be considered when the level of infection is below about 4% of the cattle population. Brucellosis control areas must be established and testing and disposal of reactors and their calves at foot is carried out. Financial compensation is paid for disposal of reactors. Infected herds are quarantined and retested at intervals until negative; in heavily infected herds complete depopulation is often necessary. Brucellosis-free areas are established when the level of infection is sufficiently low, and the movement of cattle between areas is controlled to avoid the spread of infection.

Farms with a low incidence may find it possible to engage in an eradication program immediately provided the incidence on surrounding farms is low. Breakdowns may occur if there are accidental introductions from nearby farms, and in these circumstances it is hazardous to have a herd that is not completely vaccinated. When the area incidence is low enough (about 5%) that replacements can be found within the area or adjoining free areas, and immediate culling of reactors can be carried out without crippling financial loss, compulsory eradication by testing and disposal of reactors for meat purposes can be instituted. Compensation for culled animals should be provided to encourage full participation in the program.

The work of testing can be reduced by using screening tests to select herds for more intensive epidemiological and laboratory investigation. In dairy herds the milk ring test is useful. In beef herds, the favored procedure is the collection of blood from drafts of cattle at the abattoir and use of the rose Bengal test. The same technique has also been used to screen shipments of beef destined for countries with an aversion to meat infected with *B. abortus*. An additional means of reducing labor costs in an eradication program is

the use of automated laboratory systems such as the one available for the rose Bengal agglutination test and the one based on the agglutination and complement fixation test. An educational program to promote herd owners voluntarily submitting all aborted fetuses to a laboratory for bacteriological examination is also deemed necessary in any eradication scheme. When an area or country is declared free, testing of all or part of the population need be carried out only at intervals of 2–3 years, although regular testing of bulk milk samples and of culled beef cows in abattoirs and examination of fetuses should be maintained as checks on the eradication status. Such a program has achieved virtual eradication of the disease in Switzerland, Sweden, and Northern Ireland.

In all eradication programs some problem herds will be encountered in which testing and disposal do not eliminate the infection. Usually about 5% of such herds are encountered and are best handled by a 'problem herd' program. Fifty percent of these herds have difficulty because of failure to follow directions. The other half usually contain infected animals that do not respond to standard tests. Supplementary bacteriological and serological tests as set out above may occasionally help these spreader animals to be identified and the disease to be eradicated.

USA

The **Cooperative State–Federal Brucellosis Eradication Program of the USA** is making progress. Efforts to eradicate brucellosis **associated with** *B. abortus* in the USA began in 1934 as an economic recovery program to reduce the cattle population because of the great depression. Brucellosis was considered the most significant livestock disease at that time, with a reactor rate of 11.5%.[56] In 1954, a cooperative federal and state program was launched based on calfhood vaccination and test and slaughter with compensation. Two very effective surveillance programs for detecting brucellosis were the market cattle testing and milk ring testing of dairy herds. As of December 2000, there were no brucellosis-infected herds in the USA.[56] Infected animals (reactors) are traced to farms of origin. The number of human cases of brucellosis declined with the decline in number of cases in animals. As of 2002, about 100 human cases per year are reported. Most cases are associated with consumption of unpasteurized milk and milk products of goat origin infected with *B. melitensis*.[56] A critical element in a successful surveillance program is **individual animal identification.** A uniform national identification system is being developed to insure the ability to trace animals to their herds of origin.

Bison and elk in the greater Yellowstone area are the last known remaining reservoir of *B. abortus* in the USA. Control of brucellosis in these species on public lands requires special consideration in order to preserve the largest wild, free-ranging population of bison in the USA. Vaccination trials are under way.

As of December 2004, the overall status of the Cooperative State-Federal Brucellosis Eradication Program is that 48 states are designated as Class Free for brucellosis and two states, Texas and Wyoming, are designated as Class A. Puerto Rico and the Virgin Islands maintain their Class Free status. The development of the National Animal Identification System and the National Surveillance Unit will assist in the final eradication of brucellosis.

The USA Department of Agriculture, Animal and Plant Health Inspection Service, in October 2003, published *Brucellosis Eradication: Uniform Methods and Rules* (UM&R), which includes the minimum standards of the Cooperative State–Federal Brucellosis Eradication Program.[57] These UM&R contain minimum standards for certifying herds, classifying states and areas, and detecting, controlling and eradicating brucellosis, as well as minimum brucellosis requirements for the intrastate and interstate movement of cattle and bison.

The publication is divided into two chapters that are further subdivided into parts. Chapter 1 deals with general provisions for cattle and/or bison. Part I of Chapter 1 contains definitions. Part II covers procedures used in the Cooperative State–Federal Brucellosis Eradication Program, and part III explains participation in area plans. Chapter 2 deals with all of the classifications of herds and areas for bovine brucellosis: Certified Brucellosis-Free Herds (part I), Class Free Status (part II), Class A Status (part III), and Class B Status (part IV).

The provisions of the UM&R were approved by the USDA-APHIS Veterinary Services. They may be amended in the future by replacing pages or by adding new pages.

The USA Department of Agriculture, Animal and Plant Inspection Service, in September 2003, published *Brucellosis in Cervidae: Uniform Methods and Rules* (UM&R), which provides minimum program standards and procedures of the Cooperative State–Federal Cervid Brucellosis Program to eradicate and monitor brucellosis in farm or ranch-raised Cervidae.[58] Content was approved by the USDA-APHIS Veterinary Services, incorporating recommendations from the state animal health authorities, industry representatives and the USA Animal Health Association. This UM&R may be amended in the future by replacing pages or by adding new pages.

The primary surveillance methods for testing eligible cattle in the US have been the **market cattle testing** program in the beef industry and the **milk ring testing** in the dairy industry. They are constant and can survey virtually all of a specific animal population.

Market cattle testing

Surveillance by this method is part of the marketing process. Testing is done at livestock markets, slaughterhouses, livestock buying stations, or dealer premises. This type of testing is very effective, especially if required at the first point of assembly of cattle after leaving the farm of origin. In the USA, 95% of more of cows and bulls 2 years of age or older are required to be tested for brucellosis at slaughter. Essential factors of this method of surveillance are animal identification and records so that infected animals (reactors) can be traced to the farms of origin.

In the Market Cattle Identification (MCI) program, cattle are identified at each point of sale by application of a paper backtag held on with glue. The type of animal eligible for backtagging and testing differs between states. In the slaughterhouses, inspectors collect blood samples from all tagged animals. Samples and tags are sent to the laboratory and reactors are traced back to the herd of origin. Epidemiological studies have shown a distinct herd size bias in the MCI surveillance system. For example, the probability of detection in a nine-cow herd is 24%, compared to 85% for a 645-cow herd 1 year after infection. This herd size bias implies that secondary testing may be efficiently used by concentrating testing in smaller herds when funds for secondary testing are limited.

Milk ring testing

Surveillance by this method involves the regular, periodic testing of milk or cream from commercial dairy herds. Milk ring testing is required twice annually in commercial dairy herds in states officially declared free of brucellosis, and four times annually in states not officially free of brucellosis. This test is very sensitive and is done on a small sample of milk from the entire herd. The milk ring test itself is simple and inexpensive. A well-managed testing program is important to public health and can reduce the exposure potential of contaminated dairy products to humans by quickly identifying affected herds.

Australia

In Australia, under range conditions, considerable progress towards eradication of brucellosis in large beef herds has been possible. Management must be motivated and confident that the disease can be permanently eradicated. All cattle should be permanently identified, security between subherds must be good, vaccination histories must be accurate, and accurate round-up (mustering) of cattle must be possible. Quarantine facilities for infected subherds must be strict and absolutely reliable, and fence lines must be impenetrable. The development of a two-herd system, based on segregation of weaned heifer calves from adult cows and maintenance of testing pressure on the adults, will reduce the chance of infection of heifers. All calves from reactor dams are discarded, which necessitates positive identification. Only bulls or semen from brucellosis-free herds should be used in clean herds. In some situations, a laboratory is established on the ranch and equipped to do the rose Bengal test and CFT. This increases the efficiency of the testing program and creates an excellent team effort between management, laboratory personnel and the field veterinarian.

New Zealand

In New Zealand, the brucellosis status of accredited herds is monitored by a triennial complement fixation test with a sensitivity of greater than 95%.[58] Slaughterhouse surveillance, as carried out in Australia, has a low probability of identifying infected herds. A skin test for brucellosis is attractive because it could be used at the same time as routine tuberculin testing.[50]

Chile

In a region in Chile, a brucellosis eradication program was very successful in 5 years.[59] There was a decrease in the incidence and prevalence of brucellosis-infected herds and in the surveillance rates monitored during the interval. The key components were: implementation of an epidemiological surveillance system that detects the occurrence of infection, an orientation of the state effort towards the cleaning of infected herds, the use of an effective vaccine that doesn't interfere with the diagnosis of the infection, and the active participation of farmers, veterinarians, private laboratories, and the cattle industry.

Canada

In Canada, the bovine brucellosis eradication program is a success story that began in 1950 when the national prevalence of infection was about 9%. With the cooperative Federal–Provincial Calfhood Vaccination Program, the prevalence of infection was reduced to 4.5% by 1956. In 1957, a test and slaughter program was begun in which brucellosis control areas were established and mandatory testing of all cattle was done using the tube agglutination test. Reactors were identified and ordered to be slaughtered, and compensation was paid. Infected herds were quarantined and retested until negative or in some cases completely depopulated. When the infection rate was reduced to below 1% of the cattle population and 5% of the herds, the area was certified for a period of 3 years. When the infection rate was reduced to below 0.2% of the cattle in the area and 1% of the herds, the area was designated brucellosis-free and certified for a period of 5 years. In the 1960s the milk ring test and the market cattle testing programs were introduced as surveillance procedures. These are done on a continuing basis, are effective in locating infected herds and have reduced the volume of on-farm testing required to recertify areas.

When the national level of infection was reduced to below 0.2%, calfhood vaccination was de-emphasized to overcome the problem of distinguishing between persistent vaccinational titers and titers due to natural infection. Thus all seropositive animals could be disposed of and no vaccination privileges allowed. In 1973 an increase in the incidence of brucellosis occurred, which necessitated some modifications in the eradication program. The intensity of milk ring testing was increased, herds adjacent to infected herds were tested, the length of quarantine of infected herds was increased, and calves from reactor dams were ordered to be slaughtered. In heavily infected herds and in those in which it is not possible to maintain effective quarantine, it was preferable to completely depopulate a herd rather than conduct tests and successive retests. In the Canadian experience, brucellosis-free herds usually became infected when the owner unknowingly purchased an infected animal. The uncontrolled movement of infected animals from infected herds to brucellosis-free herds was a major obstacle in the final stages of the eradication.

The rate of progress in an eradication program is determined mainly by the rate at which herds that are accredited free of the infection become reinfected. The severity of reinfection (or **breakdown**) is dependent upon the proportion of the herd that has been vaccinated as calves. The cessation of compulsory calfhood vaccination results in a large proportion of cattle that are fully susceptible to *B. abortus* infection. The prevention of reinfection requires a constant surveillance system.

In Canada, **three concerns** followed eradication of brucellosis in 1985:

- The **first** concern was the need for continuous surveillance to identify hidden foci of infection that might be present but not become apparent until a full generation of cattle had passed, and to detect infection that might be imported with livestock brought into the country. A related concern was the presence of infection in Canadian wildlife, particularly bison and elk, which are the species of choice in game farming
- The **second** concern was the dilemma faced by livestock owners to use the vaccine, when normally they do not use it, to vaccinate cattle intended for export to importing states or countries that require vaccination. The continued use of the vaccine in a brucellosis-free area or country perpetuates the diagnostic problem
- The **third** concern was the importation of cattle from countries or regions that had not eradicated brucellosis.

The importance of unknown infected or latent carriers that may be seronegative is a major concern because it can result in herd epidemics of abortion in unvaccinated cattle. The risk can be minimized by preentry and postentry testing combined with certification of the animals on the basis of the regional and herd health status. Limiting the importation of cattle from areas where brucellosis persists and the use of embryo transfer technology can also reduce the risk of introducing infection. Vaccination of adult cattle in Canada was not permitted.

Canada was declared free of bovine brucellosis in 1985. No cases of bovine brucellosis have been identified since an atypical biovar 5 *B. abortus* was isolated in 1989 from a beef cow vaccinated with strain 19 *B. abortus*. A field strain *B. abortus* has been found in one herd of farmed bison in 1988 and has never been reported in farmed Cervidae in Canada.

In 1997, a comprehensive review of Canada's bovine brucellosis surveillance program was undertaken. As a result of the findings of this review, a number of modifications to the surveillance program were introduced in 1999. The routine serological testing of market and slaughter cattle and the routine milk ring testing of all dairy cattle were discontinued in 1999. However, auction market testing of cattle 24 months and older continues in the five markets in northern Alberta and British Columbia in response to the disease risk associated with the infected free-roaming

bison herds in and around Wood Buffalo National Park.

In 1998/99, a bovine serum survey was conducted involving the collection and testing of 17 170 randomly selected sera. Twenty samples were positive to the buffered plate agglutination test and, when the competitive-ELISA was applied to these 20 sera, one weak positive sample was found. This result was considered to be insignificant. From this survey, it was concluded that the prevalence of bovine brucellosis in Canada's cattle population is less than 0.02%.

The next bovine serum survey was postponed from 2001/02 to take advantage of the implementation of the national cattle identification program to assist in the trace-back of any suspicious findings. This survey commenced in 2003 and is nearing completion. All samples are being screened using FPA and any positive samples are subject to confirmatory testing using the competitive ELISA. To date, no evidence of bovine brucellosis has been detected.

In addition, in 2002, 80 253 cattle were tested for brucellosis in conjunction with modified market and slaughter cattle testing (27 814), export and artificial insemination center testing (43 664), investigatory testing (7130), and for other reasons (1645). Thirty-three suspect animals were detected and investigated, with negative results.

In April 2000, the vaccination of calves with reduced dosage strain 19 *B. abortus* vaccine was discontinued. Strain RB51 *B. abortus* vaccine is not licensed for use in Canada.

Bovine brucellosis in wildlife is restricted to free-roaming bison in and around Wood Buffalo National Park in northern Canada. Information on this occurrence is found in Canada's report to the OIE Wildlife Diseases Working Group.

Porcine brucellosis (Brucella suis)

Canada continues to be free of porcine brucellosis. *B. suis* biovar 1 has never been found in Canadian pigs. Surveillance for porcine brucellosis is based on a national serological survey of slaughter sows that is conducted every 3 years. A survey conducted in 1997/98 concluded that the prevalence of porcine brucellosis in Canada's pig population is less than 0.02%. *B. suis* biovars II and IV occur in *Rangifer* spp. (caribou and reindeer) in the Canadian Arctic. Movement controls within the country prevent these animals from entering the livestock-producing areas of Canada.

BRUCELLOSIS ASSOCIATED WITH *BRUCELLA OVIS*

Synopsis

Etiology *Brucella ovis*

Epidemiology Disease of sheep. Organism carried by sexually mature rams with spread by direct contact or passive venereal infection

Clinical findings Clinical or subclinical disease. Infertility in rams due to epididymitis. Epididymal abnormality can be detected by palpation in some affected rams. Abortion in ewes and neonatal mortality in lambs are also occasionally caused by the infection

Clinical pathology Semen examination. Serology of most value including complement fixation, gel diffusion, and ELISA

Diagnostic confirmation Physical palpation of the contents of the scrotum combined with cultural examination of semen (or aborted material), and serological examination

Treatment Oxytetracycline in valuable rams

Control Total segregation of normal and young rams. Initial culling of rams with palpable scrotal abnormality and subsequent repeated serological testing and culling of seropositive rams. Alternative is vaccination with live *B. melitensis* strain Rev. 1

ETIOLOGY

Brucella ovis has significant DNA homology with other members of the genus *Brucella*[1,2] and also shares many antigenic and other characteristics but it is permanently rough.

EPIDEMIOLOGY

Geographical occurrence

Brucellosis of sheep associated with *B. ovis* has been reported in most of the **major sheep-producing regions** of the world and is present in Australia, New Zealand, North and South America, Central Asia, Russia, South Africa, and Europe but is not a major cause of ram wastage in Great Britain. When the disease is first diagnosed in a country, and before control procedures are established, the **flock prevalence** of infection can be as high as 75% and as many as 60% of rams may be infected.[3,4] The prevalence of infection is generally much lower in countries and in flocks that have established control programs.

Host occurrence

In nature only **sheep** are affected, although the ram is more susceptible than the ewe. Infection can be established experimentally in laboratory animals only with difficulty.[3] White-tailed deer and goats can be infected experimentally, leading to the development of an epididymitis, but there is no evidence of natural infection in goats, even in those that cohabit with infected sheep.

The **Merino breed** and Merino-derived crossbreeds show a much lower incidence of the disease than do British breeds. The disease is most important in large flocks where there is multi-sire breeding.

Source of infection

The **infected ram** is the source of infection and perpetuates the disease in a flock. The majority of infected rams excrete the organism in semen[5] and in most rams the active excretion in semen probably persists indefinitely.

Ewes are more resistant to infection but the organism can be isolated from them in infected flocks.[6] After being bred by an infected ram, the majority will not carry infection for more than one or two heat cycles.[7] Infection may result in early embryonic death and occasionally abortion or the birth of weak and poorly viable lambs.[3] In ewes where the infection does persist to produce abortion, the organism is present in the placenta, vaginal discharges, and milk.

Transmission

Transmission between rams occurs via passive venereal infection and by direct ram-to-ram transfer.[3,7]

Passive venereal infection occurs from ewes that have been bred by an infected ram in the same heat cycle. Under natural conditions, this may be the major from of transmission from ram to ram that occurs during the breeding season. Infection can also be transmitted between rams in the nonbreeding season that are housed together or **grouped together** on pasture. This occurs as they sniff and lick each other's prepuce and by homosexual activity. Submissive rams may lick the prepuce of dominant rams as a trait in the dominance hierarchy. Spread of infection in a group of virgin rams is recorded.[8] Lambs born from infected ewes and drinking infected milk do not become persistently infected.

The organism can survive on pasture for several months but transmission by fomites appears is believed to have no practical significance. However, transmission from infected rams to infection-free red deer stags grazed on the same pasture can occur and it is not known if this results from direct contact between the animals or indirectly via environmental and pasture contamination.[9]

Host risk factors

All postpubertal rams are susceptible to infection, but disease occurs more commonly in adult rams and **disease prevalence increases with age**, probably because of greater exposure to infection.[4] Differences between flocks in the prevalence of disease suggest that environmental factors and stress may modulate susceptibility[7] but the risk factors are poorly defined. When the number of affected rams in a flock is greater than about 10%, the fertility of the flock is appreciably decreased.

Experimental reproduction

Experimentally, rams can be infected by the intravenous, subcutaneous, intratesticular, oral, **conjunctival**, **and preputial** routes but the latter two are the most effective.[3,10,11] The first observable abnormality is the presence of inflammatory cells in the semen, which appear at 2–8 weeks. *B. ovis* appears in the ejaculate at approximately 3 weeks but it is not invariably present in all examinations of an infected ram. Testicular and epididymal lesions can be palpated at about 9 weeks after infection but may occur earlier in some rams. A significant proportion of infected rams have no palpable lesions but still excrete the organism.

Ewes in early pregnancy can also be infected by the oral and intravenous routes but many of these infections are transient and do not result in abortion. Abortion due to **placentitis** has been produced experimentally. Intrauterine infection produced experimentally also causes lesions in, and death of, the fetus but the significance of this to natural cases is undetermined.

Economic importance

The economic effects of the disease are subtle but significant. The effect of the disease on **ram fertility** can influence the number of rams that are required in a flock: the required ram to ewe ratio is significantly reduced in *B. ovis*-free flocks. The percentage of lambs born early and within the first 3 weeks of the lambing period is also markedly increased. Lambing percentage may be reduced by 30% in flocks recently infected and by 15–20% in those where the infection is endemic.[7] Additional costs are the loss of rams of high genetic potential and the cost of repeat serological testing. In the USA, an additional return of US$12 per ewe mated has been calculated as the advantage in a control program.[12]

Zoonotic implications

B. ovis is not a zoonosis but live *Brucella* vaccines used for prevention of this infection in some countries, such as Rev. 1 *B. melitensis* vaccine, are pathogenic to humans and should be handled and used with due caution.

PATHOGENESIS

There is an initial bacteremia, often with a mild systemic reaction, and the organism can be isolated from the internal organs of animals slaughtered after experimental infection. However, systemic disease is not a feature of the natural disease, and clinical disease results from localization and inflammation in the **epididymides**. Inflammation in this area results in sperm stasis and extravasation with a subsequent immunological reaction that is usually in the tail and unilateral, causing a **spermatocele** and therefore reduced fertility. Not all infected rams have palpable lesions in the epididymis: infection can also establish in the seminal vesicles and ampullae. In either case the organism is shed in the ejaculate.

In general, the evidence is that *B. ovis* has low pathogenicity for ewes: the primary effect of infection is a **placentitis**, which interferes with fetal nutrition, sometimes to the point of causing fetal death but more commonly producing lambs of low birth weight and poor viability.

CLINICAL FINDINGS

The first reaction in rams is a marked deterioration in the quality of the semen together with the presence of leukocytes and *Brucella*. Acute edema and inflammation of the scrotum may follow. A systemic reaction, including fever, depression, and increased respiratory rate, accompanies the local reaction.

Regression of the acute syndrome is followed, after a long **latent period**, by the development of **palpable lesions in the epididymis and tunicae** of one or both testicles.

The palpation of both testicles simultaneously from behind is the best method of examination. The epididymis is enlarged and hard, more **commonly at the tail**, the scrotal tunics are thickened and hardened, and the testicles are usually atrophic. The groove between the testis and epididymis may be obliterated.

The abnormalities are often detectable by palpation but many affected rams show no acute inflammatory stage and others may be actively secreting *Brucella* and poor-quality semen in the chronic stage in the **absence of palpable abnormalities**. Palpable abnormality of the scrotal contents may be present in less than 50% of serologically positive rams.[3] Affected rams have normal libido.

There are usually no clinical signs in the ewe but in some flocks infection causes abortion or the birth of weak or stillborn lambs, associated with a macroscopic placentitis.

CLINICAL PATHOLOGY

Semen examination, including culture of the ejaculate, and serological tests are used in suspect individuals and in groups of rams. The complement fixation or other serological tests (agar gel immunodiffusion, ELISA) are by far the most important; many infected rams have palpably normal scrotal contents and microbiologically negative semen.

Semen examination

A combination of semen examination and palpation of the testicles for abnormality is stated to identify approximately 80% of infected rams.[12] In affected animals the findings are a general reduction in semen quality, a reduced total sperm output, poor motility, and a high proportion of spermatozoa with secondary morphological abnormalities.

Culture

B. ovis is fastidious in its growth and requires special cultural techniques. The examination of the semen for the presence of leukocytes has been used to determine those sheep that should be cultured for *B. ovis* but this criterion is not highly sensitive.[13,14] PCR for detection of *B. ovis* in semen has equivalent sensitivity to culture.[15]

Serology

The complement fixation test is the standard test in many countries, is the prescribed test for international trade and, when used in conjunction with genital palpation and semen culture, has allowed the eradication of *B. ovis* from flocks. However, a small proportion of infected rams are negative to the complement fixation test, which can compromise eradication programs. A number of tests, including ELISA tests,[16–18] immunoblotting,[19] and gel diffusion tests,[18] are also used.

The sensitivity and specificity of the various serological tests depend mainly on the antigens used and the serological cutpoints,[3,18,20] which may vary between countries and laboratories. One study[20] reported the sensitivity of the ELISA, gel diffusion, and complement fixation tests as 97.6%, 96.4%, and 92.7% respectively, with all tests 100% specific. Studies in other countries support this ranking[3,7,21,22] and the ELISA is becoming more commonly used. Other studies suggest that the ELISA has no advantage in specificity over the classic complement and gel diffusion tests.[18] A combination of serological tests may improve sensitivity to 100%.[20,21,23]

Serological tests will not differentiate vaccinated from infected sheep or sheep infected with *B. melitensis*.

In Australia, there has been an unexpectedly high prevalence of false-positive reactors in some flocks because rams exposed to infection have developed a positive reaction to a serological test but have not developed the disease. These transient infections have not been found to be a problem in other regions.[20,21]

NECROPSY FINDINGS

In the acute stage, there is inflammatory edema in the loose scrotal fascia, exudate in the tunica vaginalis and early granulation tissue formation. In the chronic stage, the tunics of the testes become thickened and fibrous and develop adhesions. There are circumscribed indurations in the epididymis and these **granulomata** may also be present in the testicle. In advanced stages they undergo **caseation necrosis**. As the epididymis enlarges the testicle becomes atrophied. *B. ovis* can usually be isolated from the genital organs, especially the tail of the epididymis, and rarely from internal organs and lymph nodes.[24]

The abortus is characterized by thickening and edema, sometimes restricted to only a part of the placenta, with firm, elevated yellow-white plaques in the intercotyledonary areas and varying degrees of cotyledonary necrosis. Microscopically, organisms are visible within the cytoplasm of trophoblasts of the inflamed placenta. A vasculitis is often present. The organism can be isolated from the placenta and the stomach and lungs of the lamb.

Samples for confirmation of diagnosis

- Bacteriology – epididymal granuloma, seminal vesicle, inguinal lymph node/fetal lung, stomach content, placenta (CULT – has special growth requirements, CYTO – Stamp's or Kosters' stain on placental smear)
- Histology – formalin-fixed epididymis, testicle, inguinal lymph node/placenta, fetal lung, liver, spleen, kidney, heart, brain.

DIFFERENTIAL DIAGNOSIS

Many rams with abnormalities of intrascrotal tissues do not have brucellosis.[5] Most are cases of epididymitis and need to be differentiated.

Abortion in ewes may be associated with a number of infectious diseases, summarized in Table 18.8.

TREATMENT

Treatment of naturally occurring cases is rarely undertaken.

In experimentally infected rams, the intramuscular administration of long-acting oxytetracycline at 20 mg/kg BW, given every 3 days for 24 days, along with the daily intramuscular administration of 20 mg/kg of dihydrostreptomycin sulfate, has resulted in bacteriological cure in 11 of 12 rams.[25] Oxytetracycline alone is less effective. In another study using a similar treatment, seven of nine rams had bacteriological cure.[13] Treatment is economically practicable only in valuable rams and must be instituted before irreparable damage to the epididymis has occurred. The treatment of rams that are infected but without palpable lesions results in a significant improvement in breeding soundness classification on examinations subsequent to treatment.[13]

CONTROL

Control is by the prevention of spread of infection between rams and the detection and culling of infected rams. In small commercial flocks, **culling** of all rams and replacement with *B. ovis*-free rams may be the most economical approach. A measure of control can be achieved using **scrotal palpation** to detect infected rams but this must be coupled with **repeated serological examinations** if eradication is the goal. Vaccination may be the most economical and practical means of controlling the disease in areas with a high incidence of infection and in regions of the world where eradication by test and slaughter is impractical.[14]

Eradication

In a herd where the diagnosis has been confirmed all rams are palpated and those with scrotal abnormalities are culled. The remainder are tested serologically and reactors are culled. Serological tests are repeated at monthly intervals, with

Table 13.3 Diagnostic summary of infectious abortion in ewes

		Epidemiology			Laboratory findings	
Disease	**Transmission**	**Time of abortion**	**Clinical data**	**Fetus**	**Serology**	**Vaccination**
Brucellosis (*Brucella ovis*)	Passive venereal, ram to ram	Late or stillbirth, weak lambs	Epididymitis in rams. In ewes abortion only	Organisms in fetal stomach and placenta	Complement fixation test (CFT) or ELISA	Simultaneous strain 19 *Brucella abortus* and killed *B. ovis* adjuvant vaccine. Rev. 1 vaccine
Campylobacter fetus or *jejuni*	Ingestion	Last 6 weeks of pregnancy, stillbirths, weak lambs	Metritis in ewes after abortion	*Campylobacter* in stomach, large necrotic foci in liver	Agglutination test, flock only	Adjuvant vaccine doubtful efficacy
Enzootic abortion of ewes (*Chlamydophila abortus*)	Ingestion	Last 2–3 weeks. Stillbirths, weak lambs	No sickness in ewes, neonatal mortality	*Chlamydophila* in fetal cotyledons. Degenerative changes in placenta	ELISA, complement fixation, PCR	Killed vaccine gives moderate immunity. Live attenuated vaccine
Listeriosis (*Listeria monocytogenes*)	Probably ingestion	After 3 months	Retained placenta and metritis. Septicemia in some ewes	Organisms in fetal stomach. Autolysis, necrotic foci in liver	Agglutination and complement fixation of doubtful value	Killed vaccine, live attenuated vaccine in some countries
Salmonellosis (*Salmonella abortusovis*)	Probably ingestion. Carrier sheep	Last 6 weeks	Metritis after abortion	Organisms in fetal stomach. Not in USA	Agglutination test	Doubtful efficacy
Salmonellosis (*Salmonella dublin, S. montevideo, S. typhimurium*)	Ingestion	Last month	Abortion: fetal metritis, neonatal mortality	Organisms in stomach	Agglutination test	–
Toxoplasmosis	Ingestion	Late or stillbirths. Liveborn weak lambs	Abortion, stillbirths and neonatal mortality. No illness in ewe	Multiple small necrotic foci in fetal cotyledons. Toxoplasma in cells of trophoblast epithelium	Modified agglutination test, ELISA of limited value in adult. Test pleural fluid of fetus. PCR	S48 tachyzoite in some countries
Rift Valley fever	Insects	–	Important cause of abortion in all species Central Africa. Heavy mortality in young animals	Acidophilic inclusions hepatic cells	Hemagglutination inhibition and ELISA. Fluorescent antibody for tissues	Available
Coxiella available	Inhalation, ingestion	Later term and weak lambs	No illness in ewe, neonatal mortality	Fetus fresh, Intercotyledonary necrotizing placentitis	Fluorescent antibody and PCR. Serology of limited value	Vaccine not available in most countries
Tick borne fever	Ticks	Late, following systemic disease	Fever and abortion	None specific	Giemsa smear of blood, PCR. Counterimmuno-electrophoresis	None
Border disease	Ingestion	All stages, stillbirth	Infertility in ewes, Hairy shaker lambs	Virus isolation	See text description	None that are specific for sheep strains

culling of reactors, until all rams are serologically negative. A further test, 6 months later, is used for confirmation.[23]

The **rate of spread** of infection is high during the mating season and it is not recommended that eradication should be attempted until after the breeding season. During breeding it may be wise to run two breeding flocks, with virgin rams and rams known to be free of infection separate from older or suspicious rams. Strict separation of the two ram flocks must be maintained at all times of the year, and the clean group must not mate ewe flocks that have been mated to these older rams.

The use of the ELISA test available in the USA has allowed the eradication of the disease in flocks with as few as four tests.[12]

Several countries have voluntary accreditation schemes.

Vaccination

A number of vaccines are in use but none is fully effective. In some countries vaccination is not permitted and eradication by test and slaughter is the only method of control.

Killed *B. ovis* vaccines, even when adjuvanted, have poor efficacy.[7,15] The use of a killed vaccine may be inadvisable in flocks where eradication is being attempted, as it may protect against clinical disease but allow a carrier state in some rams in which there is excretion of the organism in animals that become seronegative.[15] An experimental vaccine prepared from enriched outer membrane proteins and rough lipopolysaccharide of *B. ovis* has given equivalent protection in challenge studies to that given by *B. melitensis* Rev. 1 vaccine.[26]

A combined vaccine containing killed *B. ovis* in an adjuvant base and *B. abortus* strain 19 gives a high-level, durable immunity but the vaccine has several disadvantages. Vaccinated animals become

seropositive, which hinders subsequent use of serological tests for eradication. Strain 19 itself can cause epididymitis and vaccinated rams may excrete strain 19 in their semen.[3] Severe outbreaks of osteomyelitis and epiphysitis have been recorded in rams following vaccination.[27]

Live *B. melitensis* strain Rev. 1 has been found to be **most effective** and is generally recommended.[3,28,29] Strain Rev. 1 is avirulent for rams, and subcutaneous or conjunctival vaccination provides protection against experimental and field challenge. Vaccinated animals become positive to the complement fixation test and ELISA test, but the titers produced are low and can be minimized by using the conjunctival route for vaccination.[29,30]

***B. suis* strain 2 (S2)** has been used in China for vaccination of all target species against brucellosis. It is given orally in the drinking water and colonizes the cranial lymph nodes. In a comparative study of S2 vaccine and Rev. 1 vaccine, S2-vaccinated rams had less protection than Rev. 1-vaccinated rams when challenged with *B. ovis* and an equivalent degree of protection to the nonvaccinated controls.[31]

***B. abortus* RB51 vaccine** does not protect rams against experimental challenge with *B. ovis*.[32]

Outer membrane protein (Omp) antigens are currently being examined as vaccine candidates. A detergent-extracted Omp31 from *B. melitensis* produced in *E. coli* has been shown to be a protective immunogen against *B. ovis* in a mouse model and to induce antibody and a cellular immune response in sheep.[33] Its efficacy in protecting sheep against experimental or natural infection is not reported.

In all vaccination programs there should be a concurrent program of culling of clinically abnormal rams. All ram replacements should be yearlings vaccinated at 4–5 months.

BRUCELLOSIS ASSOCIATED WITH *BRUCELLA SUIS* IN PIG

Etiology Disease in pigs is caused by *Brucella suis* biovars 1, 2, and 3. Biovars 1–4 cause rare disease in cattle
Epidemiology Disease in pigs is transmitted by contact, ingestion, and venereally
Clinical findings Sows: infertility, irregular estrus, small litters, and abortion. Boars: orchitis, lameness, incoordination, and posterior paralysis. Piglets: mortality
Clinical pathology Isolation of organism. Several serological tests available but none with good sensitivity
Necropsy Metritis, orchitis, osteomyelitis. Granulomatous inflammation and foci of caseous necrosis
Diagnostic confirmation Isolation of *Br. suis* and herd serology tests
Treatment None satisfactory
Control Serological testing and disposal of reactors. No effective vaccine. Humans, and occasionally cattle. Transmission congenital or by ingestion or contact with infected placenta, vaginal discharge, or milk
Clinical findings Abortion storms, abortions often in last 2 months of pregnancy. Weak-born lambs
Clinical pathology Culture of organism. Serological tests and skin hypersensitivity testing for herd diagnosis
Necropsy findings Placentitis
Diagnostic confirmation Only by isolation of the organism
Control Slaughter eradication. Vaccination with Rev. 1 vaccine. Rev. 1 vaccine will produce abortion in pregnant animals

ETIOLOGY

The disease is associated with *Brucella suis*. There are **five biovars**, of which biovars 1, 2, and 3 are important in pigs. Biovar 4 is a cause of rangiferine brucellosis and biovar 5 of murine brucellosis. Biovar 4 can transmit to cattle but does not appear to be a disease of pigs.

Biovar 3 has close similarity to *B. melitensis* biovar 2 and requires phage typing, oxidative metabolic testing or PCR for differentiation.[1]

EPIDEMIOLOGY

Geographic occurrence

Biovars 1 and 3

Disease associated with biovars 1 and 3 occurs in many countries and continents, including Europe, South America, particularly Venezuela,[2] Africa, the Indian subcontinent, Central Asia, south-east Asia, Australia, and the Pacific islands. The infection has not been recorded in Britain, Canada is free of biovars 1 and 3, and prevalence in the USA is very low.[3]

Biovar 2

Domestic livestock disease associated with biovar 2 is confined to Europe and is of particular interest in the wild boar and domestic livestock in Croatia.[4] It is also seen in the Czech Republic.[5]

Biovar 4

This occurs in mainland caribou (*Rangifer tarandus*) in Canada and has been isolated from a herd of commercial reindeer (*Rangifer tarandus tarandus*) in Canada.[6]

Host occurrence

Biotypes 1 and 3

Domestic, wild, or feral **pigs** are the host for biotypes 1 and 3 and widespread infection in **feral pigs** is recorded in Queensland, Australia[7,8] and the southern states of the USA.[3,9] Bison may remain reservoirs.

Cattle and horses may be infected, especially if they share a range with feral pigs[10] and this association adversely affects the status of cattle herds undergoing brucellosis eradication programs.[8] Cattle are **noncontagious hosts**, but an outbreak in Switzerland where the disease had not appeared since 1946 has been attributed to a spread of infection from horses.

Biovar 1 has been isolated from the semen of a ram.[11]

Infection in dogs, usually symptomless but occasionally producing orchitis or epididymitis, can result from eating raw pig meat.

Biovar 2

In addition to the pig, the European hare (*Lepus capensis*) is also a major host for biovar 2 and this biovar is common in central Europe.[12]

Biovar 4

This can transmit to cattle in contact with infected reindeer.[6] Wild canids can also be naturally infected with biovar 4, presumably by ingestion.[12]

Source of infection

The introduction of **infected pigs** or the communal use of an infected boar is the common means of introduction into a pig unit. Artificial insemination using non-certified or untreated semen can also spread the disease.

The feeding of kitchen waste containing **raw pig meat** also presents a risk. Domestic herds are also at risk when they are kept under extensive husbandry methods in areas where there is a high prevalence of infection in feral pigs. Cattle infected with biovar 1 are noncontagious to other livestock and can have normal pregnancies and give birth to uninfected calves.[10]

Wild animals, including hares and rats, may provide a source of infection with biovar 2 and ticks are also suspected of transmitting the disease.

Transmission

Within a piggery the disease is spread by **ingestion** and by **coitus**. The ingestion of food contaminated by infected semen and urine and discharges from infected sows are also important methods of spread. Dried secretions, if frozen, may remain infective. Most disinfectants and sunshine kill the virus.

Host and pathogen risk factors

The fact that it survives so well in raw meat, e.g. 128 days in sausage meat, means that prepared pork products are always a source of infection.

B. suis is more resistant to adverse environmental conditions than *B. abortus*, although its longevity outside the body has not been fully examined. It is known to survive in feces, urine, and water for 4–6 weeks.

Amongst pigs, susceptibility may vary with age. The prevalence of infection is much higher in adults than in young pigs, although this may represent an **exposure risk** rather than an age-related risk.[12] Susceptibility is much greater in the postweaning periods and is the same for both sexes, but there may also be genetically determined differences in susceptibility. Some piglets acquire infection from the sow, either from the ingestion of infected milk or by congenital infection.

Lateral spread through a herd is rapid because of the conditions under which pigs are kept. **No durable herd immunity** develops and, although a stage of herd resistance is apparent after an acute outbreak, the herd is again susceptible within a short time and a further outbreak may occur if infection is reintroduced.

In an enzootic area, the proportion of herds infected is usually high (30–60%). The prevalence of seropositivity in an infected herd varies but can be as high as 66%.[13] Seroprevalence in feral pigs is also high, is higher in adult pigs than pigs under 6 months of age, and varies between populations of feral pigs.[9]

Economic importance

The disease owes its economic importance to the infertility and reduction in numbers of pigs weaned per litter. Mortality in liveborn piglets, which occurs during the first month of life, may be as high as 80%. The mortality rate is negligible in mature animals but sows and boars may have to be culled because of sterility, and occasional pigs because of posterior paralysis. In addition, eradication involves much financial loss if complete disposal of a registered herd is undertaken.

Zoonotic implications

Biovar 2 is not a zoonosis but biovars 1 and 3 have considerable significance for public health and are very pathogenic to humans. In countries where pigs are a significant part of animal farming and the **human diet**, *B. suis* is the major cause of **human brucellosis**. A recent report describes the death of a retired pig farmer at least 20 years after her last exposure to livestock.[14]

B. suis presents an **occupational hazard**, particularly to abattoir workers, and to a lesser extent to farmers and veterinarians. *B. abortus* and *B. melitensis* may also be found in pig carcasses and present similar hazards. *B. suis* can be widespread in the carcass of infected pigs, and undercooked meat can be a source of human infection.[12] This is particularly true for wild boar and feral pigmeat. A recent experiment described infection with biovar type 1 and its transmission to negative pigs after 4–6 weeks. Antibody was detected in blood samples from farmers and abattoir workers.[15]

In infected cattle *B. suis* localizes in the mammary gland without causing clinical abnormality and, where cattle and pigs are run together, the hazard to humans drinking **unpasteurized milk** may be significant.[10] Biovar 4 causes human disease associated with consumption of caribou.[16]

PATHOGENESIS

As in brucellosis associated with *B. abortus*, there is initial systemic invasion, the organism appearing in the bloodstream, usually within 1–7 weeks and persisting for up to 34 weeks. However, infection with *B. suis* differs from that associated with *B. abortus* in that **localization** occurs in several organs in addition to the uterus and udder, the organism being found in all body tissues and producing a disease similar to undulant fever in humans. The organisms persist in lymph nodes, joints, bone marrow, and the genital tract. The more common manifestations of localization are abortion and infertility due to localization in the uterus; lymphadenitis, especially of the cervical lymph nodes; arthritis and lameness due to bone and joint localization; and posterior paralysis due to osteomyelitis. In boars, involvement of the testicles often leads to clinical orchitis.[12] Widespread infection makes handling of the freshly killed carcass hazardous and creates a risk for brucellosis in humans eating improperly cooked pork.

CLINICAL FINDINGS

Do not forget that clinical signs in pigs may also be produced by *B. abortus* and *B. melitensis*.

The clinical findings in swine brucellosis vary widely, depending upon the site of localization. The signs are not diagnostic and in many herds a high incidence of reactors is observed with little clinical evidence of disease. Reproductive inefficiency is the common manifestation.

Sows

Infertility, irregular estrus, small litters, and abortion occur. Mummification and stillbirths do occur. The incidence of abortion varies widely between herds but is usually low and is usually early on. Infection of the fetus may lead to abortion. As a rule, sows abort only once in a lifetime and this is most common during the third month of pregnancy. Affected sows usually breed normally thereafter. Sows may remain carriers and may shed organisms in milk and uterine discharges. These discharges may be extremely bloody. They may be accompanied by an endometritis and retained placenta.

Boars

Orchitis with swelling and necrosis of one or both testicles is followed by sterility. Lameness, incoordination, and posterior paralysis occur reasonably commonly. The onset is gradual, and signs may be caused by arthritis or, more commonly, osteomyelitis of lumbar and sacral vertebral bodies. Testicular atrophy may result. Boars have a low rate of recovery (less than 50%). After infection, enough animals remain infected to perpetuate the disease.

Piglets

A heavy mortality in piglets during the first month of life is sometimes encountered but most piglet loss results from stillbirths and the death of weak piglets within a few hours of birth. Up to 10% may contract infection when they are young and retain the infection until adulthood.

CLINICAL PATHOLOGY

Culture

Laboratory identification of the disease is difficult. Isolation of the organism should be attempted if suitable material is available. Such material for culture includes aborted fetuses, testicular lesions, abscesses, lymph nodes, and blood. The organism is a small, slender, aerobic, Gram-negative organism that produces 1–2 mm colonies on blood agar after 2–4 days.

Serology

There is **no satisfactory** serological test. Some animals remain seronegative to all tests. Recently two ELISAs have been developed.[17,18] An ELISA compared with complement fixation was found to be just as sensitive and as specific a test for both pigs and hares for *B. suis* infections.[19] A meat juice ELISA has also been shown to be a valuable method for testing both hares and wild boars.[20] There is considerable individual variation in the antibody response of pigs following infection – some may be culture-positive but have negative or indefinite titers to the common tests.[12] Pigs under 3 months of age have a poor antibody response to infection.[12]

Serological tests in common use include the rose Bengal plate agglutination test, Rivanol test, rose Bengal card test, complement fixation, agar gel immunodiffusion, and tube agglutination. The preferred test varies between countries but most use the rose Bengal plate or card test. *B. abortus* antigens are used for diagnosis as *B. suis* has the same surface lipopolysaccharide antigens. Estimates of the sensitivities of the complement fixation and tube agglutination tests range from 40–51%, and from 62–79% for the rose Bengal plate test.[12,21] The immunodiffusion test has poorer sensitivity than the standard serological tests.[2] The sensitivity and specificity of all the tests have been shown to vary with the stage of infection in the experimental disease and it has been recommended that more than one test should be used for diagnosis.[21,22] A recent study[23] showed a range of sensitivity from 84–100% with the CFT low at 84% and the serum agglutination test high at 100%. The sensitivities ranged from 79.7–100%, with the serum agglutination test low at 79.7% and indirect ELISA and competitive ELISA high at 100%. A recent validation of the polarization assay as a serological test for the presumptive diagnosis of porcine brucellosis has shown promise.[24,25]

NECROPSY FINDINGS

Many organs may be involved in chronic cases. Chronic **metritis** manifested by nodular, white, inflammatory thickening, 2–5 mm in diameter, and abscessation of the uterine wall is characteristic. Arthritis may be purulent and necrosis of vertebral bodies in the lumbar region may be found in lame and paralyzed pigs. The clinical **orchitis** of boars is revealed as testicular necrosis, often accompanied by lesions in the epididymis and seminal vesicles. Splenic enlargement and pronounced lymphadenopathy, due to hyperplasia of mononuclear phagocytes, occur in some cases. Typical histological changes consist of granulomatous inflammation and foci of caseous necrosis in liver, kidney, spleen, and reproductive tract.

Samples for confirmation of diagnosis

- Bacteriology – *adults:* culture swab from joint, lymph nodes, spleen, uterus, epididymis, or other site of localization; *fetus:* lung, stomach content, placenta (has special growth requirements)
- Histology – formalin-fixed samples of above tissues (LM).

Note the zoonotic potential of this organism when handling carcasses or submitting specimens.

DIFFERENTIAL DIAGNOSIS

The protean character of this disease makes it difficult to differentiate. Syndromes that need differentiation include:

- Abortion and infertility in sows (Table 20.2)
- Posterior paresis diseases of spinal cord
- Mortality in young pigs is also caused by many agents and the important entities are listed under disease of the newborn (Chapter 3).

TREATMENT

Treatment with a combination of streptomycin parenterally and sulfadiazine orally, or with tetracycline, is ineffective. It is unlikely that treatment will ever be attempted on a commercial scale.

CONTROL

Vaccination

No suitable vaccine is available. Strain 19 *B. abortus*, *B. abortus* 'M' vaccine, living attenuated *B. suis* vaccines and phenol and other extracts of *B. suis* are all **ineffective**.[12]

Test and disposal

In herds where the incidence of reactors is high, complete **disposal** of all stock as they reach marketing age is by far the best procedure because of the difficulty in detecting individual infected animals. This is most practicable in commercial pork-producing herds. **Restocking** the farm should be delayed for 6 months. The existing serological tests can be used for certifying herds free of infection that can then provide replacement stock. Repopulation programs can also use specific-pathogen-free pigs.

The alternative is to commence a **two-herd segregation program**, and this is recommended for purebred herds that supply pigs for breeding purposes. Total disposal is not usually economical in these herds. Once a herd diagnosis has been established, all the breeding animals must be considered to be infected; all piglets at weaning are submitted to the serum agglutination, Rivanol or other test and, if negative, go into new quarters to start the nucleus of a free herd. It is probably safer to wean the pigs as young as possible and test again before mating. If complete protection is desired, these gilts should be allowed to farrow only in isolation, should then be retested, and their piglets used to start the clean herd. A modified scheme based on the above method of weaning and isolating the young pigs as soon as possible but without submitting them to the serum agglutination test has been proposed, but its weakness is that infections may occur and persist in young pigs.

After eradication is completed, **breakdowns** are most likely to occur when infected animals are introduced. All **introductions** should be from accredited free herds, should be clinically healthy and be negative to the serum agglutination test twice at intervals of 3 weeks before introduction.

Eradication of swine brucellosis from an area can only be achieved by developing a nucleus of accredited free herds and using these as a source of replacements for herds that eradicate by total disposal. Sale of pigs for breeding purposes from infected herds must be prevented.

BRUCELLOSIS ASSOCIATED WITH *BRUCELLA MELITENSIS*

Etiology *Brucella melitensis*
Epidemiology Disease of goats, sheep, humans, and occasionally cattle. Transmission congenital or by ingestion or contact with infected placenta, vaginal discharge, or milk
Clinical findings Abortion storms, abortions often in last 2 months of pregnancy. Weak-born lambs. Important zoonotic disease in humans
Clinical pathology Culture of organism. Serological tests and skin hypersensitivity testing for herd diagnosis
Necropsy findings Placentitis
Diagnostic confirmation Only by isolation of the organism
Control Slaughter eradication. Vaccination with Rev. 1 vaccine. Rev. 1 vaccine will produce abortion in pregnant animals

ETIOLOGY

Brucella melitensis causes brucellosis in goats and sheep and is capable of infecting most species of domestic animal. There are three biovars of the organism that have differing geographical distribution but no difference in pathogenicity or animal species affected. There is a close relationship to other members of the genus.[1]

EPIDEMIOLOGY

Geographical occurrence

The distribution of *B. melitensis* is more restricted than that of *B. abortus* and its primary area of occurrence is in the **Mediterranean** region, including southern Europe. Infection is also present in west and central Asia, Mexico and countries in Central and South America, and in Africa. Northern Europe is free of infection, except for periodic incursions from the south, as are Canada, the USA, south-east Asia, Australia, and New Zealand.

Host occurrence

Goats and sheep are highly susceptible. Susceptibility in sheep varies with the breed, with Maltese sheep showing considerable resistance. The organism is capable of causing disease in cattle and has been isolated from pigs. The prevalence of infection varies between countries and regions but in many countries prevalence has declined in the past decade in association with mandatory vaccination policies.[2]

Source of infection

The source of infection is the **infected carrier animal**. Introduction to a naive herd or flock occurs with the introduction of an infected animal and persistence results from sheep or goats that are prolonged excreters. Excretion is from the reproductive tract and in milk.

Reproductive tract

Infected does and ewes, whether they abort or birth normally, discharge large numbers of brucellas in their uterine exudates and **placenta**. The organism can be present in uterine discharge for at least 2 months following parturition in infected goats.[3] The vaginal exudate of infected virgin or open animals may also contain the bacteria but transmission between animals is most likely from the massive exposure that only an infected placenta can provide.

Milk

The majority of goats infected during pregnancy will excrete the organism in milk in the subsequent lactation and many will excrete it in all future lactations.[3] In sheep the period of excretion of the organism from the uterus and in milk is usually less than in goats but the organism can be present in milk throughout lactation.[4] The duration of excretion in cattle is not known.

Transmission

Routes of infection for both adults and young are via ingestion, by nasal or conjunctival infection, and through skin abrasions, with infected placenta and uterine discharge as a major source.

In utero infection

Infection of the fetus during pregnancy does not necessarily result in abortion: infected kids and lambs may be born alive but weak or they may be quite viable. In some cases the infection persists in a **latent** form until sexual maturity, when pregnant animals may abort the first pregnancy.[4] However, others, if weaned early from their dams and from the infected environment, become free from the infection as adults.[3]

Colostrum and milk

Latent infection can also be acquired from the ingestion of infected colostrum and milk; this is a major route of transmission and perpetuation of infection in a herd or flock.[4]

Host and pathogen risk factors

The organism is reasonably **resistant** to environmental influences and under suitable conditions can survive for over 1 year in the environment. *B. melitensis* is susceptible to disinfectants in common use at recommended concentrations.

In goats and sheep the infection of a naive herd or flock will produce an abortion storm, following which most animals are infected but immune; further abortions are usually limited to introduced or young animals. Because of the limited periods of excretion in sheep the disease tends to be **self-limiting** in **small flocks** that have few new introductions. It can be a **continuing problem in large flocks** because of massive environmental contamination of areas used for pregnant and lambing ewes.[3] In some areas the prevalence of brucellosis associated with *B. melitensis* is linked to the practice of animal movement to summer and mountain pastures where there is commingling of sheep and goats from a variety of sources on the same pasture.[5]

Spread in beef cattle is slow, presumedly because they do not abort. Spread in dairy herds can be more extensive,[6] possibly via milking procedures.

Economic importance

Brucellosis has major veterinary and human importance in affected countries. Costs include production loss associated with infection in animals, the considerable cost of preventive programs, and human disease.[2] There is further loss from restriction in international trade in animals and their products.

The occurrence of *B. melitensis* in the sheep and goat population of countries that have eradicated *B. abortus* poses a threat for the continuing problem of brucellosis in cattle herds.

Zoonotic implications

B. melitensis is the **most invasive and pathogenic** for humans of the three classical species of the genus, and is the cause of **'Malta'** or **'Mediterranean' fever** in humans, an extremely debilitating disease. It is an important zoonosis in areas of the world where *B. melitensis* is enzootic in goats and sheep. The disease in humans is **severe** and **long-lasting** and often occurs in communities with limited access to antimicrobial therapy.

Control and eradication of the infection in animal populations has high priority in all countries.

Large numbers of organisms are excreted at and following parturition, providing a source of infection for humans managing the herd or flock and also for people in the immediate vicinity from **aerosol infection** with contaminated dust. The risk of infection is high in cultures that cohabit with their animals or when weak, infected newborn animals are brought into the house for warmth and intensive care. Milking of sheep and goats is usually manual, often with poor sanitation and milking-time hygiene. **Raw milk and cheese products** from infected goats, sheep, or cattle also provide a risk and were the mechanism for the occurrence of Malta fever that initiated the definition of the disease.

Abattoir workers, shearers, and people preparing goat and sheep skins are also at risk. The risk for **veterinarians** is primarily with dystocial problems in infected animals and herds but is also present in the examination of any animal that is subclinically infected. There is also the risk of accidental self-inoculation during vaccination against the disease.

Vaccination of small ruminants with *B. melitensis* Rev. 1 vaccine is a primary method in controlling the human disease. In Greece a 15-year period of vaccination was associated with a drop in the incidence of human brucellosis but when this program was stopped the prevalence of abortions in animals and the incidence if brucellosis in humans increased dramatically, only to be controlled by the reinstitution of vaccination of animals as an emergency mass vaccination program.[7] However, while the Rev. 1 vaccine is attenuated when compared with field strains, it retains some virulence and incorrect selection from the seed stock can result in vaccines with considerable virulence for both vaccinated animals and in-contact humans.

In view if its pathogenicity to humans and animals, *B. melitensis* requires major consideration as an **agent of bioterrorism** and agroterrorism. It is believed that fewer than 10 cfu are capable of infecting humans and infection can occur from aerosol infection. This would require mass therapy of human populations and destruction of animal populations, with associated problems.[8]

PATHOGENESIS

The organism is a facultative intracellular parasite. As in other forms of brucellosis, the pathogenesis depends upon localization in lymph nodes, udder, and uterus after an initial bacteremia. In goats, this bacteremia may be sufficiently severe to produce a systemic reaction, and blood culture may remain positive for a month. Localization in the placenta leads to the development of placentitis, with subsequent abortion. After abortion, **uterine infection** persists for up to 5 months and the **mammary gland** and associated lymph nodes may remain infected for years.[3,4] Spontaneous recovery may occur, particularly in goats that become infected while not pregnant. In sheep the development of the disease is very similar to that in goats. In cattle, *B. melitensis* has a similar pathogenesis and produces a persistent infection in the mammary gland and the supramammary lymph node, with obvious significance for public health.[6]

CLINICAL FINDINGS

Abortion during late pregnancy is the most obvious sign in **goats and sheep**, but as in other species there may be a 'storm' of abortions when the disease is introduced, followed by a period of flock resistance during which abortions do not occur. Abortion is most common in the last 2 months of pregnancy. The excretion of the organism in milk is not accompanied by obvious signs of mastitis. Infection in males may be followed by orchitis, which is frequently unilateral.

In experimental infections, a systemic reaction occurs, with fever, depression, loss of weight, and sometimes diarrhea. These signs may also occur in acute, natural outbreaks in goats and may be accompanied by mastitis, lameness, and hygroma; however, they are uncommon in the natural disease and their occurrence in the experimental disease reflects a massive challenge dose.[3] Osteoarthritis, synovitis, and nervous signs may occur in sheep.

In pigs the disease is indistinguishable clinically from brucellosis associated with *B. suis*.

In many instances, *B. melitensis* infection reaches a high incidence in a group of animals without signs of obvious illness and its presence may be first indicated by the occurrence of disease in humans infected from the herd or flock. This is so in **cattle** where the infection is subclinical and does not produce abortion, but the organism is shed in milk.

CLINICAL PATHOLOGY

Culture

Positive blood culture soon after the infection occurs, or isolation of the organism from the aborted fetus, vaginal mucus, or milk, are the common laboratory procedures used in diagnosis. The organism is moderately acid-fast and staining smears from the placenta and fetus with a modified Ziehl–Neelsen method may give a tentative diagnosis; however this does not distinguish this infection from *B. ovis* or the agent of enzootic abortion, and culture is required.

The organism can be detected by PCR in the abomasal fluid of aborted fetuses and, compared with culture, PCR has a sensitivity and specificity of 97.4% and 100%, respectively.[9] PCR can also be used to detect the organism in semen.[10]

Serology

The **conventional serological tests** for the diagnosis of *B. melitensis* – agglutination, CFT, and the rose Bengal or card test – use the same antigens as are used for the diagnosis of *B. abortus* infections.

The rose Bengal test and CFT are the prescribed tests for international trade. In most laboratories these tests, in **unvaccinated** animals, are 100% specific and have high sensitivity. However the sensitivity is not sufficiently high to allow completely accurate detection of infection in an individual animal.[11,12] They can be used for the detection of infected herds for slaughter eradication of the disease but have significant limitations when used for selective culling of positive animals within an infected herd.

Conventional serological tests will **not differentiate** infection with different species of *Brucella* nor will they differentiate infection associated with *Y. enterocolitica* type O:9. **Other tests** that have been developed include ELISA tests, radial immunodiffusion, and counterimmunoelectrophoresis; the sensitivity and specificity of these appears to vary between laboratories.[12–15] An ELISA test using purified antigen is described as being able to differentiate the seropositivity of *B. melitensis* from that of *B. ovis*.[16]

The rose Bengal test has excellent specificity and high sensitivity,[11,15] is easy to perform, and is suitable for **herd and flock testing**.[3]

For the testing of infection status of **individual animals**, the rose Bengal test and the CFT have the highest sensitivity in most studies. A combination of tests and tests carried out on several occasions may increase the accuracy of detection of infected animals.[17] If only one test is possible, the CFT is recommended but it suffers from the requirement for a sophisticated laboratory, which is not always available in affected areas.[3]

Brucella-free animals are serologically positive for long periods following **vaccination**, with a difference in persistence with different serological tests. The period of seropositivity is shorter in animals vaccinated conjunctivally.[12,13,15]

Milk tests

Tests are also conducted on milk. They include the milk ring test, the whey CFTs, whey Coombs or antiglobulin test, whey agglutination tests, and an ELISA.[3,18] They

have no apparent advantage over serological tests and in many cases are less sensitive and are unsuitable as screening tests using flock or herd pooled milk samples. An ELISA test using crude polysaccharide from *B. melitensis* biovar 1 as antigen has a better sensitivity and may be of greater value as a screening test, although there are limited field data.[19]

Allergic tests

An intradermal allergic test using 50 mg of brucellin INRA can be used for diagnosis. The injection sites in goats are the neck or caudal fold and in sheep the lower eyelid. Reactions are read in 48 hours. The test has high specificity in flocks that are free of infection and are not vaccinated. However, it has little advantage over conventional serological tests in infected herds and Rev.-1-vaccinated animals can react for years.[3,15,20] It has particular value in identifying animals that are false-positive reactors due to antibody to cross-reacting bacterial antigens. It can differentiate infections with *Y. enterocolitica*, but cannot differentiate *B. ovis* infections in sheep. **Anergy** occurs between 6 and 24 days after injection.[15] Vaccinated sheep retain an allergic state for at least 2 years.[3]

NECROPSY FINDINGS

There are no lesions that are characteristic of this form of brucellosis. The causative organism can often be isolated from all tissues but the spleen, lymph nodes, and udder are the most common sites for attempted isolation in chronic infection.

Samples for confirmation of diagnosis

- Bacteriology – **adults**: spleen, lymph node, udder, testicle, epididymis; **fetus**: lung, spleen, placenta (CULT – has special growth requirements, CYTO – Stamp's or Kosters' stain on placental smear); **fetus**: PCR detection in fetal abomasal fluid
- Histology – formalin-fixed samples of above tissues.

Note the zoonotic potential of this organism when handling carcasses or submitting specimens.

DIFFERENTIAL DIAGNOSIS

The primary differential is from other forms of brucellosis (this chapter) and other causes of abortion in small ruminants

TREATMENT

Treatment is unlikely to be undertaken in animals and is also unlikely to be economically or therapeutically effective. A cure rate of 65% and 100%, respectively, is reported following the daily intraperitoneal administration of 500 mg and 1000 mg of tetracycline to naturally infected goats for a period of 6 weeks.[21] A dose of 1000 mg of long-acting tetracycline given every 3 days for a period of 6 weeks achieved a cure rate of 75%.

CONTROL

Hygiene

Control measures must include hygiene at kidding or lambing and the disposal of infected or reactor animals. Separate pens for kidding does that can be cleaned and disinfected, early weaning of kids from their does and their environment, and vaccination are recommended. In endemic areas all placentas and dead fetuses should be buried as a routine practice.

Eradication

Where a group is infected for the first time it may be most economic to dispose of the entire herd or flock. **Test and slaughter** procedures are prolonged because of the inaccuracy of the tests.

Many countries that have this disease have statutory control measures. The disease can be eradicated and Cyprus has recently achieved this.[22] *B. melitensis* also can be eradicated, with difficulty, from dairy cattle.[5] However, vaccination may be the only practical method of control in areas where there is a high prevalence of the disease, extensive management systems, communal grazing and a low socioeconomic level.[23,24]

Rev. 1 vaccination

The universally recommended vaccine is Elberg's Rev. 1, which is effective in both sheep and goats.[2,24,25] Rev. 1 vaccine is a live, attenuated *B. melitensis* strain derived from a virulent *B. melitensis* isolate. It stimulates protection against infection with *B. melitensis* in sheep and goats and also protects rams against infection with *B. ovis*. However, this is at the expense of a persistent serological response. Further, although this vaccine is attenuated when compared with field strains it retains some virulence and incorrect selection from the seed stock can result in vaccines with considerable virulence for both vaccinated animals and in-contact humans.[26,27]

Vaccination with Rev. 1 produces a bacteremia that is cleared by 14 weeks in goats and a shorter time in sheep. Vaccination of animals 3–8 months of age confers a high degree of immunity that lasts for more than 4 years in goats.[4,28] and 2.5 years in sheep.[25] The initial recommendations for use were vaccination of replacement animals with the expectation that herd/flock immunity would develop over the years; however, this has proved ineffective in some regions and whole-flock/herd vaccination is now recommended in certain countries.[23]

Vaccination of pregnant goats and sheep, especially in the second and third month of pregnancy, will result in **abortion** and the excretion of the living *B. melitensis* vaccine organism in the vaginal discharge and the milk. The vaccine should not be used in pregnant animals or for 1 month prior to breeding. Vaccination of lactating animals may be followed by a temporary period of excretion of the organism in the milk.[3,18] Neither **reduced dose vaccination** nor **conjunctival vaccination** significantly reduces the risk of vaccine-induced abortions in pregnant animals,[23] although reduced-dose Rev. 1 vaccination has been shown to provide protection for at least 5 years in endemically infected areas.[29]

Conjunctival vaccination does decrease the period of seropositivity following vaccination.[17,19] Vaccine efficacy and safety can vary with the manufacturer.[17,19] National policies promoting widespread vaccination of sheep and goats with Rev. 1 vaccine have resulted in a significant reduction in the prevalence of small ruminant brucellosis and in the incidence rates of human brucellosis.[7,25,30] However, Rev. 1 vaccine is also pathogenic to humans and its excretion and persistence in milk following vaccination can result in human infection.[27]

The general approach in endemically infected countries is to institute a whole-flock vaccination scheme followed by a young-stock vaccination scheme until the prevalence of the disease is reduced, at which time test and slaughter can be implemented to eradicate the disease. This ignores the risk of adverse disease in the vaccinated animals and the risk for human infection from the vaccine strain. There is an urgent need for a non-virulent vaccine that induces seropositivity that can be differentiated from the seropositivity resulting from natural infection.[27]

Other vaccines

To circumvent the problem of persistent serological response, attempts are being made to develop defined rough mutant vaccine strains that would be more effective against *B. melitensis*. Various studies have examined cell-free native and recombinant proteins as candidate protective antigens, with or without adjuvants. Limited success has been obtained with these, or with DNA vaccines encoding known protective antigens, in experimental models.[26,27]

A formalin-killed adjuvant vaccine, called **53H38 vaccine**, has been used but it confers less immunity than Rev. 1 and

causes local reactions and a prolonged allergic and serological response.[23] The rough mutant vaccine, **RB51**, is not of value in sheep or goats.[31]

***B. abortus* strain 19** has been used for vaccination and appears to give protection that is as good as that achieved with the attenuated *B. melitensis* vaccine.

A ***B. suis* strain 2** vaccine has been used in China for some years. It can be administered in the drinking water and is used in areas where the terrain does not allow the regular handling of animals. In a comparative study of S2 vaccine and Rev. 1 vaccine, S2-vaccinated pregnant ewes had less protection than Rev.-1-vaccinated ewes when challenged with *B. melitensis*, and an equivalent degree of protection to the nonvaccinated controls.[20]

Initial studies on the pathogenicity and immunogenicity of **gene-deleted mutant *B. melitensis* Rev. 1** live vaccines in mice suggest that they might be an effective alternate to the standard vaccines used in small ruminants. Serological testing would allow the differentiation of infection. The use of these vaccines would allow the serological differentiation of seropositive vaccinated sheep from infected sheep; however, these vaccines have not yet been tested in small ruminants.[32]

Diseases associated with *Moraxella*, *Histophilus*, and *Haemophilus* species

INFECTIOUS KÉRATITIS OF CATTLE (PINKEYE, BLIGHT)

Synopsis

Etiology *Moraxella bovis* is the primary infectious agent. Pili and hemolysin are the main virulence factors. Solar radiation, flies, and dust are contributing factors
Epidemiology Cattle of all ages are susceptible. Source is carrier cattle, with transmission by mediate contagion and by flies. More common in summer months. Usually multiple cases in a herd
Clinical findings Conjunctivitis, lacrimation, blepharospasm, photophobia, central corneal opacity
Diagnostic confirmation Culture
Treatment Self-limiting disease. Topical antibiotics, subconjunctival penicillin, parenteral oxytetracyclines. Protection of eye from sunlight
Control Current vaccines have limited efficacy. Fly control

ETIOLOGY

Hemolytic *Moraxella bovis* is the primary infectious agent concerned, although other organisms can exacerbate the severity of the disease.[1] Experimental infections in calves and studies on corneal tissue culture show a great variation in virulence between strains.[2] Beta-hemolysin, pili, leukotoxin, and proteases are **virulence factors**.[3] *M. bovis* has serologically distinct shared and variable pilus epitopes, and strains can be distinguished by their pilus antigens into seven distinct **serogroups**.[4,5] There are two distinct types of **pilus**, I and Q (formerly α and β). **Q pili mediate bacterial adhesion** to the cornea and the establishment of infection[6] by preventing removal of the organism by the continual flushing effect of ocular secretions and the mechanical action of blinking. Beta-hemolysin is **cytotoxic** and produces corneal damage.[7] In some outbreaks of pinkeye more than one serotype can be isolated from affected eyes.[5]

Whereas *M. bovis* initiates the disease, **other agents** can be responsible for some of the severe keratitis that occurs. *Rickettsia*, *Chlamydia*, *Neisseria*, *Mycoplasma*, and *Acholeplasma* spp. and viruses have been identified as common participants.[1] Infectious bovine rhinotracheitis virus causes ocular disease in its own right but it may also be involved with *M. bovis* in causing the more severe disease. Clinical disease in experimentally induced infectious bovine keratoconjunctivitis has been shown to be more severe when the calves are concurrently given a modified live infectious bovine rhinotracheitis virus vaccine.[8]

Conjunctival infection with *Mycoplasma bovoculi* has been found to enhance the colonization of *M. bovis*[9] and it is possible that other organisms can act in a similar way. *Branhamella ovis* causes a severe conjunctivitis in sheep and goats and is also recorded from outbreaks of keratoconjunctivitis in cattle in Israel;[10,11] it may be a cause of vaccine breakdown in other countries.

Because the naturally occurring disease is usually much more severe than that produced experimentally, factors other than infectious agents have been examined. **Solar radiation**, **flies**, and **dust** have been shown to have an enhancing effect.[1] Cultural characteristics of the organisms isolated from the conjunctiva can change with the level of solar ultraviolet radiation.[12]

EPIDEMIOLOGY

Occurrence

The disease occurs in most countries of the world and, although it can occur in all seasons, is most common in **summer and autumn**. The prevalence and severity of the disease vary greatly from year to year, and it may reach epizootic proportions in feedlots and in cattle running at pasture. Only cattle are affected, the young being most susceptible, but in a susceptible population, cattle of all ages are likely to be affected. There is no mortality, and cases in which there is permanent blindness or loss of an eye are rare. However, the morbidity rate can be as high as 80%, with the peak infection rate at weeks 3–4 of the outbreak. Severe outbreaks can be experienced in **winter**, especially if the cattle are confined in close quarters such as barns or intensive feedlots.

Source of infection

Cattle are the reservoir and the organism is carried on the conjunctiva and also in the nares and vagina of cattle. Persistence of the disease from year to year is by means of **infected animals**, which can act as carriers for periods exceeding 1 year.[13] Receptors for **I-pili** may be found on tissues other than the cornea and facilitate colonization of noncorneal tissue and inapparent infection,[6] and the organism can switch from expression of one pilus type to the other.[5]

Transmission

The disease is most common in summer and autumn and reaches epizootic proportions when **flies and dust** are abundant and **grass** is long; transmission is thought to be by means of these agents contaminated by the ocular and nasal discharges of infected cattle. Under experimental conditions, transmission is unusual in the absence of flies[14] and occurs generally in their presence.[15] The face fly (*Musca autumnalis*) and Asian face fly (*Musca bezzii*), because of feeding preference for the area around the eyes, are important vectors. *Musca autumnalis* is known to remain infected for periods of up to 3 days. *M. bovis* can be isolated from the crops of *Musca autumnalis* that have fed on the eyes of infected cattle.[16]

Animal risk factors

It is commonly observed that there is a much higher prevalence of the disease in *Bos taurus* cattle as distinct from *Bos indicus* cattle,[17] and the severity and proportion of bilateral infections is much greater in *B. taurus* cattle than in crossbreeds. Charolais and Chianina cows may be less susceptible than Hereford cattle.[18] In British-bred cattle there is also a relationship between rate and severity of infection and the degree of **eyelid pigmentation**, eyes with complete pigmentation being less affected. This effect of pigmentation on susceptibility may be the basis of an apparent inherited resistance of some families of Hereford cattle.[19] The exposure of the eye to **ultraviolet light** may increase susceptibility to the disease and the severity of signs resulting from it.

Immune mechanisms

Previous infection appears to confer a significant immunity that lasts through to the next season, when further reinfection, usually with minimal clinical disease, confers further immunity. Lacrimal secretions contain antibody, and antibody directed against the **pilus antigens** of *M. bovis* will prevent adherence of the organism to the cornea. In experimental infections, significant protection against challenge can be achieved by prior vaccination with pilus antigens of the homologous strain.[20–22]

However, there is antigenic diversity in pili from different strains of *M. bovis* and vaccines composed of pili from one strain only confer protection to challenge with organisms of the same serogroup.[20] Further, *M. bovis* in the eye can **switch** their pilus antigenicity in response to antibody presence and render monovalent vaccines ineffective.[22] A polyvalent vaccine might provide protection but polyvalent vaccines are less immunogenic than monovalent vaccines because of antigenic competition.[22]

Experimental production

Experimental reproduction is usually preceded by irradiation of the eye with ultraviolet light prior to inoculation. Under these conditions, inoculation with Q-piliated *M. bovis* produces a relatively high frequency of infection and keratoconjunctivitis, I-piliated organisms produce a lower frequency, and nonpiliated organisms do not produce infection.[6]

Economic importance

Infectious keratoconjunctivitis is a prominent disease in surveys of the predominant diseases in cattle.[23] Loss of milk production or body condition may be caused by the discomfort, failure to feed, and temporary blindness. The conditions under which calves are reared can affect the importance of the disease. In veal calves, the disease may have no measurable effect on growth[24] but in calves running at pasture it can result in a significant reduction of weaning weight. Occasionally, animals become completely blind and those at pasture may die of starvation.

There is also a welfare concern.

PATHOGENESIS

Attachment of *M. bovis* to the corneal epithelium is mediated by the presence of pilus antigens, and **Q-piliated** organisms are **more infectious** than I-piliated strains.[5,6]

Microscopic corneal erosions are present within 12 hours of infection and occur at this time in the absence of a significant inflammatory response, indicating that the initial production of the corneal ulceration is due to the direct cytotoxic activity of the organism.[3] This is followed by focal loss of corneal epithelium, degeneration of keratocytes, and invasion of the corneal stroma with fibrillar destruction. An inflammatory reaction occurs several days postinfection and results in enlargement of the corneal ulcers with deeper stromal involvement, corneal edema, and corneal neovascularization. The lesions are localized in the eye and there is no systemic infection.

CLINICAL FINDINGS

An incubation period of 2–3 days is usual, although longer intervals, up to 3 weeks, have been observed after experimental introduction of the bacteria. Injection of the corneal vessels and edema of the conjunctiva are the **early signs** and are accompanied by a copious watery lacrimation, blepharospasm, photophobia and, in some cases, a slight to moderate fever with fall in milk yield and depression of appetite.

In 1–2 days, a small **opacity** appears in the center of the cornea and this may become elevated and ulcerated during the next 2 days, although spontaneous recovery at this stage is quite common. With progressive disease the opacity becomes quite extensive and at the peak of the inflammation, about 6 days after signs first appear, it may cover the entire cornea. The color of the opacity varies from white to deep yellow. As the acute inflammation subsides, the ocular discharge becomes purulent and the opacity begins to shrink, complete recovery occurring after a total course of 3–5 weeks.

One or both eyes may be affected. The degree of ulceration in the early stages can be readily determined by the infusion of a 2% fluorescein solution into the conjunctival sac, the ulcerated area retaining the stain.

About 2% of eyes have complete **residual opacity** but most heal completely with a small, white scar persisting in some. In severe cases the cornea becomes conical in shape, there is marked vascularization of the cornea, and ulceration at the tip of the swelling leads to under-running of the cornea with bright yellow pus surrounded by a zone of erythema. These eyes may rupture and result in complete blindness.

A proportion of cases develop minimal clinical lesions and heal spontaneously, and the severity of clinical disease can also vary between outbreaks.

CLINICAL PATHOLOGY

The organism can be identified by culture or fluorescent antibody. The hemolytic form of the bacterium is noticeably more pathogenic than the nonhemolytic form. Serum agglutinins (1:80 to 1:640) are present 2–3 weeks after clinical signs commence, and a modified gel diffusion precipitin test is capable of detecting *M. bovis* antibodies. An ELISA test is also used for antibody detection in experimental studies; however, neither agglutinating antibody nor antibody detected by ELISA correlates well with individual animal resistance to infection.[20] There is little indication for serological examinations in clinical practice. Necropsy examinations are not usually necessary.

DIFFERENTIAL DIAGNOSIS

- **Traumatic conjunctivitis** is usually easily differentiated because of the presence of foreign matter in the eye or evidence of a physical injury
- ***Pasteurella multocida* (capsular type A)** has been isolated from the eyes of housed heifers that experienced outbreaks of severe keratitis with severe loss of corneal stroma within 72 hours of onset
- ***Mycoplasma bovis*** has been isolated from the eyes of steers with an outbreak of severe conjunctivitis with corneal opacity and ulceration, disease being followed by serological conversion in affected animals.[25] Involvement of the eyelids with marked swelling was prominent. Conjunctivitis is prominent in other mycoplasmal infections that produce keratoconjunctivitis[26]
- ***Listeria monocytogenes* iritis**
- **Infectious bovine rhinotracheitis**
- **Bovine malignant catarrh**
- **Thelaziasis**
- **Chlamydial keratoconjunctivitis** presents with identical clinical findings but has a protracted course despite treatment and a higher morbidity.[27] *Chlamydiophila* DNA can be detected by PCR in conjunctival swabs. This disease is a possible zoonosis

TREATMENT

Bovine infectious keratoconjunctivitis is frequently a **self-limiting disease**. Recovery commonly occurs without treatment, although early treatment will reduce the incidence of scarring of the eyes. Antibacterial treatment is commonly used and mass treatment of the herd as opposed to just affected individuals may halt the occurrence of further cases.[28] The route of administration is often determined by ease of repeated access to the animals, and cost.

Topical therapy

Early, acute cases respond to treatment with ophthalmic ointments and solutions containing antibiotics but they need to be instilled in the conjunctival sacs at frequent intervals, which may be impractical under field conditions. The organism is **sensitive** to most antibiotics and sulfonamides but is resistant to erythromycin, lincomycin, and tylosin. The administration of an oil-based formulation containing 375 mg of benzathine cloxacillin has been found to be effective in therapy in controlled trials.[28–30] Two doses, 72 hours apart, are recommended.

Subconjunctival therapy

Subconjunctival therapy with antibiotic is effective, and when corneal vascularization is extensive the injection of a mixture of corticosteroid and antibiotic under the **bulbar** conjunctiva is recommended to promote healing. Often one injection is sufficient, but it may be necessary to repeat it daily for a few days in advanced cases. Recovery may require 3–4 weeks and daily examination of the eye should be made to detect any complication that may occur. Another technique for prolonging the maintenance of high levels of antibiotic in the conjunctival sac is the use of collagen inserts impregnated with an antibiotic.

Subconjunctival procaine penicillin ($3–6 \times 10^5$ IU) given through the skin of the upper eyelid or under the bulbar conjunctiva gives prolonged therapeutic concentrations in conjunctival secretions[31] and is commonly used in therapy, alone or in combination with subconjunctival dexamethasone. Injection of the penicillin through the skin of the upper eyelid rather than through the conjunctiva confers a significantly longer presence of penicillin in the conjunctival fluids.[32] Therapy must be administered under the bulbar conjunctiva and is ineffective if given in the superior palpebral conjunctiva.[33,34] A controlled trial found that subconjunctival penicillin was effective in treatment but recurrence was higher than with treatment with parenteral oxytetracyline[34] and mass treatment of calves with subconjunctival penicillin does not eliminate infection.[35]

Parenteral therapy

Parenteral therapy with sulfadimidine at the normal dose rate of 100 mg/kg BW is an effective parenteral treatment, and a single treatment with long-acting oxytetracycline (20 mg/kg intramuscularly) has shown efficacy in controlled field trials.[36] Parenteral treatment with two doses of long-acting oxytetracycline (20 mg/kg) 72 hours apart, coupled with oral administration of oxytetracycline at 2 g/250 kg BW for 10 days, is credited with markedly reducing the herd incidence of the disease.[28,34] Recent studies comparing other antimicrobials with oxytetracycline suggest that recovery rates are faster following therapy with florfenicol or tilmicosin.[37,38]

Ancillary therapy

Severe cases should be placed in a dark shelter out of direct sunlight. If housing is not possible, eye flap **patches** are available and effective. They are glued on above the eye and can be flipped up for medication of the eye.

When corneal ulceration has occurred recovery is always protracted. The use of topical ophthalmic anesthetics combined with atropine administration may be indicated to minimize ciliary spasm and pain. Severe cases may require that the third eyelid be temporarily sutured across the globe of the eye for several days to promote healing.

CONTROL

Eradication or prevention of the disease does not seem possible under extensive range conditions because of the method of spread, but if **fly control** can be fitted into the farm's management program this should significantly reduce the infection rate. Insecticide impregnated ear tags may help in the control of the disease but do not prevent it. In many herds the best that can be done is to keep animals under close surveillance and isolate and treat any cattle that show excessive lacrimation and blepharospasm. Cattle that have had the disease should not be mixed with those that have not until after the fly season.

Vaccination

There has been considerable effort to develop methods of immunoprophylaxis; however the commercial bacterins, although available for over 30 years, have given inconsistent results, providing at best limited protection from subsequent infection and clinical disease. Killed, whole-cell vaccines require repeat injections, may be associated with anaphylactic reactions and have not proven effective in the field. To avoid the need for repeated injections an adjuvant vaccine has been tested, but without apparent benefit.

Vaccines containing pilus antigens, with or without cornea-degrading enzyme antigens, protect against challenge with homologous strains of *M. bovis*[20,39,40] and some field trials report efficacy in naturally occurring outbreaks.[40,41] However, others do not[42,43] and the results of field studies that have shown a beneficial effect from vaccination have been criticized on the basis of bias in the selection of controls.[43] It is probable that currently available vaccines do not contain the diversity of antigens required to protect against the variety of strains that occur in natural outbreaks. Autogenous vaccines are a consideration in individual herds but a recent controlled trial of an autogenous vaccine administered by subcutaneous or subconjunctival injection found no significant effect of either route or the vaccine on the incidence of disease.[44]

Weekly treatment of both eyes of calves, but not the cows, with a furazolidone eye spray has been shown to be a more effective prophylaxis than vaccination with a commercial bacterin in some areas.[45]

Total eyelid pigmentation may reduce the incidence of this disease but the recorded differences[19] are unlikely to arouse enthusiasm for a genetic approach to the problem.

SEPTICEMIA AND THROMBOTIC MENINGOENCEPHALITIS IN SHEEP ASSOCIATED WITH *HISTOPHILUS SOMNI*

Synopsis

Etiology *Histophilus somni* (formerly *Haemophilus agni*, *Histophilus ovis*)
Epidemiology Worldwide occurrence but not a common disease. In affected flocks cases occur over several weeks to result in a significant population mortality

Clinical findings Acute disease and affected sheep commonly found dead. Septicemia, polyarthritis, and occasionally meningitis primarily in lambs 4–7 months of age
Necropsy findings Multiple hemorrhages throughout the carcass. Focal hepatic necrosis. Polyarthritis, meningoencephalitis
Diagnostic confirmation Isolation of the organism
Treatment and control Oxytetracycline

ETIOLOGY

Histophilus somni falls within the family Pasteurellaceae. This organism, previously known as *Haemophilus agni* and *Histophilus ovis*, has been isolated from sheep with a number of different pyogenic conditions including septicemia, polyarthritis, thrombotic meningoencephalitis, general pyemia, metritis, mastitis, abortion, neonatal mortality, and epididymitis.[1–5]

EPIDEMIOLOGY

Disease associated with *H. somni* in sheep has worldwide occurrence but is not common.

The most common presentation is lameness and septicemia in lambs aged 4–7 months[6–9] but infection with this organism can also result in polyarthritis in lambs 1–4 weeks of age. The morbidity rate varies between outbreaks but the case fatality rate is likely to be 100% unless treatment is undertaken, and the population mortality rate can approach 10%.[8] Outbreaks may last several weeks and, within a flock, cases of the disease occur sporadically but over a long period.

In some outbreaks, both in lambs and adult sheep, meningoencephalitis is the primary presentation and the clinical and pathological findings are similar to thromboembolic meningoencephalitis in cattle.[3,10,11] The method of transmission is unknown but the disease does not appear to spread by pen contact nor can it be produced by oral, nasal, or conjunctival exposure to the organism. Environmental or other stress may be a predisposing factor.[9]

PATHOGENESIS

The organism colonizes the respiratory and reproductive tract mucosa and invades to produce septicemia and disseminated bacterial thrombosis, leading to a severe focal vasculitis.

CLINICAL FINDINGS

Affected sheep are often found dead. Depression, high fever (42°C, 107°F), disinclination to move and collapse with movement are the obvious clinical signs and affected lambs may die within 12 hours of becoming ill. Lambs that survive more than 24 hours develop a severe [illegible] increase in joint fluid and heat in the joints. They are usually recumbent and those with meningoencephalitis show hypersalivation, convulsions and opisthotonos. The clinical course is short.

CLINICAL PATHOLOGY

Hematology and blood chemistry are not commonly conducted because of the acute nature of the disease and the availability of carcasses for postmortem. Initially there is leukopenia and neutropenia with a neutrophilia and left shift in more prolonged cases. Total cell count is elevated in cerebrospinal fluid and joint fluid and these also can be cultured for the organism. Antibody detected by complement fixation persists for about 3 months in animals that survive.

NECROPSY FINDINGS

At necropsy the most striking feature is the presence of multiple hemorrhages throughout the carcass. Focal hepatic necrosis surrounded by a zone of hemorrhage is also a constant finding. Lambs that die in the early stages of the disease show minimal joint changes but those that survive for more than 24 hours develop a fibrinopurulent arthritis. Histologically, the disease is a disseminated bacterial thrombosis leading to a severe focal vasculitis. This change is most apparent in the liver and skeletal muscles. A basilar meningitis will be present in more protracted cases.

Samples for confirmation of diagnosis

- Bacteriology – culture swabs from joint fluid, liver, meningeal fluid (CULT)
- Histology – formalin-fixed liver and brain.

DIFFERENTIAL DIAGNOSIS

Because of the acute nature of the clinical disease, the disease is likely to be confused with acute septicemia associated with *E. coli* or *P. trehalosi*, and with enterotoxemia. The characteristic hepatic lesions and histology serve to identify the disease, and final diagnosis depends on isolation of the organism.

TREATMENT AND CONTROL

Antimicrobials, such as tetracyclines, need to be given very early in the course of the disease if they are to be effective. Because of the acute nature of the disease, vaccination is likely to be the only satisfactory method of control.[8] Although there is no label, vaccine immunity after a field attack seems to be solid. Mass treatment of the group of sheep at risk with long-acting tetracyclines is a possible strategy to reduce the occurrence of further cases.

HAEMOPHILUS SEPTICEMIA OF CATTLE (*HISTOPHILUS SOMNI* OR *HAEMOPHILUS SOMNUS* DISEASE COMPLEX)

Synopsis

Etiology *Histophilus somni* (formerly *Haemophilus somnus*)
Epidemiology High prevalence of infection in cattle population; low incidence of disease. Occurs in North American feedlot cattle, also in the UK and some European countries. Young growing cattle and those 6–12 months of age are most commonly affected, nursing beef calves less commonly. Originally, meningoencephalitis was most common lesion but pleuropneumonia and myocarditis now common. Several virulence attributes of organism may account for different forms of disease. Organism resides in respiratory and reproductive tracts of both females and males
Signs Meningoencephalitis with fever, ataxia, joint swellings, fundic lesions, weakness, recumbency, and death in 12–24 hours. Pleuropneumonia and myocarditis with rapid death
Clinical pathology Marked changes in leukon. Demonstrate and culture organism from cerebrospinal fluid, joint fluid, pleural cavity, and myocardium
Lesions Meningoencephalitis, hemorrhagic infarcts in brain, retinal hemorrhages, pleuropneumonia, myocarditis with abscessation

Differential diagnosis
- **Pneumonia and pleuritis**: Pneumonic pasteurellosis and pleuritis
- **Myocarditis**: Other causes of sudden death and congestive heart failure
- **Meningoencephalitis**: *Listeria* meningoencephalitis, polioencephalomalacia, hypovitaminosis A

Diagnostic confirmation Culture organism
Treatment Antimicrobials
Control Unreliable. Mass medication of individual animals on arrival in feedlot. Vaccination with bacterin

ETIOLOGY

Histophilus somni is the cause.[1,2] Earlier investigations have shown that *H. somni*, *Haemophilus agni*, and *Histophilus ovis* represent the same species and recent analysis of genes of strains supports the allocation of this species to a novel genus within the family Pasteurellaceae as *Histophilus somni*.[3] *H. somni* causes a variety of diseases in cattle, including septicemia, thrombomeningoencephalitis, pleuropneumonia, myocarditis, reproductive failure, and in sheep mastitis, septicemia, and epididymitis.

EPIDEMIOLOGY

Prevalence of infection

The prevalence of infection of *H. somni* in the cattle population is much higher than the incidence of clinical disease. More than 50% of normal bulls, 8–10% of normal cows, and 10% of normal rams have *H. somni* in their reproductive tract.[4] Among those that have had the disease and survived, the serological reactor rate varies from 50–100%. Some surveys found more positive reactors in beef cattle and dairy cattle from infected herds than in dairy cattle from clinically normal herds. The percentage of cattle that seroconvert may be higher in dairy herds of more than 100 cows than in smaller herds.

Occurrence of disease

Infection of cattle with *H. somni* may cause septicemia, thrombotic meningoencephalitis, polysynovitis, pleuritis, suppurative bronchopneumonia, myocarditis, otitis media, mastitis, and reproductive tract diseases. When infection of cattle with the organism was first described in 1956, the primary form of the disease was thrombotic meningoencephalitis. Since that time, many different clinical forms of the infection have been described. Suppurative bronchopneumonia, fibrinous pleuritis, and myocarditis are now being recognized with increased frequency in feedlot cattle and are being attributed to *H. somni* infection.[5,6] Based on necropsy examinations over a 20-year period in a Saskatchewan diagnostic laboratory, there has been an increasing percentage of cattle with pneumonia and myocarditis associated with the organism and a decreasing percentage with meningoencephalitis.[5] However, because of the practical difficulties in making a specific clinical, pathological, and microbiological diagnosis in situations where the disease complex occurs, there is some uncertainty about the relative importance of the organism in causing certain diseases such as pneumonia of feedlot cattle. For example, because of the variability of the nature and extent of the lesions in bovine respiratory disease in feedlot cattle, the several factors that can influence the laboratory isolation of some bacteria from affected tissues, and the common occurrence of mixed infections, it is difficult to determine whether *H. somni* or *M. haemolytica* is the primary pathogen.

The disease occurs most commonly in **feedlot cattle** in North America after they have been commingled from different sources. The disease has also been recognized in the UK, Germany, Switzerland, and recently in Israel.[7] The disease also occurs in nursing beef calves and young cows on pasture and in young dairy cattle, but to a much lesser extent. The organism has been found in the tonsillar tissues of American bison (*Bison bison*)[8] and has been the cause of bronchopneumonia in bison.[9]

The incidence rate of the nervous form of the disease in a susceptible group of calves is low, averaging about 2%, but may be up to 10% in some outbreaks. The case fatality rate, however, is 90% if affected animals are not identified and treated early in the course of the disease.

The **nervous form** of the disease occurred historically most commonly in feedlot cattle from 6–12 months of age during the fall and winter months, which may be a reflection of stress associated with crowding and cold and changing weather. In Canada the nervous form occurred most commonly in cattle about 4 weeks after arrival in the feedlot, with a range of 1 week to 7 months. The nervous form has also occurred in feedlot cattle in Argentina.[10]

The disease complex that is encountered more commonly now is characterized by **pleuritis**, **myocarditis**, and **pneumonia**, and can be the most significant cause of mortality in fall-placed weaned beef calves in large commercial feedlots in western Canada.[11] Death from pneumonia due to the infection occurred mainly during the first 5 weeks in the feedlot; death from myocarditis, pleuritis, thrombotic meningoencephalitis, septicemia, and euthanasia because of polysynovitis occurred mainly after the third week.[11] Furthermore, this disease complex is occurring despite routine vaccination of calves on arrival in the feedlot.[11] A history of respiratory tract disease preceding the outbreak is common and in some cases meningoencephalitis had occurred in the same herd in the previous year. Myocarditis due to *H. somni* in a 6-month-old bull calf has been described in the UK.[12]

H. somni also causes various forms of reproductive failure in cattle. A review of the literature on this subject is available.[3] The importation of infected young rams into a flock can have a deleterious effect on the percentage of ewes that lamb.[13] Purchasing replacement animals and having cattle on the same farm were risk factors for infection in the flock. The possibility of interspecies transmission between cattle and sheep requires further study.

Risk factors

Animal risk factors

The meningoencephalitis, pleuropneumonia, and myocarditis forms of the disease occur most commonly in feedlot calves 6–12 months of age. The disease may occur in unvaccinated cattle or cattle not vaccinated soon enough before entry into the feedlot. Most weaned beef calves placed into commercial feedlots in Canada are not vaccinated for *H. somni* before entry into the feedlot but rather on arrival.

In Canadian feedlots, feedlot calves that have significant *H. somni* serum antibody levels on arrival or that are able to increase their levels after arrival tend to have a reduced risk of bovine respiratory disease.[14–16]

Environmental and management risk factors

No information is available.

Pathogen risk factors

The literature on the virulence factors of the organism has been reviewed.[4] Several virulence factors have been identified, including lipo-oligosaccharide phase variation, induction of apoptosis, intraphagocytic survival, and immunoglobulin Fc binding proteins.[4] *H. somni* is able to synthesize and secrete histamine, which may contribute to the pathogenesis of respiratory disease.[17] The organism is able to survive and multiply in bovine alveolar macrophages and blood monocytes, which may be related to its ability to escape macrophage killing and disseminate in the body.[18]

The organism is an obligate inhabitant of mucosal surfaces and an opportunistic pathogen. It colonizes the surface of mucous membranes; in the asymptomatic carrier state the organism remains at the mucosal surface without invading cells.[2] The organism is able to persist in the lungs of calves for 6–10 weeks in the presence of specific antibody and in the absence of clinical abnormalities other than sporadic coughing. Attachment may be all that is necessary to produce infertility due to endometritis or degeneration of embryos. The organism attaches in large numbers to bovine vaginal epithelial cells.[2] It has the ability to invade the circulatory system, resulting in septicemia. Various strains of *H. somni* adhere to bovine aortic endothelial cells and the adherence is enhanced by the tumor necrosis factor.[4]

Some isolates of the organism are able to multiply in vivo because they are resistant to complement, and bovine leukocytes are incapable of destroying the organism in the absence of specific antibody. Certain suppressive components in *H. somni* have been identified that inhibit the function of polymorphonuclear leukocytes. *H. somni* antigen has been found in heart and lung tissues in association with chronic pneumonia due to *Mycoplasma bovis* and BVDV.[19]

The organism also has cytotoxic properties that may be related to the production of endotoxin.[2] Some strains are serum resistant and others serum sensitive, which may explain the ability of certain strains to invade beyond mucous membrane surfaces. Another virulence determinant is a nonimmune binding mechanism that is present on the surface of the organism.[4] This determinant may be related to the organism's resistance to complement-mediated killing, its persistence at mucosal surfaces, its capacity to evade host effector functions in vivo and its ability to cause a range of bovine infections. Differences between pathogenic and preputial isolates have been identified.[4] Similarly, there are pathogenic strains of the organism in the genital tract of apparently normal cows as well as those with inflammatory disease.[4]

Virulence differences also exist between *H. somni* strains following intratracheal challenge of bovine lungs.[20] Those strains isolated from encephalitic lesions, or from the prepuce, will not produce the same degree of experimental pneumonia as those strains isolated from lung lesions. Preputial and septicemic isolates of ovine *H. somni* are similar to bovine *H. somni* in pathogenicity and in surface antigens. Ovine isolates given by intracisternal inoculation to 2–3-month-old lambs caused fatal meningoencephalitis and myelitis.

In summary, many virulence factors are involved in several steps of pathogenesis. Adherence is likely to be important in colonization, complement resistance in survival in the circulation or inflammatory sites, and cytotoxicity in evading killing by phagocytes and in initiation of vasculitis, as well as invasion through the endothelium. The host damage that occurs as a result may be further exacerbated by inflammatory mediators released by the host in response to *H. somni*.

Methods of transmission

The method of transmission and portal of entry are unclear. A feature of infections with this organism is its persistence at mucosal sites in both subclinical and diseased animals. The organism can be isolated from the respiratory and reproductive tracts of normal animals.[3]

In bulls, the organism has been isolated from semen and the preputial orifice, preputial cavity, urinary bladder, accessory sex glands, ampulla of the ductus deferens and the preputial washings of steers. Most bulls harbor the organism in the prepuce. Thus, the potential exists for venereal transmission of *H. somni*, for lateral spread from the genital tract and for environmental contamination by the organism.

The organism has also been isolated from the vagina, vestibular gland, cervix, uterus, and bladder of cows. The prevalence of infection in normal cows varies depending on the herd and geographical location but 10–27% can harbor the organism.[3] The organism can colonize the vagina of cows without causing disease and it is thought to have a primary etiological role in vaginitis and cervicitis in cows.

The role of *H. somni* in diseases of the bovine reproductive tract has been reviewed.[3] The organism has been isolated from the udder secretions of cattle with naturally occurring mastitis.

Urine is also a source of the organism. The young beef calf in a cow–calf herd can become infected as early as 1 month of age and become a nasal carrier of the organism without showing any signs of clinical disease. The mature cow is considered to be a major source of the organism for the calf. The method of transmission is presumed to be by contact with infective respiratory and reproductive secretions or by aerosol transmission, especially in close-contact feedlots.

The organism can survive more than 70 days when it is mixed with cerebrospinal fluid, whole blood, blood plasma, vaginal mucus, or milk and frozen at –70°C (–94°F). At 23.5°C (73.5°F) it can survive beyond 70 days when mixed with whole blood and nasal mucus. The viability of the organism in urine at all temperatures is less than 24 hours and less than 15 minutes at 20°C (68°F) and 37°C (98°F). It survives for less than 1 day in milk at room temperature or when incubated at 37°C, and should be considered as a possible cause of mastitis in cases that are negative on routine bacteriological culture.

Immune mechanisms

Serum antibody tests measured by several serological tests do not correlate with susceptibility to clinical disease. Naturally acquired humoral immunity does not influence the outcome of experimental intravenous inoculation of the organism. Also, the role of naturally acquired antibodies in protecting cattle from disease is uncertain. The levels of naturally occurring serum bactericidal activity to *H. somni* are low or absent in calves at 4–6 months of age, when they are most susceptible to the nervous form of the disease. The levels increase with age and are high in mature cows; yearlings have intermediate levels.

Experimentally, convalescent sera from calves with experimental *H. somni*

pneumonia protects calves against acute *H. somni* pneumonia.[21] Marked serum exudation characterizes the early stages of experimental pneumonia, and antibody should be involved in protection. The specificity of this protection is directed primarily against surface-accessible antigens of the bacterial outer membrane. These antigens may also be useful in serological diagnosis because convalescent calves have high IgG_1 and IgG_2 titers to *H. somni* for several weeks. The measurement of serum IgG_1 is a more reliable test to detect a current or recently active infection. Later, there is a sustained increase in IgG_2. The role of $IgG_{2\alpha}$ antibodies in providing protection against *H. somni* pneumonia has been examined.[22] The development of a systemic IgG_2 antibody response is the basis for local immunological protection in the bovine reproductive tract.

The immune response in cattle to the major outer membrane protein during infection is weak and directed to antigenically variable determinants in a strain specific manner that may have important implications in protective immunity.[23] Vaccination of 1–2-month-old calves with commercial aluminum-hydroxide-adjuvanted *H. somni* bacterins elicits an ELISA-detectable IgE response 14 days after injection, which may be associated with severe clinical disease associated with type I hypersensitivity.[24]

PATHOGENESIS

H. somni first establishes itself in the host by colonizing the surface of the mucous membranes. Some strains of the organism are able to invade the circulatory system and cause septicemia, with localization in many tissues and organs, causing a vasculitis. The ability of *H. somni* to survive in both mononuclear phagocytes and neutrophils may be important in the establishment of the chronic multisystemic infection characteristic of bovine haemophilosis.[18] In the thrombotic meningoencephalitic form of the disease, the sequence of events in the genesis of the lesions may be adhesion of the organism to vascular endothelial cells. The organism lipo-oligosaccharide induces endothelial cell apoptosis, which may play a role in producing vasculitis.[25] Contraction and desquamation of cells, with exposure of subendothelial collagen, thrombosis and vasculitis, is followed by ischemic necrosis of adjacent parenchyma. The common site of localization is the brain, causing a thrombomeningoencephalitis. Multifocal areas of hemorrhagic necrosis occur throughout the brain, resulting in the major clinical findings of depression, paresis, and recumbency. Localization in synovia results in polysynovitis. Fibrin thrombi occur in the small vessels and capillaries of the liver, spleen, kidney, lung, heart, and brain, which suggests that disseminated intravascular coagulation may be a feature of the pathogenesis of *Haemophilus* septicemia. Myocarditis has been recognized with increased frequency[6,26] and is characterized by acute or chronic heart failure.

The pathogenesis of the pneumonia is not clear. Although *H. somni* has been isolated from cattle with bronchopneumonia and fibrinous pneumonia in pure culture and in combination with *Pasteurella* spp., the lungs of cattle dying with thrombomeningoencephalitis are not usually affected with a fibrinous pneumonia. The pneumonia that is attributed to the organism is characteristically subacute or chronic and it is probable that the portal of entry is via the upper respiratory tract. However, it is difficult to reproduce the disease by aerosol challenge with *H. somni*.[20] The organism produces and secretes histamine, which may be enhanced by carbon dioxide concentrations that approximate those in the bronchial tree.[17] This may explain some of the postvaccination reactions.

The microscopic lesions in the lungs of cattle with pneumonia from which *H. somni* is isolated consist of suppurative to necrotizing bronchiolitis, particularly in calves with subacute to chronic pneumonia. The experimental pneumonia is characterized by purulent to fibrinopurulent bronchiolitis accompanied by alveolar filling with fibrin, neutrophils, and macrophages. Laryngitis and polypoid tracheitis have also been attributed to *H. somni*, but the evidence for a cause and effect relationship is limited.

Hemorrhagic necrotic lesions also occur in the spinal cord, which contributes to the muscular weakness, recumbency, and paralysis encountered in some cases with or without brain lesions. Lesions in the esophagus, forestomachs, and intestines may account for the bloat and alimentary tract stasis that occurs in the experimental disease.

The septicemia usually causes a marked leukopenia, neutropenia, and degenerative left shift.

Cattle dying of experimentally induced and naturally occurring disease have high levels of agglutinating anti-*H. somni* antibody, but not of complement-fixing antibody. Because septicemia can occur even with high levels of serum antibody, it is hypothesized that the formation of antigen–antibody complexes may contribute to the development of the vasculitis. It is possible that previous exposure to *H. somni* infection is necessary for typical thrombomeningoencephalitis to occur. Inoculation of colostrum-deprived calves with *H. somni* causes septicemia but does not produce lesions typical of thrombomeningoencephalitis. This suggests that the disease may be an example of a type III hypersensitivity reaction or serum sickness.

The organism can cause inflammatory disease in the genital tract of cows or may merely colonize the healthy genital mucosa.[3] Vaginitis, cervicitis, and endometritis have been associated with infection by *H. somni*. Experimentally, the organism can be embryocidal, which indicates a possible role in early embryonic mortality. Sporadic abortions have been reported following septicemia.[3]

CLINICAL FINDINGS

The range of clinical findings associated with *H. somni* infection in cattle has changed remarkably in the last two decades. Historically, thrombotic meningoencephalitis was the major form of the disease. However, fewer cases of the nervous form are being diagnosed now while many more cases of other forms of the disease are becoming prevalent.[6]

Meningoencephalitis

In the typical **nervous form** of the disease, it is common for several animals to be affected within a few days or at one time, but single cases do occur. Some affected animals may be found dead without any premonitory signs and often this may be the first sign of disease in the group.

In the more common acute form, in which there is usually neurological involvement, cattle may be found in lateral or sternal recumbency and may or may not be able to stand. The temperature is usually increased up to 41–42°C (105.8–107.6°F) but in some cases it may be normal. Depression is common, the eyes are usually partially or fully closed and, while blindness may be present in both eyes, it is usually confined to one eye, or the eyes may be normal. Originally the disease was called the '**sleeper syndrome**' because the eyes were partially closed. Recumbent cattle that attempt to stand may have considerable difficulty and exhibit obvious ataxia and weakness. Others that are able to stand, when attempting to walk, knuckle over on the hind fetlocks, are grossly ataxic, and usually fall after walking a short distance. In the recumbent position, opisthotonos, nystagmus, muscular tremors, hyperesthesia, and occasionally convulsions will occur, but the emphasis is on muscular weakness and paralysis rather than signs of irritation. Otitis media with concurrent meningitis may also occur.

The **nervous form** of the disease is rapidly fatal in 8–12 hours if not treated

when signs are first noticed. Affected cattle that are treated before they become recumbent commonly recover in 6–12 hours, which is an important clinical characteristic of the disease. Once recumbent, particularly with obvious neurological involvement, they will either die in spite of treatment or remain recumbent and fail to improve or get worse over several days. Secondary complications, such as pneumonia and decubitus ulcers, usually result. The organism has been isolated from a 5-month-old ram that died suddenly with pathological evidence of septicemia.

The **ocular lesions** consist of foci of retinal hemorrhages and accumulations of exudate that appear like 'cotton tufts'. While these fundic lesions are not present in all cattle affected with *H. somni*, they are a valuable aid to the diagnosis. The organism has been isolated from the conjunctival sacs of feedlot cattle affected with conjunctivitis.

Otitis in feedlot cattle has also been attributed to the organism. The ears are commonly drooping and affected animals appear depressed. A combination of otitis and meningitis young cattle associated with the organism has been described.[27]

The **synovitis** is characterized by distension of the joint capsules, usually the major movable joints such as the hock and stifle joints but any joint may be involved. Pain and lameness are only mild and, when treated early, the synovitis usually resolves in a few days. In a few cases there is marked lameness and a preference for recumbency associated with hemorrhages in muscle. The organism has been isolated from a calf with a urachal abscess.[28]

Respiratory disease

The clinical findings of the **respiratory form** of the disease, which has been diagnosed with increased frequency in the last decade, have not been clearly described. There are no published descriptions available of the clinical findings of pneumonia or pleuritis associated with the organism. It is unlikely that there are any distinctive clinical features. Most feedlot calves with pleuritis due to *H. somni* die in the pen without ever having been treated.

Epidemiological surveys of weaned beef calf mortality due to pneumonia and pleuritis associated with *H. somni* suggest that death from pneumonia occurred during the first 5 weeks after arrival in the feedlot.[11] The **median fatal disease onset** for pneumonia was day 12, and for myocarditis and pleuritis, day 22. It is suggested that pneumonia and pleuritis should be suspected in feedlot cattle that have been treated unsuccessfully for bovine respiratory disease in the previous several days. Laryngitis, tracheitis, pleuritis, and pneumonia can occur alone or in combination with the acute neurological form of the disease. The laryngitis is characterized clinically by severe dyspnea, mouth-breathing, and stertor. Conjunctivitis similar to that seen in infectious bovine rhinotracheitis may occur and isolation of the organism from ocular swabs is necessary to make the definitive diagnosis. Chronic suppurative orchiepididymitis in a calf from which *H. somni* was isolated has been described.

Myocarditis

In the **myocardial form** of the disease, affected animals may be found dead without any previous illness having been recorded or they may have been treated for respiratory disease within the previous few weeks with a variable response. If seen early in the course of the myocarditis, the most common clinical findings are a fever and depression.[14] With advanced stages of myocarditis, exercise intolerance, mouth-breathing, and protrusion of the tongue occur. Affected animals may collapse and die while being moved from their home pen to the hospital pen in the feedlot. Most animals with myocarditis have a previous history of being treated for an undifferentiated fever and depression within the previous 10–14 days. When returned to their home pens, they may be found dead or in severe respiratory distress.

Chronic free-gas bloat is a not uncommon finding in naturally occurring cases and occurs frequently in the experimental disease.

CLINICAL PATHOLOGY

Hematology

In most cases there are changes in the total and differential leukocyte count. Leukopenia and neutropenia may be present in severe cases while in less severe cases a neutrophilia with a left shift is more common. In the cerebrospinal fluid, the total cell count is markedly increased and neutrophils predominate. The Pandy globulin test on cerebrospinal fluid is usually strongly positive. In the synovial fluid the total cell count is also increased and neutrophils predominate.

Culture of organism

The organism can be cultured from blood, cerebrospinal fluid, synovial fluid, urine, brain, kidney, and liver, less commonly from pleuritic fluid and tracheal washings. The laboratory isolation of *H. somni* from swabs, tissues, and body fluids requires special transport media and selective culture media to insure reliable recovery. It is difficult to determine whether a positive culture of the organism from a mucosal surface indicates an etiological role or merely a carrier role. The PCR technique is a more sensitive method for detection of the organism on swabs from either the cut surface or from a bronchus than bacterial culture and immunochemistry.[29]

Serology

Cattle with experimental or naturally occurring disease have high levels of agglutinating anti-*H. somni* antibody. Recovered animals are positive to the CFT within 10 days following infection and titers begin to decline to low levels 30 days after infection. Acute and convalescent sera are required for accurate interpretation of results.

A microagglutination test is available but most cattle are positive. Naturally or experimentally infected animals have elevated IgG_2 antibody titers compared to controls. However, there is no significant difference in serum IgG_2 titers between culturally negative and culturally positive but asymptomatic animals. An immunoblot test can detect an immune response after experimental abortion, experimental pneumonia or vaccination with a killed vaccine. It is also able to distinguish between animals with an immune response due to disease or vaccination with the organism and those animals that are asymptomatic carriers, culture negative or infected with closely related bacteria.

NECROPSY FINDINGS

The characteristic lesions of the nervous form are hemorrhagic infarcts in any part of the brain and spinal cord. These are usually multiple and vary in color from bright red to brown and in diameter from 0.5–3 cm. Cerebral meningitis may be focal or diffuse and the cerebrospinal fluid is usually cloudy and slightly yellow-tinged. Hemorrhages may also be present in the myocardium, skeletal muscles, kidneys, and the serosal surfaces of the gastrointestinal tract.

There may be petechiation and edema of the synovial membranes of joints. There is an excessive quantity of synovial fluid, which is usually cloudy and may contain fibrinous flecks. The articular cartilage is usually not affected.

Pulmonary involvement is characterized by a fibrinopurulent bronchopneumonia, although the posterior aspects of the lung may be edematous and have a rubbery consistency. Histologically there is fibrinosuppurative bronchiolitis accompanied by filling of the alveoli with fibrin, neutrophils, and macrophages. Peribronchiolar fibrosis and bronchiolitis obliterans, interlobular fibrosis and thrombosis of interlobular and pleural lymphatics develop in chronic cases. Fibrinous or serofibrinous inflammation of the peritoneum, pericardium, or pleura is found in more than 50% of cases. There

may be focal ulceration and fibrinonecrotizing inflammation extending from the pharynx down into the trachea. Polypoid tracheitis has also been reported.

Histologically, vasculitis and thrombosis with or without infarctions and a cellular component composed almost entirely of neutrophils may be seen in all tissues where localization occurs, especially the heart. Myocardial abscesses may develop and are most common in the left ventricular free wall, particularly in the papillary muscles.

H. somni is easily cultured from the tissues of untreated animals but immunohistochemical techniques can be attempted to demonstrate the organisms if culture is unsuccessful.[30,31]

Samples for confirmation of diagnosis

- Bacteriology – culture swabs from brain/meningeal and joint lesions; lung, spleen, heart (CULT)
- Histology – formalin-fixed brain, lung, heart, kidney, synovial membrane (LM, IHC).

DIFFERENTIAL DIAGNOSIS

Meningoencephalitis due to *H. somni* is characterized by sudden onset of weakness, ataxia, depression, fever, enlarged joints and rapid death within 12–24 hours. There are marked changes in the cell count of the cerebrospinal fluid and the leukogram. There is a rapid response to treatment in the early stages.

- In **polioencephalomalacia**, blindness, normal temperature, nystagmus, opisthotonos, and convulsions are common
- In ***Listeria* meningoencephalitis** there is unilateral facial paralysis with deviation of the head and neck and a normal or slightly increased temperature. The cerebrospinal fluid in listeriosis usually contains an increased number of mononuclear cells
- **Hypovitaminosis A** in young cattle 6–12 months of age is characterized by sudden onset of short-term convulsions and syncope lasting 10–30 seconds, during which they may die but from which they more commonly recover to appear normal. Exercise such as walking from pasture to the farmstead will commonly precipitate the seizures. Eyesight may be slightly impaired but the menace reflex is usually present. The differential diagnosis of diseases of the brain of cattle is summarized in Table 31.3

Pneumonia and pleuritis associated with *H. somni* cannot be distinguished clinically from the other common causes of pneumonia in cattle and the diagnosis is usually made at necropsy.

Myocarditis due to *H. somni* may cause sudden death or congestive heart failure, which will require a necropsy examination for a diagnosis.

TREATMENT

Cattle with the nervous form of the disease must be treated with antimicrobials as soon as clinical signs are obvious. Florfenicol, an analog of thiamphenicol, at a dose of 20 mg/kg BW intramuscularly and repeated 48 hours later, is effective for the treatment of acute undifferentiated fever in feedlot calves[32] and may be the antimicrobial of choice if *H. somni* infection is a major cause of mortality in feedlot calves. Oxytetracycline at 20 mg/kg BW intravenously daily for 3 days is effective when treatment is begun within a few hours after the onset of clinical signs. The prognosis in recumbent cattle is unfavorable but treatment for 2–4 days may be attempted. A failure to respond after 3 days of treatment usually indicates the presence of irreversible lesions. The MICs of 33 antimicrobial agents for *H. somni* indicated high susceptibility to penicillin G, ampicillin, colistin, and novobiocin. Oxytetracycline also revealed high activity. Once the disease has been recognized in a group, all in-contact animals should be observed closely every 6 hours for the next 7–10 days to detect new cases in the initial stages so that early treatment can be given. Mass medication of the feed and water supplies may be indicated but efficacy and benefit–cost data are not available.

The treatment of pneumonia and pleuritis due to *H. somni* is the same as for acute undifferentiated bovine respiratory disease.

CONTROL

Satisfactory control procedures are not available because the pathogenesis and epidemiology of the disease are not well understood. When an outbreak of the nervous form of the disease is encountered, the provision of constant surveillance and early treatment is probably the most economical and effective means of control.

Mass medication

Postarrival mass medication with long-acting oxytetracycline has been evaluated to reduce the risk of hemophilosis mortality in feedlots.[33] Mass medication did not reduce the risk of hemophilosis mortality but it reduced the risks of bovine respiratory disease morbidity and mortality by 14% and 71%, respectively.[33] Hemophilosis accounted for 40% of the mortality in the feedlot calves for each year over 3 years.

Vaccination

Vaccines have been available for use in North America but their efficacy is uncertain. One bacterin is immunogenic and will protect vaccinated cattle against the **nervous form** of the infection produced by intravenous and intracisternal inoculation of the organism.[6] Two injections of the bacterin given subcutaneously 2–3 weeks apart are recommended. Controlled field trials indicate that the bacterin reduces the morbidity and mortality rates of nervous system disease in vaccinated cattle compared to nonvaccinated animals. However, the efficacy of the bacterin has been difficult to evaluate because the incidence of naturally occurring disease in nonvaccinated control animals is usually low and may not be significantly greater than in vaccinated animals.

The efficacy of a *H. somni* bacterin to reduce mortality was evaluated in auction-market-derived beef calves vaccinated immediately upon arrival at the feedlot.[34] The vaccine had no significant effect on overall crude mortality but appeared to reduce the incidence rate of fatal disease during the first 2 months in the feedlot when the risk of fatal disease onset was highest. When mortalities unlikely to be associated with *H. somni* were removed from the analysis, the mortality rate in male calves was reduced by about 17% in the vaccinated group. The incidence rate of fatal disease was higher in female calves during the first week. A second vaccination 2 weeks after arrival did not reduce the mortality risk.

Vaccination of feedlot calves on arrival with a genetically attenuated leukotoxin of *M. haemolytica* combined with bacterial extracts of *H. somni* increased serum antibody titers to both organisms and reduced acute undifferentiated bovine respiratory disease.[35] However, it is not known what proportion of the respiratory disease was due to *H. somni*.

Vaccinating calves twice with a killed whole-cell bacterin reduced the clinical and pathological effects of experimentally induced *H. somni* pneumonia. Calves vaccinated once were incompletely protected.

There is no published evidence to indicate that vaccination of feedlot calves before or after entry into the feedlot with any of the available *H. somni* vaccines will provide protection against the various forms of clinical disease, particularly the respiratory and myocardial types described earlier. The disease complex is occurring in feedlot calves in spite of vaccination.[11] A rational vaccination program would consist of vaccinating calves at least twice, 2–4 weeks apart, with the second vaccination occurring at least 2 weeks before entry into the feedlot.

INFECTIOUS POLYARTHRITIS (GLASSER'S DISEASE, PORCINE POLYSEROSITIS AND ARTHRITIS)

Synopsis

Etiology *Haemophilus parasuis*
Epidemiology Common in pigs several weeks after weaning and up to 4 months of age. Sporadic outbreaks. Environmental stressors are risk factors
Signs Sudden onset of anorexia, dyspnea, lameness, swollen joints, fever, nervous signs, and death
Clinical pathology Culture organisms from serous membranes
Lesions Peritonitis, pleuritis, synovitis, meningitis
Diagnostic confirmation Culture organism and a variety of new techniques
Differential diagnosis Erysipelas, mycoplasmal and streptococcal arthritis, other serositis, also *Actinobacillus pleuropneumoniae* infection, vitamin E deficiency
Treatment Antimicrobials
Control Minimize stressors at weaning and in nursery barns

ETIOLOGY

Initially, the agent was thought to be *Haemophilus influenzae suis*, now known to be *Haemophilus parasuis*.[1,2] Now recognized as one species, it is, however, extremely pleomorphic. There were many serovars, reported first in 1952[3] and many of these were incorporated into a modified classification[4] of 15 major serotypes. *H. parasuis*, together with other *Haemophilus* spp. has an affinity for the mucosa[5] of the oropharyngeal and upper respiratory tract.[5–7] *H. parasuis* can be isolated from the nasal cavity,[8] tonsillar area,[9] and trachea.[10] It may be a true commensal in the upper respiratory tract.[7] Responsible for a severe polyserositis in young pigs, it may also occasionally cause an arthritis in older pigs and the individual sow. The organism, like the others with a similar name, *Actinobacillus suis* and *Streptococcus suis*, has been called one of the 'suis-cides' of pigs, which are responsible for considerable economic loss in high-health herds and herds that practice very early weaning.[11] *H. parasuis* is also commonly isolated from lungs with lesions of enzootic pneumonia.[12–16]

EPIDEMIOLOGY

Although the disease occurs worldwide, reports used to be rare and mainly from Europe. However, since the onset of separate site production, and the occurrence of porcine reproductive and respiratory syndrome, virulent forms of swine influenza and PCV2-associated diseases the disease (*H. parasuis*) has become one of the most common of the so-called secondary infections. It is a significant contributor to the porcine respiratory disease complex. In naive or specific-pathogen-free herds when it first occurs it may be a common cause of sudden death and cases may be numerous. It also under these circumstances affects younger animals. When the disease becomes endemic it may affect older animals with less sudden death but more chronic polyserositis. The disease has also been observed in Australia, the USA,[17,18] Canada,[19] and the UK. The disease accounted for less than 1% of total mortalities of pigs submitted to veterinary diagnostic laboratories over an 11-year period in Ontario.[19] However, the disease was the second most common cause of mortality in test station boars. In a survey of 19 excellent specific-pathogen-free pig herds, 16 were positive and the average number of culture-positive pigs per herd was 6/10 for positive herds.[19]

It is probably spread by aerosol and certainly by nose-to-nose contact.

The disease occurs as sporadic outbreaks – usually in weanling to 4-month-old pigs that have been recently chilled, transported, weaned or moved to different pens. The onset is sudden, with several pigs in the group affected, and occurs within 2–7 days of the initiating stress. Occasionally, it causes arthritis in older animals, or even sow herds. The case-fatality rate is high in untreated pigs. Acute myositis in primary specific-pathogen-free sows has been associated with *H. parasuis*.[20]

Little is known of the method of transmission of the disease. The causative organisms are facultative pathogens and can be frequently isolated from pig lungs diseased from other causes, even though they are generally not present in normal lungs. It is probable that a respiratory carrier state does exist and that invasion with subsequent septicemia and polyserositis is initiated by stress situations in young pigs that have lost maternal immunity but have not yet gained active immunity. Piglets probably acquire the infection soon after birth but maternal antibody protects them from clinical disease until they are 2–4 weeks of age. Animals that are weaned early are likely to have this infection so the supposition is that most pigs acquire the infection at or immediately after birth. *H. parasuis* has been found in the tonsil using IHC and EM.[8]

There are several pathogenic serovars of *H. parasuis*.[2,8] Serotypes 3, 6, 7, 8, 9, and 11 are considered to be avirulent, 15 more pathogenic and 1, 4, 5, 10, 12, 13, and 14 virulent.[21] However this pattern cannot be considered permanent as genes can be shared and in any case up to 50% of isolations are considered nontypeable. In the USA and Canada 15.2% were classified as untypeable,[2] 26.2% in Germany,[22] 29.3% in Spain,[23] and 41.9% in Australia.[24] In a particular pig herd, many strains can be isolated but, in most cases, one or two strains predominate.[25] In many herds the untypable outnumber the typable. Of seven reference strains examined, only serotypes 1 and 5 were pathogenic[26] and the seven strains have common antigenic determinants. Within specific-pathogen-free herds, many herds have common strains; no strains are common to both conventional and specific-pathogen-free herds, which is a reflection of little or no movement of pigs

between these types of herd. Specific-pathogen-free pigs are often free of this organism and are highly susceptible to the infection even at several months of age if they are mixed with conventionally raised pigs that may be infected. Outbreaks with rapid spread and high mortality have been reported in specific-pathogen-free pigs.[27] It has been suggested that the causative bacteria are common in most herds and that the disease arises only when pigs from uninfected herds are introduced to a contaminated environment, especially if they have been exposed to environmental stress during transport. When infection is introduced into a previously noninfected herd the disease may act as a contagious disease until herd immunity is developed or the infection eliminated. Recently, it has been suggested that the nasal cavity strains may be nonpathogenic and form a completely different population to the pathogenic strains.[25] Serotypes from nasal and tracheal cultures were shown to be similar in one study.[28] They found that there was a lower level of colonization in the litters of the young sows. The genetic diversity of the strains is not well understood.[29] Several serotypes may be isolated from the same herd or even from the same pig.

PATHOGENESIS

One of the key factors may be that maternal antibody does not last a long time and may be gone by 2-4 weeks of age but will last until 6–8 weeks if sow antibody titers are high. It is the animals that become infected after their maternal protection has waned that have resulting clinical disease. Serovar 5 is highly virulent when inoculated into specific-pathogen-free piglets 6–8 weeks of age.[30] *Bordetella bronchiseptica* increases *H. parasuis* colonization of the nasal cavity.[31] However, it is also said that previous infection with PRRSV has no effect on the occurrence.[32] The severity of the disease increases with the increase in the dose of the organisms.[33]

The precise relationship between protein patterns, serovars, and virulence potential remains to be defined.[34] A new technique called differential display reverse transcription PCR (RT-PCR) has been used to search for virulence factors.[35] The pathogenic *H. parasuis* may have an outer membrane protein, fimbriae and lipopolysaccharides and a cytotoxin has yet to be described but may be a membrane neuraminidase.[36] The outer membrane protein may be iron-regulated and appear to have similar outer-membrane protein profiles.[37] A fibrinous meningitis, polyserositis and polyarthritis are typical. A fatal septicemia can occur spontaneously or following the intraperitoneal inoculation of pigs with *H. parasuis*. The intranasal inoculation of *H. parasuis* into cesarean-derived colostrum-deprived pigs results in a suppurative rhinitis, which may represent an initial event in the pathogenesis of the systemic infection in pigs.[5] After infection with *H. parasuis* there is a highly significant rise in radical formation and monocyte proliferation was reduced. Neutrophils reacted inconsistently.[38] In this experimental study the $CD25^+$ marker cells were markedly reduced. Experimental infections[39] showed that not all field isolates are pathogenic and it may be that route of infection and dosage are most important in determining the outcome of infections. In a new study, polyacramide gel electrophoresis (PAGE) typing of *H. parasuis* and virulence potential based on site were looked at together.[40] PAGE group I had 83.4% of the isolates from the upper respiratory tract (these were mostly of serotype 3 or untypable) but of the PAGE group II isolates 90.7% of all the isolates were from the systemic sites (these are mostly serotypes 1, 2, 4, 5, 12, or 14). It may be that there is also a tropism for some of the sites in that some strains are only found in the brain and others in the pericardium.[41] This means that the systemic sites are the best sites for the identification of pathogenic *H. parasuis*.

Most practitioners have the opinion that the problem is more apparent when there is predisposing viral infection, particularly PRRS, swine influenza, or PCV2. Although most practitioners would say that the prevalence of PRRS-associated *H. parasuis* infections have increased the natural occurrence of *H. parasuis*, experimental confirmation is lacking.[32,42] Only PRRS consistently increased the isolation of *H. parasuis* from the lung.[43]

On the other hand, both PRRS and *B. bronchiseptica* increase the colonization of the upper respiratory tract by *H. parasuis*. There is no additive effect here. There is no doubt that the occurrence of the vasculitis plays a part in the pathogenesis.

CLINICAL FINDINGS

In the naive herd and where specific-pathogen-free animals have entered commercial herds, sudden death may be the only feature. Some people are of the opinion that there may be polyserositic, arthritic, and meningitic forms.

The onset is sudden, with a fever, an unusual rapid, shallow dyspnea with noisy lung fields, an anxious expression, extension of the head, and mouth-breathing. There may be a serous nasal discharge and coughing may occur. Depression and anorexia are observed. The animals are very lame, stand on their toes, and move with a short, shuffling gait. All the joints are swollen and painful on palpation and fluid swelling of the tendon sheaths may also be clinically evident. In many animals there may be just a single joint affected and that is often the hock. A red to blue discoloration of the skin appears near death. Most cases die 2–5 days after the onset of illness. Animals that survive the acute stage of the disease may develop chronic arthritis, and some cases of intestinal obstruction caused by peritoneal adhesions occur. Meningitis occurs in some pigs, particularly when these are naive or where there is an acute onset, and is manifested by muscle tremor, paralysis and convulsions. Although Glasser's disease can occur in pigs of any age, weanling pigs are most commonly and most seriously affected. In chronic cases, pigs may lose part of an ear as a result of ischemic necrosis. There may be also wasting piglets who fade and die.

Another type of syndrome of necrosis of the masseter muscles was described[44] in which sows had swollen, cyanotic heads with *H. parasuis* isolated from the affected muscles. Purulent rhinitis has also been described.[45,46]

CLINICAL PATHOLOGY

The disease is essentially a polyserositis and arthritis and as a result the organism is recoverable from joint fluid and pleural exudate. Material aspirated from joints may be serous, fibrinous, or purulent. It may just be a few fibrin tags that have organized from an initial fibrinous exudate. The disease can be diagnosed serologically on the presence of precipitins in the serum of recovered pigs, and complement-fixing antibody can be detected following infection. But these are not reliable methods. In an experiment where 183 specific-pathogen-free pigs were given infections, the hemoglobin concentrations and hematocrit fell.[47] Leukopenia developed 1–2 days after infection, with leukocytosis later. Any changes in the cerebrospinal fluid were not related to the clinical signs. One of the common findings in *H. parasuis* infections is vitamin E deficiency, and this is most likely to be as a result of the toxic oxygen radical damage.

NECROPSY FINDINGS

In the main, Glasser's disease is associated with three main lesions: fibrinous polyserositis and arthritis, signs of septicemia, toxemia and in some cases no gross lesions at all.

In some cases all that is seen is a small amount of peritoneal fluid or a very thin fibrin strand (tag).

A serofibrinous or fibrinous pleuritis, pericarditis and peritonitis are usually present but the exudate is scanty in some cases. Pneumonia may also be apparent. There is inflammation and edema of the periarticular tissues and the joint cavities contain turbid fluid and flattened, discoid deposits of yellowish green fibrin. A suppurative rhinitis is also possible. A fibrinopurulent meningitis is common. In specific-pathogen-free pigs, the lesions may be minimal and only successful isolation of the organism permits the differentiation of Glasser's disease from other causes of sudden death. The distinction may be a difficult one because of the fastidious culture requirements of *H. parasuis*. Eventually, all surfaces are covered with a thick mat of fibrin where the individual organs may be difficult to recognize. This eventually becomes fibrotic. The spleen and liver may be enlarged.

Histologically, acutely affected serosal surfaces are thickened by neutrophils entrapped in a matrix of fibrin. As these lesions age, fibrous adhesions may develop and lead to chronic pleuritis, arthritis and pericarditis. Such cases are often culture-negative, even when selective media are used. Most isolates are made from the lungs.

Samples for confirmation of diagnosis

Bacteriology

The collection of samples from animals that have been dead for several hours is not worth considering even at the best of times and certainly not when *H. parasuis* is suspected. An acutely affected live pig, freshly autopsied, will give much better results, especially if there is no overheating of the carcass postmortem or subsequent cooling, as the organism is temperature-sensitive. Transport media to the laboratory will also be beneficial in recovery rates. It is said that culture of the nasal swabs will be as rewarding as collecting tracheal swabs but it is likely that the larynx and below is normally sterile. What you isolate from the nasal cavity may then be a commensal population of largely nontypable species, whereas the trachea harbors the pathogenic forms. Other authors say that they are the same serotypes.[28] These authors have also found that a lower level of colonization was found in the litters of young sows, and a low level of colonization at weaning probably predisposed pigs to clinical disease in the nursery, assuming the presence of a virulent serotype.

Culture swabs from serosal surfaces, including joints and meninges. It is essential to collect samples from areas that are not enclosed in fibrin. Nasal swabs are more easily collected than tracheal but may indicate a different population of *H. parasuis*.[28] It is usually said that it is difficult to isolate from fluids[48] but is easier from the lesions. It is necessary to have a fresh pig with no antibiotic therapy. It may also be necessary to use Amies transport medium to preserve *H. parasuis* on the way to the laboratory.[49]

H. parasuis is a Gram-negative rod existing as a coccobacillus to long filamentous chains. There is usually a capsule but the expression of this is influenced by culture.[2] NAD orV factor is required for growth (chocolate agar or staph streak and then there is satellite growth). The availability of NAD may determine growth capabilities.[50,51] After 24–48 hours the colonies are small, translucent and nonhemolytic on chocolate agar.

Histology

Formalin-fixed brain, synovial membranes, liver, lung (LM). Immunohistochemistry can be used to show the organisms in the cytoplasm of neutrophils and macrophages in the lungs and in the mononuclear cells in the subscapular and medullary sinuses of the lymph nodes.[52] Immunofluorescence was observed on the bronchiolar epithelium in the alveoli and in the lung parenchyma.[53]

Serology

Recently an indirect hemagglutination test has been described for the serotyping of field isolates.[49] A new indirect hemagglutination technique has just been described[21] and it is rapid and effective. It is also much more sensitive than the immunodiffusion test.

DIAGNOSIS

The first improvement in the diagnosis of *H. parasuis* occurred with the development of an oligonucleotide-specific plate hybridization assay[54,55] that could be used on the nasal swabs. The assay detects fewer than 100 cfu/mL in a pure culture and gives a positive result when *H. parasuis* is present in the ratio of $1:10^3$–10^4 in a mixed culture. The assay is more sensitive than culture for detection of *H. parasuis* in nasal swabs.

In-situ hybridization[56] will demonstrate a patchy to multifocal distribution of *H. parasuis* in the lung.

A repetitive-element-based polymerase chain reaction (rep-PCR) has been developed,[19,57] which is a technique that compares very favorably with traditional microbiology. The rep-PCR uses repetitive sequences within the bacterial genome to produce strain-specific fingerprints, allowing comparison and differentiation between *H. parasuis* strains. This enables comparison of these strains and allows the source of virulent strains to be identified.

Another new technique is ERIC-PCR,[24] and this is very successful compared with conventional microbiological techniques. Identification and differentiation of *H. parasuis* using a species-specific PCR with subsequent DNA fingerprinting using the digestion of PCR products using Hind III endonuclease has been described.[58] This PCR-RFLP (restriction fragment length polymorphism) enabled eight patterns to be determined for the untypable strains.

Recently, a technique for the computer-based analysis of *H. parasuis* protein fingerprints has been described that is a considerable improvement on serotyping.[40] It was shown[59] that there is a high genetic diversity within the serovars. The authors described at least 12 different strains within the type 4 serovar and genetic diversity in the other serotypes as well. Nontypable isolates were divided into 18 genotypes. The major advantage of this technique is that there is no need for isolation, culture, and biochemical identification of the isolates. In addition, all strains can be identified, not just those of certain serotypes.[59] At the moment there is no direct demonstration of a linkage between PCR-RFLP, OMP patterns and serotyping and rep-PCR. In a recent study,[60] 32 strains were grouped into six serovars and 11 genotypes. This led to the hypothesis that *H. parasuis* strains with a similar distribution of repetitive sequences can express different antigens.

DIFFERENTIAL DIAGNOSIS

The unusual combination of arthritis, fibrinous serositis, and meningitis is sufficient to make a diagnosis of Glasser's disease, but differentiation from the many similar disease entities apparently caused by other agents can only be confirmed by bacteriological examination.

The disease may be confused with erysipelas, mycoplasma arthritis, and streptococcal arthritis on clinical examination. Mycoplasmosis is a much milder disease and is manifested principally by the presence of a few unthrifty or lame pigs in the litter just before weaning, rather than an acute outbreak with a high mortality. Differentiation between cases of Glasser's disease with meningitis and the other diseases of the nervous system in young pigs, especially streptococcal meningitis and Teschen disease, may not be possible without necropsy examination.

TREATMENT

Pigs are usually ill with this disease, so parenteral treatment is required first, followed by water medication, as they do not drink as they would usually, before in-feed medication is given when they are beginning to recover.

Treatment with penicillin, trimethoprim–sulfadoxine, or oxytetracycline is effective in the early stages of the disease.[61]

Resistance has been reported for penicillin[62] and numbers of strains are resistant to tetracyclines, erythromycin, and other aminoglycosides. Tilmicosin can be used for effective treatment[63,64] as it is concentrated in the macrophages and neutrophils.[65] These can migrate to the site of infection and therefore there may be higher levels of antibody in the tissue.[66]

Medication of the water supply for several days may also be effective.

CONTROL

Control is only possible if there is (1) diagnosis of infection, (2) identification of prevalent strains, (3) use of autogenous vaccines, and (4) management of new strains.[67]

Avoidance of undue exposure to adverse environmental conditions at weaning is recommended. Prophylactic dosing at the time of shipping or medication of feed or drinking water on arrival with the above-mentioned drugs may be of value in preventing outbreaks. Feeding a mixture of 3% sulfamonomethoxine and 1% trimethoprim at 160 and 240 ppm for 5 days and challenging with *H. parasuis* at 3 days prevented clinical disease and bacteria were not recovered.[68]

Maternal antibody does not interfere with vaccination of pigs at 1–3 weeks of age.[69]

A formalin-killed bacterin administered before weaning with two injections at 5 and 7 weeks of age has proved highly effective in preventing the disease.[70] A formalin-killed whole-cell culture bacterin developed in Ontario is effective in protecting 4-week-old pigs against experimental challenge with the organism.[71–73] A recent trial[74,75] showed that vaccinating sows at 80 and 95 days of pregnancy with a commercial bacterin containing *H. parasuis* 2, 3, and 5 was useful in reducing pneumonic lesions and arthritic joint changes in subsequently challenged piglets. Vaccination of piglets seem to have no effect. The vaccination of the sows seemed to have no effect on the colonization of the nasal mucosa by the *H. parasuis*, nor on the timing.[28]

Autogenous vaccines against homologous strains have been shown to work[69,72,73] but vaccination failures do occur.[1] There may be little cross-protection between strains.[2,72,76]

A new serotype 5 vaccination was described[70] and the subsequent challenge with serotypes 1, 12, 13, and 14 produced different responses in control pigs.

Vaccination has three important components.[77] First, there is the decision of commercial or autogenous vaccination and this depends on the strains in the field and whether they are in the commercial vaccine. Second, the timing of vaccination should take into account the length of persistence of maternal antibody and the peak of piglet mortality. If this peak is at 2–3 weeks then the sows should be vaccinated. The piglets should then be vaccinated at weaning and 2 weeks later. Third, since sow and piglet vaccination together is not recommended, as the sow's vaccination can produce maternal antibody that interferes with the piglet's active immunity, you should make a choice of one or the other.

Recently, the technique of introducing known populations of live *H. parasuis* to the young piglet shortly after birth, thus allowing a slow rate of acquisition of organisms, has been advocated.[33,59,78]

All-in/all-out by age is absolutely essential to prevent carry-over of infection and it is likely that nose-to-nose transmission is important, so solid partitions between different litters may help.

Diseases associated with bacteria – IV

19

Diseases associated with *Mycobacterium* spp.

TUBERCULOSIS ASSOCIATED WITH *MYCOBACTERIUM BOVIS*

Synopsis

Etiology *Mycobacterium bovis*
Epidemiology All age groups and species are susceptible but infection is predominantly in cattle and pigs. Infected cattle are the main source of infection but wildlife reservoirs are important in some regions and preclude the eradication of bovine tuberculosis in some countries. Inhalation is the major method of transmission
Clinical findings Progressive emaciation, capricious appetite, and fluctuating temperature with signs referable to localization such as respiratory disease, pharyngeal obstruction, reproductive disorder, mastitis. In pigs the disease is subclinical but tuberculous lesions in cervical lymph nodes
Clinical pathology Tuberculin testing. Single intradermal test is the official test in most countries with the comparative test for cattle suspected as false-positive reactors. Interferon-gamma testing
Necropsy findings Tuberculous granulomas may be found in any of the lymph nodes, or there may be generalized tuberculosis
Diagnostic confirmation Culture of organism or identification by polymerase chain reaction (PCR) or other molecular techniques
Control Test and slaughter. Most countries have official eradication programs

ETIOLOGY

Mycobacterium bovis is the specific cause of tuberculosis in cattle. Identification of the organism has been, until very recently, dependent on laborious determinations of cultural characteristics and susceptibility to therapeutic agents. Exact definition of mycobacteria is now possible by nucleic acid probes and molecular techniques.[1]

In addition, a new species, *Mycobacterium bovis* subsp. *caprae* previously classified as *Mycobacterium tuberculosis* subsp. *caprae* has been identified as a cause of infection in goats and humans in Spain and goats, cattle, deer, and swine in Europe.[2]

EPIDEMIOLOGY

Occurrence

All species, including humans, and age groups are **susceptible** to *M. bovis*, with cattle, goats, and pigs most susceptible and sheep and horses showing a high **natural resistance**. In developed countries that have had rigorous TB control programs in place for many years, tuberculosis in animals is now a rarity, with occasional severe outbreaks occurring in a small group of herds. The presence of the disease is usually signaled by detection in carcasses at abattoirs.

Source of infection

Cattle

Infected cattle are the **main source** of infection for other cattle. Organisms are excreted in the exhaled air, in sputum, feces (from both intestinal lesions and swallowed sputum from pulmonary lesions), milk, urine, vaginal and uterine discharges, and discharges from open peripheral lymph nodes. Animals with gross lesions that communicate with airways, skin, or intestinal lumen are obvious disseminators of infection. Cattle in the early stages of the disease, before any lesions are visible, may also excrete viable mycobacteria in nasal and tracheal mucus.[3] In experimentally infected cattle excretion of the organism commences about 90 days after infection.[4]

Wildlife reservoirs

A large number of wildlife and feral species are naturally infected with *M. bovis*.[5,6] While most wildlife and feral animals are unimportant as sources for infection to cattle, in some areas of the world certain wildlife species appear to be a significant maintenance host and reservoir for infection in cattle. This reservoir escapes traditional test and slaughter control programs and results in regions where the disease remains endemic in cattle herds.

- In areas of south-west **England** and the Republic of **Ireland** infected badgers (*Meles meles*) are significant in the epidemiology of the disease in cattle and infection of cattle is believed to be from badger urine contamination of pastures.[7,8] Badgers have also been found to make nocturnal visits to farm buildings and cattle troughs to feed during which they defecate and urinate directly onto the cattle feed[9]
- In **New Zealand** infection occurs in the brush-tail possum (*Trichosurus vulpecula*) and produces lesions in peripheral lymph nodes with discharging sinuses. Much of New Zealand's residual problem with bovine tuberculosis is in cattle running on the pasture–bush margin where there is ample opportunity for cattle–possum contact. Infection to cattle is believed to occur when curious cattle sniff moribund possums[10,11]
- Mule deer (*Odocoileus hemionus*), white tailed deer (*O. virginianus*), elk (*Cervus elaphus canadensis*) and bison (*Bison bison*) in **North America**,[12,13] and red deer in Great Britain and Ireland can all act as maintenance hosts and in some regions spread infection to cattle through comingling or sharing of winter feed resulting in foci of herd infections[14,15]
- Buffaloes (*Syncerus caffer*) in **South Africa**[16] and water buffaloes (*Bulbalis bulbalis*) in **Australia** can also act as maintenance hosts in these countries.

Methods of transmission

Commonly, entry is effected by inhalation or ingestion. **Inhalation** is the almost invariable portal of entry in housed cattle, and even in those at pasture it is

considered to be the principal mode of transmission.

Ingestion

Infection by ingestion is possible at **pasture** when feces contaminate the feed and communal **drinking water** and **feed troughs** but a large infective dose is required. Under natural conditions, stagnant drinking water may cause infection up to 18 days after its last use by a tuberculous animal, whereas a running stream does not represent an important source of infection to cattle in downstream fields.

The **survival** of the organism in the environment is influenced by temperature, moisture, exposure to the desiccating effect of sunlight, and ultraviolet light. The organism can survive for long periods in feces and soil but most studies show that survival on pasture is measured in weeks rather than months[10] and that environmental contamination of pasture is **not of major importance** in the epidemiology of the disease in cattle.[17]

Other routes

The drinking of **infected milk** by young animals is a common method of transmission where the disease is endemic, but mammary infection occurs late in the course of the disease and is less common in countries with advanced control programs. Other uncommon routes of infection include **intrauterine infection** at coitus, by the use of infected semen or of infected insemination or uterine pipettes, and **intramammary** infection by the use of contaminated teat siphons or by way of infected cups of milking machines. The feeding of **tuberculous cattle carcasses** to pigs has also caused a severe outbreak of the disease. Unusual sources of infection are infected cats, goats, or even humans. Stockmen with genito-urinary infections have transmitted infection to cattle through urinating in the cattle environment.[18]

Experimental reproduction

Pulmonary disease with typical tuberculous lesions in the pulmonary parenchyma and tracheobronchial and mediastinal lymph nodes can be produced by aerosol delivery of *M. bovis* to cattle.[19]

Risk factors

Environment risk factors

Housing predisposes to the disease, as does high stocking intensity and a large number of animals on a farm[20] so that the disease is more common and serious where these forms of husbandry are practiced. The closer the animals are in **contact** the greater is the chance that the disease will be transmitted. In spite of the low overall incidence in countries where cattle are at pasture all the year round, individual herds with 60–70% morbidity may be encountered.

Amongst beef cattle the degree of infection is usually much lower because of the open range conditions under which they are kept. However, individual beef herds may suffer a high morbidity if infected animals are introduced and large numbers of animals have to drink from stagnant water holes, especially during dry seasons.

Host risk factors

Zebu (*Bos indicus*) type cattle are thought to be much more resistant to tuberculosis than European cattle, and the effects on these cattle are much less severe but under intensive feedlot conditions a morbidity rate of 60% and a depression of weight gain can be experienced in tuberculous Zebu cattle.

In **pigs**, disease levels reflect those in the local cattle population from which the infection derives either by the ingestion of dairy products or by grazing over the same pasture as cattle. The lower relative prevalence in pigs is due to a number of factors, particularly the tendency of the disease to remain localized in this species and the early age of slaughter. Prevalence is higher in older pigs. When the disease is common among dairy cattle in an area, 10–20% of the local pigs are likely to be infected. A high prevalence has been observed in pigs bedded on shavings infected with *M. bovis*.

Feral pigs can be infected but the prevalence also reflects the prevalence in local cattle populations and they appear to be end-hosts.[21]

Goats are quite susceptible and if they are maintained in association with infected herds of cattle the incidence may be as high as 70%. **Sheep** have always been considered to be resistant, but experience in New Zealand has shown that the disease can be quite prevalent in this species with up to 5% of flocks being infected,[22] probably due to a high prevalence in local cattle and possums. Tuberculosis can be a problem in **farmed deer**.[6]

In **horses** the disease occurs rarely, largely due to limited exposure to infection, but natural resistance also appears to play a part.

Tuberculosis may also be encountered in elk, wild deer of various species, water buffalo, camels, bison, wild carnivores, monkeys and other wild fauna, and birds. Most are dead end-hosts but some may act as important reservoirs of infection for cattle as mentioned earlier.

Pathogen risk factors

The causative organism is moderately resistant to heat, desiccation, and many disinfectants. It is readily destroyed by direct sunlight unless it is in a moist environment. In warm, moist, protected positions, it may remain viable for weeks.

Economic importance

Tuberculosis occurs in every country of the world and is of major importance in dairy cattle. It is under strict control in most developed countries but is still a major cause of loss in many less well-endowed countries. Apart from actual deaths, infected animals lose 10–25% of their productive efficiency. Because the disease is relatively benign in pigs, major financial loss from clinical disease does not occur but at slaughter organs with tuberculous lesions are discarded and the entire carcass may be condemned or require heat treatment before being released for human consumption.

Zoonotic importance

The current increasing incidence of tuberculosis in humans, particularly in immunocompromised humans, has given a renewed interest in the zoonotic importance of *M. bovis*, especially in developing countries[23] and the ease and frequency of the spread of tuberculosis from animals to humans in an uncontrolled environment makes this an **important zoonosis**. *M. bovis* can be responsible for 5 to 10% of human tuberculosis with higher rates in children in some areas.[24] Infection in humans occurs largely through consumption of infected raw milk and raw milk products by children but spread can also occur by inhalation. Transmission to humans can be significantly reduced by pasteurization of milk but only complete eradication of the disease can protect the farmer and his family.

Transmission from cattle to humans in developed countries is an unlikely event nowadays but still occurs and resurgence of the disease in association with wildlife reservoirs has resulted in a spillover into human populations.[25,26]

The widespread occurrence of tuberculosis in exotic animals maintained in captivity adds to the public health importance of these infections.

PATHOGENESIS

Tuberculosis spreads in the body by two stages, the primary complex and post-primary dissemination. The **primary complex** consists of the lesion at the point of entry and in the local lymph node. A lesion at the point of entry is common when infection is by inhalation. When infection occurs via the alimentary tract, a lesion at the site of entry is unusual, although tonsillar and intestinal ulcers may occur. More commonly the only observable lesion is in the pharyngeal or mesenteric lymph nodes.

A visible primary focus develops within 8 days of entry being effected by the bacteria. **Calcification** of the lesions commences about 2 weeks later. The developing necrotic focus is soon

surrounded by granulation tissue, monocytes, and plasma cells and the pathognomonic 'tubercle' is established. Bacteria pass from this primary focus, which is in the respiratory tract in 90–95% of cases in cattle, to a regional lymph node and cause the development of a similar lesion there. The lesions in the lungs in cattle occur in the caudal lobes in 90% of cases.[27] In calves fed tuberculous milk the primary focus is likely to be in the pharyngeal or mesenteric lymph nodes, with hepatic lesions as the major manifestation of post-primary spread.

Post-primary dissemination from the primary complex may take the form of acute miliary tuberculosis, discrete nodular lesions in various organs, or chronic organ tuberculosis caused by endogenous or exogenous reinfection of tissues rendered allergic to tuberculoprotein. In the latter case there may be no involvement of the local lymph node. Depending upon the sites of localization of infection, clinical signs vary but, because the disease is always progressive, there is the constant underlying toxemia which causes weakness, debility, and the eventual death of the animal.

In **cattle, horses, sheep**, and **goats**, the disease is progressive and, although generalized tuberculosis is not uncommon in **pigs**, localization as non-progressive abscesses in the lymph nodes of the head and neck is the most common finding.

CLINICAL FINDINGS

Cattle

Although signs referable to localization in a particular organ usually attract attention to the possible occurrence of tuberculosis, some general signs are also evident. Some cows with extensive miliary tubercular lesions are clinically normal but in most cases **progressive emaciation** unassociated with other signs occurs, and should arouse suspicion of tuberculosis. A **capricious appetite** and **fluctuating temperature** are also commonly associated with the disease. The hair coat may be rough or sleek. Affected animals tend to become more docile and sluggish but the eyes remain bright and alert. These general signs often become more pronounced after calving.

Lungs

Pulmonary involvement is characterized by a chronic cough due to bronchopneumonia. The **cough** is never loud or paroxysmal, occurring only once or twice at a time and is low, suppressed, and moist. It is easily stimulated by squeezing the pharynx or by exercise and is most common in the morning or in cold weather. In the **advanced stages** when much lung has been destroyed, **dyspnea** with increased rate and depth of respiration becomes apparent. At this stage, abnormalities may be detected by auscultation and percussion of the chest. Areas with no breath sounds and dullness on percussion are accompanied by areas in which squeaky crackles are audible, often most audible over the caudal lobes. Tuberculous **pleurisy** may occur but is usually symptomless because there is no effusion. Involvement of the bronchial lymph nodes may cause dyspnea because of constriction of air passages, and enlargement of the mediastinal lymph node is commonly associated with recurrent and then persistent ruminal tympany.

Intestine

Rarely tuberculous ulcers of the small intestine cause diarrhea. Retropharyngeal lymph node enlargement causes **dysphagia** and **noisy breathing** due to **pharyngeal obstruction**. Pharyngeal palpation, or endoscopy, reveals a large, firm, rounded swelling in the dorsum of the pharynx. Chronic, painless swelling of the submaxillary, prescapular, precrural, and supramammary lymph nodes is relatively rare.

Uterus

Reproductive disorders include uterine tuberculosis which is uncommon with bovine strains except in advanced cases. Spread by contiguity from the uterus causes peritonitis, bursitis, and salpingitis, the lesions in the salpinx taking the form of small enlargements containing a few drops of yellow fluid. In tuberculous metritis, there may be **infertility**, or conception may be followed by recurrent **abortion** late in pregnancy, or a live calf is produced which in most cases dies quickly of generalized tuberculosis. Lesions similar to those of brucellosis occur on the placenta.

In cows that fail to conceive, there may be a chronic purulent discharge heavily infected with the organism and the condition is very resistant to treatment. A number of cows will have an associated tuberculous vaginitis affecting chiefly the ducts of Gartner. Rare cases of tuberculous orchitis are characterized by the development of large, indurated, painless testicles.

Mastitis

Tuberculous **mastitis** is of major importance because of the danger to public health, and of spread of the disease to calves, and the difficulty of differentiating it from other forms of mastitis. Its characteristic feature is a marked **induration** and hypertrophy which usually develops first in the upper part of the udder, particularly in the rear quarters. **Palpation** of the supramammary lymph nodes is essential in all cases of suspected tuberculous mastitis. Enlargement of the nodes with fibrosis of the quarter does not necessarily indicate tuberculosis but enlargement without udder induration suggests either tuberculosis or lymphomatosis. In the early stages, the **milk** is not macroscopically abnormal but very fine floccules appear later and settle after the milk stands, leaving a clear, amber fluid. Later still the secretion may be an amber fluid only.

Pigs

Tuberculous lesions in cervical lymph nodes usually cause **no clinical abnormality** unless they rupture to the exterior. Generalized cases present a syndrome similar to that seen in cattle although tuberculous involvement of the meninges and joints is more common.

Horses

The commonest syndrome in horses is caused by involvement of the cervical vertebrae in which a painful osteomyelitis causes stiffness of the neck and inability to eat off the ground. Less common signs include polyuria, coughing due to pulmonary lesions, lymph node enlargement, nasal discharge, and a fluctuating temperature.

Sheep and goats

Bronchopneumonia is the commonest form of the disease in these species and is manifested by cough and terminal dyspnea. In some goats intestinal ulceration, with diarrhea, and enlargement of the lymph nodes of the alimentary tract occur. In both species the disease is only slowly progressive, and in affected flocks many more reactors and necropsy-positive cases are often found than would be expected from the clinical cases which are evident. In kids the disease may be more rapidly progressive and cause early death.

CLINICAL PATHOLOGY

Because of the universal dependence on the tuberculin test for diagnosis, and the policy of slaughtering all positive reactors whether they are open cases or not, few clinicopathological tests are carried out. Sputum or discharges may be examined by inoculation into guinea-pigs but improved cultural techniques, and the use of nucleic acid probes[28] make this unnecessary.

The basis of all tuberculosis eradication schemes to date is the **tuberculin test** and a knowledge of the various tests used, their deficiencies and advantages, is essential. It should be remembered, however, that clinical examination is still of value, particularly in seeking out the occasional advanced cases which do not give a positive reaction to a tuberculin test.

Single intradermal (SID) test

This test is applied by the intradermal injection of bovine tuberculin PPD into a skin fold and the subsequent detection of swelling as a result of delayed hypersensitivity. The tuberculin is prepared from cultures of *M. tuberculosis* or *M. bovis* grown on synthetic media. **Bovine tuberculin** is more potent and specific.[29] The reaction is read between 48 and 96 hours after injection with a preference for 48–72 hours for maximum sensitivity and at 96 hours for maximum specificity, and a positive reaction constitutes a diffuse swelling at the injection site.

Site of injection

In some countries the injection is made into an anal or caudal fold at the base of the tail. In others it is made into a cervical fold, a fold of skin picked up in the center of the lateral aspect of the neck. The cervical fold test is thought to provide greater sensitivity, the caudal fold providing the greater specificity. An additional injection is sometimes made into the lip of the vulva at the mucocutaneous junction. In **England and Europe** the injection is made into the skin of the neck and the injection site is measured with calipers. The subjective method of palpation is more accurate. It also permits a decision to be shaded by the nature of the lesion. Neck skin is more sensitive than that of the tail area but it is necessary to restrain each animal and measure all reactions carefully. In the **United States, Canada, Australia**, and **New Zealand** the site is the caudal fold of the tail.

Dose

The exact dose for the particular tuberculin should be strictly adhered to when the cervical skin test is used. In the United States, 0.1 mL is recommended for herds of unknown status and 0.2 mL in known infected herds when cases with low sensitivity are to be carefully sought. The method of injection of tuberculin also has some importance when the cervical site is used. A careful intradermal injection produces the largest swelling and a quick thrust the least. Variations in technique appear to have little effect on the size of reaction when the caudal fold is used.

Disadvantages of SID

The main disadvantage of the SID test is its lack of specificity and the number of **no-visible-lesion reactors** (NVLs) which occur. Mammalian tuberculin is not sufficiently specific to differentiate between reactions due to infection with *M. bovis* and infection with *M. avium*, *M. tuberculosis*, *M. paratuberculosis* (including vaccination), or *Nocardia farcinicus*. The maximum permissible rate of NVL reactors is 10% and when this rate is exceeded, tests other than the SID test should be used.

Other disadvantages of the SID test include failure to detect cases of minimal sensitivity such as may occur in the early or late stages of the disease, in **old cows** and in cows which have **recently calved**. This failure to detect tuberculous animals can be of considerable importance and must receive close attention when reactors are detected at an initial test. Serological tests to detect these cases of minimal sensitivity are described below. Other field tests devised to overcome these deficiencies of the SID test are the short thermal, Stormont, and comparative tests. Of these, the comparative test is most commonly used.

Short thermal test

Intradermal tuberculin (4 mL) is injected subcutaneously into the neck of cattle which have a rectal temperature of not more than 39°C (102°F) at the time of injection and for 2 hours later. If the temperature at 4, 6, and 8 hours after injection rises above 40°C (104°F), the animal is classed as a positive reactor. The temperature peak is usually at 6–8 hours and is generally over 41°C (105.8°F). Occasional deaths due to anaphylaxis occur at the peak of the reaction.

Stormont test

The test is performed similarly to the single intradermal test in the neck with a further injection at the same site 7 days later. An increase in skin thickness of 5 mm or more, 24 hours after this second injection, is a positive result. The increased sensitivity begins at the 5th day, is at its peak at the 7th and ends on the 12th day after the injection. Cattle infected with *M. avium* do not give a positive reaction but 'skin tuberculosis' cases do. It is more accurate than the single intradermal test but a practical difficulty is the necessity for three visits to the farm. Special purified protein derivative (PPD) tuberculin of a specified potency must be used to fulfill the requirements of the test.

Comparative test

Where the presence of **Johne's disease** or **avian tuberculosis** is suspected or **'skin tuberculosis'** is apparent, non-specific sensitization must be considered, and a comparative test used. Transitory sensitization may occur in cattle due to the presence of human tuberculosis in their attendants but the comparative test will not differentiate the sensitivity from that due to bovine strain infection.

The comparative test depends on the greater sensitivity to homologous tuberculin. **Avian and bovine tuberculin** are injected simultaneously into two separate sites on the same side of the neck, 12 cm apart and one above the other, and the test is read 72 hours later. Care must be taken in placing the injections as sensitivity varies from place to place in the skin. The greater of the two reactions indicates the organism responsible for the sensitization. The test is not generally intended for primary use in detecting reactors but only to follow up known reactors to determine the infecting organism. Its use as a primary test is recommended when a high incidence of avian tuberculosis or Johne's disease is anticipated, or when vaccination against Johne's disease has been carried out. The comparative test is adequate to differentiate between vaccination against Johne's disease and tuberculosis and the distinction is easier the longer the time between vaccination and testing.

Special aspects of sensitivity to tuberculin

Site of injection

Sensitivity to tuberculin injected intradermally varies considerably from site to site on the body. In cattle the relative sensitivities of different areas to tuberculin and to johnin have been determined as follows: back 1, upper side 1.75, lower side 2.5, neck 2.75–3. The cervical area is also much more sensitive than the anal fold, and has the advantages that reactions are more pronounced, animals can be retested immediately, and the area is more sanitary. Its disadvantages are that restraint of each animal is necessary and the proportion of NVL reactors increases.

Potency of tuberculins

For maximum specificity tuberculin prepared from *M. bovis* is recommended, and for preference it should be a **purified protein derivative** (PPD). One of the important problems in tuberculin testing is deciding the optimum amount of tuberculin to be used to get maximum specificity. A dose rate between 5000 and 10 000 tuberculin units (0.1 mL tuberculin containing 0.1 or 0.2 mg of bovine PPD) is considered to be most suitable. The 0.2-mg dose is preferred as detecting more infected animals. For farmed deer a special tuberculin is used which contains 2 mg tuberculin/mL.

Desensitization during tuberculin testing

When a suspicious reactor is encountered, the question of when to retest is complicated by the phenomenon of desensitization caused by the absorption of tuberculin and other foreign proteins. Desensitization is more marked and of longer duration after a subcutaneous than after an intradermal injection. After a SID test the period of **desensitization** is short but, as a practical procedure, it is recommended that animals giving a suspicious result to

a SID test be not retested before 60 days. However, after a Stormont test desensitization may persist for as long as 6 months.

The desensitization phenomenon can be used to obscure a positive reaction. If tuberculin is injected so that the test is made in the desensitized period, no reaction will occur in infected animals.

Postparturient desensitization

Tuberculous cattle go through a period of desensitization immediately before and after calving and as many as 30% give false-negative reactions returning to a positive status 4–6 weeks later. The loss of sensitivity is probably due to the general immunological hyporeactivity that occurs associated with parturition. Calves drinking colostrum from infected dams give positive reactions for up to 3 weeks after birth even though they may not be infected.

Anergy

Anergic animals are those with visible lesions of tuberculosis but which do not react to a cutaneous, delayed hypersensitivity test. The number of these can be reduced by being careful to inject sufficient tuberculin (0.2 mg) at the right site, and to read the test at 48–72 hours. There is still a residuum of cases which do not respond, especially those with extensive pulmonary involvement.

Summary of testing procedures in cattle

In summary, it is usual to use the single intradermal test as a routine procedure.

Annual testing of all cattle, quarantine of test-positive herds, and a movement ban into TB-free areas has historically been effective in TB control schemes.[30] The sensitivity and specificity of the skin test is moderately high but false-positive and false-negative reactions occur.[31]

False-positive reactions (no gross lesion reactors) may be given by:

- Animals sensitized to other mycobacterial allergens, including those of human or avian tuberculosis or Johne's disease, relatively non-pathogenic mycobacteria, e.g. skin tuberculosis, and, by ingestion, non-pathogenic mycobacteria in permanent waters inhabited by birds, or poultry litter fed to cattle when the birds are infected with *M. avium*
- Animals sensitized to other allergens, e.g. *Nocardia farcinicus*
- Animals injected with irritants at the injection site prior to reading of the tuberculin test, when compensation rates for reactors exceed true cattle prices.

The proportion of false-positive reactions is likely to increase as control programs progress towards eradication and can undermine farmers' confidence in the control program. Reactors which are thought to be non-specific should be retested by the comparative test in the cervical region 7 days after the response to the caudal fold test. Alternatively cattle can be re-tested using the whole blood interferon-gamma assay 8–28 days after the skin test.

False-negative reactions may be given by:

- Advanced cases of tuberculosis
- Early cases until 6 weeks after infection
- Cows which have calved within the preceding 6 weeks
- Animals desensitized by tuberculin administration during the preceding 8–60 days
- Old cattle
- Low-potency tuberculin or bacterial contamination of the tuberculin
- Variable dose with multidose syringes.

Tuberculin testing in pigs

The most generally used method is the **SID test**, injecting 0.1 mL of standard potency mammalian tuberculin into a fold of skin at the **base of the ear**, but the test is relatively inaccurate in this species. The test is read 24–48 hours later and an increase in skin thickness of 5 mm or more constitutes a positive reaction. In positive animals the skin thickening often exceeds 10 mm and shows superficial necrosis and sloughing.

If the animal is infected with *M. avium*, the maximum skin thickening may not occur until 48 hours after injection. When no attempt is being made to determine the type of infection, mixed avian and mammalian tuberculins may be used and the test read at 24–48 hours. If avian tuberculin alone is used, the test should be read at 48–72 hours and an increase in skin thickness of 4 mm is classed as positive.

Many suspicious reactions occur in pigs because of the tendency of lesions to regress and the sensitivity to tuberculin to diminish, maximum sensitivity occurring 3–9 weeks after infection. A **retest** in 6–8 weeks should determine whether or not the disease is progressing. Although positive reactors may in time revert to a negative status, there may be macroscopic lesions in these animals at necropsy. However, viable organisms are not usually recoverable from the lesion, the infection apparently having been overcome.

The Stormont test is unlikely to have any application in pigs because there is no local increase in skin sensitivity after one injection. Some decrease in skin sensitivity after parturition occurs in sows infected with *M. bovis* but may not occur when the infection is associated with *M. avium*. Comparative tests work efficiently in this species with little or no reaction to heterologous tuberculin.

Tuberculin testing in other species

Horse

The results obtained with subcutaneous and intradermal tuberculin tests are very erratic and must be assessed with caution especially when the test is positive because many **false-positives** occur. The horse appears to be much more sensitive than cattle to tuberculin and much smaller doses of standardized tuberculin are required. As little as 0.1 mL of PPD tuberculin is sufficient to elicit a positive reaction and testing may provoke an **anaphylactic reaction**. No safe recommendations can be made on tests in this species because of lack of detailed information, but the occurrence of a systemic reaction with a positive cutaneous test can be accepted as indicating the presence of infection.

Sheep and goats

The single intradermal test is relatively inaccurate, some tuberculous animals giving negative reactions, although on the basis of results achieved in experimentally infected goats[32] it is adequate. The test injection is usually given in the **caudal fold** as in cattle but injection into the skin of the inside of the **thigh** of sheep is also satisfactory. An increase in thickness of 5 mm in the fold constitutes a positive reaction.

Serological tests for diagnosis of tuberculosis

In the final stages of a tuberculosis eradication program the percentage of reactors, which are not in fact tuberculous, increases to the point where a more discerning test than the one based on cutaneous hypersensitivity is required. Most of the tests tried so far have been serological ones. Their aim is to identify anergic animals and cases sensitized by some other bacteria.

Serological tests including complement fixation, fluorescent antibody, direct bacterial agglutination, precipitin, and hemagglutination tests have been developed but have little potential value for the routine diagnosis of tuberculosis.

Early enzyme-linked immunosorbent assay (ELISA) tests to crude mycobacterial antigens had limited value but an ELISA which examines antibody to defined antigens of *M. bovis* before and after skin testing appears useful in detecting non-specific reactors.[33]

An in vitro assay of cell-mediated reactivity by detection and quantitation of γ-interferon known as the **interferon-γ assay** (IFN-γ) is licensed and commercially available in some countries. It is based on

the detection of IFN-γ liberated from white blood cells in whole blood cultures incubated with PPD tuberculin and has the advantage that tested cattle need only be handled once. It can detect infected cattle earlier in infection than can the skin test. It also has value in retesting skin-test-positive cattle that may be false-positive reactors but for this purpose should be used between 8 and 28 days after skin testing because assay reactions are diminished if conducted on samples taken at the 3 day reading re-visit after skin testing.[34,35]

Ideally the test should be set up in the laboratory on the same day as sampling or, at the most, after overnight storage of the blood.[31] Current testing is with *M. bovis* PPD which can contain cross-reacting antigens to other mycobacterial species and more specific and sensitive tests using antigens specific to *M. bovis* are being evaluated.[31,36]

NECROPSY FINDINGS

Cattle, sheep, and goats

These show similar lesions with a standard distribution. Tuberculous granulomas may be found in any of the lymph nodes, but particularly in bronchial, retropharyngeal, and mediastinal nodes.[37,38] In the lung, miliary abscesses may extend to cause a suppurative bronchopneumonia. The pus has a characteristic cream to orange color and varies in consistency from thick cream to crumbly cheese. Tuberculous nodules may appear on the pleura and peritoneum.

All localized lesions of tuberculosis tend to stimulate an enveloping fibrous capsule but the degree of encapsulation varies with the rate of development of the lesion. Generalized cases are denoted by the presence of **miliary tuberculosis** with small, transparent, shot-like lesions in many organs, or by pulmonary lesions which are not well-encapsulated and caseated. The presence of bronchopneumonia or hyperemia around pulmonary lesions is highly suggestive of active disease. Cases with tuberculous mastitis or discharging tuberculous metritis must also be considered as likely to be potent spreaders of the infection.

Chronic lesions are characteristically discrete and nodular, and contain thick, yellow to orange, caseous material, often calcified and surrounded by a thick, fibrous capsule. Although such lesions are less likely to cause heavy contamination of the environment than open lesions, affected animals are important as sources of infection. It should be noted that suspect cattle slaughtered as part of bovine tuberculosis eradication programs may be culture-positive and yet have no typical gross or microscopic lesions.[38]

Pigs

Generalized tuberculosis, with miliary tubercles in most organs, is seen in pigs but the common finding is localization in the tonsils, and the submaxillary, cervical, hepatic, bronchial mediastinal, and mesenteric lymph nodes. The nodes are markedly enlarged and consist of masses of white, caseous, sometimes calcified, material, surrounded by a strong, fibrous capsule and interlaced by strands of fibrous tissue. Because of the regressive nature of the disease in pigs, these lesions are often negative on culture.

Horses

The characteristic distribution of tubercules in horses includes the intestinal wall, mesenteric lymph nodes, and spleen. The cut surface of these firm nodules has a fleshy appearance similar to that of neoplastic tissue. There is also a tendency for lesions to develop in the skeleton, particularly the cervical vertebrae.

Histologically, there is some variation between the domestic species with regard to features such as mineralization and the degree of tissue necrosis. In some cases acid-fast bacilli may be difficult to demonstrate using conventional stains. A comparison of the infection in cattle and cervid species suggests that tuberculosis should be considered in cervids even when the lesions have a suppurative and necrotizing character, with a minimal granulomatous component.[39] Culture of *M. bovis* is difficult, time-consuming and poses a considerable public health risk. Methods such as immunoperoxidase staining and PCR can permit detection of the organisms while minimizing public health risks.

Samples for confirmation of diagnosis

- Bacteriology – affected lymph nodes, lung, granulomas from viscera (CULT (has special growth requirements), PCR)
- Histology – formalin-fixed samples of these tissues (LM, IHC, PCR).

Note the zoonotic potential of this organism when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

Because of the chronic nature of the disease and the multiplicity of signs caused by the variable localization of the infection, tuberculosis is difficult to diagnose on clinical examination. If the disease occurs in a particular area, it must be considered in the differential diagnosis of many diseases of cattle. In pigs the disease is usually so benign that cases do not present themselves as clinical problems and are found only at necropsy. The rarity of the disease in horses, sheep, and goats makes it an unlikely diagnostic risk except in groups which have had abnormally high exposure to infected cattle.

Mycobacteriosis is associated with the *M. avium–intracellulare* complex and atypical mycobacteria and *M. tuberculosis*

- Lung abscess due to aspiration pneumonia
- Pleurisy and pericarditis following traumatic reticulitis
- Chronic contagious bovine pleuropneumonia
- Upper respiratory disease
- Actinobacillosis
- Bovine leukosis
- Lymphadenopathy
- Other causes of mastitis.

TREATMENT

Because of the progress being made in the treatment of human tuberculosis with such drugs as isoniazid, combinations of streptomycin and *para*-aminosalicylic, and other acids, the treatment of animals with tuberculosis has undergone some examination and claims have been made for the efficiency of long-term oral medication with isoniazid both as treatment and as prophylaxis. It is not a favored option in eradication-conscious countries.

CONTROL

Eradication of bovine tuberculosis has been virtually achieved in many countries. The methods used have depended on a number of factors but ultimately the **test and slaughter policy** has been the only one by which effective eradication had been achieved.

Control on a herd basis

Control in a herd rests on removal of the infected animals, prevention of spread of infection, and avoidance of further introduction of the disease.

Tuberculin testing

Detection of infected animals depends largely upon the use of the tuberculin test. All animals over 3 months of age should be tested and positive reactors disposed of according to local legislation. Suspicious reactors are retested at intervals appropriate to the test used. At the **initial test**, a careful clinical examination should be conducted on all animals to insure that there are no advanced clinical cases which will give negative reactions to the test. Doubtful cases and animals likely to have reduced sensitivity, particularly old cows and those that have calved within the previous 6 weeks, may be tested by one of the special sensitivity or serological tests described above or re-tested subsequently. The comparative test should be used where infection with *M. paratuberculosis* or *M. avium* is anticipated or where a high

incidence of reactors occurs in a herd not showing clinical evidence of the disease.

Retesting

Until recently, if the incidence of reactors was high at the first test or if 'open' lesions were found at necropsy in culled animals, emphasis was placed on repeat testing at short intervals to avoid the situation in which the spread of the disease might overtake the culling rate. It is now thought that all animals with tuberculosis should be regarded as equally potent disseminators of the infection.[7] Retests of the herd should be carried out at 3-monthly intervals until a negative test is obtained. A further test is conducted 6 months later and if the herd is again negative, it may be classed as free of the disease. Subsequent check tests should be carried out annually.

Prevention of spread

Hygienic measures to prevent the spread of infection should be instituted as soon as the first group of reactors is removed. Feed troughs should be cleaned and thoroughly disinfected with hot, 5% phenol or equivalent cresol disinfectant. Water troughs and drinking cups should be emptied and similarly disinfected. Suspicious reactors being held for retesting should be isolated from the remainder of the herd. Separation of infected and susceptible animals by a double fence provides practical protection against spread of the disease.

It is important that calves being reared as **herd replacements** be fed on tuberculosis-free milk, either from known free animals or pasteurized. Rearing calves on skim milk from a communal source is a dangerous practice unless the skim milk is sterilized. All other classes of livestock on the farm should be examined for evidence of tuberculosis. **Farm attendants** should be checked as they may provide a source of infection.

If a number of reactors are culled, attention must be given to the possibility of **infection being reintroduced** with replacements, which should come from accredited herds. Failing this, the animals should be tested immediately, isolated and retested in 60 days. Infection from other herds should be addressed by preventing communal use of watering facilities or pasture, and by maintaining adequate boundary fences.

It is inadvisable to attempt a control program until it can be guaranteed that all animals can be gathered, identified, tested and segregated, a difficult proposition in cattle run on extensive range country with little manpower and few fences.

Control on an area basis

The method used to eradicate bovine tuberculosis from large areas will depend on the incidence of the disease, methods of husbandry, attitude of the farming community, and the economic capacity of the country to stand losses from a test and slaughter program.

Education

An essential first step is the prior education of the farming community. Livestock owners must be apprized of the economic and public health significance of the disease, its manifestations, and the necessity for the various steps in the eradication program. Eradication must also be compulsory since voluntary schemes always leave foci of infection. Adequate compensation must be paid to encourage full cooperation by way of payment for animals destroyed, or bonuses for disease-free herds or their milk or beef.

Staging

It is essential at the beginning of a program to determine the incidence and distribution of the disease by tuberculin testing of samples of the cattle population and a meat inspection service. **Eradication** can commence in herds and areas which have a low incidence of the disease. These will provide a nucleus of tuberculosis-free cattle to supply replacements for further areas as they are brought into the eradication scheme.

Vaccination

Vaccination may offer a major alternative to test and slaughter in the control of bovine tuberculosis but currently suffers from both lack of efficacy and the problem of vaccinated cattle reacting to current tests for TB. Vaccination may be used as a temporary measure when the incidence of tuberculosis is high and a routine test and slaughter program may be economically impossible until it is lowered, or when an eradication program cannot be instituted for some time but it is desired to reduce the incidence of the disease in preparation for eradication.[40]

BCG vaccination is the only method available for field use. Vaccination must be repeated annually and the vaccinated animal remains positive to the tuberculin test. Calves must be vaccinated as soon after birth as possible and do not achieve immunity for 6 weeks. The immunity is not strong and vaccinated animals must not be submitted to severe exposure. In field circumstances where the disease is prevalent, only modest results, if any, can be expected.[40–42]

There are a number of newer, prospective vaccines including subunit and synthetic peptide vaccines, antigenically improved BCG, attenuated mutants of *M. bovis* and protective antigens expressed in attenuated live vaccine vectors.[42] Detection of vaccinated cattle from naturally infected cattle could be possible with vaccine-specific antigens in the interferon-gamma assay.

Test and slaughter

When the overall incidence of tuberculosis is 5% or less, compulsory testing and the slaughter of reactors is the only satisfactory method of eradication. A combination of lines of attack is usually employed.

Accredited areas are set up by legislation, and all cattle within these areas are tested and reactors removed. **Voluntary accreditation** of individual herds is encouraged outside these areas. In some countries, focal points of extensive infection outside accredited areas have been attacked under special legislation.

When an area or country has been freed from the disease, quarantine barriers must be set up to avoid its reintroduction. Within the area, the recurrent cost of testing can be lessened by gradually increasing the inter-test period to 2 and then to 3 or even 6 years as the amount of residual infection diminishes. Meat inspection services provide a good observation point should any increase in incidence of the disease occur. Amongst range beef cattle it is usual to check samples of animals at intervals rather than the entire cattle population.

Problems in tuberculosis eradication

Complete eradication of tuberculosis has not really been achieved in any country. In many, a state of virtual eradication has been in existence for years but minor recrudescences occur. In the final stages of an eradication program a number of problems achieve much greater importance than in the early stages of the campaign. The major problems which arise are as follows.

No visible lesion reactors

The percentage of reactors with no gross lesions or no visible lesions (NVL) at slaughter rises steeply as the disease prevalence decreases. In part this occurs because gross examination has poor sensitivity for detection of infection, but it is also inevitable given the falling prevalence of disease and the specificity of the tuberculin test.[10,37] NVL reactors create administrative and public relations difficulties. Resolution of this problem awaits the validation of the interferon-gamma assay, or other accepted serological test.

'Breakdowns'

Individual herds which have been accredited after a number of free tests may be found to have the disease again, often with a very high incidence. These may be because an anergic carrier has been left in the herd, and tests have been too far apart, or because of a break in the security of the herd with infection from

purchased cattle or transmission between cattle in neighboring herds.[43]

'Traceback'

A principal source of information on the location of infected herds in the final stages of a program could be a traceback originating from infected animals at packing plants. It is often impossible, and a major advance would be a suitable method of **identifying individual animals** which could be utilized up to the killing floor. The two most popular methods are fabric labels stuck on the rump with skin contact glue, and wraparound plastic or metal tail-tags bearing an identification number for the farm of origin. They have two problems. They can be removed at the abattoir and reused; they fall off if the tail is docked, a popular practice in some areas. Electronic identification might solve this problem but meets political and other resistance in many countries. Recent experience with bovine spongiform encephalopathy and other concerns for food safety will likely remove this resistance and most countries have or are developing effective traceback programs.

Large herds

Another kind of difficulty in eradication is where cattle are run under very extensive conditions on **large ranches** or stations as in North America, South America, and Australia. There can be difficulty in insuring a complete muster and there is a great need for a test that does not require that cattle be held in a mustering site for 3 days before the test is read. Problems with continuing infection also occur in **large intensive dairies** where the policy is test and cull, and the whole dairy can not be depopulated at one time.

Wildlife reservoirs

Spread to cattle from wild fauna is a major problem in the UK where badgers and deer are important sources of infection, in New Zealand, where the brush-tailed possum plays the same role, and a risk from deer exists in several countries. In New Zealand, the possum is considered a pest, does considerable damage to the ecosystem, and possum control programs are accepted. However, the badger in Britain, and deer in most countries, are protected species and suitable control programs, acceptable to animal protectionists, are difficult to negotiate in this sensitive area of public relations.[42,44] DNA fingerprinting can establish sources of infection and the importance of wildlife reservoirs to cattle.[1,45]

Control of tuberculosis in pigs

M. bovis infection in pigs usually results from the feeding of infected milk, skim milk or whey to pigs, or allowing cattle and pigs to graze the same pasture. The first step in the control of tuberculosis in a pig herd is to remove the source of infection, and then to test and remove the reacting animals, not an efficient procedure because of the relative inaccuracy of the tuberculin test in this species. The non-progressive nature of the disease means that transmission between pigs is unlikely to occur to a significant extent except perhaps in breeding animals.

MYCOBACTERIOSIS ASSOCIATED WITH *MYCOBACTERIUM AVIUM–INTRACELLULARE* COMPLEX AND WITH ATYPICAL MYCOBACTERIA

Etiology *Mycobacterium avium–intracellulare* complex and other mycobacteria
Epidemiology Ubiquitous in nature. Infection by ingestion. High concentration can build up in animal bedding of various types. Domestic or wild birds are a source of classic avian tuberculosis serovars
Clinical findings Most infections are of the draining lymph nodes of the alimentary tract, are subclinical, but can result in carcass condemnation. Generalized cases manifest with chronic weight loss and diarrhea
Clinical pathology Tuberculin testing in cattle and swine. Culture, PCR
Necropsy findings Microgranulomas, with or without caseation, in lymph nodes
Control Reduction of environmental contamination

ETIOLOGY

The *M. avium* complex is comprised of *M. intracellulare* and the subspecies of *M. avium*, which are *M. avium* subsp. *avium*, *M. avium* subsp. *paratubercosis*, and *M. avium* subsp. *sylvaticus*. *M. avium* subsp. *paratubercosis* is the cause of Johne's disease and is discussed elsewhere.

Mycobacteriosis is associated with members of the *Mycobacterium avium–intracellulare* complex (*M. avium* subsp. *avium* and *M. intracellulare*), and occasionally by other less well-defined mycobacterial species such as *M. kansasii*, *M. chelonae*, *M. fortuitum*, *M. aquae*, *M. cookii*, and *M. scrofulaceum*. Accuracy in the identification of these organisms has been enhanced by the use of modern molecular techniques, but the epidemiology of infection with most is poorly understood.

The *M. avium–intracellulare* complex consists of 28 serovars and two species. Currently, serotypes 1–6, 8–11 and 21 are *M. avium* and serotypes 7, 12–20, and 25 are *M. intracellulare*. The remaining serotypes do not fit with either species.[1,2] The classical *M. avium* serovars 1–3 are the cause of tuberculosis in domestic and wild birds. Serovars 1, 2, 4–6, 8–10, and 21 appear to be the most common in infections of domestic livestock. Individual

pigs may be infected with more than one serovar.[3] Recently it is proposed to restrict the designation of *M. avium* subsp. *avium* to the 'bird-type' isolates serotypes 1–3 and to use the designation *M. avium* subsp. *hominissuis* for serotypes 4–6, 8–11, and 21.[4]

The *M. avium–intracellulare* complex comprises ubiquitous opportunist pathogens of a large range of species, and in livestock have most importance in swine. Tuberculosis associated with these organisms in livestock is usually not manifest clinically and is not a major disease problem, but infected animals react to the mammalian **tuberculin test**, creating difficulty in *M. bovis* tuberculosis eradication programs. Outbreaks in pig herds can cause significant losses because of **carcass condemnation**. In pigs, a significant proportion of reactors to tuberculin are due to infection with organisms of this complex and infected cattle and pigs are potential sources of infection for the increasing number of *M. avium* complex infections in humans.

EPIDEMIOLOGY

Occurrence

Lymphadenitis in pigs associated with these organisms is reported from all continents.[3]

Source and transmission

Organisms of the *M. avium–intracellulare* complex are **ubiquitous** in nature and can be isolated from soil, plants, water, and animal feed and animal bedding. Infected birds nesting in animal or feed buildings are the most common source of *M. avium* subsp. *avium* of serotypes 1–3, and contaminate feed and water supplies. In contrast, isolates of *M. avium* subsp. *hominissuis* (serotypes 4–6, 8–11, and 21) are commonly isolated from the environment and can be isolated from various species of flies and beetles that inhabit the ground, bedding and feed in farm environments.[5–7] The organisms are resistant to acidic environments which allows them to survive in the acidic, humid environments of peat bogs and decomposed feces and the lipopolysaccharide bacterial wall promotes survival in environments inside and outside barns for extended periods of time.[7]

Ingestion appears the normal route of infection and pigs infected with some serovars excrete the organism in **feces**. In pigs the use of dirt **floors** or deep litter, rather than bare concrete or slats, increases the risk of infection and the development of macroscopic lymphadenitis in large numbers of pigs. The length of time that pigs are kept on the litter is also important and severe outbreaks can occur in pigs kept on litter for the entire period from weaning to slaughter. Sawdust, straw, peat, and wood shavings have all been found to be highly infected. Serovars 4 and 8, in particular, have been associated with infection from bedding.[8,9] Sphagnum moss infected with *M. cookii*, and environmental exposure to other mycobacteria, may result in sensitization of cattle to *M. bovis* tuberculin.[10,11]

The classic *M. avium* serovars 1–3 are the cause of tuberculosis in domestic and wildbirds which are infected by ingestion of contaminated feed or soil and excrete large numbers of organisms in feces. Although infection in domestic livestock is commonly contracted from domestic poultry, from soil-borne infection, or from pen floors or feeds contaminated by wild birds, pig to pig transmission can also occur.[12]

Economic importance

Clinical disease is not important, but at slaughter organs with tuberculous lesions are discarded and the entire carcass may be condemned or require heat treatment before being released for human consumption.

Zoonotic importance

Infections with atypical mycobacteria are not uncommon in humans and have higher prevalence in immunodeficient humans. Members of the *Mycobacterium avium–intracellulare* complex cause both pulmonary infections in immunocompetent individuals and disseminated diseases in acquired immunodeficiency syndrome.

Animals, or animal products, may be a source for human infection but direct associations are difficult to prove. Although not clinically ill, human workers have been found to be infected on farms when the disease occurred in pigs. It is likely that infections in humans and animals on the one farm come from the one source, but it is also possible that spread from animals to humans occurs.

CLINICAL AND NECROPSY FINDINGS

Pigs

Infection is **usually sporadic** in pigs in herds but in some herds can be enzootic.[13] The naturally occurring disease is non-progressive and usually restricted to the lymph nodes of the head and neck and the mesenteric lymph nodes. Occasional generalized cases occur and an outbreak of pulmonary tuberculosis associated with *M. avium* has been recorded in pigs. The lesions may be free of suppuration and resemble neoplastic tissue but granulomatous and occasionally caseous lesions in lymph nodes also occur. Similar lesions are associated with *Rhodococcus equi*. Granulomatous lesions which develop in the tonsils and intestinal wall result in the passage of organisms in the feces for at least 55 days[14] and **transmission to in-contact** pigs occurs readily.

Tuberculosis produced experimentally in pigs by the oral administration of *M. avium* is generalized, provided the inoculation dose is sufficiently large. Transmission from these pigs to contact pigs occurs. Vaccination of pigs with BCG vaccine provides partial protection against experimental infection with *M. avium*.

M. bovis also can infect pigs and *M. fortuitum* is recorded as a cause of chronic arthritis in pigs.[15]

Cattle

With classic avian tuberculosis, sensitivity to tuberculin may disappear soon after cattle are removed from contact with infected birds. Infection with this group of organisms produces **microgranulomas in lymph nodes**. Local lesions may persist in the mesenteric lymph nodes, the meninges, and in the uterus and udder, and occasional cases of open pulmonary tuberculosis have been observed. In uterine infections recurrent abortion may occur, and mammary localization causes induration and involvement of lymph nodes, similar to the lesions associated with *M. bovis*. Generalized tuberculosis can occur in up to 50% of cases.

Horses

Horses are **resistant** to infection with *M. avium* complex, although rare, generalized cases of tuberculosis have been recorded in this species with serovars 1, 2, 4, 5, and 8.[16–18] It is possible that disease occurs only in horses that are immunosuppressed by other factors. A common history is chronic diarrhea and weight loss. Less common manifestations include dermatitis, alopecia, and skin ulceration. **Granulomatous enteritis** is commonly present at necropsy. Two cases have been recorded in which the lesions in the cervical lymph nodes were accompanied by lesions in cervical vertebrae. The lesions were similar to those seen in cervical vertebral osteomyelitis associated with *M. bovis*.

Goats and sheep

Goats and sheep appear to have a strong natural resistance to infection with *M. avium* complex. A high incidence of avian tuberculosis has been observed in a flock of goats and, although the disease progresses slowly, this species may act as reservoirs for other species. Animals with progressive disease show anorexia and chronic diarrhea and wasting.[19]

Deer

Infection in wild and farmed deer[20] occurs and may serve as a source of infection for carrion-eating birds.

CLINICAL PATHOLOGY

The lesions at postmortem or slaughter inspection are characteristic but culture and identification of the organism is

required for confirmation. Growth is slow and PCR technologies offer faster diagnosis with some ability to distinguish between individual species and serovars.[21] Smears of lesions associated with some of these agents **do not stain positive** with acid-fast stains.[9,18]

Tuberculin testing

With infections in **cattle**, sensitivity to tuberculin occurs to both avian and bovine tuberculin but is greater to avian tuberculin. With atypical mycobacteria the response is also short-lived, significant changes in sensitivity occurring between successive tests.[22] The comparative tuberculin test is becoming more widely used because of the growing importance of these infections. It is not uncommon for there to be more than one species of mycobacteria causing disease in a herd at the one time.

The use of a comparative tuberculin test in **swine** to differentiate between infections with *M. avium–intracellulare* complex and *M. bovis* is discussed in the previous section.

Tuberculin skin testing in **horses** is not conducted as 70% of clinically normal horses show positive reactions.

TREATMENT AND CONTROL

Treatment is not usual, except possibly in horses. Antimicrobial treatment in humans for this complex of organisms includes amikacin, ciprofloxacin, rifampin, and the macrolide azithromycin.

In swine herds with enzootic infection culling on the basis of skin sensitivity is usually not practical because of the high prevalence of infection and high environmental contamination. Control procedures concentrate on the reduction of **environmental contamination** by a change from bedding to solid or slatted floors, frequent washing and disinfection of pen floors, separate weaner and grower facilities, and exclusion of wild birds from buildings and feed areas.[23]

TUBERCULOSIS ASSOCIATED WITH *MYCOBACTERIUM TUBERCULOSIS*

Mycobacterium tuberculosis is occasionally isolated from cattle or pig livestock with tuberculous lesions but this is rare.[1–3] Outbreaks of tuberculosis in animals associated with *M. tuberculosis* of human origin are transitory, and removal of tuberculous humans from the environment usually results in the disappearance of positive reactors in cattle. In cattle herds the reactors and necropsy lesions are most common in the young stock. Many reactors have no visible lesions: those which do occur are small and confined to the lymph nodes of the digestive and respiratory systems. Pigs may develop minor lesions in lymph nodes, but sheep, goats, and horses appear to be resistant. *M. tuberculosis* infections in pigs are usually the result of feeding offal from a tubercular household or contact with a tuberculous attendant.

SKIN TUBERCULOSIS

Chronic indurative lesions of the skin in cattle, occurring usually on the lower limbs, are called 'skin tuberculosis' because they frequently sensitize affected animals to tuberculin.

ETIOLOGY

Acid-fast organisms can often be found in the lesions in small numbers. They have not been identified and are probably not true pathogens. Iatrogenic lesions may be caused by aluminum adsorbed vaccines which produce subcutaneous granulomas, colonized by acid-fast bacteria.

EPIDEMIOLOGY

The disease occurs in most countries of the world, particularly where animals are housed and incur minor abrasions and pressure sores. The frequent occurrence of lesions on the lower extremities suggests **cutaneous abrasions** as the probable portal of entry of the causative organism.

The lesions cause little inconvenience but they are unsightly and affected animals may give a suspicious or positive reaction to the tuberculin test when they are in fact free of tuberculosis. This becomes important when herds and areas are undergoing eradication and attention is focused on any condition which complicates the tuberculin test.

PATHOGENESIS

Tuberculoid granulomas occur at the site of infection with spread along local lymphatics but without involvement of lymph nodes.

CLINICAL FINDINGS

Small, 1–2 cm diameter lumps appear under the skin. The **lower limbs** are the most common site, particularly the forelimbs, and spread to the thighs and forearms, and even to the shoulder and abdomen, may occur. The lesions may be single or multiple and often occur in **chains** connected by thin cords of tissue. The nodules are attached to the skin, may rupture and discharge thick cream-to-yellow pus. Ulcers do not persist. Individual lesions may disappear but complete recovery to the point of disappearance of all lesions is unlikely if the lesions are large and multiple.

CLINICAL PATHOLOGY

Affected animals may react to the tuberculin test. Bacteriological examination of smears of pus may reveal the presence of acid-fast bacteria.

NECROPSY FINDINGS

The lesions comprise much fibrous tissue, usually containing foci of pasty or inspissated pus, and are sometimes calcified.

DIFFERENTIAL DIAGNOSIS

In herds with tuberculosis, reactors which have lesions of skin tuberculosis are disposed of in the usual way. In herds free of tuberculosis a positive reaction to the tuberculin test in animals with skin tuberculosis is usually taken to be non-specific and the affected animal is retained provided it is negative on retest.

- Bovine farcy
- Ulcerative lymphangitis.

TREATMENT AND CONTROL

Treatment and control measures are not usually instituted although surgical removal may be undertaken for cosmetic reasons.

BOVINE FARCY

Bovine farcy is a chronic infectious disease of Zebu cattle which is endemic to regions of East and central Africa and a cause of considerable economic loss. In some area 25 to 30% of cattle are affected.[1,2] The disease is slowly progressive and affects primarily adult cattle. Lesions

occur in superficial lymph nodes, mostly in the prescapular and precrural lymph nodes. Affected lymph nodes suppurate and there is induration of the lymphatic vessels. There can be infection in the mesenteric lymph nodes with some cases having lesions in the udder or the lung. Lesions are common in areas of the body where *A. variegatum* attaches.[2] Histological examination shows a severe granulomatous reaction with lymphocyte macrophage and giant cell infiltration.[3]

Mycobacterium farcinogenes and *M. senegalense* have been considered the principal, if not sole, causal agents[1] but there is some debate on the etiology.[4]

PARATUBERCULOSIS (JOHNE'S DISEASE)

Synopsis

Etiology *Mycobacterium avium* subspecies *paratuberculosis* (*Map*)
Epidemiology Occurs in cattle, sheep, and goats. High prevalence of infection in cattle population and among herds. Incidence of clinical disease in herds about 1% annually. Transmitted by fecal–oral route. Prenatal infection occurs. Infection occurs soon after birth. Long incubation period
Clinical signs
Cattle Chronic progressive intractable diarrhea and emaciation in adult cattle extending over several weeks and months
Sheep Chronic wasting disease of adult sheep; diarrhea not a distinct clinical finding. Common cause of emaciation in ewes
Clinical pathology Culture feces. Serological tests (ELISA, AGID, CF). Low serum protein and marked hypoalbuminemia in affected sheep
Lesions Chronic granulomatous enteritis
Diagnostic confirmation Presence of intestinal lesion and culture of organism. Positive serological test
Treatment No specific treatment of significant value
Control Identify and eliminate clinical cases and subclinically infected animals. Test herd serologically. Identify and cull positive animals. Improve management and hygiene to minimize spread of infection in herd with emphasis on avoiding infection of newborn calves. Vaccination prevents clinical disease but not infection
Differential diagnosis list
Diarrhea in adult cattle
- Intestinal parasitism (ostertagiasis)
- Salmonellosis
- Secondary copper deficiency

Emaciation in adult cattle
- Chronic traumatic reticuloperitonitis
- Malnutrition
- Pyelonephritis
- Lymphosarcoma
- Amyloidosis

Diarrhea and weight loss in sheep and goats
- Gastrointestinal parasitism

Chronic weight loss in sheep and goats
- Internal abscesses
- Caseous lymphadenitis
- Caprine arthritis-encephalitis
- Ovine progressive pneumonia
- Dental disease

ETIOLOGY

There are at least two main strain types of *Map*, designated C (cattle) and S (sheep), which can be distinguished by restriction fragment length polymorphism patterns.[1,2] *Map* isolates analyzed by pulse-field electrophoresis appear to segregate into distinct clusters: Type I comprises the pigmented ovine isolates, and Type II comprises isolates from a wider host range.[3] Four Type I (sheep) isolates of *Map* have been differentiated from nine Type II (bovine) isolates.[3] It is hypothesized that *Mycobacterium avium* subsp. *paratuberculosis* Type I strains are an evolutionary intermediate between *M. avium* subsp. *avium* and *M. avium* subsp. *paratuberculosis I* Type II isolates or share a subset of *M. avium* subsp. *avium* type-specific loci through horizontal transfer. There is also evidence of a goat-specific strain in Norway which does not appear to be pathogenic for calves. A unique bison (*Bison bison*) strain has been found in Montana.[4,5]

Molecular epidemiology studies of *Map* have identified a high degree of genetic similarity within the bovine isolates, regardless of geographic origin, indicating that only a few closely related clones of *Map* may be responsible for widespread infection in cattle, other ruminants, and possibly wildlife.[6] There is a higher degree of genetic heterogeneity among *Map* isolates recovered from human and ovine sources.[6] Extensive analyses of the IS900-RFLP patterns have identified that Johne's disease in cattle and other species such as goats and rabbits is associated with indistinguishable strains. Johne's disease in sheep appears to be associated with a different strain which also infects goats and deer. The occurrence of a 'sheep strain' in cattle with Johne's disease has been reported, indicating that interspecies transmission is possible.[2] Bovine strains infect cattle, goats, and deer, and rarely sheep.

EPIDEMIOLOGY

Occurrence

Cattle, sheep, and goats

The disease occurs worldwide most commonly in cattle and to a lesser extent in sheep and goats.[7] The disease is widespread in cattle in Europe and has been spread to many countries by the export of infected clinically normal purebred stock. It is of major importance in cattle and sheep in temperate climates and some humid, tropical areas. The incidence is greatest in animals kept intensively under climatic and husbandry conditions which are conducive to the spread of infection.

The Icelandic story of paratuberculosis is an example of the risk of importing animals into a country without accurate tests or testing. In 1933, 20 stud rams of the Karakul breed were imported from Germany into Iceland to improve the quality of the skin of Icelandic sheep. The imported sheep appeared healthy and had certificates of good health control. After 2 months of quarantine they were distributed to 14 farms in the main sheep farming areas. The first clinical case of paratuberculosis in sheep was diagnosed in 1938 or 5 years after the arrival of the sheep. Gradually, infection spread from these five original farms during the next few years, and over the next 18 years, 20–30% of the farms in the sheep breeding areas were infected.[8] Within 16 years paratuberculosis together with other diseases (maedi-visna and jaagsiekte) almost ruined the sheep industry, the main agricultural industry in Iceland. The first clinical case of Johne's disease in Iceland occurred on these sheep farms in 1944. The annual morbidity of sheep during the epidemic averaged 8–9% in affected areas and was up to 40% on individual farms.

Johne's disease was first confirmed in Australia in 1980, and by 1999 had spread to some other states.[9] It is presumed that infection originated from sheep imported from New Zealand in the 1970s.

Johne's disease is not known to exist in Western Australia.[10] A requirement that imports be derived from flocks which had negative surveillance tests to Johne's disease provides the necessary protection for the sheep industry in Western Australia.

In South Africa, ovine paratuberculosis was unknown until an infected Merino ram was imported in 1967.[11] During the 1990s the disease spread among sheep farms in the Western Cape and Eastern Cape provinces. Links between infected farms indicated a positive correlation between acid soils and occurrence of infection.

Sheep are easily infected experimentally and excrete large numbers of the organism but many recover spontaneously. However,

the disease can also cause significant financial losses to the sheep farmer. For example, the disease has become established in sheep flocks in Cyprus where sheep are farmed semi-intensively for milk production for cheese, and losses can be as high as 4% per year.

The disease is being recognized with increased frequency in goats and when established in goat flocks can cause large losses. In Australia, Johne's disease occurs in dairy goat breeds with some endemic foci in south-eastern Australian states. Western Australia is free of Johne's disease in goats, sheep, and cattle.[12]

The occurrence of Johne's disease in cattle in Ireland is very low.[13] In the 51-year period from 1932 to 1982 there were only 92 cases diagnosed. The disease has been compulsorily notifiable in the Republic of Ireland since 1955 and all confirmed or suspected *Map* animals are slaughtered. The disease has been associated most frequently with imported pedigree stock. In the early 1990s, sporadic cases of the disease have been diagnosed annually. There is concern that the incidence could increase with the continuing intensification of dairy herds and following the importation of high-merit breeding heifers into many dairy herds from continental Europe where the incidence is high. Serological and fecal culturing screening of animals imported into the Republic of Ireland revealed that some animals were carriers of *Map*.[14] Culture-positive animals had been imported from the Netherlands, France, and Denmark. None of the culture-positive animals gave a positive serological reaction.

Morbidity and case fatality

The incidence of clinical disease in an infected herd is very low at any one time and rarely exceeds 5% of mature animals. The population mortality rate is less than 1% per year. In exceptional circumstances it can be as high as 5–10%. Although death losses are not high, when they are added to the losses caused by long periods of ill-health and reduced productivity the economic losses can be significant. For every clinical case of Johne's disease in a herd, it is estimated that there are 15–25 additional infected animals in various stages of clinical disease, 4–8 cases of subclinical disease and carrier adults, and 10–14 with silent infection in calves, young cattle, and adults.[15]

Wildlife and exotic species

M. avium subsp. *paratuberculosis* has a very broad host range. Infection may also occur in many different wildlife and exotic species. Water buffalo, captive and free-living wild ruminants including deer, bighorn sheep, Rocky Mountain goats, aoudads, mouflon sheep, camels, mountains goats, reindeer, antelopes, llamas, and yaks are all susceptible. The disease has been diagnosed in alpacas in Australia. Outbreaks of the disease have occurred in farmed red deer and the incidence is increasing in some regions. The organism has been isolated from the intestinal tissues of Eastern white-tailed deer killed on a farm with a history of Johne's disease.

There is evidence that wildlife in Scotland are naturally infected with *Map* and that the host range is much wider than previously thought. The organism has been found in fecal cultures from foxes, stoats, crows, weasels, jackdaws, hares, badgers, rooks, rats, and wood mice.[17] Such environmental contamination with the organism can thereby pose a risk to grazing livestock and farms adjoining paratuberculosis-infected properties. Paratuberculosis has been found in wild rabbits (*Oryctolagus cuniculus*) in Scotland.[17–19] Analysis indicates a significant relationship between a past or current problem of paratuberculosis in cattle and in the wild rabbit population on infected farms.[17] The organism can be found in rabbit fecal pellets and urine.[19] On infected farms rabbits potentially input millions of viable *Map* organisms per ha per day onto pasture grazed by livestock through fecal contamination. Also, grazing cattle do not avoid rabbit fecal contaminated pasture which is the only recorded example of a herbivore species not avoiding their own feces or the feces from sympatric wildlife species.[18] The greatest overlap between habitat use by rabbits and livestock grazing occurred in rough grazing and gorse scrub habitats particularly in autumn and where adjacent habitats were favored by rabbits. Therefore, a reduction in potential transmission risk could be achieved by reducing contact between livestock and rabbits in these habitats, especially reducing access to these habitats by young livestock as they are more susceptible to infection.

In the Czech Republic, paratuberculosis has been diagnosed in all four of the most common wild ruminant species including red deer, roe-deer, fallow deer, and moufflon.[20] The highest incidence of clinical disease in wild ruminants was in farmed deer. Using restriction fragment length polymorphism (RFLP) (molecular epidemiology), transmission between domestic and wild ruminants and between ruminant and non-ruminant species was examined. Transmission from domestic infected ruminants to wild animals occurred but the transmission from wild animals to domestic ruminants is uncertain. Non-vertebrates, wild ruminants, or non-ruminant wildlife can be vectors and potentially become a risk factor in the spread of *Map*.

Johne's disease was recognized in farmed deer in New Zealand in the 1980s and by 2000, the disease has been diagnosed in 619 animals from 299 herds, representing approximately 6% of deer herds in New Zealand.[21] In 60% of the herds only one infected animal was identified. The majority (90%) of the 619 cases were identified from lesions in mesenteric lymph nodes, including the ileocecal lymph nodes, identified at meat inspection. Only 5.8% cases came from clinically affected animals identified on farms by veterinarians. These survey data suggest that without rapid control intervention, the disease will become endemic in farmed deer. The disease has occurred in farmed red deer in Belgium.[22]

The epidemiological implications of cattle and wildlife co-mingling on the same pasture are unknown. The rate of infection can be the same in both species and it seems that both share a common source, which might well be a common herd of deer and cattle. Pigs mixed with infected cattle may develop enlargement of the mesenteric lymph nodes suggestive of tuberculosis and from which the causative organism can be isolated. Pigs and horses infected experimentally develop granulomatous enteritis and lymphadenitis. Mice and hamsters are also susceptible and are used in experimental work.

Prevalence of infection

The prevalence of infection in a region is difficult to estimate because of the uncertainty of the diagnosis and the failure to report cases unless a specific survey or eradication program is undertaken. It appears that the prevalence of infection has been increasing in the last 10 years and there are large variations in the estimates of prevalence.[15]

Because of the insidious nature of Johne's disease, it is considered to be potentially a hidden threat to the livestock industry.

Cattle

Most surveys of prevalence have been based on the results of culture of fecal or tissue samples collected from cull cows at slaughter. Some examples of prevalence rates are as follows. Depending on the region studied, 2.6–18% of cows were found infected. The prevalence of the organism in the ileocecal lymph nodes of cattle culled in the United States was 1.6% overall, with 2.9% in dairy culls and 0.8% in beef culls. Abattoir surveys in Wisconsin found a prevalence of 10.8% and in Connecticut 18%. In Ontario, the organism was isolated from the distal ileum and/or ileocecal lymph node of 5.5% of 400 cull cows, and based on a lipoarabinomannen antigen ELISA on

sera, the predicted true prevalence among 304 dairy herds was 6.1%. Based on a systematic random sampling of culled dairy cattle in Atlantic Canada and Maine, the prevalence of infection was 16.1%. Mesenteric lymph nodes and ileum from 984 dairy cows were examined by histologic and bacteriologic methods.[23]

In Louisiana beef herds the individual animal prevalence is estimated at 4.4% and prevalence among herds is 30%. A serological survey in Florida reported a seroprevalence of 8.6% in beef cattle and 17.1% in dairy cattle. Using an absorbed ELISA, in a survey of herd prevalence and geographic distribution of infection in 158 Wisconsin dairy herds and 4990 cattle the calculated true prevalence of infection from the apparent infection indicated that 4.79% of cattle and 34% of the herds had serologic evidence of infection. Among the herds classified as positive on the basis of true prevalence estimation, the mean number of test-positive cattle was 20.3%. The geographic distribution was not uniform but certain districts had a larger number of infected herds than others. In a Missouri survey, the apparent seroprevalence in dairy cattle and beef cattle was 8% and 5%, respectively; and 74% of dairy herds and 40% of beef herds were positive, respectively.

There is considerable variation in the prevalence of infected herds in different countries and within specific geographic areas.[15] Surveys done in the US have found seroprevalences up to 7.29% of cows and 50% of herds, and fecal-culture prevalences of 3.05%.[24] Based on seroprevalence studies the true prevalence of *Map* infection in the Belgian cattle population is 6% and the true herd prevalence is 10%.[25] In dairy herds in Alberta, Canada, the true-herd prevalence determined by ELISA was 26.8%.[26] The true herd-prevalence as determined by fecal culture ranged from 27 to 57%. In beef herds on community pastures in Saskatchewan, Canada, using a test sensitivity of 25% and specificity of 98%, the true sample prevalence was 0.0% and the average herd apparent prevalence was 3% or very low.[6] In beef cow–calf herds in the United States, using the ELISA, 7.9% of herds had one or more positive animals and only 0.4% of animals were positive.[28] In dairy herds in Colorado, 4.12% of cows were positive; within-herd prevalence of seropositive cows ranged from 0% to 7.82%.[29] Cows in herds that had imported more than 8% of their current herd size annually during the preceding 5 years were 3.28 times as likely to be seropositive as were cows in herds that imported less than 8% of cows. Cows in herds with ≥600 lactating cows were 3.12 times as likely to be seropositive as were cows in herds with <600 lactating cows. Cows in herds with a history of clinical disease were 2.27 times as likely to be seropositive as were cows in herds without clinical Johne's disease. In dairy herds in the United States, the overall seroprevalence ranged from 5 to 17%. Dairies in western United States have been expanding since 1980 but few producers have tested for *Map* infection prior to purchase. In California the true prevalence in dairy cattle overall was 9.4% with variations from 7.5 to 14.15% depending on different regions of the state.[24] In a survey of 1155 cows in 22 Danish dairy herds the prevalence of cows was 8.8%; and 19 of 22 herds had ≥1 test-positive cow.[30] The highest probability of a negative test result was found in a large-breed cow, in first parity, in a small herd, having calved more than one month previously; the highest probability of a positive test result was found by testing a cow in parity ≥5, in a large herd, in the first month after calving.

The prevalence of *Map* infection in dairy herds in the Netherlands is high with a herd-prevalence of 55% and cow-prevalence of 2%.[31] In vaccinated herds, the cow-prevalence was 23% and in non-vaccinated herds, 2.5%. A possible role for sheep in the epidemiology of *Map* in cattle herds in the Netherlands has been identified.[32]

Sheep

Johne's disease in sheep in Australia was first diagnosed in 1980 in central New South Wales.[33] The disease has a highly clustered geographic distribution in Australia. Based on surveys as of the year 2000, the 95% probability limits for flock-prevalence were 0.04–1.5%, 8–15%, and 29–39% for low, moderate, and high prevalence regions in New South Wales, respectively. The other states had an upper 97.5% probability limit of about 1% or less. Based on these estimates about 6–10% of flocks in New South Wales and 2.4–4.4% of flocks Australia-wide are likely to be infected. More than 80% of affected flocks are in a relatively small geographic area of NSW. Some states such as Queensland and Western Australia have a prevalence equal or close to 0%.

Methods of transmission

Exposure to the organism can occur by a variety of routes. The most common is through nursing from an infected dam (via contaminated teats or direct shedding of the organism into the colostrum/milk) or ingestion of fecally contaminated solid feed and water.

Infected cows and other species excrete *Map* directly into the milk during at least the late disseminated stage of the infection.[15] Up to 45% of clinically affected cows may excrete the organism in milk.[34]

The organism can be found in the colostrum of subclinical cases; the organism was found in 36% of colostrum samples from heavy shedders and 9% of samples from light shedders, nearly three times as often as it is found in milk.[35] Thus colostrum of infected cows, if fed to calves, could serve as a potential source of infection. Some herds have attempted to avoid this route of infection by pasteurizing colostrum and raw milk.[36]

There is firm evidence of the presence of *Map* in commercially pasteurized cow's milk manufactured for retail sale.[37] The potential public health aspect is an issue given that an association with Crohn's disease in humans is possible but uncertain. However, the presence of the organism in pasteurized milk is undesirable. The organism has been found in raw goat's milk in Norway.[38] Conditions in cheese production have been shown to have little effect on the viability of *Map* and viable bacteria have been found in hard and semi-hard cheese 12 days after production. Therefore consumption of cheese manufactured from raw goat milk in Norway might lead to transmission of *Map* to humans.

Because of the normally long incubation period, infected animals may excrete organisms in the feces for 15–18 months before clinical signs appear. Also, animals reared in a contaminated environment may become permanent or temporary excretors of the organism without becoming clinically affected. The organism has been isolated from the genitalia and the semen of infected bulls, survives antimicrobial addition and freezing, and as a result intrauterine infection may occur. However, small numbers of the organism experimentally inoculated into the uterus of cattle at the time of insemination are destroyed and do not result in systemic infection of the dam or persistent hypersensitivity. It is possible to isolate the organisms from the uterine flush fluids of clinically infected cows and experimentally the organism may adhere to the ova in spite of a 10-step wash procedure to insure the removal of potential pathogens from embryos. Isolation of *Map* from the semen of bulls and rams is unusual and represented by single case reports.

Serologically positive animals, which are moderate shedders of *Map* might be used as donors of embryos without transmitting the organism.[39] The data indicate that transmission of the organism from moderate shedders via the trophoblast is unlikely before the stage of development of cotyledons. However, this does not exclude the possibility of transmission of the organism at a later stage in pregnancy (over 60 days). It is hypothesized that the

epithelio-chorial placenta is impermeable to the organism from 42 to 49 days post-insemination but that this could change after 60 days.

All of these modes of transmission are most significant in animals in relatively advanced stages of the disease and provide the passage of the organism from one generation of hosts to the next, and are the reason for recommending artificial rearing of calves and culling of progeny from infected cows during control and eradication programs.[40]

Spread of the organism from farm to farm is usually due to trading of livestock which are unknown infected carriers and shedders of the organism but lateral spread of feces across boundary fences also occurs.

Tracer sheep have been used to detect the sheep strains of *Map* on pasture.[41] Lambs, weaners, and adult ewes are introduced to pasture with varying amounts of *Map* contamination and monitored using skin tests, gamma interferon assay, fecal culture, and serial necropsy of small groups for up to 15 months after first exposure. Culture from tissues was the most sensitive method for detecting early infection in sheep and serologic tests had low sensitivity during the early stages of naturally acquired infection. Experimental infection of weaner sheep at 12–16 weeks of age with the S strain of *Map* and detection of infection was accomplished within the first few months post-exposure.[41]

Field studies have shown that the nymphs of the Oriental cockroach (*Blattia orientalis*) may serve as a passive vector of *Map*.[42] Also, earthworms and adult Diptera may be vectors of the organism on cattle farms with paratuberculosis. Ovine trichostrongylid larvae (*Haemonchus contortus, Ostertagia circumcincta, Trichostongylus colubriformis*) may become contaminated with *Map* and may play a role in the transmission of the organism.[43]

The survival of *Map* in amitraz-based dip fluid for at least 2 weeks suggests that dips could play some role in the transmission of Johne's disease in cattle.[44] The main risk is to calves suckled by cows that have just been dipped and whose udders are covered in dip fluid.

Fetal infection

Fetal infection can occur in cattle with and without clinical signs of disease. The prevalence of fetal infection was as high as 37% of cows with clinical signs of the disease, compared with 8.6% of fetuses from cows without signs of disease.[45] Fetal infection is more likely to be associated with more advanced stages of infection when the pregnant female is a heavy shedder of the organism. In a study of fetal infection in sheep a total of 83% of fetuses from clinical cases in ewes were infected. From subclinically infected ewes, only 1.6% of fetuses were infected, and no fetuses were infected from a sample of uninfected ewes.[46]

Risk factors

Animal risk factors

Age of animal

A distinguishing characteristic of Johne's disease is that infection occurs in animals at an early age, usually under 30 days of age, and clinical disease does not occur until 3–5 years of age. This age limit should not be used as a reliable diagnostic criterion; in extreme circumstances, for example calves reared on infected nurse cows, clinical disease can occur at 12–18 months of age. Exact details of the effect of exposure to infection in adults are not available, but it is probable that some animals exposed for the first time as adults develop clinical disease while others develop only a sensitivity to johnin for short periods although they may become carriers of the organism without manifesting clinical signs.

Breed incidence and genetic susceptibility

The information on breed incidence is controversial. Field observations indicate a much higher incidence in the Channel Island and Shorthorn breeds of cattle, but this may be related to increased exposure rather than to increased breed susceptibility. The frequency of disease in any particular breed is proportional to the abundance of that breed, and paratuberculosis will occur with highest frequency in the most predominant breed. In comparison to dairy breeds, beef cattle generally range over greater areas and have less exposure to other cattle and their feces. Thus, the prevalence of infection is usually lower in beef than in the dairy breeds. Since Holstein cattle are the predominant dairy breed in the United States, the disease occurs with a greater frequency in that breed than in any other breed.

In Australia, fine wool Merino sheep are more likely to die from ovine Johne's disease than other sheep breeds.[47]

The estimated heritability of cattle to *Map* was low at 0.06 for a sample population of 3020 cows which is comparable to the heritabilities of many other disease traits.[48]

Other diseases and stressors

The possible cross-protection between tuberculosis and paratuberculosis suggests that eradication of tuberculosis may make the cattle population generally more susceptible to Johne's disease, but this has not been borne out by field experience in North America.

Other factors which affect susceptibility to infection include size of infective dose, level of dietary iron intake, age, stress, and immunosuppressive agents such as bovine virus diarrhea (BVD) virus. These factors may affect the probability of development of clinical disease but they have not been well-documented. Field observations indicate that stress, including parturition, transportation and nutritional deficiencies or excesses may influence the development of clinical disease. Housed animals are subjected to a high risk of infection because of the heavy contamination by feces and the long survival of the bacteria in protected sites.

Herd characteristics

A computer simulation model of paratuberculosis in dairy cattle has been used to examine the course of the disease in a herd. Seven variables were specified at the initial stage of the model:

- herd size
- annual herd birth rate
- annual herd replacement rate
- number of infected cows at time zero
- number of herd replacements purchased each year
- risk of purchasing an infected heifer
- number of effective cow–calf contacts per year.

All variables affect the course of paratuberculosis spread in herds, but the model is most sensitive to the effective contact rate. This is consistent with the findings of other infectious disease models and with recommendations on Johne's disease control, namely **minimize cow–calf contact** to prevent transmission of infection.

The prevalence of infection in **purchased cattle** directly affects the risk of buying infected cattle and the rate at which herds become infected in the model. Purchase of a large percentage of replacement heifers from populations with modest infection rates annually will quickly result in infection of a herd. Age-specific culling rates are also important in the development of the model. Accurate prediction of the rate at which infected cattle leave a herd was a major determinant of the course of the epidemic because each year an infectious cow remained in the herd, the cow contributed in an exponential manner to the generation of infected calves and thus the number of infected herd replacements. Over the range of realistic values for all variables in the model, the prevalence of the disease in infected herds continued to increase until a plateau was reached. True prevalence rates in the model generally plateaued at 40–60% of the herd. These data results suggest infection is spreading

quickly in dairy cattle as well as in sheep and goats. Paratuberculosis could become epidemic in dairy cattle and may become a greater problem for the dairy industry than was tuberculosis or brucellosis. In dairy herds in the Canadian Maritimes, the seroprevalence for Johne's disease was higher in herds which purchased replacements.[49]

Environmental and management risk factors

The relationship between on-farm management practices and the prevalance of infection in Wisconsin dairy herds has been examined. The management factors which are important in influencing the prevalence of infection include:

- newborn calf care
- bred heifer management
- environmental conditions
- handling of manure
- care and management of growing calves.

These are not cause and effect relationships but hypotheses based on observations in dairy herds.

Care of the newborn calf

Care of the newborn calf is correlated with apparent prevalence and is reflected in the level of hygiene used to collect colostrum from the calf's dam. Failure to be concerned about a dirty udder during collection of colostrum may increase the risk of contaminating the colostrum with the organism. Removal of the calf within 1 hour after birth, rather than leaving it with the dam for 8–12 hours, may minimize exposure to the fecal-laden calving environment.

Care and feeding of the growing calf, not the milk-fed calf or the weaner/starter calf, is correlated with prevalence. It is suggested that contact of postweaned calves with adult cattle manure should be avoided in order to limit new infections of young calves. In high-prevalence dairy herds in Wisconsin, calves were separated after weaning into calf barns and hutches rather than into pens in the cow barn more often than in herds with lower prevalence. Calves in this age group may be able to transmit the infection to other calves with which they are housed. The factors identified as having low association with apparent prevalence may be de-emphasized in control programs and allow the operators and managers to emphasize control or modification of those risk factors which are considered to be more important in affecting apparent prevalence.

The herd management practices associated with paratuberculosis seroprevalence in Dutch dairy herds have been examined compared to seronegative herds.[50] Important management measures for the prevention of paratuberculosis, such as calving in a cleaned calving area, removing the calf immediately after birth, and feeding non-contaminated roughage to calves were used only rarely. Four factors were statistically different between seronegative and seropositive herds: herd size, cows with clinical signs of paratuberculosis, prompt selling of clinically affected cattle, and feeding milk replacer.

In a study of more than 1000 dairy herds in the United States, from 20 states, the herd-level risk factors for infection with *Map* and association between familiarity of the herd manager with the disease or prior diagnosis of the disease in that herd and use of preventive measures were examined.[51] Serologic testing revealed that 3.4% of cows and 21.6% of dairy herds were infected with *Map*. Factors which increased the herd status for the disease included increasing herd size, percentage of cows born on other dairy herds, use of group housing for periparturient cows during the previous year, and use of group housing for calves prior to weaning during the previous year. Only 68% of dairies washed the teats and udder before collecting colostrum or the calf sucking the cow. It was also evident that neither familiarity of the herd manager with Johne's disease nor prior diagnosis of the disease in the herd had any significant influence on the use or implementation of measures to control or prevent the disease. In the US, 44% of dairy herds introduce new cattle each year and it is critical that prepurchase testing for *Map* be instituted to avoid even greater dissemination of infection among dairy herds. Less than 1% of US dairy herds participate in a Johne's disease certification program. These findings emphasize the need for renewed and vigorous educational efforts to effect control of Johne's disease on a national basis.

In Michigan dairy herds, use of an exercise lot for lactating cows was associated with a three-fold increase in odds of a herd being positive for *Map*.[52] Cleaning of maternity pens after each use was associated with a three-fold reduction in odds of a herd being positive for *Map*. Application of lime to pasture areas resulted in a ten-fold decrease in odds of a herd being positive for *Map*. Cleaning of calf hutches and pens was associated with an almost three-fold reduction in odds of being positive for *Map*.

A survey of farms in Scotland found that the factors which increased the likelihood of a farm having Johne's disease included large numbers of rabbits, access of wildlife to feed supplies, the application of manure to grazing pasture, the type of water supplies, and the number of crows.[53]

Soil characteristics and manure handling

An association between high prevalence of *Map* infection in ruminants and soil type has been recognized. The literature on the possible links between the clinical expression of paratuberculosis and deficiency of macro- and micronutrients has been reviewed.[54] The evidence strongly implicates regional soil acidification, excesses of iron and molybdenum, and marginal deficiencies in copper and selenium in the progressive expression of Johne's disease. Spatial distribution of cattle herds in Indiana, USA, with greater than the median seroprevalence of paratuberculosis was associated with soil characteristics.[55] Survival of the organism may be enhanced by silt or sand content in loamy soils. In Australia, mortality from Johne's in sheep was higher on farms with light sandy soils and those with a high percentage of improved pastures containing subterranean clover.[47] Winter shearing was also associated with clinical expression of Johne's disease in sheep.

Environmental conditions and manure handling are correlated with prevalence and are reflected in overall cleanliness of the farm, and the amount of contamination resulting from faulty design, maintenance, location of housing facilities, and frequency of cleaning by the farm operator.

The distribution of *Map* in the environment surrounding dairy farms and its relationship to fecal pool prevalence in herds known to be infected and uninfected was described and compared.[56] Eighty percent of the infected herds had at least one positive pool. Environmental samples were culture positive in 78% of infected herds. Seven percent of the uninfected herds had one positive pool, and one herd had one positive environmental pool. Environmental samples were cultured positive in cow alleyways (77% of herds), manure storage (68%), calving areas (21%), sick cow pen (18%), water run-off (6%), and postweaned calves areas (3%). There was an association between maximum level of colonies per tube from cow alleyways and manure storage and fecal pool prevalence. Herds with both areas cultured negative were estimated to have 0.3–4% fecal pool prevalence. Herds with both areas having a heavy load of bacteria were estimated to have 53–73% fecal pool prevalence. This indicates that targeted sampling of cow alleyways and manure storage areas appears to be an alternative strategy for herd screening and *Map* infection status assessment and for estimating herd fecal prevalence.

Pathogen risk factors

M. avium subsp. *paratuberculosis* is an obligate pathogen and parasite of animals,

and in theory can be eradicated by removal of all infected animals.[57] However, the organism can survive for long periods outside the host, enabling it to persist and spread in the grassland environment and to withstand a periodic lack of suitable hosts.

Survival and dormancy of organism in the environment

Bovine strains of *Map* can be extremely persistent in nature, with survival for more than one year. Studies of the survival of the organism on Australian farms where Johne's disease is prevalent indicate that when the organism in feces becomes mixed with soil, there is a reduction of 90–99% in the apparent viable count of the organism.[57] This is thought to be caused by binding of bacteria to soil particles, which are excluded from culture by sedimentation during sample preparation. Survival of the organism in fecal material applied to soil was greatest (55 weeks) in a fully shaded environment and was least where fecal material and soil were fully exposed to the weather and where vegetation was also removed. The organism survived for up to 24 weeks on grass that germinated through infected fecal material applied to the soil surface in completely shaded boxes and for up to 9 weeks on grass in 70% shade. Dormancy of the organism appears to be a feature in the Australian environment and the dormancy characteristics are related to genetic elements present in the genome of the organism.[57] However, survival was finite. Significant degrees of pasture decontamination can be achieved in a relatively short period which will have benefit for disease reduction in a herd or flock because of the beneficial effects lower doses of the organism would have on incubation period and disease outcome. Pasture management, such as selective grazing with no susceptible hosts or mechanical slashing, may be used to maintain a relatively low level of shade at the soil surface to hasten decontamination.

The organism persists without multiplication in pasture for long periods and such pastures are infective for up to 1 year. The organism is relatively susceptible to sunlight and drying, to a high calcium content and high pH of the soil and continuous contact with urine and feces reduces the longevity of the bacteria. However, in slurry stored in tanks the organism can survive for 98–287 days depending on the composition and alkalinity of the slurry. The alkalinity of the soil may also influence the severity of the clinical signs. Herds raised on alkaline soils, particularly in limestone areas, may have a high incidence of infection but little clinical disease. A high prevalence of infection is recorded in the USA on acid soils in contrast to alkaline soils. Adult cattle moved from herds where the soil is alkaline to areas where the soil is acid often develop severe fatal clinical disease. This observation may have some practical value in the control of the disease, but it is probable that factors other than the dietary intake of calcium or the pH of the soil will also influence susceptibility to infection.[15]

Thermal resistance of organism

The survival of the organism was seen in colostrum subjected to pasteurization temperatures of 63°C for 30 minutes. Pasteurization lessened but did not eliminate the growth of the organism from experimentally inoculated colostrum. Pasteurization of colostrum resulted in a significant decrease in colostral IgG concentrations but not to a level which would preclude its use for passive transfer. Pasteurization of milk experimentally inoculated with the organism at 63°C for 30 minutes killed 90% of four different isolates of the organism; the effect of commercial pasteurization of naturally infected milk is unknown.

Pathogenicity

Studies of the molecular cause for pathogenicity of *Map* have identified three novel *Map* operons present within a 38-kb locus.[58]

Economic importance

The economic losses associated with Johne's disease in dairy cattle can be substantial and occur across all herd sizes and regions. Lost milk production and higher net cow-replacement costs contribute to decreased value of production per cow inventory in affected herds.[59] In a 1996 study of the National Animal Health Monitoring System, affected herds experienced an economic loss of about $US100 per cow compared to Johne's-free herds. In herds with at least 10% of their culls cows with clinical signs of the disease, economic losses were over $US200. These high prevalence herds experienced reduced milk production of over 700 kg per cow, culled more cows but had lower cull-cow revenues, and had greater cow mortality than negative herds. In dairy herds in the Canadian Maritimes, total annual costs for an average Johne's disease-infected, 50-cow herd were $US2472.[49]

Losses at herd level

The economic losses due to subclinical Johne's disease include:

- reduced feed efficiency
- decreased milk production
- decreased milk fat and protein
- reduced slaughter weight at culling
- decreased fertility
- premature culling
- increased incidence of mastitis.[15]

The salvage value of clinically affected animals is negligible because of severe emaciation. The basis for the effects of infection are negative energy balance and impaired cellular immunity.[15] The slow spread and chronic disease results in a recurrent, rather than an acute, economic loss. Most economic studies have investigated associations between production and clinical and subclinical paratuberculosis as defined by bacteriology or histopathology at culling. The economic losses which have been examined have been associated with levels of mastitis, calving intervals, milk production per lactation, and premature culling. In Michigan dairy herds, ELISA-positive cows on average had a 28-day increase in days open compared to negative cows.[60]

Earlier observations indicated that infected cattle also have significantly higher mastitis and infertility rates than non-infected cattle but the results are inconsistent. The associations between subclinical disease and its effect on production and economics do not necessarily support a cause and effect relationship of the disease on production. In dairy herds subclinical disease, as determined by an ELISA, and milk production were associated with a 4% reduction in milk yield but no differences were found in lactation average, percentage of fat and protein, or somatic cell count linear score. In dairy cattle with clinical illness there can be a decrease in milk production of 19.5% in the current lactation compared with the lactation 2 years before culling. The period in which there is reduced production coincides with the period of shedding of the organisms. Using the LAM–ELISA test as the test for subclinical disease, a positive serological status was associated with higher milk somatic cell counts at both the herd average and individual cow levels. There was no relationship between LAM–ELISA results and calving intervals. The relation between LAM–ELISA results and milk production was inconsistent but there was a trend to a positive association with the amount of milk produced per cow per year. This suggests that cattle with a high production potential may be at a greater risk of later being culled for paratuberculosis.

The effect of subclinical *Map* infection on mature equivalent milk, protein, and fat production in a sample of Michigan dairy herds with a history of cows positive for *Map* diagnosed by fecal culture was examined.[61] Subclinical *Map* test-positive cows had no significant effect on mature equivalent milk, fat, or protein production.

The magnitude and direction of the association between subclinical *Map* infection and milk production depends upon the parity of the animal, stage of disease, and stage in lactation being monitored. In herds with an average parity of 2 or less, subclinical infection may have little impact on milk production. In herds maintaining an average herd parity of 2, many subclinical infected animals would be culled before experiencing any decline in milk production in which case the direct economic losses attributable to reduced milk production would be negligible. The average dairy cow was 44 months of age (3.67 years) which means the cows would have a parity of approximately 2. If significant reductions in milk production occur primarily at later lactations, herds with an average parity of 2 may not demonstrate losses in milk production due to subclinical *Map* infection.

In a sample of Danish dairy cows, there was a significant relationship between milk antibody response to *Map* and milk production. There was poor persistency and considerable milk loss, especially for second-parity cows. In third and later parities, milk yield is depressed through the entire lactation but only at very high milk antibody levels.[62]

Losses at national dairy industry level

In 1996, averaged across all dairy herds in the US, Johne's disease cost the dairy cattle industry, in reduced productivity, $US22–$27 per cow or $200–$250 million annually.[59] The economic impact of the disease in Australia and New Zealand and regions of the United States have been estimated but their validity is questionable because of the accuracy of the diagnostic tests and the survey methodology. Some observers have indicated that Johne's disease has emerged as one of the most prevalent and costly diseases of dairy cattle but this is not well-documented. There is insufficient information available on the economic importance of Johne's disease in the beef cattle industry.

Zoonotic implications

Potentially, *Map* is of great public health significance because it is speculated to be involved in Crohn's disease in humans.[63] The literature on the possible relationship between *Map* and Crohn's disease has been reviewed.[15,63]

In 1913 the similarities between segmental human intestinal disease and granulomatous intestinal disease in cattle were identified. It is rational to consider that an infectious etiology for Crohn's disease might be acquired through ingestion of food-stuffs. Also, the epidemiology of the disease, which includes rising incidence rates in Western societies concurrent with low rates in developing countries over the second half of the 20th century and high rates among immigrants to Western societies, is consistent with the possibility that a critical infection may be acquired from cattle or other farm animals via milk or meat ingestion, staples of Western diets, and cause Crohn's disease in subjects with appropriate genetic predisposition.[64]

The isolation of *M. paratuberculosis* from some human patients with Crohn's disease has prompted investigations into a possible link between the organism and the disease in humans.[15] The finding of *Map* in breast milk supports the possibility that it can be a systemic infection in humans. Some studies claim the rate of detection of *Map* in individuals with Crohn's disease is highly significant.[65] The organism has been cultured from the peripheral blood of a higher percentage of individuals with Crohn's disease than in controls which does not prove that *Map* is a cause of the disease but suggests that a larger-scale investigation is needed to ascertain the role of the organism in the illness.[66]

In Manitoba, Canada, the reported incidence of Crohn's disease at 15 patients/100 000 people per year is among the highest in the world.[64] Population-based case-control studies of seroprevalence of *Map* in patients with Crohn's disease and ulcerative colitis have concluded that a high seroprevalence in Manitoba raises the possibility that the high rates of Crohn's disease in Manitoba could be related to high exposure rates for *Map*.[64] However, *Map* is not serologically specifically associated with Crohn's disease in a community with a relatively high prevalence of Crohn's disease.[64]

Crohn's disease, also called Crohn's colitis, Crohn's ileitis, or regional ileitis, is a chronic granulomatous ileocolitis of humans of unknown etiology. Pathogenetically, it is an immunologic hyperresponsive lesion to an exogenous and/or endogenous antigen. It is characterized clinically by chronic weight loss, abdominal pain, diarrhea or constipation, vomiting, and generalized malaise. Surgical resection of the affected intestine is often necessary because of complications. Original studies published in 1984 reported isolation of three strains of the organism from 26 patients with Crohn's disease but none from control patients. However, using acid-fast light microscopy and immunohistochemistry the organism has not been found within diseased intestinal tissues of patients with Crohn's disease. But mycobacterial DNA has been found in tissues of patients with Crohn's disease and in some controls, which suggests that environmental mycobacteria may colonize the disrupted mucosa of both Crohn's disease patients and controls. A species-specific insertion sequence of *M. paratuberculosis* of a cell wall-deficient isolate of the organism (IS900-PCR) has been detected in about one-third of the intestinal cultures from Crohn's disease. In summary, no consistent or reproducible immunologic response to *M. paratuberculosis* or any other *Mycobacterium* spp. has been demonstrated in patients with Crohn's disease. There is no epidemiological evidence at present to indicate that the incidence of Crohn's disease is associated with possible exposure to organisms such as might be expected in farmers, animal health care workers, or other individuals having direct contact with infected animals.

If *Map* does have a role in Crohn's disease, then milk from infected animals may be a potential vehicle of transmission of the organism from animal to man.[67] *Map* has been cultured from milk from cows with subclinical and clinical Johne's disease. Published reports indicate it may not be completely inactivated by the pasteurization of milk at 72°C for 15 seconds.[67] This resulted in the UK dairy industry in 1998 increasing holding time for commercial milk pasteurization to 25 seconds in an effort to increase the effectiveness of the pasteurization process. However, a survey of commercially pasteurized milk samples in the UK found that *Map* in naturally infected milk may even survive 72°C for 25 seconds.[67] The tendency of *Map* to exist as clumps may aid in its survival during heating.

The organism can also survive in cheese made from raw milk. *Map* are resilient and are able to withstand the acidic conditions in cheese. During the laboratory manufacture of soft cheese using raw milk spiked with *Map*, the majority of *Map* cells are concentrated into the cheese curd rather than lost with the whey. When the resulting soft cheese was stored at 4°C, *Map* could still be cultured after 35 days.

The United Kingdom Food Standards Agency found confirmed *Map* isolates in 1.6% and 1.8% of raw and pasteurized cow's milk, respectively.[37] All indications were that pasteurization had been done effectively at all of the culture-positive dairies. Thus viable *Map* is occasionally present at low levels in commercially pasteurized cow's milk in the United Kingdom. The literature relating to the characteristics of *Map*, its potential significance for public health, its survival in pasteurized milk and other dairy products, current detection methods for the organism in milk, and possible strategies for preventing contamination of milk with *Map* at the farm level has been reviewed.[67]

PATHOGENESIS

Following oral ingestion, the organism localizes in the mucosa of the small intestine, its associated lymph nodes and, to a lesser extent, in the tonsils and supra-pharyngeal lymph nodes. The primary site of bacterial multiplication is the terminal part of the small intestine and the large intestine. At least three different groups of animals can occur depending on the host–bacteria relationship that becomes established. In the first group, animals develop resistance quickly, control the infection and do not become shedders (**infected-resistant**). In the second group, the infection is not completely controlled; some animals will partially control the infection and will shed the organism intermittently, others will become **intermediate** cases which are incubating the disease and will be heavy shedders of the organism.

In the third group, the organism persists in the intestinal mucosa and from among these animals the **clinical** cases develop. The different possibilities are summarized in Table 19.1.

The organism is phagocytosed by macrophages which in turn proliferate in large numbers and infiltrate the intestinal submucosa which results in decreased absorption, chronic diarrhea, and resulting malabsorption. There is a reduction in protein absorption and leakage of protein into the lumen of the jejunum. In cattle, the loss of protein results in muscle wasting, hypoproteinemia, and edema. In sheep, a compensatory increase in protein production in the liver masks the protein loss and clinical signs appear only when this compensatory mechanism fails. Within the macrophages, the bacteria remain viable and protected from humoral factors. In vitro studies indicate that blood-derived macrophages from clinically normal cows or cows infected with *M. paratuberculosis* were incapable of destroying the organism.

Immune response and spectrum

The patterns of immune response to infection with *Map* in cattle have been reviewed.[68,69] There are three main stages of infection: **early infection**; **subclinical infection**; and **clinical disease**.

Cattle and other ruminants are usually exposed to *Map* within the first months of life, either via the fecal–oral route or by ingestion of infected colostrum. The outcome of infection is largely dependent upon a variety of genetic elements. Cattle older than 10 months appear to be resistant to the onset of disease, although susceptibility to infection may not change. Acquired resistance to disease may involve maturation of the immune system, including the balance between various T-cell subsets and the specific tissue distribution of immune cells.

The first line of defense against invading *Map* in the ruminant intestine involves M cells (special epithelial cells associated with ileal Peyer's patches and lymphoid follicles that actively take up particulate matter from the intestinal contents; they are the portal of entry for bacteria and viruses), and phagocytic macrophages.[69] In early stages of infection the organism is found in phagocytic macrophages in the intestine. Once inside the phagosome of an infected macrophage, the organism interferes with the normal course of phagosome maturation into phagolysosome, thereby escaping the process of destruction. The infection of inactivated macrophages within the intestine is the first step in establishing persistent infection and in the subsequent development of disease. The host immune system begins a series of attacks against *Map*-infected macrophages, including the rapid development of activated T cells, $CD4^+$ T cells, and cytolytic $CD8^+$ cells. These cells interact with the persistently infected macrophage and with each other through a complex network of cytokines and receptors. Despite these aggressive efforts to clear the infection, *Map* persists and the constant struggle of the immune system leads to pronounced injury to the intestinal epithelial cells.

During the early subclinical stages of infection, the organism elicits a cell-mediated response by the host that can be characterized by strong delayed-type IV hypersensitivity reactions, lymphocyte proliferation responses to mitogens, and production of cytokines by stimulated T lymphocytes.[69] As the disease progresses from subclinical to clinical stages, the cell-mediated immune response wanes, and a strong humoral response becomes dominant. However, this depends highly on the antigens and isotypes used to study the disease. The classical patterns occur only with purified protein derivative (PPDP) antigens and the IgG1 isotype.[70] For other antigens and isotypes and the total IgG levels, the response pattern is different and indicates that there is no uniform association with increased antibody responses during the progression from the subclinical stage to the clinical stage of bovine paratuberculosis. When comparing total IgG1 and IgG2 concentrations, it appears that there is no general increase in humoral responses in clinically diseased animals. Progression of cattle from subclinical to clinical Johne's disease is associated with a decreased ability of mononuclear cells to produce IFN-gamma, both specifically and non-specifically at the site of infection and in the blood.[71] The loss of putatively protective $CD4^+$ T cells leads to a lack of control of mycobacterial replications and, subsequently, to the progressive granulomatous enteritis typical of bovine paratuberculosis.[72]

Using a lipoarabinomanann-based ELISA, specific serum immunoglobulin can be detected as early as 134 days after experimental infection of calves with *Map* into the tonsillar crypts.[71] This indicates that mycobacteria-specific antibody is detectable early in the course of experimental Johne's disease, even preceding the development of specific cell-mediated responses. Both humoral and cellular immune responses were detected. Specific $CD4^+$ cell proliferative and IFN-gamma responses occurred concurrently with humoral responses to a LAM-enriched antigen preparation. A commercially available ELISA kit (IDEXX Laboratories) did not detect serum antibody responses in the experimental calves at any time point during the study.

Antibody to *Map* does not protect the host against disease; rather, TH-1-mediated immunity appears to be essential to keep the infection under control. During the final stages of disease, lack of antigen-specific cell-mediated immune response or complete anergy may result, allowing for rapid dissemination of the infection throughout the host.

The host response varies between species. Bison calves are more susceptible to tissue colonization than beef calves after challenge with the cattle isolate and, conversely beef calves were more susceptible to the bison strain of *Map*.[73] Interferon-gamma (IFN-gamma) responses were noted in some calves by one month post-inoculation and were sustained

Table 19.1 The relationship between the stages in the pathogenesis of Johne's disease, the presence of clinical disease and the results of diagnostic tests

	Resistant animals	Intermediate (incubation period)	Advanced clinical disease
Clinical signs present	–	+	+++
Fecal shedding	+ (–)	++	+++
Antibody response	–	++	+++
Skin test	+ (–)	+ (–)	+ (–)
Lymphocyte transformation	+++	+++	+ (–)

longer in beef calves after challenge with the bison isolate. Antibody was not detected in either beef or bison calves during the 6-month infection period.

There appears to be an immune spectrum and no serological or cellular immunity test will identify all animals in the spectrum. There are infected-resistant animals which control their infection but are unable to completely eliminate the organism. These animals do not react in antibody assays, only rarely or never shed organisms and respond to the lymphocyte transformation test because their circulating lymphocytes are sensitized. In the intermediate stage, the animal fails to control the infection, antibodies appear in the serum and organisms are shed in the feces. In the stage of clinical disease, the organisms are shed in the feces and the antibody responses and skin tests are variable.

The immunological response following infection is variable and depends on the stage of the infection and whether or not clinical disease develops. In general, infected animals initially develop a cell-mediated response, followed by a humoral response initiated by the release of bacteria by dying macrophages as the disease progresses. In the late stages of clinical disease, anergy may occur and neither cell-mediated nor humoral immunity may be detectable. These immunological features occur independently of the stages of clinical disease and may appear at any time during the clinical course. Additional details of the cellular components of the immune mechanisms are available.[69,72]

In sheep with paratuberculosis with or without clinical signs, a range of intestinal lesions according to histological appearance are characteristic. Two distinct histological types of granulomatous enteritis occur with a significant relationship between the infiltrating cell type and the degree of intestinal mycobacterial infection.[74] At the two ends of the spectrum of lesions are two widely differing forms:

- **tuberculoid extreme**, with a strong cell-mediated immune response and lesions consisting of small granulomata composed of epithelioid cells surrounded by many lymphocytes and with few or no bacilli in the lesions
- **lepromatous extreme**, with a strong humoral immune response and lesions composed of accumulations of macrophages containing large numbers of mycobacteria.

Between these two extremes are the so-called 'borderline forms', which tend to be associated with the most severe clinical disease. Most sheep with Johne's disease have the multibacillary lesion (lepromatous) with extensive diffuse macrophage infiltrate within the intestinal mucosa and submucosa. In the paucibacillary lesion (tuberculoid) there is a marked lymphocytic and giant cell infiltration of the intestine. There is also a correlation between high numbers of acid-fast bacteria and a positive serum antibody test result.[74] In sheep, the local release of macrophage and other lymphocyte-derived cytokines may exert an influence on the type of inflammatory and immune response which develops during infection. It is proposed that the elevated production of cytokines along with a failure to clear a heavy burden of bacteria may be one factor encouraging the chronic inflammatory lesion in paratuberculosis. Experimental infection of vaccinated lambs accelerates the progress of the infection, and results in more rapid healing. It seems that infection with *M. paratuberculosis* is closely associated with organized lymphoid tissue of the intestine such as Peyer's patches. This may explain the location of the lesion in the ileum of clinical cases and the lower susceptibility of adult animals in which the intestinal lymphoid tissue is markedly reduced.

The bacteria are carried by macrophages to other sites, particularly the uterus, the fetus, and the mammary gland, and the testes and semen of bulls. The post primary dissemination of the lesions is more widespread in adult animals than in calves and the early lesions are more severe in the former but the organisms do not persist. Disseminated lesions consisting of microgranulomas in other lymph nodes and organs have been described in mature cattle. In calves, the organism proliferates slowly, particularly in the small intestinal site, which results in a massive cellular infiltration of the intestinal submucosa. In adult cows, infection may penetrate to the fetus and cause prenatal infection.[40] Uterine infection occurs more frequently than is commonly thought, and often in animals which are clinically normal. There is evidence that intrauterine infection occurs in sheep. From experimental observations in sheep and calves it appears that vaccination against Johne's disease does not prevent infection but restricts the cellular response to the intestinal wall and thus prevents the onset of clinical disease.

Important features of the natural history of the disease are the long incubation period of 2 years or more and the development of sensitization to johnin and to mammalian and avian tuberculin. This sensitivity develops in the preclinical stage but has disappeared in most cases by the time clinical signs are evident. On the other hand, complement-fixing antibodies appear late in the disease and in general increase with increasing severity of the lesions. This suggests that two independent antibodies are involved in the two reactions.

CLINICAL FINDINGS

Cattle

Stages of disease

Four stages of paratuberculosis in cattle have been described:[15]

Stage one

Silent infection. Calves, heifers, and young cattle up to 2 years of age. There are no clinical signs and no effects on body weight gain or body condition but these animals may shed the organism. Clinicopathologic tests cannot detect the infection but culture of the feces or demonstration of the organism in tissues may be possible.

Stage two

Subclinical disease. Carrier adults: no clinical signs but may be affected by other abnormalities such as mastitis or infertility. Most of these animals will be negative on fecal culture but 15–25% may be positive on fecal culture. These are also negative to most serological tests and if not culled will move onto stage 3.

Stage three

Clinical disease. Clinical disease is the tip of the iceberg in terms of the total number of infected animals in the herd. The 'Iceberg concept' states that for every animal with clinical signs born in the herd, another 15–20 animals are infected but less than half of whom will be detected by a sensitive fecal culture.[75] Clinical signs do not appear before 2 years of age and are commonest in the 2 to 6-year age group. Cases occur only sporadically because of the slow rate of spread of the disease. Gradual loss of body weight despite a normal appetite. During a period of several weeks, concurrent with the weight loss, diarrhea develops. Milk production declines and the temperature, heart rate, and respirations are within normal limits. The fall in milk yield is often apparent in the lactation before diarrhea commences. The animal eats well throughout but thirst is excessive. The feces are soft and thin, like thick pea soup, homogeneous, and without offensive odor. There is marked absence of blood, epithelial debris, and mucus. Diarrhea may be continuous or intermittent with a marked tendency to improve in late pregnancy only to reappear in a severe form soon after parturition. A temporary improvement may also occur when animals are taken off pasture and placed on dry feed.

Stage four

Advanced clinical disease. As the disease worsens, emaciation is the most obvious abnormality and is usually accompanied by intermandibular edema which has a tendency to disappear as diarrhea develops. The diarrhea is characterized by a fluid 'waterhose' or 'pipestream' passage of feces. The course of the disease varies from weeks to months but always terminates in severe dehydration, emaciation, and weakness necessitating destruction.

Sheep and goats

In sheep and goats the disease is manifested principally by emaciation, and shedding of wool may occur in sheep. Diarrhea is not severe but the feces may be soft enough to lose their usual pelleted form in both species. Affected sheep may lose weight for up to 4 months, be partially anorexic and their feces may appear normal until the terminal stages when the feces may become soft and pasty. Depression and dyspnea are evident in goats but are less obvious in sheep.

CLINICAL PATHOLOGY

In an infected herd, animals may be divided into four categories:

- Animals with clinical disease and shedding the organism
- Subclinical infection and shedding the organism (intermediate and incubating)
- Infected, but neither ill nor shedding enough bacteria to be culturally detectable (infected-resistant)
- Uninfected cattle.

For successful eradication and control of the disease the diagnostic tests must be able to identify the intermediate group. The primary hindrance to making a diagnosis in the live animal is the paradoxical immune response during various stages of the disease. Subclinical infection is characterized by a strong cell-mediated immune response which can be detected by such assays as lymphocyte proliferation to a T-cell-independent mitogen and delayed-type hypersensitivity reactions or skin tests. A negligible humoral response during subclinical infection reduces the usefulness of serological diagnostic tests. In contrast, clinical disease is characterized by a strong humoral immune response and a weak cell-mediated response. During clinical disease, high numbers of *M. paratuberculosis* are shed in the feces and one of the definitive tests is culture of the organism from feces.

The clinicopathological tests used to help in the diagnosis of Johne's disease are described below for each of the animal species involved. They have always been difficult to interpret, and control of the disease has been correspondingly delayed. What follows is a summary of the position at the present time and it is apparent that many questions still remain to be answered.

Predictive value of a test

This is a function of disease **prevalence** and the **sensitivity** and **specificity** of a given diagnostic test. **Sensitivity** is the percentage of diseased animals with a positive test among all the diseased animals tested. **Specificity** is the percentage of non-diseased animals with a negative test result among all the non-diseased animals. Both sensitivity and specificity are intrinsic properties of a given diagnostic test and remain constant regardless of the number of animals tested. **Prevalence** is the most important factor affecting the usefulness of a diagnostic test result. The **predictive value of a positive test** decreases as the specificity of the test declines. The **predictive value of a negative test**, however, is not seriously affected by test sensitivity. Thus a diagnostic test for Johne's disease to identify infected animals for culling from herds must have a high specificity while some compromise in test sensitivity can be tolerated. The predictive value model illustrates that a single diagnostic test for Johne's disease applied to populations of cattle with a low to moderate prevalence of disease, such as 5%, must have a specificity of ~99.8% and a sensitivity of ~40% to yield results that indicate the correct disease status with 90% probability.

False-positive results are due to cross-reactivity and resistant animals which have recovered. Cross-reactivity can occur as a consequence of infection with other *Mycobacterium* spp., *Actinomyces* spp., *Dermatophilus* spp., *Nocardia* spp., *Streptomyces* spp., and *Corynebacterium* spp. *M. avium*, and *M. paratuberculosis* cannot be distinguished by immunological methods.

False-negative results occur as a result of tolerance and anergy which occurs most often during the terminal stages of clinical disease, but it may occur at any stage of chronic infection.

Cattle

Because of the very long incubation period during which infected animals shed very large numbers of *M. paratuberculosis* to contaminate the environment, the control of Johne's disease cannot be contemplated without a test to detect the clinically normal carrier. This need has dominated recent research into the disease and although finality has not been achieved a reasonable attempt can now be made. However, no single test will suffice. It is necessary to use at least two tests in a diagnostic profile. These need to match the stages of pathogenesis of the disease as set down in Table 19.1. The serological tests are, in general, too inaccurate although the complement fixation test is still required by many statutory agencies.

Diagnostic tests in cattle

Culture or detection of organism

Bacteriological examination. Examination **of the feces** is a valuable diagnostic aid for detecting infection in clinically diseased animals and to some extent in apparently healthy cattle in known infected herds. **Fecal culture** is presently recognized as the most reliable index of infection in live cattle. The sensitivity and specificity are both 100% on a herd basis, assuming herds of about 50 or more animals and an infection rate of 20% or more within the herds. A major advantage of fecal culture is that it can identify cattle 1–3 years prior to the appearance of clinical signs. But current procedures are laborious and fail to detect animals shedding low numbers of organisms, and require approximately 8–16 weeks of incubation for the development of colonies. Because of the relatively low sensitivity of conventional fecal culture in subclinically infected animals, and because *Map* grows very slowly on artificial media, much has been done to improve performance of the procedures including hybrid test procedures.

Several procedures are used to improve the sensitivity of detecting *Map* by culture including decontamination of specimens, and concentration of the organism from specimens. Conventional *Map* culture consists of decontaminating the specimen, concentrating the organisms, and inoculating a growth medium. The literature on the medium constituents and techniques for culture of *Map* has been reviewed.[75] A molecular-based confirmatory test, such as PCR to detect the *Map* marker sequence IS900, can be used to confirm positive specimens on the fecal culture slant after 6 weeks incubation.[76] The sensitivity and specificity of a CS-PCR test on fecal culture were estimated at 72.1% and 98.9%, respectively.

The main criteria for differentiating *M. paratuberculosis* from other mycobacteria are the extreme slow growth and dependence on mycobactin for growth.[15] *M. paratuberculosis* is a slow-growing mycobactin-dependent myobacterial species.

Fecal culture by radiometric technique is also available and is considered the most sensitive and least expensive compared to conventional fecal culture and DNA probes.[15] The radiometric system in most common use is the BACTEC system which is highly automated, faster, and has

slightly higher sensitivity than conventional culture systems but is more expensive and requires the use of radioisotopes.[15] A confirmatory test such as IS900 PCR is required on positive specimens.

Pooled fecal samples and culture. The culture of pooled fecal samples from several animals in a herd or flock has been evaluated as a means of determining a herd's infection status. Pooling samples reduces the number of fecal cultures necessary to determine infection, thereby reducing the cost of a large-scale Johne's disease control or eradication program. Strategically pooled culture specimens (five animals of the same age per pool) compared with individual fecal specimens can yield a sensitivity and specificity of 86% and 96%, respectively.[77] This would reduce the cost considerably when a herd is not suspected of being infected. If a herd is infected, individual cultures or other organism-based tests would be necessary to identify infected individuals. A comparison culture of individual and pooled fecal samples in dairy cattle herds found that pooled fecal samples detected at least 88% of samples that contained feces from at least one animal shedding moderate to high concentrations of *Map*.[78] Culture of 10 pooled fecal samples (50 animals/herd) was satisfactory for detection of most infected herds, with an estimated 79 and 99% of infected herds with <10 or ≥10% prevalence of infection detected, respectively.[78] The use of pooled fecal samples from 10 cows is a cost-effective method for herd screening and can provide a reliable estimate of the percentage of *Map*-infected cows in large dairy herds with a low prevalence of infection.[79] Estimated sensitivity for pooled fecal samples among all dairy herds was 0.69. Sensitivity increased as the number of culture-positive samples in a pool increased. Herd-level sensitivity estimates ranged from 90 to 100% and was dependent on prevalence in the population and the sensitivity for culture of pooled fecal samples.

Targeted sampling of cow alleyways and manure storage areas appears to be an alternative strategy for herd screening and *Map* infection status assessment and for estimating herd prevalence.[56] *See earlier under Environmental and management risk factors.*

Pooled fecal culture is a highly sensitive and specific flock-test for detection of ovine Johne's disease and is substantially more sensitive than serology using AGID.[80] The estimated minimum flock-specificity of pooled culture when used for surveillance and assurance testing is 99.1%. Surveillance and assurance programs in Australia are designed to provide a flock sensitivity of 95% for an assumed prevalence of 2%. The costs are much lower at 30% of those for serologic testing. Pooling of samples is possible because of the large numbers of *Map* present in the feces of sheep with multibacillary disease. The average rate of excretion of *Map* in such sheep is 1.09×10^8 organisms per g of feces. As the analytical sensitivity of similar culture methods has been estimated to 100 CFU per g of feces, the pooling rate could be large.

Microscopic examination of Ziehl–Neelsen stained smears of feces for the presence of typical clumps of acid-fast bacteria has been an attractive alternative to fecal culture since the results are available within an hour. However, the sensitivity and specificity of the microscopical examination have always been in doubt. It may be difficult to distinguish the Johne's bacillus from other acid-fast organisms which are frequent in feces. Also it may be necessary to examine smears on several occasions to obtain a positive result. Of the infected animals some are non-shedders, some are light shedders (less than 100 organisms/g of feces) and some are heavy shedders and, of these, the heavy shedders develop clinical disease. Clumps of acid-fast bacteria in epithelial cells are diagnostic and are more likely to be observed during a diarrheic phase, when epithelial cells are more likely to be shed, than in a period when feces are normal. In general, the microscopical examination of fecal smears for the presence of acid-fast clumps is an unreliable method of detecting *M. paratuberculosis* in bovine feces, and culture is superior. A pinch biopsy collected with the fingernails, or scrapings of rectal mucosa, are of no great advantage compared to fecal smears, as it is probably only in the late clinical stages that the rectal mucosa is invaded. If rectal scrapings or rectal pinch biopsy are used a positive finding is clumps of acid-fast bacilli in epithelial cells or macrophages.

Genetic probe. Molecular genetics provides a new way to identify organisms through the use of DNA probes. A genetic element unique to *Map* is an insertion element designated as IS900.[15] Strains of the organism infecting goats are genetically similar to cattle strains.[81] Genetic probes for detection of IS900 in clinical samples such as feces are available as commercial kits and employ the polymerase chain reaction. The sensitivity of the test is superior to the commercial PCR test. The advantage is speed; the assay requires only 3 days and thus identification of fecal shedders can be rapid compared to fecal culture requiring up to 12 weeks. The disadvantages are its low sensitivity and high cost, and the assay requires skilled and experienced technicians and special equipment. False-positives are common due to contamination of samples by gene products from the laboratory.

Because of the demand for fast and reliable methods to distinguish *Map* from closely related mycobacteria and for strain-specific typing of clinical isolates for epidemiological studies, the IS900/ERIC-PCR has been used to distinguish *Map* from closely related mycobacteria.[82]

A fast and sensitive alternative to bacterial cultures of feces is an extraction method based on buoyant density centrifugation in Percoll along with a sequence capture PCR combined with a dot blot assay. Its sensitivity allows detection of low numbers of *Map* likely to be found in subclinically infected animals.[82] The test achieved a sensitivity of 10^3 CFU/g feces.

Detection of nucleic acids specific to *Map* in fecal samples is a technique that circumvents the culture method. A rapid, simple, and effective method to extract DNA from fecal samples with a modification of a PCR assay for optimal sensitivity of detection has been described.[84] An evaluation of 1000 well-characterized fecal samples indicated that sensitivity was highly dependent on the load of bacteria in the fecal samples with an 81% detection of samples containing >70 colony-forming units/g of feces and a 45% detection rate for samples containing less than 1 cfu/g. The reproducibility of the technique between two laboratories was much higher (75%) for the fecal samples containing high numbers of *Map* and only 25% for samples with less than 1 cfu/g. An overall specificity of 83% was obtained for negative samples. The method is rapid, simple, and inexpensive compared with other techniques and can detect animals which are shedding less than 1 cfu/g.

Culture of milk and blood. The organism can be cultured in the milk of subclinically infected cows[15] and the prevalence of infection of milk is highest in samples from cows with heavy fecal shedding and lowest with light shedding. A nested PCR test has been used to detect *Map* in the blood and milk of cattle with clinical and subclinical infection.[85] Between 8 and 22% of subclinically infected and about 35% of clinically affected cows harbor *Map* in their udders.

Biopsy. Surgical biopsy of the terminal ileum and mesenteric lymph node of sheep for detection of *Map* has been described.[86] Histological examination and bacteriological culture are highly specific and sensitive. Early detection of animals is a major advantage but the time and costs involved are major disadvantages and its use may be restricted to special

circumstances and valuable pedigreed sheep.

Serological tests

Serological tests are potentially cheaper and much more rapid than fecal culture, and several are available. Problems with sensitivity and specificity are common.

Four serological tests, the complement fixation test (CFT), an agar gel immunodiffusion (AGID) test, and two commercial ELISAs, for bovine paratuberculosis have been evaluated and compared in dairy cattle with subclinical infection.[15] The diagnostic specificities were high and ranged from 95 to 99%. The sensitivities were low and ranged from 14 to 47% for non-shedders and from 40 to 65% for shedders, with the ELISAs providing the best performance. The sensitivity of the tests increases as the prevalence of infection increases in the herd. Conversely, as the prevalence of infection decreases the sensitivity decreases. Thus as the sensitivity of the tests decreases it is necessary to use additional tests such as detection of the organism in the feces.

CFT Up until recently the most widely used serological test for the diagnosis of bovine paratuberculosis was the complement fixation test (CFT). Many foreign countries require that cattle have a negative CFT prior to importation. Because of the limitations of the CFT, these countries usually require negative results of intradermal johnin testing or fecal cultures. The limitations of the CFT include false-negative and false-positive test results. Diagnostic sensitivities of approximately 90%, and specificities of approximately 70%, for the CFT in clinical disease have been reported.[15] This reflects severity of lesions rather than severity of the clinical abnormality, but early cases and non-clinical carriers fail to give positive reactions and a number of non-specific, transient, positive reactions do occur. The diagnostic accuracy of the CFT is reduced when applied to subclinical infections.

The test sensitivity in subclinically infected cattle shedding low numbers of organisms is about 54%. The CFT does not have sufficient sensitivity to be used as a single test for definitive identification of cattle with subclinical infection. However, the specificity is high enough so that any positive test result can be regarded as a presumptive diagnosis of infection and fecal culture can be done to confirm. In cattle with subclinical infection detected by fecal culture, the sensitivity estimates of the CFT and the AGID test were 11% and 19%, respectively. In cattle classified as disease-free, the specificity estimates of the CFT and the AGID test were 97.4% and 99.4%, respectively. Negative tests obtained with the use of either test in apparently normal cattle should be interpreted with caution because both tests suffer from low sensitivities in subclinically infected animals.

False-positive results with the CFT in infected herds are due to cross-reactions with other bacteria, early antibody response to infection before detectable fecal shedding, and simple exposure to the organism rather than infection.

AGID The sensitivity of the agar gel immunodiffusion (AGID) test for the diagnosis of clinical paratuberculosis is 96% with a specificity of 94%. The AGID test is considered to be the most appropriate available for the diagnosis of clinical disease. The test has one-third the diagnostic sensitivity of fecal culture in the diagnosis of subclinical infection. The test is rapid, inexpensive, and accurate and the results are available within 48 hours. Because positive reactions are given by tuberculous animals, the test is limited to use in tuberculosis-free herds.

A fluorescent antibody test is available but is unable to distinguish between the antigens of *M. avium* and *M. paratuberculosis*. It does distinguish between *M. paratuberculosis* and *Corynebacterium renale* which are easily confused by the complement fixation test. Combined with the CFT the fluorescent antibody test is used to detect early, subclinical cases, but the results are far from accurate. A refinement of the conventional fluorescent antibody test which gives greater accuracy in identifying specific mycobacterial antigens is the observation of the uptake by macrophages of fluorescein-coated insoluble spheres. The trouble with all of these serological tests is the failure to detect early cases.

ELISA Several different enzyme-linked immunosorbent assays (ELISA) tests are available.[15] The original ELISA test was considered to be sensitive but had low specificity. A modified ELISA had a sensitivity of 57% and a specificity of 98.9% in cattle positive on fecal culture. A new commercial kit known as the **Johne's Absorbed ELISA** (Herd Chek *Mycobacterium paratuberculosis* test kit, IDEXX Laboratories) has been evaluated.[87] Using samples from uninfected cattle, subclinically infected cattle shedding low numbers in the feces, subclinical heavy shedders, clinical cases, and randomly selected cattle in an abattoir the test had an overall sensitivity of 45% with a specificity of 99%. The sensitivity was 87% for clinical cases of Johne's disease and lowest for subclinical, light shedding cattle at 15%. Changing the cut-off point did not improve performance of the test. The test detected 60% of animals that shed the organism in their feces, as defined by conventional fecal culture, at the time of serum collection.

Other evaluations of the IDEXX test on individual cattle yielded a sensitivity varying from 15.4% to 88.1%, depending on the clinical stage and bacterial shedding of the animals.[88] Variability also occurs between samples collected at variable intervals. Repeated sampling of individual dairy cattle at intervals ranging from 77 to 600 days found that cows with an initial high S/P value (≥0.70) (a ratio for the value of the sample to the value of positive-control serum (S/P)) as determined by measurement of optical density (OD) were more likely to maintain positive status than cows classified as positive on the basis of cutoff values of ≥0.25 or ≥0.40.[89]

The herd sensitivity of the Herd Chek test has been evaluated in the Voluntary Johne's Disease Herd Status Program for identifying herds free from paratuberculosis in the United States.[90] Sensitivity at the herd level of the testing strategy used in Level 1 of the program (use of the ELISA to test samples from 30 cows followed by confirmatory fecal culture of positive cows) ranged from 33 to 84% for infected herds, depending on the percentage of cows in the herd with positive fecal culture. If followed-up fecal culture was not used to confirm positive ELISA results, sensitivity ranged from 70 to 93% but probability of identifying uninfected herds as infected was 89%. The test will fail to identify as infected most dairy herds with a low prevalence of paratuberculosis.

In dairy cattle herds participating in the Victorian Bovine Johne's Disease Test and Control Program (Australia), the ELISA sensitivities at the first test round in herds achieving 5, 6, and 7 annual herd tests were 16.1, 14.9, and 13.%, respectively.[91] The ELISA sensitivity in 2, 3, and 4-year-old animals at the first test round in herds testing seven times was 1.2, 8.9, and 11.6%, respectively. The estimated adjusted sensitivity of the absorbed ELISA for detection of *Map* in an unselected cattle population on the study ranged from 13.5 to 16.7% which is considerably lower than the estimates of 43–65% at which testing confidence in the program was planned to operate.

The proportion of ELISA-positive reactors in dairy cattle in Victoria, Australia, subsequently found to be infected on the basis of histological examination or culture increased from 70.1% to 89.4% over a 5-year period as more reactors were confirmed by culture of tissues at slaughter each year.[92] In Northern Australian cattle the estimates of specificity for the absorbed ELISA in mature cattle were 98.0% in beef cattle, 98.3% in dairy cattle.[93]

The ELISA response to *Map* may also vary according to the characteristics of the cow and stage of lactation.[94] The probability of being ELISA positive may be 2 to 3 times lower for cows in parity 1 compared to cows in later parities. In early lactation the probability of being positive was highest in the milk ELISA. In the serum ELISA the odds of being positive was highest at the end of lactation.

In Australia, in a population of sheep with a high prevalence of subclinical infection the sensitivity of the AGID test was 38–56% and the sensitivity of the absorbed ELISA was 34–54%.[95] The AGID was much better at detecting infected sheep in low body condition than the ELISA. But the ELISA was superior in detecting infected sheep with lesions localized or contained small numbers of acid-fast bacilli. In goats in Australia, the specificity of the AGID tests was 100% and the absorbed ELISA were 99.7 to 99.8%[96] but the ELISA is more sensitive for detection of infected goats and is recommended in preference to the AGID.

These results demonstrate the effect of stage of infection on serodiagnosis. The subclinical, light-shedding cattle are usually seronegative, whereas heavily infected animals are usually seropositive. In most cows in the early stages of infection when fecal shedding is low, the humoral antibody response is below the limit of detection, and currently available serologic tests are inadequate to detect those animals. As the infection progresses, the humoral response increases, and heavy fecal shedders and clinically affected animals are more readily detected.

Using milk samples from dairy cows to detect antibodies to the organism would facilitate the testing of large numbers of animals and potentially could be incorporated into routine milk testing programs. However, the milk ELISA for the detection of exposure to the organism in dairy cows lacked correlation with serum ELISA.[97]

In a single herd, 84 cows with signs of Johne's disease were tested before being sent to slaughter.[13] The disease was confirmed in 56 animals by culture and histopathology. *Map* was isolated from 70% of 56 fecal samples cultured from confirmed cases and acid-fast organisms were observed in smears from 23.6% of samples examined. The absorbed ELISA was positive in 76.8% of the animals. Serum samples from 58.9% had CF titers of 1/5 or greater and 41.4% had titers greater than 1/10. Overall the ELISA was the most sensitive and rapid method for identifying infected animals.

Immunity tests The in vivo tests of cell-mediated immunity included the skin and intravenous johnin tests which were the original tests used. They are no longer used because of inadequate sensitivity and specificity. The interferon gamma assay (IFN-γ) has been compared with serological tests for the diagnosis of *Map* in experimentally infected sheep[98] and for the natural disease in pygmy goats.[99] A modified interferon gamma assay has been evaluated for detection of paratuberculosis in dairy herds.[100] The combined use of the IFN-γ test and the absorbed ELISA antibody test accurately predicted infection status of 73% of cows from dairy herd with a high level of *Map* infection and 90% from a well-charaterized group of dairy cows. The antigen-specific IFN-γ assay is a very sensitive diagnostic aid for detection of subclinical infection in cattle and may be valuable on an individual animal basis to remove infected animals from the herd.

Skin testing as a means of measuring cell-mediated immunity has been replaced by assays for cytokines. A cytokine assay is available but insufficient data are available to recommend its use.[15]

Summary of diagnostic testing Only repeated testing of cattle, especially young animals, from infected herds will provide the data to determine the true infection rates within infected herds.[75] Based on monitoring 10 dairy herds tested repeatedly over 4 years the estimated sensitivity of fecal culture was 33%. The specificity of fecal culture has been accepted as 100%. The reported overall sensitivity of ELISA test ranges from 40 to 55% but most often in relationship to an insensitive fecal culture method. The sensitivity of the ELISA test is highest in those animals in the later stages of the disease, usually when the animals develop clinical disease. The estimated ELISA sensitivity for Stage 1 animals infected, but not detectable by fecal culture is unknown. However, the absorbed ELISA sensitivity for Stage 1 animals will be low at about 10%. Overall the absorbed ELISA detects approximately 35% of the animals found positive by concurrent fecal culture.

Tests for different situations

The above diagnostic tests are used under different situations which are outlined here.

- **Diagnosis confirmation.** The most rapid and accurate, and least expensive, test to confirm a clinical case of Johne's disease in cattle is the ELISA (USDA-licensed).[15] More than 85% of clinical cases with diarrhea and weight loss will be seropositive
- **Seropositive confirmation.** Confirmation of a seropositive animal may be desirable as in the case of valuable animals in a Johne's disease-free herd which are found unexpectedly positive or a bull of proven merit in an artificial insemination unit which is found positive. A positive fecal culture or surgical biopsy of ileocecal junction including one or two lymph nodes for histopathological examination
- **Estimation of prevalence.** The most rapid and easiest method to estimate prevalence of infection is to test all animals over 2 years of age with the ELISA.[15] The results are most reliable in herds confirmed to be infected by isolation of the organism. The true prevalence of infection in the herd is twice the apparent prevalence of infection as determined by the results of the ELISA (a test sensitivity of 50%). The diagnostic tests are most useful for estimation of prevalence in herds which have not been routinely tested, and for culling seropositive animals. The prevalence of infection will be underestimated in herds which have been culling clinical cases
- **Disease control.** The first herd diagnostic step in a control program is to test all animals over 2 years of age and consider culling all seropositive animals. After the ELISA-positive animals are culled from the herd, a second ELISA can be done on the entire herd again. An alternative is fecal culture which is more expensive but will detect animals missed by the ELISA. It is suggested that every third or fourth test should be a fecal culture.[15] The frequency of testing and the types of tests used will depend on factors such as: the type of farm enterprise and the use of the animals, the estimated prevalence of infection, the owner's perception of the importance of the disease and how it has affected productivity, the willingness of the owner to invest in the costs of the tests, how quickly the owner wishes to begin a control program, and the eagerness of the owner to control the disease
- **Herd certification.** A model herd certification program for Johne's disease was adopted by the US Animal Health Association in 1993.[15] The goal of the program is to establish uniform herd certification standards among the states. Identification of herds free of infection is vital to preventing spread of infection nationally and internationally. Certification of laboratories in performing the diagnostic tests such as being able to

culture the organism is an important part of the program. The model herd certification program consists of using the ELISA and an organism detection test, such as fecal culture, on an alternating basis annually on all animals in the herd more than 20 months of age. Herds are given levels of certification based on the number of herd negative tests up to level 5. After attaining a level 5 Johne's-free certification, herds can maintain certification by retesting annually with either a serum antibody test or organism detection-based test

- **Herd screening.** Testing herd replacements raised on the farm before they are nominated for breeding (15 months of age) would be a desirable strategy but the available tests are unlikely to detect subclinically infected animals at that age
- **Prepurchase testing.** Herds become infected by the introduction of unknown subclinically infected animals. The estimated risk of purchasing an infected animal from an auction mart or cattle dealer is 10% based on the overall prevalence of infection in the cattle population. Ideally, purchased herd replacements should be obtained from certified paratuberculosis-free herds. If these are not available the next best option is to purchase from herds which have had no recent history of clinical disease. Then a prepurchase plan should be arranged with the seller to test the animals, and the costs should be determined. If the seller is unwilling to cooperate with a prepurchase testing as a condition of sale, the buyer may wish to purchase the animal, and quarantine it until testing on the farm is completed. The ELISA is recommended for purchased animals but replacement heifers 12–15 months of age are unlikely to be seropositive and fecal culture would improve the accuracy of testing
- **Export testing.** The testing requirements for export of animals to other countries are set by the importing country. The complement fixation test has been commonly used but has insufficient sensitivity in young animals under 2 years of age. The ELISA may soon be accepted as an alternative but because of 50% sensitivity in young animals may also be inadequate. There is no available test which can detect subclinically infected breeding animals, which are commonly purchased under 24 months of age.

Sheep and goats

The tests used in cattle are applicable in sheep and goats but the diagnosis, particularly in sheep, and in an individual animal, is much more difficult than in cattle. Procedures for detecting the organism in feces, by microscopic examination, polymerase chain reaction assay, or culture are of limited value either because of low sensitivity or because of technical demands. The ELISA used in cattle is being used for the diagnosis in sheep and goats. The sensitivity and specificity are similar to those in cattle but cross-reactions occur due to *Corynebacterium pseudotuberculosis* and sera absorbed with those heat-treated organisms improve the results. The AGID and ELISA have been evaluated and compared in adult sheep culled from flocks with a history of severe chronic weight loss. The sheep were examined at necropsy, and sensitivity and specificity evaluated using histopathologic findings as a reference. The sensitivity and specificity of the AGID was 37% and 100%, respectively. The sensitivity of the ELISA was 48% but the specificity was only 89%. Other studies in diseased sheep report that the ELISA and AGID test had sensitivities of 62% and 78%, respectively. In sheep, a histopathologic spectrum is defined by the existence of two widely differing forms of the disease: a tuberculoid form with strong cell-mediated immune response and lesions characterized by small granulomata composed of a few epithelioid cells surrounded by a large number of lymphocytes and with no or few bacilli in the lesions; and a lepromatous form, with a strong humoral immune response accompanied by lesions consisting of macrophages full of large numbers of mycobacteria. The sensitivities of the ELISA and AGID test were 86% and 100%, respectively, in sheep with lepromatous lesions but the sensitivities in sheep with tuberculoid lesions were only 10–50% and 30%, respectively. Thus there is a close correlation between serologic response to AGID and the presence of acid-fast bacilli in the intestinal tissues, and the diagnosis of tuberculoid cases remains difficult. However, the AGID is rapid, inexpensive, easily available, technically easy to perform, and has practical efficacy compared to bacteriological culture of feces. The AGID is useful for flock-screening programs to identify infected sheep with chronic weight loss due to paratuberculosis, to confirm infection in sheep with clinical disease, and to identify sheep shedding the greatest number of organisms.

Serum biochemistry

A simple serum biochemistry profile of serum proteins and mineral status may provide a useful preliminary diagnosis of Johne's disease in emaciated and unthrifty sheep. Sheep with clinical Johne's disease have decreased serum concentrations of calcium, total serum proteins, and serum albumin compared with controls.[101] Serum protein concentrations in animals with Johne's disease ranged from 49 to 5 g/L with controls at 68 g/L. Serum albumin concentrations in affected sheep ranged from 14 to 19 g/L with controls at 29 g/L.[101] Sheep with the lepromatous lesions are more severely affected for calcium and protein depletion than the tuberculoid cases.

Deer

Deer and other wild species present a special problem because their capture and restraint are so hazardous. A single capture technique is required and this eliminates any delayed hypersensitivity skin tests. Fecal culture, complement fixation, and lymphocyte immunostimulation tests are satisfactory, with a preference for the latter as being most accurate.

NECROPSY FINDINGS

Cattle

Lesions are confined to the posterior part of the alimentary tract and its associated lymph nodes. The terminal part of the small intestine, the cecum, and the first part of the colon are usually affected. In advanced cases the lesions may extend from the rectum to the duodenum. Typically, the intestinal wall is three or four times normal thickness, with a corrugated mucosa and prominent thickened serosal lymphatics. The ileocecal valve is always involved, the lesion varying from reddening of the lips of the valve in the early stages to edema with gross thickening and corrugation later. A high incidence of arteriosclerosis has been observed in advanced cases of Johne's disease, with a distinct correlation between the vascular lesions and macroscopic changes in the intestine. The mesenteric and ileocecal lymph nodes are enlarged and edematous, but unlike tuberculosis, foci of necrosis and mineralization are rarely visible. The characteristic microscopic findings include large numbers of epithelioid macrophages and multinucleate giant cells within the lamina propria and submucosa of affected gut segments and within the paracortical areas of draining lymph nodes. A granulomatous lymphangitis is often visible.

Rabbits

In natural paratuberculosis in rabbits there are no macroscopical lesions suggestive of Johne's disease.[102] Histopathologically, the lesions are either severe or mild. Severe lesions consist of extensive

macrophage granulomata and numerous giant cells, with many intracellular acid-fast bacteria in the small intestine.

Sheep and goats

Gross necropsy lesions are often minimal despite severe clinical signs during life. Emaciation and subcutaneous edema are usually present. In sheep there may be a deep yellow pigmentation of the intestinal wall and of the cortex of the draining lymph nodes. The intestinal wall may be thickened, although corrugation of the mucosa is not a common finding. Serosal lymphatics are often very prominent. Caseation and mineralization of the lymph nodes or enteric tubercules may occur. The pattern of lesions seen in cases of ovine paratuberculosis may be classified into two major types and detailed descriptions of these histopathologic changes are available.[74]

Bacteremia occurs with *M. paratuberculosis* infection, so granulomatous lesions are sometimes identified in filtering organs such as the liver, lung, and spleen. No lesions occur in an infected fetus but the organism can be isolated from its viscera and from the placenta and uterus. Traditionally, the most accurate postmortem tests to detect *M. paratuberculosis* have been a combination of histopathologic examination and bacteriological culture. The development of PCR techniques may eventually provide a higher level of sensitivity. For most clinical cases of paratuberculosis, the demonstration of acidfast bacilli within typical lesions is sufficient for confirmation of the diagnosis at necropsy. *M. paratuberculosis* can be detected in ruminant tissue sections from formalin-fixed, paraffin-embedded blocks with a PCR technique that utilizes primers specific for the IS900 sequence of the organism.[103] The technique is more sensitive than acid-fast Ziehl–Neelsen and immunohistochemical staining.

In adult goats with clinical and subclinical paratuberculosis, the lesions were divided into four categories.[104] Focal lesions consisted of small granulomata in the ileocecal Peyer's patches or related lamina propria. Diffuse multibacillary lesions consisted of a granulomatous enteritis, affecting different intestinal sites. Numerous macrophages containing many mycobacteria are usually present, resulting in macroscopical changes in the normal gut morphology. In diffuse lymphocytic lesions, the lymphocyte was the main inflammatory cell, with some macrophages. In diffuse mixed lesions the infiltrate consisted of numerous lymphocytes and macrophages, with small numbers of mycobacteria. The three types of diffuse lesions are often associated with necrosis in the lymph vessels of the mucosa, mesentery, and lymph nodes, and with greater thickening of the jejunum than of the ileum.

Experimental subclinical infection of goat kids with *Map* at several weeks of age and killed 2 years later, results in lesions predominantly associated with intestinal segments containing persistent organized lymphoid tissue, the distal jejunum, and proximal ileum being without lesions.[105]

Bison

The lesions of paratuberculosis in the American bison (*Bison bison*) are similar to those in cattle.[5] Gross intestinal lesions are most common in the distal segments of the small intestine and the mesenteric lymph nodes are grossly enlarged. In a study of 70 bison suspected of having Johne's disease the AGID test identified only 3% of the morphologically positive animals, the ELISA identified 69%, and of a sample of 25/70, only 40% were positive on fecal culture. The fecal PCR identified 73% and the tissue PCR identified 100% of the morphologically positive animals.[5]

Samples for confirmation of diagnosis

- Bacteriology – distal ileum, colon, ileocecal lymph node (CULT (has special growth requirements), DIRECT SMEAR (acid-fast stains), PCR)
- Histology – formalin-fixed samples of these tissues (LM, PCR).

DIFFERENTIAL DIAGNOSIS

The characteristic features of clinical Johne's disease include chronic diarrhea which does not respond to therapy, progressive weight loss, and emaciation in a single animal. The definitive etiological diagnosis can be obtained by using a combination of serological tests, fecal culture, and biopsy of intestine.

Cattle

In cattle the clinical disease must be differentiated from diseases which cause chronic diarrhea in adult cattle. The chronic nature of Johne's disease is usually sufficient to differentiate it from the other common enteritis of cattle. **Salmonellosis, coccidiosis**, and **gastrointestinal helminthiasis** are usually acute and the latter two occur principally in younger animals and are distinguishable on fecal examination for oocysts and helminth eggs. **Secondary copper deficiency (chronic molybdenum poisoning)** is likely to be confused with Johne's disease in cattle, but is usually an area problem affecting large numbers of animals and responds well to the administration of copper. Other debilitating diseases in which diarrhea is not an important clinical finding are **malnutrition, chronic reticuloperitonitis, hepatic abscess, pyelonephritis, lymphosarcoma, and amyloidosis.**

Idiopathic eosinophilic enteritis in cattle is characterized clinically by chronic diarrhea and weight loss, and recovery may occur following treatment with dexamethasone.[106]

Sheep and goats

The characteristic features of clinical Johne's disease in sheep and goats are emaciation, weakness, and normal feces with intermittent bouts of mild diarrhea. The other causes of unexplained weight loss in sheep and goats include **caseous lymphadenitis, internal abscesses, gastrointestinal parasitism, caprine arthritis-encephalitis, ovine progressive pneumonia, dietary deficiencies, and dental disease.** A guide to the differential diagnosis, therapy, and management of unexplained weight loss in sheep and goats is available.

The major difficulty encountered in the diagnosis of paratuberculosis is the accurate identification of subclinically infected animals which are negative to the serological tests but are in the intermediate stage of the diseases and excreting the organism in their feces. This is a major diagnostic problem in the individual animal. On a herd basis the serological tests will usually indicate if the infection is present or absent in the herd and this can then be followed up by fecal culture to identify animals which are shedders. A combination of a highly sensitive and specific serological test, with fecal culture should improve the accuracy of diagnosis.

TREATMENT

Currently, no antimicrobials are approved for the treatment of Johne's disease. *M. paratuberculosis* is more resistant to chemotherapeutic agents in vitro than *M. tuberculosis* so that prospects for suitable treatment are poor. Because of this lack of efficacy and the failure of any of the antimicrobials to provide a bacteriological cure, treatment is not recommended. The antimicrobials which have been used are summarized here:

- **Streptomycin** has most activity against the organism but treatment of affected cattle with daily doses of 50 mg/kg BW IM causes only a transient improvement in clinical signs
- **Isoniazid** given to cattle at 20 mg/kg BW orally daily for up to 100 days has a minor degree of activity against the organism but failed to cure clinical cases of Johne's disease[107]
- **Clofazimine**, a phenazine dye, shows some activity against early infections in sheep, and causes transitory but obvious clinical improvement in cattle when given to cattle at a dose of 600 mg daily for 10 months[107]
- **Monensin and tilcomisin** have been evaluated as therapeutic agents in an experimental murine model. Neither

time of incubation nor concentration of medication had any effect on the infectivity of the organisms.[108] Monensin significantly reduced the number of hepatic granulomas in genetically susceptible mice while tilmicosin phosphate did not. Monensin fed to adult cows with clinical Johne's disease at a rate of 147.5 mg/kg in the feed, each cow receiving 450 mg of monensin daily for 120 days, resulted in a beneficial effect on the lesions in the ileum, liver, and rectal mucosa compared to the controls in which the course of the disease worsened.[109]

CONTROL

The control of Johne's disease in ruminants is challenging because of the ubiquitous nature of the organism, the long incubation period, most cases are subclinical, and the laboratory tests available lack sufficient sensitivity to identify infected animals which allows the infection to spread within and between herds.

Although there are large gaps in the understanding of various aspects of the epidemiology of *Map* and the diagnostic tests are not reliable in the early stages of infection, enough is known about the essentials of control programs for dairy herds which were proposed 50 years ago.[15] There is little difference from currently recommended control strategies. The implementation of herd or flock level control programs, establishment of test-negative or low-risk herds or flocks, and reduction of environment and feed contamination with *Map* are attainable goals.

Because of the inaccuracy of the diagnostic tests available, it is impossible to eradicate the disease, other than by complete depopulation of the herd and restocking with non-infected animals. Eradication strategies are usually not practical for economic reasons and the impossibility of acquiring non-infected animals. The next best option is control of the disease at a very low level of prevalence. Veterinarians usually are uncertain how to begin a control program in a herd once clinical disease has been encountered. Generic control recommendations often fail because they do not account for uncertainties inherent in control recommendations or for the unique circumstances of an individual herd. A systematic and practical farm-specific approach to control is recommended and the details are available.[110] The literature on the control of *Map* infection in agricultural species on a worldwide basis has been reviewed.[111]

A complete comprehensive control program consists of understanding three major aspects which should be explained to the producer before planning a control program:

- Issues that impede efforts to control Johne's disease
- Characteristics of tests and alternative testing strategies that influence control programs
- Developing farm-specific control programs.

Issues that impede efforts to control Johne's disease

The subclinical nature and long incubation of the disease makes it difficult to identify infected animals early enough before they shed organisms in the environment and infect other animals.[112] Because of its subclinical nature, producers tend not to recognize the importance of the disease and do not practice control measures. Successful control requires a commitment by the herd owner over many years.

The low level of clinical cases, a 5% population mortality rate per year, also impedes control efforts because the producer is not aware that the infection rate may be as high as 50% at any one time.

Incomplete understanding of some of the risk factors involved in control of the disease and the economic importance of the disease has slowed progress towards effective control procedures.

The lack of integrated national control programs in countries where the disease is endemic allows the disease to spread continuously from herd to herd and region to region. In the past many attempts have been made to decrease the prevalence of *Map* using a test-and-cull and vaccination strategies. However, none of these strategies has been effective in controlling *Map*, and the worldwide prevalence of infection continues to increase.[113] The **Voluntary Johne's Disease Herd Status Program** was developed in the United States in an effort to certify herds free of paratuberculosis. The program was intended as a model for control programs within each state, and the guidelines were considered to be minimal requirements to control the disease in dairy herds. In 2002, USDA-APHIS published the Uniform Program Standards for the Voluntary Bovine Johne's Disease Control Program.[15] The purpose of the document was to provide minimum national standards for the control of Johne's disease. The program outlines a testing strategy in addition to establishing education and management requirements for herds which choose to participate. At the state level, administrative requirements for personnel, Johne's-certified veterinarians and an advisory committee are established. Finally, performance standards for diagnostic laboratories as part of the program are identified.

Results consistently demonstrate that participation in a testing program for Johne's disease is associated with the adoption of management practices recommended for disease control.[114] Producers who believed their herds were not infected with Johne's disease might have felt it was unnecessary to adopt the management practices recommended for Johne's disease control.

A simulation model reveals that the mean prevalence of paratuberculosis as well as the economic loss attributable to the disease will slowly increase in a typical midsize dairy herd in the US if a control program is not implemented.[113] However, analysis of results indicate that the test-and-cull strategies alone do not reduce the prevalence of *Map* in cattle and are costly for producers.[113] Vaccination did not reduce the prevalence of infection but was economically attractive. Calf health management strategies were found to be critically important in every control program and most were economically attractive to midsize dairy herds in the US.[113]

The failure of herd owners to acknowledge that their herds are infected is another obstacle to control.

Failure of cattle producers to comply with the recommendations for control of Johne's disease is a major factor in failure of control programs.[111] In a survey of responses by dairy farmers in Victoria, Australia, 91% failed to comply with more than two of six important recommendations regarding calf health management.

To be effective, the control plans must be integrated with the unique resources and management skills of individual farms. The management capability of the producer, the facilities available, the nature of the herd, the disease control procedures already in place, the financial resources available, and the long-term production goals of the producer are crucial to a successful control program. Producers must be informed and understand that an effective control program may require up to 3–5 years before results are obvious.

Characteristics of diagnostic tests and alternative testing strategies that influence control programs

The diagnostic tests have been described under Clinical pathology. The veterinarian must be fully informed about the sensitivity and specificity of the tests available and select appropriate tests. The ELISA and fecal culture are most commonly used with an overall sensitivity of about 40–50% and specificity of about 98–100%. A single test with the ELISA fails to detect about 50% of infected animals. A combination of the ELISA and fecal culture is

most effective in detecting animals in the later stages of infection. The sensitivity of both tests will be higher in herds with a high prevalence of infection.

Cost of the tests is a factor. Herd testing is expensive and producers are commonly reluctant to invest in the costs necessary.

Interpretation of the results and the making of decisions about the results based on ELISA or fecal culture testing requires leadership from the veterinarian to explain the options and their consequences. Testing provides an estimate of the prevalence of infection in the herd and can be used to monitor progress over time. Testing and culling infected animals promptly reduces the prevalence of infection immediately. Animals with clinical disease shed large numbers of organisms and should be culled immediately; delaying culling merely allows spreading of infection to continue. In some cases, culling certain infected animals may not be appropriate for economic reasons, and segregating them from the rest of the herd as a separate group can be considered if facilities are available. These animals can be culled over a period of time as part of the culling program of the herd. Culling of the progeny of subclinically infected animals and those with clinical disease should also be given high priority.

How often testing should be done, which animals should be tested, and which combination of tests to be used each time are major considerations. Repeated testing following the initial test until the prevalence of infection is low is recommended.[75] Only repeated testing of cattle, including youngstock, from infected herds will provide the data to determine the true infection rates within infected herds.

Choosing which groups of animals in the herd are to be tested is a major consideration. The entire herd or subgroups can be tested initially. Testing animals under 18–20 months is usually not informative because of the low sensitivity of the test. Examples of subgroups which can be tested include those with evidence of clinical disease and their age cohorts, animals related to or exposed to infected animals, animals from the same infected source, or animals which are probably not infected. Animals being brought into the herd should be tested with the ELISA and fecal culture.

Developing farm-specific control programs

Understanding the issues that impede control and the characteristics of the tests used indicate that the development of effective on-farm control plans and strategies should be directed towards the individual farm using the principles of control.[110] Each farm and herd is different, the management capability varies considerably, and the disease status of affected herds varies widely. Therefore, the control program should be planned and implemented to meet the needs of the herd in question.

Control on a herd basis

Principles of control

The control of Johne's disease is based on two major principles:

- The identification and elimination of infected animals
- The prevention of new infections.

Dairy and beef cattle herds

Identification and elimination of infected animals

Identification of infected animals is done using the diagnostic tests available, and prevention of new infections depends on improvement of environmental management and avoiding the introduction of infected animals into the herd. Vaccination is also a control strategy to prevent clinical disease but it does not prevent infection.

Livestock owners are often unaware of the essential features of Johne's disease and must be educated by the veterinarian. A successful control program depends heavily on how well the owner understands some fundamental premises about the control of Johne's disease which are:[15,111]

- Infection occurs most commonly in calves during the first 6 months of life and the incubation period of clinical disease varies from 2 to 5 years
- The disease decreases milk production in subclinically infected cows and shortens the productive herd-life of cows
- Spread of infection occurs by the fecal–oral route, by congenital transmission, and through colostrum and milk of infected cows
- Calves born to infected cows have a higher likelihood of becoming infected than calves born to non-infected cows
- It must be managed as a herd disease, not an individual animal disease. The disease must be controlled to improve the productivity and profitability of the herd
- The rate of infection in the herd will increase with time unless control procedures are implemented
- The disease can be controlled. Diagnostic tests are available and there is sufficient information available about methods of transmission so that infected animals can be identified and new infections prevented
- Control in a herd takes time and requires changes in management to prevent new infections, and the identification and elimination by culling of both clinical affected and subclinically infected animals. Reducing the prevalence of infection to a low level requires 3–7 years; to eliminate infection and reduce prevalence to 0% 7–15 years; to reduce and eliminate clinical disease 2–5 years.

Each of these goals depends on how the owner adopts and implements the control procedures and monitors progress by continued testing.

Before undertaking a control program, the owner of the herd should address three questions:

1. What are the objectives for the herd? Milk production, meat production, or rearing of breeding stock? Commercial milk producers may not be concerned about the disease and may merely cull clinical cases as they occur. If the prevalence of infection is below 5% the effects may be minimal. Breeders and owners of pedigreed breeding stock for sale to other herds will be interested in eradication of the infection from the herd.
2. What are the long-term goals of the producer? Because of the slow spread of the disease, it takes several years for clinical disease to become evident and several years for control to be effective. Unless the owner intends to maintain the herd for several years, there may be little justification for a comprehensive program.
3. How aggressively does the owner want to adopt and implement the control program? Owners must consider their available financial and managemental resources, housing facilities, and their understanding of the concepts and requirements of control. Many Johne's disease control programs fail because of lack of client compliance and loss of interest within a short time after beginning the program.

Determination of prevalence of infection in the herd

The first step in a control program is to estimate the prevalence of infection using a diagnostic test such as the ELISA. All animals over 2 years of age are tested, and with a test sensitivity of 50% the true prevalence of infection will be approximately twice the results of the test. The first test will provide an indication of the magnitude of infection in the herd and

decisions about culling and further testing in the future can be made.

Culling clinical cases and subclinically infected animals (identification and elimination of infected animals). The simplest program is to cull clinical cases as they occur and not test the herd but this will not eliminate subclinically infected animals and the infection will continue to spread in the herd.

The first test to estimate the prevalence of infection will identify seropositive animals which along with their offspring can be culled and sold only for slaughter. Calves from infected animals can be kept separate and grown and fed under feedlot conditions until ready for market. The farm is quarantined and residual animals are retested at 6- to 12-month intervals until two consecutive negative herd tests are achieved. A combination of the ELISA and fecal culture of all animals over 2 years of age every 6 months is recommended.[15] Not all fecal-positive animals will be seropositive and fecal culture-positive cows and their offspring should be culled and slaughtered even if seronegative. The disease can be markedly reduced by this method but results depend largely on the degree of contamination of the environment. The method has the virtue that many heavy fecal shedders are detected early, and the contamination of pastures is reduced. The culture and cull method is much more accurate, but is expensive and still has the deficiency that resistant, intermittent shedders may escape detection. Another alternative is to maintain infected and non-infected herds separately. The progeny of the infected cows are raised separately from their dams and should not be returned to the uninfected herd unless tested and found to be negative.

A simulation model of the control of the disease in a dairy herd indicated that test-and-cull control procedures decrease the prevalence of infection in the herd and that test sensitivity was the sole determinant of this control strategy. A combination of test-and-cull and improved calf-management techniques provides the most rapid means of controlling the disease in a dairy herd.

An economic decision analysis model of paratuberculosis in a dairy herd indicates that a test-and-cull program should be profitable when the pretest prevalence of infection is greater than 5%. The model predicted that the best diagnostic test would be the one with the highest specificity and lowest cost, with test sensitivity of secondary importance. Given the costs of various types of diagnostic technology, it appears that the absorbed ELISA is the most efficient for testing and culling programs.

Prevention of new infections

Biosecurity. For herds free of Johne's disease, all measures must be employed to avoid the introduction of infected animals into the herd by maintaining a completely closed herd or by carefully screening purchased animals. The purchase of cattle is the most common way *Map* is introduced into a herd.[45] Purchasing cattle only from herds documented to be free of Johne's disease is preferable to testing specific cattle prior to introduction because of the low sensitivity of available tests for individual cattle.[115] Currently this is difficult because less than 1% of US dairy herds participate in a Johne's disease certification program.[51] Dairy herds using typical management practices experience preventable risks of Johne's infection and disease. A dairy herd with 400 cows in milk that introduces 40 cows per year from the general population of dairy cows has an estimated 64% probability of introducing *Map* to the herd. This risk could be reduced to 4% through the purchase of cows from herds at level 2 of the US Voluntary Johne's Disease Herd Status Program.[116] A simulation model to assess the risk of introduction of *Map* infection into a dairy herd through purchase of female replacement cattle has been used to estimate the probabilities of a producer purchasing an infected lot during a given period of time.[115] The probability of introducing infection is directly proportional to the prevalence of infection in the herds of origin.

In a control program for Johne's disease, certified *Mycobacterium* subsp. *paratuberculosis*-free cattle herds are essential as sources of non-infected cattle.

All herd replacements should be tested and found negative before being purchased and introduced into the herd. Only test-negative animals from herds with no or few positive animals should be purchased. Owners should be provided with an information sheet explaining how to limit the risk of buying subclinically infected cattle.[15]

Environment and management (preventing new infections)

Veterinarians should promote management recommendations which adapt recognized control principles to specific situations.[15] Most control measures are in one of three generally accepted categories of Johne's disease control.

Dairy Herds

1. **Minimize contact between young and older animals and from fecal contaminated feed and water:**
   - Clean and disinfect maternity and calf pens after each use
   - Calve cows in clean, dry, dedicated maternity pens
   - Remove calves immediately after birth to clean, dry calf pens, stalls, or hutches
   - Feed colostrum only from test-negative cows
   - After colostrum feeding, use pasteurized milk, or use milk replacer
   - Raise calves separate from the adult herd for at least the first year of life
   - Do not allow shared feed or water between adults and young animals; do not offer feed refusals from adult cattle to young animals
   - Avoid vehicular and human traffic from adult animal areas to young animal areas.
2. **Prevent manure contamination of feed and water sources:**
   - Use separate equipment for handling feed and manure
   - Design and maintain feedbunks and waterers to minimize risk of contamination with manure
   - Do not spread manure on grazing land.
3. **Reduce total farm exposure to the organism:**
   - Immediately cull all animals with clinical evidence of Johne's disease
   - Cull culture-positive animals as soon as possible; for cows with low or moderate fecal culture colony counts, removal at the end of lactation may be acceptable
   - Test adult cattle at least annually by serum or fecal tests; positive serum test results should be confirmed by fecal culture
   - Purchase replacement animals from test-negative herds; if this is not possible, assess the status of the herd of origin through owner or veterinarian's statements, by negative serum ELISA tests of at least 30 adult animals, or both.

Hygiene. Controlling the disease at a low level of prevalence in the herd requires hygienic precautions to limit the spread of infection. Environmental conditions and manure handling procedures correlate with prevalence of infection.[117] Overall cleanliness of the farm, especially the amount of fecal contamination resulting from the design, maintenance, location of the housing facilities, and frequency of cleaning are important items for discussion with the producer. Opportunities for exposure of young cattle to adult cattle feces, either because of direct access to water contaminated from adult cow feces or because of the common practice of using the same loader for feeding and

manure handling of young stock and adult groups of cattle are risk factors to be removed or modified. Avoidance of fecal pollution of drinking water and feed by providing troughs in high positions, fencing of marshes and ponds, and closing contaminated pastures for up to 3 years are worthwhile measures.

Strip grazing should be avoided as fecal contamination of pasture is likely to be intense. The provision of piped water supplies to cattle on pasture rather than the use of ponds and ditches has been associated with a decline in the incidence of Johne's disease. Frequent harrowing of pasture fields to disseminate dung pats facilitates destruction of the bacteria by exposing them to sun and drying. Yard and barn manure should be spread only on cultivated fields.

In infected herds, any animal with any signs suggestive of the disease should be isolated until its status has been determined. Adoption of these hygienic precautions has been shown to greatly reduce the prevalence of the disease.

Dairy calf health management. Attention to calf health management practices is a vital component of a control program.[15,117] A simulation model of the control of the disease in a dairy herd indicates that calf-management techniques that reduce the number of effective cow–calf contacts decreases the prevalence of infection in the herd. Although congenital infection may occur, it is still advisable to rear calves away from infected cows, and if possible in individual pens to prevent spread among the calves. Newborn dairy calves should be removed from the dam immediately after birth and fed colostrum by stomach tube and reared in individual calf pens. Colostrum must be collected with care to avoid contamination with feces. Dirty and fecal-stained udders of recently calved cows should be cleaned before collecting colostrum.

High-temperature, short-time (HTST – 72°C for 15 s), on-farm pasteurization of raw milk is effective for the destruction of *Map* and effectively destroys *Map* in colostrum.[36] On-farm pasteurization of moderately sized (57 L) batches of colostrum using a commercial batch pasteurizer at 63°C for 30 min produces colostrum of normal or only mildly thickened consistency which can be fed to calves.[118] Batch pasteurization does result in a significant reduction in IgG in colostrum but the concentrations are higher after pasteurization when the fresh colostrum IgG is >60 mg/mL. Feeding at least 4 L of fresh or pasteurized colostrum results in similar concentrations of serum IgG concentrations.

This provides dairy producers with an alternative to purchasing commercial replacement products, resulting in reduced costs. Pasteurized waste milk also significantly reduces the incidence of infectious diseases of calves. On-farm batch pasteurization at 65.5°C for 30 min is adequate to destroy *Map* in waste milk.[119]

Group housing for periparturient dairy cows has been considered a practice with increased risk of Johne's disease transmission because access by multiple cows to calving areas can predispose newborn calves to increased risk of exposure to *Map*.[51]

The variable use of an exercise lot for lactating dairy cows was associated with a three-fold increase in odds of a herd being positive for *Map*.

Dairy cows due to calve should be kept separately from the milking herd and calved in calving box stalls. Calves from cows which are clinically affected should not be reared as herd replacements but grown and fed for beef production. Sucking of dams and nurse cows should not be permitted. Milk for bucket feedings should be collected hygienically and rearing on milk substitutes should be encouraged. Calves from birth to breeding age should not have any contact with yearling animals or mature cows which may shed the organism. Postweaning calves should not have contact with the adult herd in order to avoid infections.[15] In dairy herds with a high prevalence of infection, calves should be moved to calf barns and hutches rather than to pens in the cow barn.

New York State Cattle Health Assurance Program (NYSCHAP). This program is designed to encourage dairy producers to adopt best management practices to minimize the transmission of infection.[120] Farms enrolled in the program were given a herd-specific plan with intervention strategies ranked to limit the risk of spread on each farm. Effective communication and understanding of the issue between farmers, veterinarians, employees, herd veterinarians, and state veterinarians, is required for success.

Beef Herds Control programs for beef cow-calf herds apply the same principles as for those in dairy herds but must adapt the procedures to meet calf health management needs. Some specific control measures for beef herds include:

- Avoid manure build-up in pastures and corrals where late-gestation cows are kept
- Provide a clean calving area, with low cow density
- Move cow–calf pairs to clean pasture as soon as bonding occurs
- Move feedbunks, waterers, and creep-feed areas frequently to avoid exposing calves to manure build-up
- Do not place weaned calves on pasture used by cows
- Blood or fecal test the entire breeding herd annually; avoid calving-out and raising offspring from test-positive animals
- If possible, calve first-calf heifers in an area separate from older cows.

Sheep and goats

Sheep

The control or eradication of Johne's disease in sheep flocks has been more widely accepted and implemented in Australia than in many other sheep-raising countries.[9,15,101] The Australian program is based on negative serologic testing (ELISA or AGID) of a sample of the adult flock (2 years or older) and culling positive animals. The flock-sampling program, which is designed to detect a 2% or greater prevalence of infection with 95% confidence, requires testing 400–500 sheep from each flock. Management procedures include boundary fencing and introducing flock additions only from flocks of similar *Map* status. Fecal culture of pooled fecal pellets from up to 50 animals per pool and use of Middlebrook agar or modified BACTEC radiometric medium have greatly improved the sensitivity of detection of positive animals.

Vaccination is a common method of control of ovine paratuberculosis. Because of the higher ratio of diagnostic test cost per individual animal value, fecal culture is not a practical test in sheep flocks. In addition, the ovine strains are more difficult to culture from feces than in cattle. An economic and epidemiological simulation of different control strategies for ovine paratuberculosis evaluated no intervention, testing and culling, vaccination, and testing and culling together with vaccination. The size of the flock was 200 and annual replacement rate by causes other than Johne's was 15%. Vaccination was considered to be 90% effective. Eradication could be reached with any of the three methods in 10 years and, in a situation of low prevalence, the costs for culling methods are higher than those of no intervention. At high prevalence rates, these methods become more profitable but do not cover the high costs of replacing the culled animals. The best strategy is to vaccinate the replacement ewes, a practice which reaches a positive benefit–cost ratio at both levels of prevalence and does not demand heavy initial investment. Use of the Weybridge vaccine given to lambs before they were 1-month-old, subcutaneously in the brisket, successfully controlled the disease after 3 years of vaccination.[121]

The use of a live-attenuated vaccine against paratuberculosis in sheep may

have therapeutic value. Vaccination of lambs with a live-attenuated vaccine two weeks after experimental infection with *Map* stimulated a host response against the organism and resulted in a reduced mycobacterial burden. Both the antibody response and the gamma interferon response were detected earlier and were more substantial in the vaccinated group.[122]

Vaccination with the Sigurdsson vaccine of heat-killed *M. paratuberculosis* in mineral oil has given excellent results, reducing the disease to negligible proportions. The use of vaccination in sheep is not impeded by interference with tuberculin testing. However, vaccination of sheep will result in positive CFT titers which can interfere with serological testing for export and diagnostic purposes.[15]

Goats

The disease can be eradicated from a goat herd by identifying positive animals by fecal culture semiannually, using AGID testing quarterly, and weighing all goats monthly. The essential elements of the control program evolved over a period of 5 years. Treatment trials were ineffective. The environmental and management changes included:

- Minimization of contamination of feed and water supplies by introduction of keyhole feeders, metal grain troughs, and automatic waterers
- Movement of goats between pens was discontinued unless essential for health reasons
- Pen cleaning was changed from once a week to three times weekly
- Pasturing of goats was discontinued
- Accumulated goat manure was spread on fields and plowed under before hay fields were reseeded
- Young and newly acquired goats were kept isolated from the general herd until their test status had been determined
- Personnel dipped their footwear in disinfecting solution before entering or exiting barns or isolation areas.

A high incidence of clinical Johne's disease in goats has been controlled by the vaccination of adult goats using a commercial inactivated vaccine.[123] The incidence of clinical cases was markedly reduced in the vaccinates compared to the non-vaccinated animals.

Vaccination of cattle

If local legislation permits it, vaccination provides protection against clinical disease and reduces the rate of spread of infection but it will not eliminate infection. Because of the potential risk of spreading *Map* from cattle vaccinated with the live vaccine, and the possible association between *Map* and Crohn's disease, only killed vaccines have been allowed for use in the Netherlands.[124] Vaccination of calves with a killed vaccine does not prevent transmission of natural infection, and therefore, management practices remain essential for control of Johne's disease.

The efficacy of vaccination has been questioned and reported results of vaccine trials are varied ranging from no reduction in infection rate, to 50–90% reduction. The current consensus is that vaccination may reduce the incidence of clinical disease, and to a lesser extent the prevalence of infection, but vaccinates are not fully protected from infection.

In a cross-section study of 25 vaccinated and 29 non-vaccinated herds the rate of shedding of *Map* was not significantly different between the vaccinated (4.4%) and non-vaccinated herds (6.7%). Two years of culturing feces of each herd at 6-month intervals, was effective in decreasing the prevalence of infection in vaccinated and non-vaccinated herds. The culling of fecal culture cows, combined with prevention of infection through proper calf health management practices were more important than vaccination.[124] Farm management practices which limited the opportunities for transmission of *Map* were as important in decreasing the rate of shedding of *Map* in the feces as did vaccination.

Vaccination is done only in calves less than 1 month of age.[15,111] Calves are not revaccinated because the degree of protection appears to diminish and because of the unsightly nodules which sometimes develop. The vaccine is of no benefit to infected animals, but it is incapable of causing the disease or of producing carriers.

A major complication is that vaccinated animals are positive to the johnin test and to the tuberculin test, using both avian and mammalian tuberculin, but much less to the mammalian tuberculin. The positive test to tuberculin is maximum at 5 weeks after vaccination and has completely disappeared at 18 months. In general terms, vaccination can be recommended in heavily infected, tuberculosis-free herds, but only in areas where tuberculosis eradication is neither underway nor projected. The comparative tuberculin test can be used to detect tuberculosis in Johne's vaccinated herds. Vaccination of calves from 5 to 40 days of age with an inactivated paratuberculosis vaccine resulted in positive ELISA titers for at least the first 15 months, which could interfere with the serodiagnosis of the disease in control programs that are based on serological tests.

Vaccination of dairy calves in the Netherlands reduced the number of clinically affected animals by almost 90%.[111] It also reduced the number of subclinically infected animals and those with a histological and/or bacteriological test result. Vaccination did not prevent loss of milk production but it reduced infection pressure and the clinical disease. Partial budgeting revealed that vaccination was highly profitable per cow. Similar vaccination trials in dairy herds indicates a reduction in clinical disease, reduction in culling due to Johne's disease, but prevalence of infection may not be reduced. In a control trial over 5 years, the vaccination of calves in a large dairy herd in which the management was not changed resulted in a marked reduction in fecal shedding.[111]

Vaccination for paratuberculosis in The Netherlands has been restricted to herds with severe clinical disease. A heat-killed vaccine was given to calves in the first few months of age.[125] The effect of the vaccine on the long-term immune response was evaluated in two Dutch dairy herds over a period of 12–14 years. The B-cell response was evaluated using both the CFT and an ELISA, and the cell-mediated immunity was evaluated using the gamma interferon assay.[125] The vaccine had a marked and prolonged effect on both the cellular and humoral immune responses, in particular to the paratuberculosis antigen and to the bovine tuberculin.

Vaccination is available on a limited basis in the United States. The vaccine currently approved for use is an oil suspension of killed Strain 18 organisms, originally considered to be a laboratory-adapted strain of *Map* but now known to be a closely related strain of *M. avium* and not subsp. *paratuberculosis*. The immune response in calves following vaccination before or after oral challenge to *Map* and using both a commercial *M. avium* Strain 18 and a field-isolate of *Map* vaccine preparations has been examined.[126] The effect of prior exposure to *Map* and the adjuvant effect of (human recombinant interleukin) rIL-12 on vaccine efficacy was also tested. A significant reduction in mycobacterial colonization was observed when calves were vaccinated with the field isolate prior to challenge but not following vaccination with Strain 18 vaccine. Vaccination with (interleukin) rIL-12 prevented infection in some calves but its overall effect on gamma interferon response and total mycobacterial load was not significant. The efficacy of paratuberculosis vaccines may be enhanced if calves are vaccinated prior to *Map* exposure with field-isolate vaccine instead of Strain 18 vaccine currently in use.

Control on a country-wide basis

Johne's disease in cattle is being recognized with increased frequency in North

America and elsewhere. The overall prevalence of infection in dairy cattle is about 10% and no reliable data are available for beef herds. Despite reports that the disease is spreading in the cattle population and the reported economic losses associated with the disease, there is no concerted national effort to control the disease.[15] The recent concern that Crohn's disease in man may be associated with *M. paratuberculosis* has increased the level of awareness of the disease and livestock producers and the veterinary profession have become interested in control programs. Livestock producers who have developed non-infected herds are also interested in maintaining their infection-free status. It has been suggested that the time has come for the livestock industry and the veterinary profession to take Johne's disease seriously. The continued spread of infection in cattle herds, the economic consequences of loss in productivity, and the biological possibility that the organism may be a food-borne disease deserves consideration by the appropriate authorities and research agencies.

Historically, national efforts to control Johne's disease have not been successful because the livestock industry was not convinced of its economic importance and because the diagnostic tests did not have a good reputation. As a result no concerted national or regional effort was made to control the disease, which allowed the continued spread of infection between herds and between regions because of the movement of breeding animals. Currently, there are wide variations in how Johne's disease is controlled by national, state, or provincial agencies. In some jurisdictions, the disease is reportable and in others it is not. The state of Wisconsin has a law concerning the sale of cattle which states that every animal sold in the state has an implied warranty that it is free of infection with *M. paratuberculosis*. However, the seller can negate this liability by providing a written statement to the buyer prior to the sale stating that the animal is not warranted as being uninfected.

In addition, veterinarians' complete health certificates for interstate or intrastate movement of cattle, and most certificates require a statement that the animals are free of certain diseases. If the animal originates from an infected herd, the veterinarian is liable if the animals are found to be infected.

Voluntary national guidelines are now available to certify herds as low-risk for paratuberculosis.[15] Voluntary national and regional Johne's disease control programs for dairy and beef cattle herds, and sheep flocks have been introduced in the United States,[15] Australia,[9,111] and New Zealand,[21] and in the Netherlands.[111,127] The disease is notifiable in Greece, Republic of Ireland, Luxembourg, Norway, Switzerland, Spain, and Sweden.[111] Most countries of Western Europe do not have strategically planned control programs. Denmark and France have implemented non-government industry-supported programs in cattle herds. The emphasis in the early stages is to control clinical disease.

A significant development in recent years has been accreditation programs for negative herds such as the United States Voluntary Johne's Disease Herd Status Program for Cattle in the US, and Johne's Disease Market Assurance Program in Australia.[15,111]

A National Paratuberculosis Certification Program has been outlined for the USA.[15]

The Johne's disease control programs for cattle and sheep in Australia are excellent models of attempts to control an infectious disease of ruminants on a national basis with cooperation between the livestock industries and the state and national governments.

In Australia, the National Johne's Disease Market Assurance Program for cattle was launched in 1996[111] and became the CattleMap. The program is a voluntary, audited, quality assurance program. It is based on negative testing of the adult herd, or a large sample of it, combined with movement controls, to assure owners and clients that participating herds have a very low risk of being infected or becoming infected. CattleMap testing in large herds is designed to achieve a probability of at least 95% of detecting infection if it is present in 2% or more of adult animals in the herd. Continued assurance is based on negative herd testing at 2-year intervals, combined with management procedures to reduce the risk of introducing infection. Herds with a high-level status may be classified as free of infection in the future depending on experience with the program.

The guidelines are intended to be used by states to establish Johne's disease-free herd certification programs. The goal is to develop a list of test-negative herds from which producers can purchase low-risk animals. Hopefully, the concept of herd certification will spread and be adopted by more producers and the national animal health agencies will promote control programs.

A herd in the CattleMap must comply with the published rules and guidelines and with a written agreement between the herd owner and his or her approved veterinarian. The state veterinary authorities train and approve private veterinary practitioners who evaluate the farm and its management, develop written farm management plans with each producer, take the blood samples and follow-up reactors, interpret results, assign herd status and issue official status certificates. Herd owners must maintain the schedule of testing, comply with management requirements of the program and ensure that the animals are only introduced from herds of the same or higher status. If a herd does not comply with its testing schedule or other requirements, the status will revert to the next lowest level, or possibly even to suspect status. Herds and veterinarians are audited annually.

In Victoria, Australia, the Victorian Johne's disease test and control program in beef and dairy cattle is based on testing cattle with the ELISA, culling positive animals, management procedures to prevent new infections, and repeated annual testing of the herds.[128,129] The program resulted in a marked decline in the number of clinical cases, and a marked reduction in prevalence of reactors only when most herd animals were born after the program began. In beef herds, the modal age of reactors and clinical cases was 5 and 6 years, respectively. In dairy herds, the average age of reactors and clinical cases was 5.7 and 5.9 years, respectively. The sensitivity of the ELISA was only about 26% in the first testing compared to those which subsequently became positive or developed clinical disease.

In Australia, the Australian Sheep Johne's Disease Market Assurance Program (SheepMap) was launched in 1999.[111] It is a voluntary, audited, quality assurance program. It is based on negative serological testing (ELISA or AGID) of a sample of the adult flock (animals 2 years and older), combined with prudent flock management (attention to boundary fencing, introduced sheep are from flocks with similar flock status), to assure owners and clients that participating flocks have a very low risk of being or becoming infected.

In 1999, in Australia, a national Ovine Johne's Disease Control and Evaluation Program was established.[9] The program is jointly funded by the sheep industries and Commonwealth and state governments, and is managed by Animal Health Australia. The plan consisted of two stages. The first stage was a control and surveillance program for 1 year, to limit further spread of the disease and to determine its distribution. Known infected and suspect flocks were subject to movement restrictions to limit further spread, and movements of sheep onto and off known infected farms were traced and investigated. This stage also included proposals for development of a market assurance program and zoning within a state, as well as advisory and research

programs. The second stage of the plan, eradication of the disease, proceeded only if this was found to be feasible after completion of stage 1.

By 2000 Johne's disease of sheep had been confirmed in every Australian state or territory except Queensland and the Northern Territory. A national program is now in place to support the control of the disease in sheep and research to determine the feasibility and cost-effectiveness of eradication.

National Johne's Disease Program Standard Definitions and Rules for sheep were endorsed early in the program. These rules provided guidelines and minimum standards for the management of Johne's disease in sheep in Australia, and provide the basis for individual state or territory control programs. Zoning and movement restrictions within Australia and classification of flocks according to their level of risk of being infected were effected. Flocks were classified into the following categories:

- Infected, where Johne's disease has been confirmed on the farm
- Suspect, where there is epidemiological evidence to suggest that the flock may have been exposed to infection but it has not yet been confirmed
- Under surveillance, where there is evidence to suspect the disease, but after investigation the risk is determined to be low
- Nil assurance where a flock has no history of Johne's disease and has not been assigned any other classification.

In 1999, zoning for Johne's disease in sheep was implemented across Australia according to the following categories:

- Residual Zones are endemic but some level of control is in place
- Control Zones may be present at a manageable level and are actively controlled
- Protected Zones occur only sporadically and eradication measures are enforced
- Free Zones. There are no known or suspected infected flocks, and the absence of Johne's has been demonstrated to the satisfaction of the veterinary committee.

Surveillance in the program has relied primarily on the testing of 'at-risk' flocks identified by tracing the movement of sheep onto and off infected farms, or as neighbors of infected farms. Abattoir surveillance in all states has substantially increased the amount of surveillance in Control and Free Zones providing much greater assurance of their status. Abattoir surveillance also provides an effective method of detecting flocks with established infection in those areas that are independent of tracing from known infected flocks. Abattoir surveillance is based on visual inspection of the intestinal tract of sheep with histopathological examination of tissue samples from any gross lesions. As a screening method replacing serology, the culture of pooled fecal samples in lots of up to 50 sheep is now being done with the BACTEC system with a *Map* confirmation by PCR testing using IS900 sequence by subculture.[9] The higher sensitivity of pooled fecal culture makes it a very useful and economic tool for market assurance testing.

Johne's Disease control in the Netherlands

In the Netherlands, cattle herds can obtain *Map*-free status following five annual herd examinations for which all results are negative.[127] The first herd examination consists of serial testing of all cattle ≥3 years of age by serology (ELISA) and individual fecal culture of seropositive animals. The second to fifth herd examinations each consist of serial testing of all cattle ≥2 years of age with pooled fecal culture and individual-animal fecal culture of positive pools. The status of these certified '*Map*-free' herds is then monitored by annual herd fecal examinations, the same as for the second and fifth herd examinations. For the pooled fecal culture, all animals ≥2 years of age are stratified by age. A pooled fecal sample is then obtained from each group of five animals and cultured as a single sample. If a pooled sample is culture positive, the five animals are re-examined by individual fecal culture. If all individual fecal samples of a previously positive pool are negative, then this pool is regarded as culture negative. To reduce the risk of introduction of *Map* infection in *Map*-free herds, cattle may be added to these herds only if the cattle originate from another *Map*-free certified herd or if they originate from a herd with an equal or higher number of negative annual herd examinations.

In 2000, the first Dutch dairy herd obtained *Map*-free status, and by the end of 2002, there were 233 *Map*-free herds certified in the Netherlands. However, it was considered to be too expensive and alternatives were examined. Using a stochastic simulation model ('JohneSim') it was concluded that the current Dutch certification-and-monitoring scheme for *Map*-free herds could be optimized by: (i) certification of *Map*-free herds after four herd examinations at 2-year intervals consisting of pooled fecal culture of all cattle ≥2 years of age; (ii) monitoring of *Map*-free herds by pooled fecal culture of all cattle ≥1 year of age at 2-year intervals; and (iii) vigorous implementation of preventive management practices against the transmission of *Map* infections. In addition, the designation '*Map*-free' should be changed to 'low-risk *Map*'.

Vaccination has been used for control of Johne's in the Netherlands.[125] *See under Vaccination of cattle.*

Johne's disease control in the United States

In the United States several attempts have been made since 1993, to establish nationwide management programs to eliminate Johne's disease from animal herds. In 1993, a task force of the Johne's disease committee of the United States Animal Health Association drafted a model herd certification program to provide states with an example from which to develop or standardize programs.[15] Some states modified their programs to conform, but relatively few herd owners elected to pursue herd certification. The primary deterrents were the amount of testing required and the associated costs.

In 1998, a revised program was adopted as the US Voluntary Johne's Disease Herd Status Program for Cattle. The standards have been adopted in whole or in part by at least 20 states. In 1999, additional guidelines were developed for Johne's disease-affected herds: the Minimum Recommendations for Administering and Instituting State Voluntary Johne's Disease Programs for Cattle.

Control programs have in general relied on management techniques to identify infected herds and then clear those herds of the disease, because effective treatment and vaccination strategies do not exist. In addition, because of the long subclinical phase and the limited sensitivity of diagnostics, eradication programs require a long-term commitment.

The US Voluntary Johne's Disease Herd Status Program for Cattle (1998) is designed as a model for improving the equivalency of state control programs, as a framework for the establishment of new state programs, and to assist state veterinarians and state Johne's disease advisory committees as they considered implementation of herd certification.[15] The model is a voluntary herd status program, which identifies minimum requirements for operation of a scientifically sound approach to identification of low-risk herds. It provides for confidentiality of testing results at the discretion of the producer (within state limits), but it also encourages producers who have entered the program to reveal test results as a way to promote the value added by Johne's disease-free herd certification.

The program consists of an initial risk evaluation, to inform producers of existing

on-farm factors associated with the spread of the disease and to introduce to them the Best Management Practices which have been identified to prevent the introduction and spread of Johne's disease. Important practices which must be adopted before entry into the program are the prevention of commingling, the prevention of exposure to the manure or raw milk of susceptible animals over a period of 12 months, and the permanent identification of individual cattle.

The program was designed to identify uninfected or low-risk Johne's disease herds. The testing protocol involves testing a subset of adult cows in a herd using a serum ELISA to detect antibodies against *Map* and follow-up testing of ELISA-positive cattle by fecal culture to confirm the presence of *Map*. The first level test (Level 1 of 4) of the program includes 30 serologic samples per herd. Because the ELISA sensitivity is low (15%) in subclinically infected low fecal shedding cows, the Level 1 test strategy detects only an estimated 33% of herds with <5% prevalence and 68% of herds with 5–9% prevalence of Johne's disease. After 2 years of testing, herds which tested negative in two consecutive ELISAs can progress to Level 3. For Level 3, the test includes fecal cultures on a statistical subset of animals ≥3 years of age.[90]

There are two paths through the program: the standard and the fast track. If the producer can certify that the herd has been free of Johne's disease for 5 years, that the farm has been free of the disease for one year, and that no cattle have been introduced from Johne's-infected herds for 5 years, then the herd can be entered into the certification program through the fast track. This allows entry directly into Level 2, by-passing the first of four levels of certification. The fast track permits producers to proceed more quickly than the standard track does, but it requires a greater financial investment at the program entry. The fast track will allow herds to reach Level 4 in 2 years with three tests to reach Level 4. However, the standard track allows entry to the program with a minimal investment of funds and gradually increases the producer's investment in the program.

The four levels differ primarily by the number of herd animals tested and the types of diagnostic tests performed (Tables 19.2 and 19.3). Previously infected herds and JD-vaccinated herds can enter the program after infected animals are removed or vaccination is discontinued and the number of non-vaccinated animals meets the testing criteria. There is also a provision for an appeal process, for example, if results from an ELISA or fecal-culture test are disputed.

Table 19.2 Standard-Track Certification from the US Voluntary Johne's Disease Herd Status Program for Cattle

Level	Criteria
1.	Program entry requirements have been met, and negative ELISA tests have been performed on 30 second- or higher-lactation animals. A sample size of 30 was selected to optimize herd sensitivity and herd specificity and to maintain a fixed cost for all herds entering the program.
2.	The herd has met the requirements for Level 1, and negative ELISA on a statistical subset of second- or higher-lactation animals has been performed. The Level 2 testing must be completed between 10 and 14 months after any Level 1 testing.
3.	The herd has met requirements for Level 2 and has negative fecal-culture-test results on a statistical subset of second- and higher-lactation animals. Bulls 2 years of age and older must be included in this testing. The fecal culture must be collected between 10 and 14 months after any Level 2 testing.
4.	The herd has met the requirements for Level 3 and has a negative ELISA on a statistical subset of second- or higher-lactation animals. Level 4 testing must be completed between 10 and 14 months after any Level 3 testing. Level 4 status is maintained by achieving negative ELISA results on 30 second- or higher-lactation animals every 10–14 months.

Table 19.3 Fast-Track Certification from the US Voluntary Johne's Disease Herd Status Program for Cattle

Level	Criteria
2.	Fast-track program entry requirements have been met, and negative ELISA results have been obtained on a statistical subset test of second- or higher-lactation animals.
3.	The herd has met requirements for Level 2 fast-track and has negative fecal-culture test results on 30 second- or higher-lactation animals. (A history of JD freedom for 5 years before program entry adds sufficient confidence to allow fast-track herds to test 30 animals rather than the statistical subset used in the standard tack to obtain Level 3 status.) Level 3 testing must be completed 10–14 months after any Level 2 testing.
4.	The herd has met the requirements for fast-track Level 3 and has negative ELISA results on a statistical subset test of second- or higher-lactation animals. Level 4 testing must be completed 10–14 months after any Level 3 testing. Level 4 status is maintained by achieving negative ELISA results on 30 second- or higher-lactation animals every 10–14 months.

On-farm biosecurity measures are required to prevent the spread of JD from animals of unknown status. Exposure to pooled milk (for calves) or to manure from untested cattle should be eliminated, and cattle should not be grazed or have other contact with other JD-susceptible species. Cattle being transported should be hauled in cleaned and disinfected trailers, and commingling should be avoided.

A key feature of the program is the status of herd additions. Young cattle are required to come from program herds of similar status. Older animals have more stringent testing and biosecurity requirements, if purchased from non-program herds.

Replacement cattle must come from herds of equivalent status. Semen and embryos may be used from any herd.

DIAGNOSIS AND CONTROL OF JOHNE'S DISEASE. NATIONAL RESEARCH COUNCIL OF THE NATIONAL ACADEMIES, WASHINGTON DC, 2003

In 2003, the NRC of the National Academies of the United States published a document on the Diagnosis and Control of Johne's Disease. Part of the Executive Summary is reproduced here as a summary of the important issues on Johne's disease which confront livestock producers, veterinary practitioners, veterinary diagnosticians, regulatory veterinarians, consumers, and others.

In July 2000, the US Department of Agriculture (USDA) requested that the Board on Agriculture and Natural Resources of the National Academies convene a committee on the diagnosis and control of JD. Specifically, the committee was instructed to conduct a thorough review, evaluation, and compilation of all scientific research related to JD in domesticated and wild ruminants. The committee's task was to: (1) review and synthesize current information regarding diagnostic techniques, mode of transmission, clinical expression, global prevalence, and potential animal and human health implications associated with JD in domesticated and wild ruminants; (2) evaluate current programs for controlling and preventing JD in

ruminants; (3) provide policy recommendations for identification, monitoring, and management strategies applicable to US livestock herds; (4) conduct an objective, critical assessment and summary of the state of knowledge regarding the relationship of JD in ruminants and Crohn's disease in humans; and (5) provide recommendations on future research priorities and potential mechanisms to facilitate prevention and control of the disease.

The committee reviewed the literature on diagnosis, modes of transmission, clinical expression, global prevalence, and potential animal and human health implications of JD with the following goals in mind:

- Determine whether JD presents a problem sufficient to warrant control efforts
  - Objectively review the data that provide the basis for control plans
  - Identify significant gaps in knowledge that affect diagnosis and control
- Differentiate well-established facts from dogma or prevailing opinion
  - Determine whether available diagnostic tests are adequate for control programs
  - Make recommendations on the research needed to fill in knowledge gaps.

The committee also evaluated existing state, national, and international control programs with the goal of identifying sound control principles to guide program development and to make recommendations for a national control program.

Finally, the committee evaluated the evidence for and against a role for *Map* in some cases of Crohn's disease in humans. Considerable controversy has surrounded this issue and there are diverse viewpoints about how some of the evidence should be weighed against other evidence. This problem is not unique to Crohn's disease. Determining the cause of chronic human diseases is a difficult and often controversial process. One outcome of the debate has been the proposal by Hill and Evans for a set of objective criteria, which, if met, could be considered sufficient evidence to determine that a causal relationship exists between an agent and a chronic disease. To approach this important task most objectively, the committee used the Hill–Evans criteria to develop a list of the research results that would be necessary to establish with reasonable certainty that infection by *Map* causes some cases of Crohn's disease. The list of necessary research results was developed before the literature review and it was used to evaluate the strength of the evidence.

Conclusions

Based on its review and synthesis of the literature, the evaluation of existing control and herd status programs, and information presented at the public workshop, the committee reached the following conclusions:

- **Conclusion 1**. Johne's Disease (JD) is a significant animal health problem that warrants implementation of control programs tailored to specific animal species and specific segments of the agriculture industry. Furthermore, JD control deserves high priority from USDA, individual states, and industry. The significance of the disease derives primarily from its consequences for animal and herd health, for the agriculture industry, and for national and international trade. The current concern about JD in industry and government agencies and the potential link with Crohn's disease in humans provide additional support for making JD control a high priority
- **Conclusion 2**. There remains insufficient evidence to prove or disprove that *Mycobacterium avium* subsp. *paratuberculosis* is a cause of some or all cases of Crohn's disease in humans; a new approach is needed to resolve the issue – one that is based on a research agenda that will provide answers to specific criteria set forward in Hill–Evans postulates. A causal link between *Map* and Crohn's disease remains a plausible hypothesis that warrants a new research approach and steps by industry and government agencies to identify and mitigate avenues of exposure
- **Conclusion 3**. Available diagnostic tests and information about the biology of JD and methods to control it are adequate for immediate implementation of control programs
- **Conclusion 4.** There are significant gaps in knowledge about some areas relevant to control that are discussed in the recommendations section. The committee emphasizes that closing knowledge gaps will improve control programs, although the need for more information should not delay implementation
- **Conclusion 5.** Control will require a long-term commitment and iterative program implementation to maximize the chance of success. This commitment must come from all constituencies, including USDA, state agencies, and industry
- **Conclusion 6.** Because control of JD is of greatest concern to the dairy industry, much of the emphasis in control recommendations is directed there. Other industries, however, should consider this an opportune time to deal aggressively with the disease, before infection prevalence increases and the disease becomes more widespread
- **Conclusion 7**. The USDA National Animal Health Monitoring System (NAHMS) prevalence surveys have been a critical element in laying the groundwork for control programs
- **Conclusion 8**. The Voluntary Bovine Johne's Disease Control Program proposed by the NJWG has most of the elements necessary for a successful control program, but prospects for success are and will be limited by a lack of uniform implementation among individual states
- **Conclusion 9**. The committee endorses the NJWG's efforts in educating producers and veterinarians, and advocates the expansion of these efforts.

Disease control

The occurrence of a particular infectious agent in a herd is a consequence of one or more environmental or management risk factors being out of control. If the focus is placed on controlling the risk factor(s), which may be common to a number of infectious agents, rather than on the agent itself, a producer will be more likely to adopt a control practice because the incidental control of other agents will result in a greater return on the investment. While the committee strongly endorses a Best Management Practices approach to control, it felt that control programs should initially focus on JD to take advantage of growing support for control of the disease. In addition, it is anticipated that funding for various aspects of control will be more readily available through government–industry partnerships if control has an easily identifiable target, such as JD, rather than a broader concept of Best Management Practices. As control efforts progress, an incremental transition to a Best Management Practices approach should be more feasible.

- **RECOMMENDATION 1**. An integrated, bottom-up approach to on-farm disease control is required that meets the needs of the livestock producer and motivates behavioral change, with support at broader industry, state, and federal levels. Components of such a control program are as follows:

At the farm level:

1. On-farm risk assessment and development of a farm plan

2. Manure management that minimizes potential for transmission of pathogens by the fecal–oral route
3. Protection of young stock
4. Acquisition of replacement animals free from infection by *Map* and other significant pathogens that are shed in the feces
5. Removal of infected animals from the farm
6. Reduction of environmental contamination by *Map*.

At the state-federal program level:

1. Minimum national standards for program implementation
2. Performance-based criteria for diagnostic testing and laboratory accreditation
3. Rapid identification and protection of JD-free herds that can be used to provide *Map*-free replacement animals
4. Incremental implementation, progressing from a voluntary herd status program to a system of strong (preferably market-based) incentives for participation and disincentives for nonparticipation, culminating in a mandated herd control program, if JD eradication is the ultimate goal
5. A gradual transition from an exclusive focus on *Map* to a broader health and market assurance program that emphasizes Best Management Practices to prevent the spread of all pathogens by the fecal–oral route
6. A mechanism for periodic program review and self-correction
7. A program to prevent the reemergence of disease after low prevalence or eradication is achieved.

Recommendations for a stepwise expansion of the federal role in JD prevention and control:

1. The government should promulgate uniform methods and rules (UM&R) for voluntary JD status and control programs. The federal standards would provide consistent definitions and program guidelines for a baseline across all states. Individual states could mandate additional requirements
2. The federal government should provide control infrastructure, including support and incentives to upgrade diagnostic laboratories across the United States, to promote large-scale testing
3. All states should be required to implement a control program that is voluntary for producers in accordance with the UM&R
4. Producers should be encouraged to test all herds and register them either in status programs or in control programs, based on test results. Federal subsidies may be needed to cover the cost of initial testing, in order to encourage participation
5. Federal restrictions should continue on interstate and international transport of cattle from *Map*-positive herds
6. A federal plan should be established to monitor the success of the control program. The plan should provide for periodic program review and self-correction.

General control program outlines for a given category of management and husbandry situation will be the same, but must be sufficiently flexible to be easily adaptable to the specific circumstances of each farm. Finally, the information must be packaged and delivered in a manner that is in harmony with the style with which the producer manages information and can motivate them to change their behavior.

This motivation may require feedback signals in the form of market price differentials established through testing of the farm product by the downstream purchaser.

While control programs for dairy herds may be of highest priority, control programs for beef cattle, sheep, goats, and captive cervids should be developed and implemented. Control programs for zoo animals and wildlife should also be monitored to insure that a non-domesticated animal reservoir does not compromise control efforts for any species.

Education and training

The National Johne's Working Group has made education of producers and veterinarians a high priority. The committee endorses this effort and offers the following additional recommendations for action by federal and state authorities:

- **RECOMMENDATION 2.** Commodity-oriented (dairy, beef, sheep, goat, llama) materials should be developed that are standardized nationally, and a rationale and guidelines for development of control and certification plans should be provided. These should not be considered the same as national program standards, but they should serve as the information base for participation in national programs.
- **RECOMMENDATION 3.** Informational resources should be developed for practicing veterinarians that includes guidance on diagnostic test selection, sample size and selection of animals for testing, interpretation of test results, development of risk assessment methods, writing of herd plans, and monitoring of compliance and progress.
- **RECOMMENDATION 4.** Educational resources that emphasize control of risk factors (Best-Management Practices) should be developed instead of materials that emphasize control of a single etiologic agent.
- **RECOMMENDATION 5.** Training programs are needed for state Johne's coordinators, USDA personnel, practicing veterinarians, and laboratory personnel to insure a uniform base of knowledge and practice.

Research

The committee identified significant gaps in the current state of knowledge of the pathophysiology, immunology, diagnosis, and control of JD in domesticated livestock and in wildlife. Choosing the research projects needed to fill those gaps will be important to the success of any JD herd status or control program. The issues also are complex enough to warrant the convening of a USDA expert panel to formulate consensus methods to address the research questions. The committee considered ongoing research to be important for the success of any control program and therefore felt that a research element should be integral to future program development. The committee developed recommendations in several areas.

Epidemiology of map infection and JD

The committee found significant gaps in the understanding of the epidemiology of JD that could affect the success of proposed control programs. In particular, the committee recommends five additional areas of research.

- **RECOMMENDATION 6.** Age-dependent dose–response curves are needed to clarify the magnitude and significance of age-related susceptibility or resistance to infection and the degree to which horizontal transmission occurs in different age groups. Use of epidemiologic modeling would help to determine the best measure of infectivity.

With the increase in concentrated calf-rearing operations, there is an urgent need to investigate the possibility of horizontal transmission in young animals. Current control strategies assume that horizontal transmission among adult cattle is insignificant, but this should be confirmed because the success of control strategies could be at stake.

- **RECOMMENDATION 7.** The effects of chronic, low-level exposure on infectivity and on the outcome of infection should be studied.

Much of the data on infectivity and age susceptibility have been derived from decades-old studies in which one or a few large infective doses typically were administered. Although this provides valuable information, because it does not mimic natural exposure, the conclusions that can be drawn are limited. It would be helpful to have a better understanding of the outcome of chronic, low-level, or intermittent exposure to *Map* in the environment.

- **RECOMMENDATION 8.** Experimental studies and field investigations of natural infection in non-ruminant and ruminant wildlife in the United States should focus initially on native lagomorphs and other small mammals prevalent on or around livestock operations with endemic JD.

Recent investigations on the role of wildlife in the epidemiology of JD in livestock in Scotland, Australia, and the Czech Republic have yielded interesting results. The identification of endemic *Map* infections in European rabbits in Scotland has important ramifications for control programs there. Little work has been done in the United States on the susceptibility of non-ruminant wildlife to *Map* infection.

Determining the prevalence of *Map* infection in wildlife on or around livestock operations will be important to understanding the success or failure of any livestock JD control programs.

- **RECOMMENDATION 9.** Results of diagnostic testing, control practices, and other epidemiologic data should be evaluated and used to answer remaining research questions and to refine and optimize control programs.
- **RECOMMENDATION 10.** The USDA NAHMS prevalence surveys should continue, with attention paid to maximizing the data obtained from the samples collected through 'add-on' projects and investigations.

As control programs are implemented, they present opportunities to take advantage of resulting 'natural experiments'. The committee recommends that these opportunities not be lost. Results of the two investigations proposed above will help regulators to establish a scientific basis for several control measures, including how long to wait before restocking contaminated land, whether environmental decontamination can expedite restocking, and whether removal of calves from dams at birth is the best means of breaking the transmission cycle.

Diagnostics and immunology

Although the committee acknowledges that available diagnostic tools are sufficient to implement control programs, significant deficiencies still exist. To address these important gaps, the committee recommends the following:

- **RECOMMENDATION 11.** Epidemiologically sound sampling and sample-pooling protocols should be developed and validated to facilitate screening and monitoring of large cattle herds and sheep flocks.

Recent research in Australia suggests that pooling of sheep fecal samples could enable more cost-effective flock screening for control programs. This work should be repeated in the United States and expanded to include cattle. Another important need is for a rapid, sensitive test to detect the presence of *Map* in bulk-milk samples. This would promote more efficient and cost-effective collection of herd prevalence data, which will be important for control. Some promising studies have been conducted, but additional research is needed in this area.

- **RECOMMENDATION 12.** Sensitive and specific serologic and fecal culture methods should be developed and validated for use in sheep and goats.

The development of diagnostic tests for JD in sheep, goats, and other species has trailed that for cattle. Although much of the current control emphasis is on dairy cattle, development of more sensitive and specific tests is needed for these other species. Recent reports suggest that the difficulty in isolating sheep strains of *Map* by fecal culture has largely been overcome, but methods are still slow and not ideal for use in control programs.

- **RECOMMENDATION 13.** Methods for detecting an early, specific immune response to *Map* should be developed.

There are no reliable tests to identify animals in the early stages of infection, before fecal shedding. Early identification of infected animals would be helpful for control programs, especially for prepurchase testing of replacement animals. Exposure to other mycobacteria, such as *M. avium* subsp. *avium*, is likely to be common in cattle, so it is essential that any test to identify animals in the early stages of infection be highly specific for *Map*. This might require identification of unique antigenic epitopes in *Map*, against which an early immune response is generated.

Map genome studies

As the committee evaluated knowledge gaps and research needs, the importance of complete sequencing of the *Map* genome became evident. Sequencing would yield many benefits, including identification of unique *Map* antigens for development of diagnostic tests and vaccines, improvement of diagnostic methods based on PCR, and identification of potential virulence factors. The *Map* genome sequencing project at USDA's National Animal Disease Center is nearing completion, and the committee strongly recommends the following:

- **RECOMMENDATION 14.** USDA and other agencies should seize the opportunity presented by the completion of the *Map* genome project to accelerate progress in JD research, diagnostic test improvement, and vaccine development.

Information about the completion of this project needs to be disseminated to the international research communities for JD and Crohn's disease, and the sequence data should be made available as soon as possible. Research funds should be directed to research and development that use the results of the *Map* genome project. The paucity of funds available for JD research has limited progress in several important areas. The completion of the *Map* genome project provides a unique opportunity to correct this oversight, and it should not be neglected.

Vaccine development

Current vaccines for *Map* are highly problematic. There are conflicting data on their ability to reduce shedding of *Map*, and the fact that they generate cross-reactions to intradermal tests for *M. bovis* makes them unsuitable for widespread use in control programs. Because vaccines can expedite the reduction of disease prevalence, the committee recommends the following:

- **RECOMMENDATION 15.** Research should be done on the nature and evolution of the immune response to *Map*, and ways to modulate the immune response to elicit protection should be studied.
- **RECOMMENDATION 16.** Research is needed on the feasibility of using recombinant-vaccine technology to create a vaccine that generates a specific, protective immune response in domesticated livestock without interfering with diagnostic tests for JD, bovine tuberculosis, or other diseases.

Development of an efficacious vaccine will require identification of unique *Map* antigens that will elicit a protective immune response without generating cross-reactions to other mycobacteria. The *Map* genome project has the greatest potential for providing the basis for these advances.

Human and animal health issues

After evaluating all of the available evidence for and against a causal role for *Map* in Crohn's disease, the committee was of the unanimous opinion that the confidence was insufficient either to establish or to refute a causal connection. The committee considered the following research to be important to the resolution of this question:

- **RECOMMENDATION 17**. A blinded study should be done for the detection of *Map* and *Map* RNA–DNA in identical coded intestinal tissue samples sent to various laboratories using standardized methods for *Map* culture and detection. This will help clarify the degree to which conflicting research results have been the result of variations in methods versus operators.
- **RECOMMENDATION 18**. A large-scale, double-blind, multicenter study should be done to detect the presence of *Map* and *Map* RNA–DNA in tissue specimens from patients with Crohn's disease, using the same standardized methods as above. The specimens should be stratified by type of disease, duration of disease, presence or absence of known Crohn's susceptibility genes, and treatment. Control subjects without Crohn's disease should be included in the study.
- **RECOMMENDATION 19**. A large-scale, multicenter, double-blind study of the treatment of Crohn's disease patients with anti-*Map* combination antimicrobial therapy should be undertaken. The patients should be stratified by type of disease, duration of disease, presence or absence of known susceptibility genes, treatment, and presence or absence of *Map* by culture or PCR methods. There also should be an appropriate control group of patients with Crohn's disease who do not receive anti-*Map* therapy.
- **RECOMMENDATION 20**. A multicenter, double-blind study is needed on the presence of *Map*, *Map* antigens, and *Map* RNA–DNA in breast milk of lactating women with Crohn's disease, compared to controls. Finding such in lactating women with Crohn's disease would provide strong support for the proposed connection between *Map* and Crohn's disease.

If a subset of CD patients responds to anti-*Map* therapy, or *Map* is otherwise implicated as a cause of CD in a subset of patients, research on methods to better identify this subset will be needed. Other research considered important by the committee included on-going studies of Crohn's susceptibility genes and familial tendencies, gene microarray studies to determine which genes are up- and down-regulated in Crohn's disease, and animal models, especially in genetically altered animals.

- **RECOMMENDATION 21**. The National Institutes of Health or a similar body should convene a panel with experts in gastroenterology, Crohn's disease, infectious disease, mycobacteriology, biostatistics, epidemiology, etc., to define the precise study designs and to rank order the various studies to be done.

Although the committee did not find sufficient evidence to implicate *Map* as a cause of Crohn's disease, there was consensus that efforts to identify and mitigate avenues of exposure to *Map* would be prudent while awaiting definitive resolution of this important question.

Identifying environmental sources of *Map* also is an important element of JD control in livestock, so there is additional justification for such investigations. The committee therefore recommends researching the following projects:

- **RECOMMENDATION 22**. Research should be conducted to determine the prevalence of viable *Map* in potable-water supplies, streams, ponds, and other bodies of water with potential for *Map* contamination. This may require development of better methods for identifying and quantifying *Map* in environmental samples.
- **RECOMMENDATION 23**. Additional studies are needed to determine whether *Map* is present in retail milk or other dairy products, as well as in pasteurized colostrum or commercial colostrum replacers that are fed to calves.
- **RECOMMENDATION 24**. Research should be done to determine the prevalence of viable *Map* in peripheral lymph nodes, muscle, and other tissues that are processed for human consumption.
- **RECOMMENDATION 25**. Research should be done to determine the prevalence and concentration of *Map* in other environmental materials likely to be contaminated with ruminant manure and associated with exposure to humans or susceptible animals. Those materials could include composted manure, fruits and vegetables, pastures, and crops fed to livestock.

If a causal relationship is established between human *Map* infection and even a subset of Crohn's disease cases, the above research recommendations will be essential for implementation of new control programs aimed at protecting public health by minimizing exposure to *Map*. Additional research would then be needed to develop methods for routine screening of dairy products, meat, and meat products for *Map*.

Diseases associated with *Actinomyces* spp., *Actinobacillus* spp., *Nocardia* spp., and *Dermatophilus* spp.

This group of infectious diseases includes actinomycosis, actinobacillosis, mycotic dermatitis, strawberry footrot of sheep, actinobacillosis in piglets, and shigellosis of foals.

Painless, granulomatous lesions of the skin (mycetoma) occur naturally, especially in horses, and have been produced experimentally by infection with *Nocardia brasiliensis* and with *Actinomadura* spp.[1] Nocardial mastitis in cattle has been dealt with in Chapter 15 on mastitis. Other infections by *Nocardia* spp. include infections in the uterus of repeat breeder cattle and mares and in granulomas in the nasal cavity or lungs of cattle but these are rare.[1–3]

Less common occurrences of infection with this group of organisms include *Actinomyces actinoides* as a secondary bacterial invader in enzootic pneumonia of calves and seminal vesiculitis in bulls, *Actinomyces bovis* in a large proportion of unopened lesions of fistulous withers and poll evil, and *Actinomyces* spp. in abscessation of the mandibular lymph node in horses.

Actinobacillus spp.

Actinobacillus spp. isolated from disease in large animals include *Actinobacillus equuli*, *Actinobacillus lignieresii*, *Actinobacillus pleuropneumoniae*, *Actinobacillus suis*, *Actinobacillus hominis*, *Actinobacillus* (*Pasteurella*) *ureae*, *Actinobacillus capsulatus*, and equine *Actinobacillus suis*-like organisms. These organisms share significant biochemical characteristics and electrophoretic patterns[4–6] and historical reports associating a given organism with a specific disease may have errors in classification. The reported taxa of the genus *Actinobacillus* includes 22 species and unnamed taxa of which 19 have been associated with animals.[7] Only four, *A. pleuropneumoniae*, *A. suis*, *A. lignieresii*, and *A. equuli* are frequently associated with disease in animals and many of the others are probably misclassified in this genus.[7,8]

Specific species causal associations, if they exist, remain to be determined for many of the diseases associated with *Actinobacillus* spp. For this reason we have chosen to describe these diseases under a broad traditional clinical classification. Future more defined etiological classification may allow a better epidemiological subdivision of these syndromes and a more refined epidemiological approach to prevention and control.

Actinobacillus suis infection in pigs is described under that heading. Organisms reported as *Actinobacillus suis* have also been isolated from **horses** with acute hemorrhagic pulmonary infarction and **necrotizing pneumonia**,[9] and as an occasional cause of **septicemia** in neonatal foals[10] and calves.[11] *Actinobacillus* spp. are also associated with **endocarditis** in horses.[12] They are also associated with **peritonitis** in horses which may be acute or manifest with chronic weight loss, ventral edema, pleurisy, and pallor of the mucosae. Abdominocentesis yields ample amber fluid with a high white cell count, up to 270 000/μL, and a marked neutrophilia. Treatment with ampicillin or penicillin/streptomycin gives excellent responses. Verminous arteritis may predispose this disease.

Actinobacillus seminis is a cause of **epididymitis** in rams and is recorded in Australia, Spain, Brazil, South Africa, New Zealand, the USA, Europe, and the UK.[13–16] Infections commonly occur in virgin rams and the infection is detected between 4 and 18 months of age[17] but also occurs in adults.[18] Fertility is reduced but the main economic impact is from the loss of purebred sales and the need to differentiate the disease from brucellosis. A very similar syndrome occurs in epididymitis produced by infection with *Haemophilus*-like organisms,[15] and the control of this complex of epididymitis has been approached by the use of a multivalent, adjuvanted vaccine to both groups of organisms and the long-term feeding of low doses of antibiotics.[18] *Actinobacillus seminis* is also recorded as a rare cause of abortion in sheep[19] and has also been isolated from the joints of lambs affected by **septicemia**, synovitis, and purulent **polyarthritis**.

ACTINOMYCOSIS (LUMPY JAW)

Synopsis

Etiology *Actinomyces bovis*
Epidemiology Inhabitant of the bovine mouth. Common but sporadic disease from infection through wounds to the buccal mucosa by feed or through dental alveoli
Clinical findings Initially painless, hard, immovable bony swelling on mandible or maxilla. Eventually discharge small amounts of pus through one or more openings in skin
Clinical pathology Presence of 'club' colonies containing Gram-positive filaments
Diagnostic confirmation Demonstration of organism
Treatment and control Surgical debridement. Iodides and/or sulfonamides orally or parenterally

ETIOLOGY

Actinomyces bovis is the primary cause but other bacteria may be present in extensive lesions including non-*bovis* *Actinomyces* spp.[1]

EPIDEMIOLOGY

The disease is sporadic but common in cattle. Occasional cases occur in pigs and horses and rarely in goats.[2] Although actinomycosis occurs only sporadically, it is of importance because of its widespread occurrence and poor response to treatment. It is recorded from most countries of the world.

Actinomyces bovis is a common inhabitant of the bovine mouth and infection is presumed to occur through wounds to the **buccal mucosa** caused by sharp pieces of feed or foreign material. Infection may also occur through **dental alveoli**, and may account for the more common occurrence of the disease in young cattle when the teeth are erupting. Infection of the **alimentary tract** wall is probably related to laceration by sharp foreign bodies.

PATHOGENESIS

In the jawbones a rarefying **osteomyelitis** is produced. The lesion is characteristically granulomatous both in this site and where visceral involvement occurs. The effects on the animal are purely physical. Involvement of the jaw causes interference with prehension and mastication, and when the alimentary tract is involved there is physical interference with ruminal movement and digestion, both resulting in partial starvation. Rarely, localization occurs in other organs, caused apparently by hematogenous spread from these primary lesions.

CLINICAL FINDINGS

Cattle

Actinomycosis of the **jaw** commences as a painless, **bony swelling** which appears on the mandible or maxilla, usually at the level of the **central molar teeth**. The enlargement may be diffuse or discrete and in the case of the mandible may appear only as a thickening of the lower edge of the bone with most of the enlargement in the intermandibular space. Such lesions are often not detected until they are too extensive for treatment to be effective.

The more common, discrete lesions on the lateral surfaces of the bones are more readily observed. Some lesions enlarge rapidly within a few weeks, others slowly over a period of months. The swellings are very **hard, immovable** and, in the later stages, painful to the touch. They usually break through the skin and discharge through one or more openings.

The discharge of pus is small in amount and consists of sticky, honey-like fluid containing minute, hard, yellow-white granules. There is a tendency for the sinuses to heal and for fresh ones to develop periodically. Teeth embedded in the affected bone become malaligned and painful and cause difficult mastication with consequent loss of condition. In severe cases, spread to contiguous soft tissues may be extensive and involve the muscles and fascia of the throat. Excessive swelling of the **maxilla** may cause dyspnea. Involvement of the local lymph nodes does not occur. Eventually the animal becomes so emaciated that destruction is necessary although the time required to reach this stage varies from several months to a year or more.

The most common form of actinomycosis of soft tissues is involvement of the **esophageal groove** region, with spread to the lower esophagus and the anterior wall of the reticulum. The syndrome is one of **impaired digestion**. There is periodic diarrhea with the passage of undigested food material, chronic bloat, and allotriophagia. Less common lesions of soft tissue include **orchitis** in bulls, the **trachea** causing partial obstruction, and abscess in the brain or lungs.[3]

Pigs

Rare cases of wasting occur due to visceral actinomycosis but extensive granulomatous lesions on the skin, particularly over the **udder**, are more common.

CLINICAL PATHOLOGY

Smears of the discharging pus stained with Gram's stain provide an effective simple method of confirming the diagnosis. Gram-positive filaments of the organism are most readily found in the centers of the crushed granules.

NECROPSY FINDINGS

Rarefaction of the bone and the presence of loculi and sinuses containing thin, whey-like pus with small, gritty granules is usual. An extensive fibrous tissue reaction around the lesion is constant, and there may be contiguous spread to surrounding soft tissues. The presence of **'club' colonies** containing the typical, thread-like bacteria is characteristic of the disease. These formations may be seen on microscopic examination of smears made from crushed granules in pus or on histological examination of section.

Granulomatous lesions containing pockets of pus may be found in the esophageal groove, the lower esophagus and the anterior wall of the reticulum. Spread from these lesions may cause a chronic, local peritonitis. There may be evidence of deranged digestion with the rumen contents sloppier than usual, an empty abomasum and a mild abomasitis and enteritis. Involvement of local lymph nodes does not occur, irrespective of the site of the primary lesion.

DIFFERENTIAL DIAGNOSIS

Abscesses of the cheek muscles and throat region are quite common when spiny grass-awns occur in the diet. They are characterized by their movability and localization in soft tissues compared to the immovability of an actinomycotic lesion. Pus may be thin, fetid, or caseous depending on the duration of the abscess. Prompt recovery follows opening and drainage.

Foreign bodies or accumulations of dry feed jammed between the teeth and cheek commonly cause a clinical picture which resembles that associated with actinomycosis and the inside of the mouth should be inspected if the enlargement has occurred suddenly.

The syndrome of indigestion caused by visceral actinomycotic lesions resembles that caused by chronic peritonitis.

Cutaneous and mammary lesions in sows closely resemble necrotic ulcers associated with *Borrelia suilla*.

TREATMENT AND CONTROL

Treatment is with surgical debridement and antibacterial therapy, particularly iodides as detailed under actinobacillosis. Additional treatment recorded as being effective includes isoniazid given orally at the rate of 10–20 mg/kg body weight daily for about 30 days. Cessation of the growth of the lesion should occur but response in advanced cases is poor.[4] Repeat cryotherapy with liquid nitrogen is reported to be effective.[5] For control, isolation or disposal of animals with discharging lesions is important, although the disease does not spread readily unless predisposing environmental factors cause a high incidence of oral lacerations.

ACTINOBACILLOSIS (WOODEN TONGUE)

Synopsis

Etiology *Actinobacillus lignieresii*
Epidemiology Organism is inhabitant of alimentary tract. Infection through abrasion. Site difference in sheep and cattle reflects differences in risk associated with prehension of food. Sporadic disease but outbreaks where herd/flock predisposing factors are present
Clinical findings Difficulty in prehension of food. Inflammation and abscessation of tongue and draining lymph nodes in cattle and of lips in sheep
Clinical pathology and diagnostic confirmation Demonstration of organism
Treatment and control Iodides, antibiotics, hygiene. Avoidance of abrasive pastures

ETIOLOGY

Actinobacillus lignieresii may be recovered in pure culture from the lesions but other pyogenic organisms may also be present. Recent investigations have shown that bacteria with phenotypic similarity to *A. lignieresii* isolated from horses are genotypically distinct from those isolated from ruminants and they have been designated as *Actinobacillus* genomospecies 1.[1]

EPIDEMIOLOGY

Occurrence

The disease in **cattle** is worldwide in distribution and usually of sporadic occurrence on individual farms. In **sheep**, the disease is common in Scotland but is recorded in most sheep-raising countries. In most instances, only occasional cases occur but in some flocks a morbidity rate of up to 25% may be encountered. Actinobacillosis also occurs, but is rare, in **horses**.

Source of infection and transmission

Actinobacillus lignieresii is a normal inhabitant of the oral cavity and rumen of ruminants. The organism is susceptible to ordinary environmental influences and does not survive for more than 5 days on hay or straw. Infection in soft tissue results from damage to the oral mucosa.

In **cattle**, infection most commonly occurs through ulcerating or penetrating lesions to the sulcus of the tongue, penetrating lesions in the apex, and lacerations to the side of the body of the tongue caused by the teeth. Abattoir surveys suggest that subclinical infections are common and have found small actinobacillary granulomas in the draining lymph nodes of the head and approximately 3% of tongues in slaughter cattle.[2–3] In **sheep**, the different nature of prehension of food leads to lesions predominantly in the lips and cheeks with occasional extension to the mucous membranes of the turbinates and the soft tissue of the head and neck.

Risk factors

The disease is usually sporadic but multiple cases in a herd and apparent outbreaks of the disease can occur when animals graze **abrasive pasture** species or pastures with **spiny awns** and transmission may be enhanced by infected discharges contaminating these pastures or feeds. A high prevalence is recorded in cattle grazing 'burnt-over' peat pastures in New Zealand. These pastures contain much gravel and ash likely to cause oral injury. A similar high incidence has been observed in sheep fed prickly pear (*Opuntia* spp.). A severe outbreak has also been reported in heifers fed on very dry, stemmy, tough haylage and in cattle fed wheat straw from a specific thresher that produced straw with sharp edges.[4] There is a higher prevalence of this disease in cattle in areas of copper deficiency.

Actinobacillosis granulomas may also occur at **atypical sites** in cattle such as the external nares or the jugular furrow following infection of **traumatic lesions** caused by nose grips or jugular venepuncture.[5] Iatrogenic infection of surgical incision wounds is also recorded.[6] Infection of the cheeks resulting in bilateral facial enlargement is also recorded.[7,8]

Zoonotic implications

Actinobacillus lignieresii is rarely associated with human disease but has been isolated from bite wounds inflicted by horses and ruminants.[9]

PATHOGENESIS

Local infection by the organism causes an acute inflammatory reaction and the subsequent development of granulomatous lesions in which necrosis and suppuration occur, often with the discharge of pus to the exterior. Spread to regional lymph nodes is usual. Lingual

involvement in cattle causes interference with prehension and mastication due to acute inflammation in the early stages and distortion of the tongue at a later stage. Visceral involvement is recorded and is identical with that described under actinomycosis.

CLINICAL FINDINGS

Cattle

The onset of glossal actinobacillosis is usually acute, the affected animal being unable to eat for a period of about 48 hours. There is excessive **salivation** and **gentle chewing** of the tongue as though a foreign body were present in the mouth. On **palpation** the tongue is swollen and hard, particularly at the base, the tip often appearing to be normal. Manipulation of the tongue causes pain and resentment. Nodules and ulcers are present on the side of the tongue and there may be an ulcer at the anterior edge of the dorsum. In the later stages when the acute inflammation is replaced by fibrous tissue, the tongue becomes shrunken and immobile and there is considerable interference with prehension.

Lymphadenitis is common and is often independent of lesions in the tongue. There may be visible and palpable enlargement of the submaxillary and parotid nodes. Local, firm swellings develop and often rupture with the discharge of thin, non-odorous pus. Healing is slow and relapse is common. Enlargement of the retropharyngeal nodes causes interference with **swallowing**, and loud **snoring** respiration.

Cutaneous actinobacillosis is also recorded[8,10] with actinobacillosis granulomas occurring on atypical but visible areas such as the external nares, cheeks, skin or eyelid, and hind limbs. External trauma from abrasive materials in the environment is the usual initiating cause. Lesions are several centimeters in diameter and are pliable or firm and painful on palpation, red, and can bleed easily. Caseated small foci may be evident in the mass when it is debulked.

Sheep

In sheep the tongue is not usually affected. Lesions up to 8 cm in diameter occur on the **lower jaw, face, and nose**, or in the skin folds from the lower jaw to the sternum. They may be superficial or deep and usually extend to the cranial or cervical lymph nodes. Viscid, yellow-green pus containing granules is discharged through a number of small openings. Extensive lesions cause the formation of much fibrous tissue which may physically impede prehension or respiration. Thickening and scabbiness of the lips may also be observed. Involvement of the nasal cavities may cause persistent bilateral nasal discharge. Affected sheep have difficulty in eating and many die of starvation. *Actinobacillus lignieresii* is also an occasional cause of **mastitis** in ewes.

Actinobacillosis has been suspected as the cause of a problem of **cud-dropping** in a group of sheep. Affected sheep showed green staining around the lips and had a lower body condition score in association with the presence of palpable, hard, raised nodules in the tongue. The problem responded to treatment with streptomycin.[11]

A similar involvement of the lips with abscessation in the area of the mandibular lymph nodes is recorded in camels.[12] In **horses** the disease is uncommon but intermandibular phlegmon, or infection of the tongue or of the muzzle can occur and also infection at other body sites.[13]

CLINICAL PATHOLOGY

Purulent discharges commonly contain 'sulfur' bodies which are granular in nature and, on microscopic examination, consist of **club-like rosettes** with a central mass of bacteria. These are not pathognomonic for *Actinobacillus lignieresii* but can also be found in purulent exudate from granulomas associated with *Actinomyces bovis*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus*. Examination of smears or culture of pus for the presence of *Actinobacillus lignieresii* is advisable.

Full-thickness incision biopsies can be of value in diagnosis and show multiple abscessation in the deep dermis with distinct club rosettes.[8,11]

NECROPSY FINDINGS

Necropsy examination is not usually carried out in cattle affected by the disease. In sheep, lymphangitis and abscesses containing thick, tenacious, yellow-green pus occur around the local lesion. Typical club colonies are visible on staining sections of affected tissue. Culture of material from lesions usually detects the presence of *Actinobacillus lignieresii*.

DIFFERENTIAL DIAGNOSIS

- Foreign bodies in the mouth
- Rabies
- Esophageal obstruction
- Tuberculosis
- Cutaneous lymphosarcoma

TREATMENT

Iodides are still a standard treatment for both actinomycosis and actinobacillosis. In the former, the results are relatively inefficient, but in actinobacillosis, response is usually dramatic and permanent. Laboratory studies suggest that iodides have little bactericidal effect against *Actinobacillus lignieresii* and that the sulfonamides are of greater value.[9] It is probable that iodides exert their effect by reducing the severity of the fibrous tissue reaction.

Oral or intravenous dosing of iodides may be used. Potassium iodide, 6–10 g/day for 7–10 days, given orally as a drench to cattle, is a time-consuming treatment but effective. Treatment may be continued until iodism develops. Lacrimation, anorexia, coughing, and the appearance of dandruff indicate that maximum systemic levels of iodine have been reached. Sodium iodide (1 g/12 kg body weight) can be given intravenously as a 10% solution in one dose to both cattle and sheep. One course of potassium iodide or one injection of sodium iodide is usually sufficient for soft-tissue lesions, the acute signs in actinobacillosis disappearing in 24–48 hours after treatment. At least one or preferably two further treatments at 10- to 14-day intervals are required for bony lesions.

Occasional animals show distress, including restlessness, dyspnea, tachycardia, and staggering during injections of sodium iodide. Abortion occasionally occurs following the treatment of heavily pregnant cows with sodium iodide. This has not been reproduced in an experimental study;[12] however, although uncommon, it is wise to advise the owner of this risk. Subcutaneous injections of sodium iodide causes severe irritation and local swelling immediately. The irritation disappears within an hour or two but the swelling persists for some days. Subcutaneous injection is the standard route of administration for sheep, the dose rate of sodium iodide being 20 mL of a 10% solution weekly for 4–5 weeks.

The sulfonamides, penicillin, streptomycin, and the broad-spectrum antibiotics are also used. Streptomycin, given by intramuscular injection (5 g/day for 3 days) and repeated if necessary, has given good results in actinomycosis in cattle when combined with iodides and local surgical treatment.[14] Isoniazid has been used as a treatment for actinomycotic infections in humans and it has been reported on favorably as an adjunct to antibiotic or iodide therapy in cattle. The daily dose rate recommended is 10 mg/kg body weight orally or intramuscularly, continued for 3–4 weeks.

Cutaneous actinobacillosis may require an extended course of treatment with streptomycin and/or dihydrostreptomycin for 2–4 weeks to achieve resolution.[8]

CONTROL

Restriction of the spread of disease is best implemented by quick treatment of affected animals and the prevention of contamination of pasture and feed troughs. Isolation or disposal of animals with discharging lesions is essential, although the

disease does not spread readily unless predisposing environmental factors cause a high incidence of oral or skin lacerations.

DERMATOPHILOSIS (MYCOTIC DERMATITIS, CUTANEOUS STREPTOTRICHOSIS, SENKOBO DISEASE OF CATTLE, LUMPY WOOL OF SHEEP)

The disease in sheep is commonly called mycotic dermatitis, in cattle cutaneous streptotrichosis, although other local names exist including Senkobo skin disease in Central Africa, Kirchi in Nigeria, and Saria in Malawi. Dermatophilosis is a name common to the disease in all species.

SYNOPSIS

Etiology *Dermatophilus congolensis*
Epidemiology Organism present in minor carriage lesions on face and feet. Serious disease occurs when body skin is broken by shearing or insect bites, or macerated by prolonged wetting, coupled with management practices that promote transmission. The disease has significant importance in cattle in tropical areas and occurs mainly in sheep and horses in high rainfall areas in temperate climates. In tropical areas ticks promote severe infection in cattle by suppression of immune function
Clinical findings *Sheep*: hard crusts distributed over backline palpable in fleece. *Cattle and horses*: non-pruritic crusting dermatitis, initially with paintbrush tufts of hair. In cattle in tropical areas extensive skin lesions
Clinical pathology Branching filaments containing cocci in pairs
Diagnostic confirmation Clinical. Organisms in scrapings or biopsy sections, culture
Treatment Antibiotics. Topical antibacterial in horses
Control Avoidance of skin trauma and of management practices that promote transmission. Use of topical bactericides to prevent infection of shear cuts, and of skin in risk periods. Acaricides in cattle

ETIOLOGY

Dermatophilus congolensis is the infective agent but requires damage to the skin from other causes to establish infection. The organism is dimorphic and grows as **branched filamentous mycelia** containing dormant zoospores which are transformed by **moisture** to the **infective stage** of motile isolated cocci. There is considerable genetic diversity between isolates. Isolates from the same geographic region are not necessarily closely genetically related[1] although a recent study found that genotypic variation between isolates did correlate with host species.[2]

EPIDEMIOLOGY

Occurrence

Geographic occurrence

The disease occurs in all areas of the world but can be epizootic in **tropical** and subtropical areas of the world where it can result in considerable economic loss.[3] Surveys of large numbers of cattle in Africa report prevalence rates approaching 15% with a 100% infection rate in some herds at the time of peak seasonal prevalence.[4] In **temperate** climates the disease is usually sporadic but can still be of considerable economic importance where predisposing factors pertain. An incidence varying from 10 to 66% is recorded in nine dairy herds where shower cooling was the predisposing factor to disease.[5]

High prevalence in sheep flocks occurs in the high and medium rainfall areas of Australia. Significant clinical disease has been reported as far north as Canada, the northern United States and Scotland, and as far south as New Zealand.

Host occurrence

Disease occurs in cattle, sheep, goats, horses, donkeys, and occasionally in deer, pigs, camels, and wildlife species.[4] Animals of all ages are susceptible, including sucklings a few weeks old.

Source of infection

The major source of infection for outbreaks of clinical disease exists with minor active lesions on the face and feet in otherwise **healthy carrier animals**, and with infection in **scabs** still carried in the hair and wool from healed lesions.[6]

D. congolensis is not highly invasive and does not normally breach the barriers of healthy skin. These barriers include the stratum corneum, the superficial wax layer produced by the sebaceous glands and, on the body of sheep, the physical barrier of the wool. On the feet and face these barriers are easily and commonly broken by abrasive terrain or thorny and spiny forage and feedstuffs.

Dermatophilus may infect these lesions and may be transmitted mechanically by feeding flies to result in minor infection on the face and feet. This **'subclinical' carriage form** of the disease is common in most herds and flocks and the minor lesions are most evident at the junction of the haired and non-haired areas of the nares and of the claws and dewclaws. Minor lesions may also be present in the haired areas of the face and feet and on the scrotum and, in lambs, on the skin along the dorsal midline of the back.[7] They are of no clinical significance to the animal except that they provide a source of more serious infection when other areas of the skin surface are predisposed to infection.

Transmission

Transmission occurs from the carriage lesions by contact from the face of one animal to the fleece or skin of another, and from the feet to the skin during mounting. Infection can be transmitted mechanically by flies and ticks and mediate infection by contaminated dips.

Environmental and management risk factors

Sheep

Prolonged wetting of the fleece is the major risk factor and leads to emulsification of the wax barrier and maceration of the skin surface with disruption of the stratum corneum. A prolonged and **heavy rain** is sufficient to do this especially if followed by warm and humid weather that retards drying of the fleece. Increased environmental humidity and temperature, as distinct from wetting of the skin, does not appear to promote the development of lesions.[8] Moisture releases infective zoospores from carriage lesions and these may be carried mechanically by flies which are attracted to the wet wool. The motile zoospores are aided in their movement to the skin surface by the moisture of the fleece and their positive chemotactic response to carbon dioxide at the skin surface.

A protracted wetting period of the fleece can also occur following **dipping**, jetting, or spraying of sheep for external parasites when these procedures are conducted at periods greater than 1–2 months after shearing; the incidence of mycotic dermatitis in sheep has been shown to increase with the time period between shearing and dipping. The infection onto the fleece comes primarily from the lesions on the face and feet and is promoted by tightly yarding sheep following these procedures.

Shearing cuts also destroy the barriers of the skin and cuts may become infected mechanically by flies, physically by **tight yarding** after shearing, and by mediate infection in **dips** when sheep are dipped immediately following shearing. The

resultant lesions do not spread over the body but provide a significant source of infection for other sheep in the flock when management or climatic circumstances lead to a high degree of flock skin susceptibility. Skin infection can also occur following infection with contagious ecthyma.[9]

Cattle

Temperate zones

Outbreaks in herds and severe disease in individuals are uncommon but can occur associated with high rainfall with attack rates of 50%.[10] There is a particular tendency for lesions to occur on the rump and back in females and males probably due to the introduction of infection through minor skin **abrasions caused by mounting**. Lesions down the flanks of cattle may also result from abrasions and direct infection from the dewclaws during mounting. Other penetrating lesions caused by ear tags or biting flies can also result in minor lesions.

The use of periodic showers or continual **misting** to cool cattle during hot periods is a risk factor for infection in dairy herds.[5,11,12] **Intercurrent disease** and stress are also risk factors and in infected dairy herds a higher incidence has been observed during the first weeks of parturition in first-calf heifers that also had endometritis or mastitis.[5,11]

Tropical zones

Climate is the most important risk factor and in tropical and subtropical regions, the disease has its highest incidence and severity during the humid, high rainfall season. Animals in which the disease regresses are usually reinfected repeatedly in successive wet seasons. As in sheep, the disease in cattle requires disruption of natural skin barriers. However, prolonged wetting of the skin of cattle does not appear to be a major predisposing factor by itself and the seasonal occurrence is associated with a concomitant increase in tick and insect infestation.[4] For example, a recent study in Ethiopia found that although prevalence was higher in cattle in the wet season, in both seasons infestation with *A. variegatum* significantly affected the occurrence of disease with infested cattle seven times at higher risk.[13]

Tick infestation, particularly with *Ambylomma variegatum*, *Hyalomma asticum*, and ***Boophilus microplus***, is strongly associated with the occurrence of extensive lesions of dermatophilosis, which can be minimized by the use of acaricides.[14]

The lesions of dermatophilosis on the body do not occur at the predilection sites for ticks and it is thought that the importance of tick infestation relates to a tick-produced **immune suppression** in the host rather than mechanical or biological transmission.[15,16]

Lesions do occur at predilection sites for **biting insects**, mainly *Stomoxys* spp. and *Lyperosia* spp., *Glossinia* spp., *Calliphoria* spp., and mosquitoes.[4,17] In Africa the disease is often combined with demodicosis to produce **'Senkobo disease'**, a more severe and often fatal combination.

Trauma to the skin produced by thorny bushes and the Ox-pecker bird (*Buphagus africanus africanus*) can also initiate lesions.

Horses

Biting flies (*Stomoxys calcitrans*) are thought to act as mechanical vectors of the infection and the house fly (*Musca domestica*) can carry infection. Skin damage from trauma or from ectoparasites can predispose disease as does wetting from rainfall or from **frequent washing**.[18]

HOST RISK FACTORS

There are **breed differences** in susceptibility in cattle and sheep. In Africa, the N'dama and Muturu cattle breeds and native sheep are resistant, while Zebu, White Fulani, and European breeds are susceptible.[4] **Within-breed differences** in susceptibility are also apparent and genetic markers have been identified in Zebu cattle[19] and Merino sheep.[20] Susceptibility in cattle can be influenced by genetic selection and selection against susceptibility to dermatophilosis based on a B0LA-DR/DQ haplotype has resulted in a reduction over a 5-year period in the prevalence of disease in Brahman cattle in Martinique.[21]

In the Merino, sheep of the strong or medium wool strains are more susceptible. Open-fleeced sheep, and sheep with a low-wax and high-suint content in their fleece are more prone to infection.

PATHOGEN RISK FACTORS

D. congolensis does not live well off the body and in the normal environment, and is susceptible to the external influences of pH and moisture fluctuations. In the laboratory it can survive for 4 years in otherwise sterile broth culture and for at least 13 years in dry scab material kept at room temperature.[22]

EXPERIMENTAL REPRODUCTION

Local lesions, but not with spread to extensive disease, can be readily reproduced in sheep and cattle by removal of the skin wax followed by local challenge.[23,24] Genetic differences modulate the severity of the lesion that occurs.[23]

ECONOMIC IMPORTANCE

Sheep

Damage to the fleece causes severe losses, up to 30% loss of value of wool and 40% loss of skin value,[25] and may be so extensive in lambs that spring lambing has to be abandoned. Other losses in sheep are caused by interference with shearing[26,27] and a very great increase in susceptibility to blowfly infestation.[28]

Cattle

In Africa the disease in cattle causes great losses and many deaths, and the disease ranks as one of the four major bacteriological diseases with equivalent importance to contagious bovine pleuropneumonia and brucellosis.[4] Goats in the same area also suffer a high incidence.[4,29] Losses are from direct animal loss, decreased work ability of affected oxen, reproductive failure from vulval infection or infection on the limbs of males preventing mounting, death from starvation of calves of dams with udder infection, loss of animal meat and milk production, and downgrading of hides.[4] In **temperate climates** deaths are uncommon but cows that fail to respond to treatment and have to be culled are not infrequent. In a study in nine herds in Israel death or culling rates from this disease ranged from 2 to 17% and there was an average 23% fall in milk production in affected cattle.[5] Reproductive inefficiency is a common accompaniment in severe cases.[30]

Zoonotic implications

Human infection is reported, such as on the hand of a veterinarian working with infected sheep,[31] but contagion from livestock is rare in spite of ample opportunity.

PATHOGENESIS

The natural skin and wool waxes act as effective barriers to infection. **Minor trauma**, or maceration by prolonged wetting, allows establishment of infection and multiplication of the organism in the epidermis. The formation of the typical **pyramidal-shaped crusts** is caused by repeated cycles of invasion into the epidermis by hyphae, bacterial multiplication in the epidermis, rapid infiltration of neutrophils, and regeneration of the epidermis. The organism in the scab is the source for the repeated and expanding invasion which occurs until immunity develops and the lesion heals.[24,32] The scab then separates from the healed lesion but is still held loosely in place by hair or wool fibers. In **sheep**, the extensive **maceration** of skin that can occur with prolonged fleece wetting can result in extensive skin lesions under the fleece. In **cattle**, tick infestation suppresses **immune function** and promotes the spread of the lesion.[24,32] Secondary bacterial invasion may occur and gives rise to extensive suppuration and severe toxemia.

CLINICAL FINDINGS

Sheep

Lesions are commonly not visible in sheep because they are obscured by the

fleece but the crusts can be palpated as hard masses at the surface of the skin (**lumpy wool disease**) and typically are distributed irregularly over the dorsal midline with 'ribs' spreading laterally and ventrally. The crusts are roughly circular, thick, up to 3 cm, often distinctly **pyramidal** with a concave base, often pigmented, and the underlying skin is moist and reddened. The muzzle, face and ears, and the scrotum of rams, may also be involved. The health of the animal is unaffected unless the lesions are widespread.

Heavy mortalities can occur in very young **lambs** where there can be extensive lesions over the body. Many develop cutaneous blowfly myiasis and in occasional cases a secondary pneumonia due to the organism may cause the death of the animal.

Cattle

The early lesion is a pustule and the hair over the infected site is erect and matted in tufts (**paintbrush lesions**) with greasy exudate forming crumbly crusts which are hard to remove. These develop to scabs which are greasy and fissure at flexion points, and finally to scabs that are hard, horny, and confluent. The scabs vary in color from cream to brown, are 2–5 cm in diameter and are often in such close apposition that they give the appearance of a mosaic. In the early stages the crusts are very tenacious and attempts to lift them cause pain. Beneath the crusts there is granulation tissue and some pus. In the later stages, the dermatitis heals and the crusts separate from the skin, are held in place by penetrating hairs, but are easily removed.

Lesions occur on the neck, body, the back of the udder and may extend over the sides and down the legs and the ventral surface of the body. Commonly they commence along the back from the withers to the rump and extend halfway down the rib cages. In some animals the only site affected is the flexor aspect of the limb joints or the inguinal area or between the forelimbs.

In young **calves**, infection commences on the muzzle, probably from contact with the infected udder or because of scalding by milk in bucket-fed calves, and may spread over the head and neck.

Horses

Lesions in horses are similar to those in cattle. The hairs are matted together over the lesion and an exudative dermatitis produces a firm mat of hairs and debris just above the skin surface. If this hair is plucked the entire structure may lift off, leaving a characteristic ovoid, slightly bleeding skin area. **No pruritus** or irritation is apparent although the sores are tender to the touch.

Infection can appear on the head, beginning at the muzzle and spreading up the face to the eyes, and if sufficiently extensive may be accompanied by lacrimation and a profuse, mucopurulent nasal discharge. In some horses the lesions are confined to the lower limbs, with a few on the belly. In very bad environmental conditions the lesions may be widespread and cover virtually the whole of the back and sides. The lesions on lower limbs are most common behind the pastern, around the coronet and on the anterior aspect of the hind cannon bones. If the underlying skin cracks, the horse can become very lame. This variable distribution of lesions may depend upon the inciting skin trauma.

Goats

Lesions appear first on the lips and muzzle and then spread, possibly by biting, to the feet and scrotum. They may extend to all parts of the body, especially the dorsal midline and inside the thighs.[29] In some cases lesions commence on the external ear.[33] Heavy crust formations may block the ear canal and the external nares.

CLINICAL PATHOLOGY

The causative organism may be isolated from scrapings or a biopsy section and is much easier to isolate from an acute case than a chronic one. Polymyxin B sulfate can be used to suppress contaminants. Typical **branching** organisms with **double rows** of zoospores can be seen in a stained impression smear made directly from the ventral surface of a thick scab pressed firmly onto a slide. The organism can also be demonstrated by fluorescent antibody.[34] ELISA and counterimmunoelectrophoresis have also been used to detect serological evidence of infection with *D. congolensis*.[35]

NECROPSY FINDINGS

In animals that die, there is extensive dermatitis, sometimes a secondary pneumonia, and often evidence of intercurrent disease.

Samples for confirmation of diagnosis

- **Bacteriology** – affected skin and draining lymph node (CYTO FUNGAL CULT)
- **Histology** – formalin-fixed samples of these tissues (LM).

DIFFERENTIAL DIAGNOSIS

- Ringworm
- Staphylococcal dermatitis/folliculitis
- Scabies
- Pediculosis
- Fleece rot – sheep.

Other causes of dermatitis are listed in Table 22.4.

TREATMENT

Sheep

Bactericidal dips are used, but have limited efficacy as topical treatments do not penetrate the scab to the active lesion, and are more appropriate for control.

Antibiotic treatment at high dose for a single treatment is effective in reducing the proportion of active lesions in an affected flock. Antibiotics that are effective include procaine penicillin combined with streptomycin at a dose of 70 000 units/kg and 70 mg/kg, respectively,[26] erythromycin at 10 mg/kg,[26] long acting tetracycline at 20 mg/kg[27] and combination of lincomycin and spectinomycin at a dose of 5 mg/kg and 10 mg/kg, respectively[21]; all treatment being given intramuscularly. Treatments appear effective in wet weather.[27] The usual strategy is to treat 8 weeks prior to shearing so that there is time for the lesions to heal and shearing to occur without interference from active lesions. Sheep may be dipped in a bactericidal dip after shearing as detailed below under control. An alternate approach is to cull affected sheep.

Cattle

With the disease that occurs in **temperate areas** tetracycline (5 mg/kg BW) repeated weekly as required is recommended, and long-acting tetracycline (20 mg/kg BW) in one injection is reported to give excellent results in cattle.[10,32] Parenteral procaine penicillin (22 000 iu/kg) daily for three days is also reported as efficacious.[5]

With the disease that occurs in **tropical areas** and associated with tick infestation, there is no completely satisfactory treatment in herds with extensive involvement, or those being constantly reinfected or exposed to predisposing causes. In general terms, better results are obtained during dry weather and in dry climates. In tropical Africa treatments which are reasonably effective elsewhere are of little or no value.

Parenteral treatment with antibiotics, as above, can be used and should be used in conjunction with **acaricides** when ticks are present.

Horses

Topical therapy is most commonly used in horses coupled with removal from whatever is causing prolonged wetness of the skin. Although horses generally respond well, in bad weather even they can be recalcitrant to treatment. Scabs can be removed by grooming under sedation and the lesions treated topically daily with povidone–iodine or chlorhexidine until the lesions heal.[36] Benzoyl peroxide has keratolytic, antibacterial, and follicular flushing properties and is reported to be effective in therapy when applied topically at a concentration of 2.5%.[37]

Severe cases can be treated daily for 3 days with penicillin at 20 000 units/kg intramuscularly alone or in combination with streptomycin at 10 mg/kg.

CONTROL

The principal approach, where possible, is the avoidance of predisposing factors. The disease usually disappears in dry weather. Isolation of infected animals and avoidance of contact by clean animals with infected materials such as grooming tools is desirable. Affected sheep should be shorn and/or dipped last.

Close yarding of sheep, or factors that promote face to skin contact immediately after shearing or after dipping, should be avoided. Insecticidal dips should contain a bactericide. Where dipping immediately after shearing is a risk factor the severity of infection can be reduced by delaying dipping, for example, from the 1st to the 10th day after shearing, or by dipping in zinc sulfate immediately following shearing with later dipping in an insecticide. Alternatively, pour-on insecticides can be substituted.

Bactericidal dips will give some protection to sheep. Spraying or dipping of sheep in a 0.5–1.0% solution of zinc sulfate immediately after shearing is used to prevent infection of shear cuts. Spraying or dipping sheep in a 1% solution of alum (potassium aluminum sulfate) provides protection against infection for up to 70 days, alum rendering the organism non-motile, and can be used to provide protection during the rainy season in woolled sheep. Alum strips from the dip and the dip requires frequent replenishment, the amount depending on wool length. An alternate treatment is to dust alum along the back of the sheep.

With cattle in tropical areas, **tick control** (Chapter 28) is most important in control of dermatophilosis. Attempts at prophylaxis by vaccination in both sheep and cattle have been unsuccessful,[32] immunity appears to be isolate-specific.[24]

STRAWBERRY FOOT ROT (PROLIFERATIVE DERMATITIS)

This is a proliferative dermatitis of the lower limbs of sheep.

ETIOLOGY

The causative agent is believed to be *Dermatophilus congolensis* (*D. pedis*).[1]

EPIDEMIOLOGY

The disease is recorded from the UK and occurs extensively in some parts of Scotland and in Australia. It is not fatal but severely affected animals do not make normal weight gains. Up to 100% of animals in affected flocks may show the clinical disease.

All ages and breeds appear susceptible but under natural conditions lambs are more commonly affected. Most outbreaks occur during the **summer months** and lesions tend to disappear in cold weather. Although the disease is recorded naturally only in sheep, it can be transmitted experimentally to man, goats, guinea-pigs, and rabbits. Complete immunity does not develop after an attack, although sheep recently recovered from contagious ecthyma may show a transient resistance.

The natural method of transmission is unknown but the frequency of occurrence of lesions at the knee and coronet suggests infection from the ground through cutaneous injuries. Dried crusts containing the causative agent are infective for long periods and ground contamination by infected animals, or infection from carrier animals, is the probable source of infection.

PATHOGENESIS

Histologically, the lesions are those of a superficial epidermitis similar to that of contagious ecthyma.

CLINICAL FINDINGS

Most cases appear 2–4 weeks after sheep have been moved onto affected pasture but incubation periods of 3–4 months have been observed. Small heaped-up **scabs** appear on the leg from the coronet to the knee or hock. These enlarge to 3–5 cm in diameter and become thick and wart-like. The hair is lost and the lesions may coalesce. Removal of the scabs reveals a **bleeding, fleshy mass** resembling a fresh **strawberry**, surrounded by a shallow ulcer. In later stages the **ulcer** is deep and pus is present. There is no pruritus or lameness unless lesions occur in the interdigital space. Most lesions heal in 5–6 weeks but chronic cases may persist for 6 months.

CLINICAL PATHOLOGY

Swabs and scrapings should be examined for the causative organism.

DIFFERENTIAL DIAGNOSIS

Lesions of strawberry foot rot closely resemble those of contagious ecthyma but are restricted in their distribution to the lower limbs, whereas lesions of contagious ecthyma occur mostly on the face and rarely on the legs. The absence of a systemic reaction and the proliferative character of the lesions differentiate it from sheep pox.

TREATMENT

There is little information on treatment. Antibiotics as used in dermatophilosis should be effective.

CONTROL

In the light of present knowledge, isolation of infected sheep and the resting of infected fields are the only measures which can be recommended.

Diseases associated with *Actinobacillus suis*

Synopsis

Etiology *Actinobacillus suis*
Epidemiology Opportunist pathogen in conventional herds producing diseases in pre-weaned pigs. Pathogen of all ages of swine in high-health herds
Clinical findings Septicemia and polyarthritis in young pigs, sudden death and respiratory disease in growing pigs, abortion in sows
Lesions Septicemia and polyserositis in young pigs, hematogenous pneumonia in grower pigs
Diagnostic confirmation Culture
Treatment Antimicrobial
Control None specific

ETIOLOGY

Actinobacillus suis is an emerging swine pathogen. Historical literature has ascribed this bacterial species to a number of diseases in different animal species. Recent studies suggest that strains of *A. suis* isolated from swine appear **swine-specific** and different from *A. suis*-like organisms from other species, suggesting that this organism has a specific role in swine disease and that other animal species are not reservoirs for the disease in pigs.[1]

EPIDEMIOLOGY

A. suis is generally a pathogen of preweaned pigs and only a pathogen of older pigs in minimal disease herds. Historically *A. suis* has been regarded as an opportunistic pathogen of conventionally reared swine that can cause sporadic disease following stress or an opportunistic pathogen causing disease in association with infections such as swine fever. However, in the past 10–15 years it has become apparent that *A. suis* can be a significant pathogen in high-health herds when it is introduced to such a herd or when high-health-status animals are mixed with conventionally reared swine.[2]

Occurrence

The infection has probable world-wide occurrence and is reported in most countries where swine are a significant agricultural industry; however, disease has particular importance in the USA and Canada.

Prevalence of infection

A. suis has been associated with disease in young piglets and, less commonly, with disease in growing and adult pigs, and with abortion The incidence of disease varies with the health status of the herd. It is usually a cause of sporadic septicemia and polyserositis in sucking pigs but in some high-health swine units a large proportion of litters can be affected with up to 30% of piglets in a litter affected and a preweaning mortality of 25% during an outbreak,[3] and in post-weaned growing pigs can be associated with short outbreaks of disease with high case fatality.[4] Abortion occurs with the highest incidence in gilts and first-parity sows with abortion rates approaching 10% in the abortion storm period.[5]

Methods of transmission

The organism colonizes the oropharynx, upper respiratory tract, and vagina of normal pigs and infection is believed to be by aerosol infection with invasion through the upper respiratory tract.[6]

Pathogen risk factors

The pathogenicity of *A. suis* in disease is still not well understood, The organism shares a number of virulence determinants with other Gram-negative organisms such as capsule, lipopolysaccharide (LPS), and pore-forming toxins. The hemolytic/cytolytic toxins produced by *A. suis* are very closely related to ApxI and ApxII toxins of *Actinobacillus pleuropneumoniae.* There are two different major LPS (O) antigen types, O1 and O2, and O2 strains are more likely to be associated with severe disease.[7,8] Geographic clustering of strains occurs.[8]

Economic importance

The disease has emerged to be an important cause of disease in high-health swine herds in North America.[9]

Zoonotic implications

The infection in pigs is not a major zoonosis but local infection in man is reported following a bite by a pig.[10]

CLINICAL FINDINGS

The disease manifests with septicemic disease with fever and sudden death in suckling or weaned pigs and less commonly older pigs. Most commonly the disease involves pigs under 2 months of age, with the major occurrence in suckling piglets and occurring in one or more litters. The presenting syndrome is usually one of sudden death of piglets associated with **septicemic** disease followed by the development of more chronic disease in the remaining piglets in the litter. Affected pigs are listless, pyrectic and show respiratory distress, neurological disturbances, and arthritis and have petechial hemorrhages or cyanotic areas in the skin most noticeable on the abdomen and ears. **Polyarthritis** manifests with reluctance to stand, lameness, and palpable swelling in the joints develops in piglets which live longer than 24 hours after clinical onset.

Manifestations of the disease in mature animals can include pyrexia and the occurrence of erysipelas-like skin lesions, abortion, metritis, and meningitis. In growers and adults in high-health herds *A. suis* can cause septicemia, respiratory distress, and brief cyanosis before death with clinical and pathological findings that superficially resemble *Actinobacillus pleuropneumoniae*.[2,11] In adult pigs a major manifestation can be signs resembling erysipelas with pyrexia and the early occurrence of round, oval, or rhomboid raised erythematous **skin lesions**.[3,12]

Actinobacillus spp. have been isolated from **aborted fetuses** in swine.[5,13,14] The abortions are usually in gilts and lower-parity sows and are late term and sporadic.

NECROPSY FINDINGS

Postmortem examination may reveal gross evidence of septicemia, such as petechial hemorrhages in the lungs and abdominal viscera, serofibrinous exudates in the pericardial, peritoneal, and pleural cavities, polyarthritis with pale yellow fibrinous joint fluid and edematous thickening of the joint capsule, and splenomegaly. Grossly, the cardiac hemorrhages and pericardial effusion can resemble mulberry heart disease.[15] Dead suckling piglets often have cyanosis of the extremities and the peritonitis may be restricted to fibrin tags over the surface of the intestines.[3,13,16] In some instances, raised, oval to rhomboidal, cutaneous plaques reminiscent of erysipelas lesions are seen in older pigs. Growers and feeders may have a lobular bronchopneumonia with a hemorrhagic and fibrinonecrotic character that is grossly somewhat similar to that produced by *A. pleuropneumoniae*.[4] Microscopic changes in all ages are typical of bacterial septicemia and can include intravascular colonies of coccobacilli in a variety of tissues. Acute myocardial and hepatic necrosis is often observed microscopically. Diagnosis is by postmortem findings and colture of the organism.

DIFFERENTIAL DIAGNOSIS

- *Streptococcus suis*
- Glasser's disease
- Erysipelas
- Pleuropneumonia
- Mulberry heart disease

TREATMENT

The organism is susceptible to most antibiotics with the exception of erythromycin, clindamycin, neomycin, and tetracyclines,[17] but the sudden onset precludes effective treatment in most pigs. Although the disease is sporadic and outbreaks are unusual, prophylactic treatment of in-contact and at-risk piglets is advisable for a short period.

CONTROL

Currently there is no effective method of control, other than strategic medication of pigs during the risk period for that herd. Nor is there a practical method of insuring that infection will not be introduced to a herd. Routine biosecurity measures should be followed. Colonization by *A. suis* is believed to occur in the first 3 weeks of age but varies between animals[17] and the value of early segregated and medicated weaning is not established for this disease. There is no commercial vaccine.

PLEUROPNEUMONIA OF PIGS ASSOCIATED WITH *ACTINOBACILLUS PLEUROPNEUMONIAE*

ETIOLOGY

Actinobacillus pleuropneumoniae (APP), formerly known as *Haemophilus pleuropneumoniae*, is the causative organism and requires factor V for growth.[1] Recently, a completely non-pathogenic species, *A. porcitonsillarum*, capable of producing some Apx toxins but not Apx IVa has been identified.[2]

EPIDEMIOLOGY

Occurrence

The only natural host is the pig but it has been isolated from cattle, deer, and lambs and some rodents can be infected experimentally.[3] The diversity of strains isolated from healthy pigs could be higher than that of strains recovered from diseased pigs.[4]

The disease occurs worldwide in growing pigs from 2 to 6 months of age with rapid spread both within the initially affected group and subsequently to other older or younger pigs in a herd. Abattoir surveys have found that the lungs of pigs from about 50% of herds monitored for several months may have lesions attributable to APP. Seroepidemiological surveys have found that pigs in 70% of herds may have antibodies to one or more of several recognized serotypes of the organism. The prevalence of infection continues to increase – presumably due to confinement rearing, crowding, inadequate ventilation, close contact, and commingling of pigs of various age groups. The incidence of clinical disease is much less than the prevalence of infection. In most countries the more dense the pig population the more prevalent the APP is likely to be and this has been documented in Belgium.[5]

Morbidity and case fatality

The morbidity rate can exceed 50% and the mortality may vary from 1 to 10% [1]

Methods of transmission

Transmission is usually by pig to pig contact. Only a few organisms need to be carried in the tonsil and nasopharynx for a pig to become infectious during travel. The subclinically infected carrier pig is the most common source of infection.[6] It has been suggested that shedding only takes place at the time of active infection not when the organism is just carried.

Transmission is by the respiratory route, principally via nose to nose contact. Overcrowding and inadequate ventilation may facilitate spread. The organism can be spread in the air for a distance of 1 m.[7] Aerosol transmission of serovar 9 was possible over 2.5 m.[8] An experiment with transferring air from a group of pigs with serotype 2 showed that if 10% of the air was transferred, then there was no transmission, but if 70% was transferred, then the APP did spread.[9] Peak transmission may occur at around 11 weeks.[10] Experimental aerosol exposure of pigs to serotype 9 results in infection and induces protection to subsequent challenge from the homologous strain.[11] Experimental intranasal challenge has been followed by death in a period as short as 24 h. The mixing of infected pigs (seeder pigs) with normal susceptible pigs for 48 h can mimic field infection with the development of clinical disease, febrile responses, lung lesions, and mortality.[12]

The subclinically infected carrier pig is the most common means by which the infection is transmitted between herds. Severe outbreaks may occur unexpectedly in susceptible breeding herds with no previous history of the disease or in intensive feeder pig operations in which pigs are introduced on a regular basis from a variety of sources. Herds which continuously introduce replacement stock are highly susceptible to an outbreak. Following the initial outbreak general herd immunity develops, but the infection persists and sporadic cases may continue to occur. The organism is not readily isolated from normal respiratory tissues, but persists in chronic lesions within the lungs of recovered and apparently clinically healthy pigs. These pigs provide a source of infection, especially in a finishing herd buying from diverse sources. The indirect transmission of infection has been proposed but may be rare. An on-farm study described five cases of being transmitted by aerosol or boots or clothes, but the other three cases could have been any combination of these three or even other indirect sources.[13]

Risk factors

Pathogen factors

Serotypes

There are two biotypes. Biotype 1 requires NAD (13 serotypes) and biotype 2 does not (2 serotypes). The isolation of biotype 2 may be increasing. In 1997, two new serotypes were proposed: serotype 14[14] and serotype 15.[15] Serotypes 1–12 form biotype 1 together with 15. Biotype 2 is serotypes 13 and 14.[16]

Serotype 5 is subdivided into subtypes A and B. Serotype 1 has also been divided into antigenic subtypes 1A and 1B.[17] The prevalence of serotypes of APP varies considerably according to geographical location. Serovars 1, 5, and 7 are common in North America, serovars 2 and 9 are common in continental Europe, while serovar 3 is common in England. Serovars 1, 7, and 12 are the most common and are present in Australian pigs,[18] with serovar 1 being the most common.[19] In Denmark they routinely find 9 strains.[20] It is usually 2 followed by 6, 5, and 12. Serotypes 1, 7, 8, and 14 are infrequent and serotypes 3, 4, 9, 11, 13, and 15 have not yet been found.[20] In North America the most common serotypes, in order of their frequency, are serotypes 1, 5, and 7.[1] Serotype 1 is most common in eastern Canada, accounting for 66–83% of the isolates, and is the second most prevalent isolate in western Canada and the USA. Serotype 2 is of low frequency in Canada, but is the dominant isolate in Sweden, Switzerland, and Denmark. However, serotype 2 has now been reported as causing disease in growing and finishing pigs in the USA.[21] Serotype 3 has a low incidence in Canada and the USA and has been reported in Ireland. Serotype 5 isolations are common in Canada and the USA. Serotype 6 has not been reported in North America but occurs in Denmark. Serotype 7 is found in Canada and the USA, and a serotype 8 has recently been identified in outbreaks of pleuropneumonia in pigs in Ireland and Denmark. APP 10 is common in France and Brazil.[22] The most common serotypes isolated in Quebec were 1, 5, 2, and 7 in that order. In the British Isles,

serotypes 2 and 8 were most common with 3, 6, and 7 also occurring frequently. Serotypes 5, 9, 10, and 12 occurred only rarely. Serotypes 1 and 4 were not isolated. Among isolates from the Irish Republic, serotype 2 was predominant and serotype 6 was absent.[23]

The serotyping of isolated strains is important in the epidemiological and immunological study of APP infection. It is also important when comparing or analyzing the effectiveness of different treatments to know the virulence of the strains and sensitivity to antimicrobials. An effective immunization program also depends on consideration of the multiplicity of immunogenic types which occur in a particular area or country. Some of the serotypes are heterogeneous (they share antigenic determinants with other serotypes). Heterogeneity has been reported for serotypes 3, 6, and 8, serotypes 4 and 7, and serotypes 1, 9, and 11.[24,25] Restriction endonuclease fingerprinting analysis can be used for comparison of serotypes.[26]

Virulence factors

APP attaches to tonsillar epithelium.[27] It also adheres to tracheal rings in vitro and alveolar epithelial cells.[28] Genes that are involved in energy metabolism, nutrient uptake, and stress response are essential for the survival of APP in the pig host.[29] These would include enzymes that are produced in vivo to ensure that there is oxygen.[30,31] A metalloprotease has been found that can degrade porcine IgA and IgG.[32]

Several other virulence attributes and their biological effects have been described.[33,34] Multiple virulence factors are involved in the development of the disease, and lesions are likely caused by toxic factors associated with the organism. The capsular components are antiphagocytic and inhibit bactericidal activity of the serum but do not cause any lesions themselves. Discovery of mutants without capsules that were no less able to adhere to respiratory tract tissues suggests that the outer membrane proteins were then unmasked (without the capsule) and these were able to adhere to epithelial cells.[35] It is therefore an LPS independent adherence.[36] The outer membrane proteins (OMP) (60 kDa) adhere to fibers of type III collagen in the lung. The outer membrane proteins appear to be common to all serotypes.

The lipopolysaccharides (LPS) of APP are serotype specific but will cross react with one another.[37] LPS of APP is an important adhesin.[38–40] It also induces inflammation by stimulating TNF α, IL-1, Il-6, and IL-8.[41,42] However, the construction of antibodies to LPS blocked adherence to tracheal cells[43] so our understanding is not yet complete. The LPS causes an endotoxemia and reproduces certain typical lesions of the natural disease but not the hemolytic or necrotizing effects. Some LPS also help APP to stick to mucus, tracheal rings, and lung, but they do not seem to be involved in adherence to cultured porcine alveolar epithelial cells.

Porcine hemoglobin also binds to LPS with APP[44] and this is a property of the APP OMP.[45]

Under iron-deficiency growth conditions, APP expresses 2 transferrin binding proteins.[46–50] Recently, a ferrichrome receptor in APP[51] has been described.

There are adhesions (fimbriae) involved.[52,53] They are particularly associated with serotype 1 but also 3 and 5 and are usually a feature of subculture 1 (56% of strains), but only 8% on subculture 2 and none on 3.[54]

Several exotoxins are produced including hemolysins.[55] The hemolytic activity of this organism is characteristic of this species of bacteria. This range of exotoxins is part of the pore-forming RTX group known as the Apx toxins. The latest is Iva.[56–58] The Apx IVa gene is found in all APP serotypes and is absent in the other related species in the Pasteurellacae and, therefore, is considered species specific for APP[59] and is, therefore, being used in a PCR to identify APP strains.[60]

The Apx toxins are described below: I–III can be produced in vitro, but Apx IVa is only produced in vivo[56] and is specific only to APP.[61] All 90 strains investigated in one study had Apx IVa genes.[59] Mutants without the capacity to produce Apx toxins do not cause disease.[62] There are basically four different patterns. Both ApxI and II are essential for the production of lesions:[63]

- ApxI is strongly hemolytic and weakly cytotoxic
- ApxII is weakly hemolytic and moderately cytotoxic
- ApxIII is not hemolytic but strongly cytotoxic
- Serotypes 1, 5a, 5b, 9, and 11 produce I and II
- Serotypes 2, 3, 4, 6, and 8 produce II and III
- Serotypes 7 and 12 produce II
- Serotype 10 only produces Apx I.

These are toxic to alveolar macrophages, neutrophils, and endothelial cells. In small doses they are stimulatory but in large doses lethal. The gene expression is controlled over the growth curve by a novel regulating pathway.[64] Several genes have recently been identified which have helped in survival including the knowledge that it can produce toxins under anerobic conditions.[65] The LPS of APP can also stimulate the release of nitric oxide from macrophages by virtue of the enzyme nitric oxide synthase which damages tissues and may disrupt vascular tone, neuronal signaling, and host defense mechanisms.[66–69] Nitric oxide synthase 2 and cycloxygenase 2 have been found in swine experimentally infected with APP.[70] Urease activity may also be required for APP to establish infection in the respiratory tract.[71]

The increase in antimicrobial drug resistance which has occurred is an indirect virulence factor and an important disease-promoting mechanism.[33] The ability of the organism to resist complement killing in vitro may reflect a virulence mechanism in vivo which assists bacteria in avoiding the pulmonary defenses of swine and promotes bacterial invasion of the lung.[72]

Differences in pathogenicity exist between serovar 1 and serovars 7, 3, and 2.[73] The differences between serotypes 1, 2, and 7 are low. Serotype 3 seems less virulent than 1. The differences in capsular structure and biochemical composition between virulent and avirulent isolates may contribute to virulence. A smooth-type lipopolysaccharide and a rough-type lipopolysaccharide have been isolated and characterized from serotype 5. The intrabronchial infusion of the preparations into pigs induces lesions typical of those in pigs which die from acute pleuropneumonia.

APP may interact with *P. multocida* to produce a severe pneumonia, whereas *P. multocida* alone is relatively nonpathogenic. Experimentally, a combination of *P. multocida* and the crude toxin of APP resulted in moderate-to-severe pneumonic pasteurellosis.[74]

Animal risk factors

The major animal risk factors are related to the immune mechanisms and the immune status of pigs of varying ages. A major animal risk factor is that clinically recovered pigs commonly serve as carriers of the organism and never fully recover from the infection. Normally, the APP is detected in mixed bacterial samples from the tonsils and/or nasal samples by PCR from the age of 4 weeks onwards but it has been detected as early as 11 days in tonsil samples, so it is possible for the sow to infect the piglet.[75] Isolations become more common from 4 to 12 weeks as maternal antibody wanes. The median length of tonsillar carriage may be 7–8 weeks. Colonization of the lungs can develop from around 12–16 weeks in some herds to as late as 23 weeks in others.

Immune mechanisms

In most herds you can still detect high antibody levels in 4-week-old piglets and

this maternal antibody (AB) continues to decrease until about 12 weeks and then the AB starts to rise with the acquisition of a pathogenic burden. The presence and decay of acquired colostral antibodies between 2 weeks and 2 months[76] determines the age at which APP infection is most likely to occur.[75,77] The maternal antibody titers halve every 3 weeks and therefore may remain for 12–56 days.[78]

Nasal colonization can occur as early as 4 weeks and APP can be found in the lungs from 12 weeks; it is usually 12–23 weeks before there is any seroconversion to Apx toxins.[77] In other words nasal colonization does not always produce antibodies.

Active immunity to disease usually follows experimentally induced and naturally occurring infections, and infection with one serotype of APP confers a strong immunity to the same serotype and a partial protection against heterologous strains. Most recovered pigs have a strong humoral immunity but it does not necessarily stop them from becoming carriers and thence possible shedders of APP.[79] Vaccination with killed bacteria produces partial protection against the homologous strain and none against heterologous strains. Second-generation vaccines with Apx toxins produce good protection against clinical disease caused by any serotype but do not prevent animals from becoming carriers through subclinical infections.[80] **However, vaccine immunity is serotype specific.**

The antibody response to APP infections or vaccination is demonstrated by the complement fixation test or other serological tests. There is a good correlation between a CF titer and resistance to infection, and the organism usually cannot be isolated from seropositive animals. Susceptibility to APP can be predicted by the absence of neutralizing antibodies to the organism, whereas protection can be predicted by the presence of these antibodies.[81] An aerosol exposure of pigs to viable or inactivated serotype 9 induced antibodies in pulmonary fluids and serum, and protected against homologous challenge.[11] However, the organism may persist in necrotic foci in the lungs or tonsils of pigs considered immune to the infection. Within 2–3 weeks of an acute disease outbreak, the morbidity decreases owing to the development of immunity. Clinical disease is unlikely in adult immune animals, and immune sows confer passive immunity to their piglets which provides protection for the first weeks of life. However, acute disease may occur in piglets 3–8 weeks of age if colostral immunity is initially low and wanes to below protective levels. Also, severe cases can occur in non-immune gilts and boars introduced into infected herds.

Pigs infected with hemolytic *Actinobacillus* spp. may become false-positive reactors for APP. Such pigs may also be less susceptible to pleuropneumonia caused by APP.

Environmental and management factors

Outbreaks of the disease appear to occur in pigs which lack immunity, are overcrowded or have been subjected to recent stressors, such as marked changes in ambient temperature or a failure in the ventilation system. Outbreaks may occur in breeding herds following transportation to and from livestock shows and sales. Presumably, the infection was contracted by commingling with clinically healthy but infected pigs. The hypothalamic–pituitary–adrenal axis is stimulated in response to a wide variety of stressors[82] and this may lead to activation of the organism from the tonsils. The highest risk is associated with the introduction of pigs from sales barns and the lowest risk from stock whose health status is known to the purchaser.

Economic importance

The economic losses associated with the disease are considered to be due to peracute deaths, the costs of treatment of individually affected pigs and mass medication of the feed and water, and chronic disease that delays the marketing of finishing pigs. Field observations indicate that 5.64 additional days are required for pigs with subclinical infection to reach market weight of 113.6 kg, compared with uninfected herdmates.[83] However, other observations and investigations indicate that average daily gain is not significantly affected by infection with APP. Undoubtedly, there are major economic losses associated with the endemic nature of the disease which is characterized by peracute deaths which recur sporadically, sometimes punctuated by outbreaks.

PATHOGENESIS

The natural route of infection is aerogenous. In growing pigs the disease appears to be a respiratory infection without septicemia, producing a fibrinous necrotizing hemorrhagic pleuropneumonia with pleuritis. Early after intranasal inoculation the bacteria were mainly associated with the stratified squamous epithelium and detached epithelial cells in the tonsil.[27] If only a few organisms are inhaled, probably they are trapped in the tonsil and remain there until they are activated. If large numbers are inhaled or if spread from the tonsil reservoir occurs, then a bacteremia probably results. Vacuolation and desquamation of the tonsillar epithelium was observed and there were many migrating neutrophils. Discharge of vesicles containing proteases and Apx toxins from the organisms themselves of serotype 1 has been described.[84] Later the bacteria are associated with the crypt walls and detached cells in the crypts.[85] Experimental aerosol exposure of pigs to APP results in a severe fibrinous hemorrhagic necrotizing pleuropneumonia which simulates the natural disease. Within a few hours following endobronchial inoculation of various doses of the organism into 12-week-old pigs, clinical evidence of dyspnea and fever are obvious. An aerosol infection with the organism results in pulmonary edema with multifocal petechial hemorrhages and a diffuse neutrophilic bronchiolitis and alveolitis within hours of infection. In the lung, the recruitment of neutrophils is directed towards the viable APP organisms and possibly 30% of the lung neutrophils respond. This is further enhanced by IL-8 activity.[86]

The lesion is particularly marked in the dorsocaudal regions of the lung. The ability of APP hemolysin to debilitate pulmonary macrophages may enhance the multiplication of the organism but experimentally the hemolysin of serovar 2 is not an essential factor for the production of the lesions.[87] In the acute stages there are marked vascular changes in the lungs. The lesions resemble infarcts because of the vasculitis, thrombosis, and hemorrhage. There are many necrotic foci which serve as reservoirs of the organism in pigs which recover. In the experimental disease, the leukogram is typical of acute inflammation; however, hypoxemia and alveolar hypoventilation are not features of the disease. The hematological and physiological findings indicate that the peracute disease resembles septic shock.[88] Immediately after infection the levels of IL-1, IL-6, and TNF-α begin to rise. Moderate levels help in defense, but high levels make things worse.[89] At the same time the IL-10 suppresses TNF-α and IL-1 production in macrophages and monocytes, which up-regulates the other inflammatory cytokines. Pretreatment of the pig with IL-10 reduces the severity of the pleuropneumonia.[90] The prolonged survival of APP during the infections may be due to the effect the organism has in down-grading the protective responses of the host.[91]

CLINICAL FINDINGS

The clinical signs vary with the immune status and environmental stress, and customarily may be seen between 6 and 20 weeks of age. In all cases there is a reduced growth rate and reduced feed intake, and, therefore, reduced weight gain.[92] There is no relationship between

average daily gain and serologic response to APP.[93] The illness may be peracute, acute, subacute, or chronic. The onset is sudden. Several pigs that were not seen ill may be found dead and others show severe respiratory distress. Affected pigs are disinclined to move and are anorexic. A fever of up to 41°C (105.8 °F) is common and labored respirations with an exaggerated abdominal component ('thumps'), cyanosis, and frequently a blood-stained frothy discharge from the nose and mouth are characteristic. In peracute cases the clinical course may be as short as a few hours, but in the majority of pigs it is 1–2 days. Chronic cases are febrile and anorexic initially, but respiratory distress is less severe and a persistent cough may develop. If affected pigs are not treated there will be a high case-fatality rate. Otitis media in a weaned pig caused by infection of the middle ear with the organism has been described.[94] There may also be lesions in the joints with fluctuating swellings of the hocks[95] and the synovial membranes replaced by granulation tissue.

The course of the disease in a herd may last for several weeks, during which time new acute cases develop and chronic cases become obvious by an unthrifty appearance and chronic coughing.

Abortions may occur and the disease may cause sudden deaths in adult pigs, particularly those that are kept outdoors during the summer months and exposed to very warm weather.

CLINICAL PATHOLOGY

Plasma cortisol rises 24 h post challenge.[96]

Haptoglobin is increased.[89,97] Within 48 h IL-1a, IL-1β, and IL-8 were increased[97] and there was a 50% reduction in iron and zinc. Plasma IGF-1 concentrations were reduced in response to the APP challenge[98] as they were with endotoxin challenge.[99] The LPS of APP produces rises in inflammatory cytokines (TNF-α, IL-6, and IL-10.[100])

Band neutrophils are significantly increased in early infections from 18 to 48 h.[97]

Culture of organism

In an outbreak, the diagnosis is preferably made by culture at necropsy. Carrier pigs can be identified by culturing the organism from the upper respiratory tract using nasal swabs from live pigs on the farm, and samples from tonsils at slaughter.[101] A selective medium for the culture of the organism from the airways of slaughtered pigs may increase the isolation rate because of the high degree of contamination.[1] The culture of APP has recently been complicated by the identification of the non-pathogenic *A. porcitonsillarum*.[102, 103]

Serotype of organism

Tests to determine the serotype include slide agglutination, immunodiffusion, ring precipitation, indirect hemagglutination, immunofluorescence, coagglutination, and counter-immunoelectrophoresis. The latter is quicker, more sensitive, and more easily performed than direct immunofluorescence and immunodiffusion procedures. The coagglutination test is simple and rapid, the immunodiffusion test is considered to be the most serotype-specific, and there is a good correlation between the rapid slide agglutination test and the indirect fluorescent antibody tests. The rapid slide agglutination test is the method of choice of some workers but the coagglutination test is serotype-specific, sensitive, simple, rapid, reproducible, and easier to read and interpret than the rapid slide or tube agglutination tests. The International Pig Veterinary Society has recommended that the coagglutination test is currently the method of choice for routine serotyping of field strains. This technique does not allow separation of the heterogeneous serovar 8 from serovars 3 and 6, the heterogeneous serovar 9 from serovar 1, or the heterogeneous serovar 7 from 4. The results are reported as group 9–1, group 8–3–6, and group 7–4 respectively. The final identification of heterogeneous serovars can only be achieved by the agar gel diffusion test and by indirect hemagglutination. Reference strains and the corresponding antisera are available in order to bring some uniformity into serotyping.

Detection of antigen

The polymerase chain reaction (PCR) is a highly sensitive test for the detection of the organism from tissue samples.[104–107] A PCR for type 4 has been developed.[108] Some detect OMP[105] others Apx genes.[109,110] Immunomagnetic separation of APP1 and 2 has been described with greater sensitivity than possible with isolation or even PCR.[111,112] A PCR-based RFLP analysis of the OM1A gene may also be of value in differentiating APP serotypes.[113] A multiplex PCR has been developed.[114,115]

Serology

For the serological diagnosis of infection in live animals the complement fixation test is reliable but an enzyme-linked immunosorbent assay (ELISA) test is highly specific and more sensitive than the complement fixation test.

The **complement fixation test** has been used routinely in some countries and has a high degree of sensitivity and specificity. It is, however, a cumbersome test and many laboratories find it difficult to perform.

The **ELISA** is a rapid and sensitive test and can be adapted to automation. The ELISA for serotypes 1, 2, 5, and 7 distinguishes exposed from unexposed pigs or herds.[116] Due to cross-reactivity with other serotypes and *Actinobacillus suis*, the serodiagnosis of serotype infections cannot be made with certainity.[117] A blocking ELISA is available for detection of antibodies against serotype 2[118] and also 2, 6, 8, and 12,[119,120] which is the dominating serotype in Danish swine herds, causing approximately 70% of diagnosed outbreaks of pleuropneumonia. A similar test is available for serotype 8.[121] A mixed-antigen ELISA for serodiagnosis of serotypes 1, 5, and 7 has a sensitivity of 96% and specificity of 99.5% and can be used for herd health monitoring programs.[122] The long-chain lipopolysaccharide of serotypes 4, 5, and 7 is a superior antigen to the crude extracts used as antigens in the ELISA for the serodiagnosis of pleuropneumonia.[123]

There are now ELISAs for the detection of antibodies to the Apx toxins[124] and the one for type II Apx was described as sensitive, inexpensive, and highly discriminatory.[125] A multiplex PCR for all toxins in one test is a reliable typing system.[126,127]

A new ELISA for the Apx IV produced by all 15 serotypes[128] means that you can detect all APP with one test. It has a specificity of 100% and a higher sensitivity than culture (93.8%). This is important because you can find Apx I–III in pigs associated with *A. suis* and *A. rossii* but Apx IV is only produced by APP in vivo. It will detect the toxin from 2 to 3 weeks post infection.

An inhibition enzyme immunoassay for the serodiagnosis of serotypes 2 and 5 had a sensitivity and specificity of 100% and 98.9%, respectively.[129]

The detection of antibodies to APP is an essential feature in the epidemiological study and control of pleuropneumonia in pigs. Serological testing can be used to monitor the level of infection in a breeding herd over a period of time and as the piglets become older. A minimum of 30 serum samples from adult pigs is necessary to provide a reliable assessment of the herd's infection status. None of these serological tests is completely reliable and in certain situations a combination of two tests is needed for interpretation of low titers in some pigs. In most instances serological diagnosis is type-specific and protection obtained by vaccination is type-specific and will protect only against the serotype contained in the vaccine. Thus, it is important to determine the serotype(s) which are causing disease in the herd.

An important strategy of control of this disease is to detect infected pigs in a herd or to exclude infected pigs from being

imported into a herd. Because there is no reliable method for the detection of every infected pig, the effectiveness of this barrier is reduced whenever pigs, such as breeding stock or weanlings, are allowed into a herd. There is a need for a highly sensitive and specific test for the identification of infected pigs. While bacteriological culture is specific it is not sensitive. The ELISA test may be a useful test for the antemortem diagnosis of infected herds.

NECROPSY FINDINGS

Characteristic lesions are confined to the thoracic cavity and consist of hemorrhagic and fibrinous pleuropneumonia with a tendency to sequestration in the chronic form. In peracute cases the lungs are swollen, firm, and dark red. Fluid and blood ooze from the cut surface and there may be marked edema of the interlobular septa, reflecting widespread thrombosis and alterations in capillary permeability.[118] In pigs which die less acutely, focal black or red raised areas of pneumonia are present. Lesions may occur throughout the lung, including the diaphragmatic lobes. The quantitative morphology of peracute pulmonary lesions induced by the organism has been described.[118] A fibrinous pleuritis overlies the affected lung tissue and a fibrinous pericarditis may also be present. The organism can be isolated from affected lung tissue, but generally not from other internal organs. Occasionally, otitis, endocarditis, pericarditis, and serous arthritis may follow, particularly when infection involves serotype 3.[130] An osteomyelitis and arthritis caused by APP has been demonstrated using fluoresecent in-situ hybridization.[131]

Histologically, vasculitis and widespread thrombosis is usually evident, in addition to an abundance of fibrin and neutrophils within alveoli. A fibrinous thrombosis with IHC demonstration of APP has been described.[132] In situ hybridization can be used to detect IL-1, IL-6, and TNF-α in streaming degenerate alveolar leucocytes (oat cells) and the boundary zone of oxidative necrosis. A less intense signal was seen in the dense zone of degenerate cells in granulation tissue surrounding the necrotic areas. IL-1 was also seen in the scattered endothelial cells bordering zones of coagulative necrosis.[67] IL-6 is the cytokine that is most elevated and serum amyloid and haptoglobin are also elevated.[133]

In a chronically infected herd, fibrous pleural adhesions may be present in a large proportion of the pigs at market as a result of infection several months earlier. Subacute to chronic lung lesions are encapsulated by fibrous tissue, and sequestra may be present.

Samples for confirmation of diagnosis

- Bacteriology – lung (CULT). They can also be isolated from pure and mixed bacterial cultures by immunomagnetic separation.[134]
- Histology – formalin-fixed lung (LM). App can be further identified by IHC[135] and ISH.[127,131]

DIFFERENTIAL DIAGNOSIS

The rapidity of onset and spread with fever, anorexia, severe dyspnea, and high mortality differentiates APP from the majority of respiratory diseases in pigs.

Enzootic pneumonia is more insidious in its occurrence and has distinctively different epidemiological, clinical, and pathological features.

Pasteurellosis is characterized by a necrotizing bronchopneumonia.

Swine influenza is characterized by an explosive outbreak of respiratory disease. However, this is not restricted to growing pigs and the mortality is low. There is a distinct difference in the respiratory lesion on necropsy examination.

Glasser's disease is characterized by serositis, arthritis, and meningitis, and occurs in younger pigs.

Mulberry heart disease may present with similar clinical findings but there is no pneumonia on necropsy examination.

TREATMENT

Antimicrobial therapy

The results of treatment are often disappointing because of the severity of acute disease and persistence of infection in recovered pigs. Although antimicrobials may reduce mortality and improve average daily gain, treated animals often continue to harbor the organism and are a source of infection to other animals. Affected and in-contact pigs should be treated parenterally with antimicrobials. Tetracycline, spectinomycin, and penicillin have been effective and are recommended unless drug resistance has occurred. Fluoroquinolones are distributed to bronchial secretions, bronchial mucosa, and alveolar macrophages. The pharmacokinetics of danofloxacin are favorable for APP treatment.[136] In fact, elevated C-reactive protein, IL-6, and haptoglobin (all elevated rapidly after infection) all return to normal, as do the reduced plasma zinc, ascorbic acid, and alpha tocopherol rapidly after treatment.[137] Ceftiofur and fluoroquinolones were the most active agents against APP.[138] APP is only eliminated from the respiratory tract in animals medicated with enrofloxacin.[139] Tilmicosin is useful for treating outbreaks.[140]

In finishing units where outbreaks of the disease have been confirmed, the twice-daily intramuscular injection of pigs early in the course of the disease with antimicrobials, based on drug sensitivity tests, daily until clinical recovery occurred, was superior to the mass medication of feed and water. A considerable amount of labor is required but it is considered to be the most cost-effective method.

Antimicrobial sensitivities

The antimicrobial sensitivities of isolates of APP have been monitored and there is some variation based on geographical location. The large expansion in the size of swine herds, and the introduction of breeding stock from many different sources, has led to an increase in the incidence of porcine pleuropneumonia and extensive use of parenteral antimicrobials. To insure an optimal response to therapy it is necessary to monitor antimicrobial sensitivity on a herd basis.

The antimicrobial sensitivity of the organism was determined in isolates from Europe, Japan, South Africa, and North America between 1989 and 1991.[141] They were highly susceptible to danofloxacin, moderately susceptible to amoxycillin, ceftiofur, and trimethoprim–sulfamethoxazole. There was widespread resistance to other currently available antimicrobials. In another study, thiamphenicol and metronidazole had good activity, and the cephalosporins and fluoroquinolones were most active.[117,142] A comparison of the minimum inhibitory concentrations (MICs) of several antimicrobials against several bacterial pathogens of swine, including APP, from the USA, Canada, and Denmark found that ceftiofur and enrofloxacin were the most active antimicrobials.[143]

Plasmid-mediated antimicrobial resistance has been found in isolates of the organism which are resistant to certain antimicrobials.[144]

Antimicrobials in experimental disease

The therapeutic efficiency of some commonly used antimicrobials has been evaluated for the treatment of experimentally induced pleuropneumonia using serotype 1 APP. Florfenicol in the feed at 50 ppm prevented pneumonia when pigs were experimentally inoculated with serotype 1, 2, 5 strains and thiamphenicol-resistant strains of the organism.[145] The combination of trimethoprim and sulfamethoxazole is superior to a combination of trimethoprim and sulfadimethoxine.[146] Oxytetracycline in the water at 222 mg/L for 7 days beginning 24 h before experimental challenge reduced the case-fatality rate, lung lesions and the isolation of the organism compared to the unmedicated group. Treatment of chronically affected pigs did not improve rate or gain, nor did it eliminate the infection. Enrofloxacin at 150 ppm in the feed provided effective control of the experimental disease.[147]

Mass medication of feed

In-feed medication with sulfadimethoxine and sulfamethoxazole in combination with trimethoprim has been described.[148]

Oxytetracycline in the feed at 1600 mg/kg of feed for 6 days before experimental challenge, and for 9 days after challenge, provided 100% protection from clinical disease, but 400, 800, or 1200 mg/kg of feed did not prevent subsequent shedding and transmission to seronegative animals.[149] Tetracycline should be administered through the feed of all in-contact pigs during the outbreak, but the persistence of the organism in chronically affected pigs may result in clinical disease when the medication is withdrawn.

Doxycycline in feed at 250 ppm for 8 consecutive days is useful for the control of APP.[150]

Tilmicosin fed to pigs at 200–400 μg/g is effective in controlling and preventing APP-induced pneumonia, using seeder pigs, when administered in the feed for 21 days.[151,152] In commercial herds, 400 μg/g of feed for 21 days is no more effective than 200 μg/g of feed for the control of naturally acquired pneumonia caused by APP and *P. multocida*.[153] Sulfathiazole at the rate of 28 g/3.8 L of drinking water for 12 days has also been successful. Tiamulin in the drinking water at a concentration to deliver 23 mg/kg BW for 5 days after an initial individual treatment of affected pigs has also been recommended.

CONTROL

It is impossible to guarantee freedom because the detection of carriers is almost totally impossible.[154] There are no techniques as yet for identifying the animal that may have only a few organisms in the tonsil. You can guarantee freedom from clinical disease at the time of inspection but little else. In a recent study of 980 pigs there was no evidence of an APP clinical or pathological case until the occurrence of PMWS resulted in the isolation of an APP7 from the series of pigs in a unit which had until that time been considered free.[155]

There are two options for the control and prevention of porcine pleuropneumonia:

1. Control at an economical level using good management combined with the possible use of vaccines
2. Eradication of the infection from the herd.

Determining which option to select requires careful consideration of the advantages and disadvantages of each option. With an understanding of the factors that result in clinical disease, it is possible to maintain an infected breeding herd and produce pigs with a small risk of clinical disease.

Control by management

Management and housing improvements can prevent clinical episodes. One of the most important things to do is to make sure that there is vaccination for enzootic pneumonia.

Control is difficult and unreliable, because pigs that recover from clinical disease provide a source of future infection for finishing operations which purchase all of their introductions. The all-in/all-out system of purchasing, feeding, and marketing pigs, with a thorough cleaning between groups of animals in a finishing operation should be adopted. The disease is highly contagious and control measures must be directed towards identifying infected pigs and eliminating their introduction into uninfected herds. When moving pigs between herds, it is critically important that the herds be matched according to their infection status. Source herds for feeder animals are serotested, and then pigs of like immune status are commingled to produce a population that is compatible immunologically. By commingling only animals from seronegative herds, the risk of disease is greatly decreased and growth performance improved. The mixing of animals from herds known to be infected with homologous serotypes is also effective.

Every economical effort must be made to identify and isolate infected pigs and to exclude the importation of clinically normal, but infected pigs into herds in which the infection is not present. This is a major challenge which is dependent on the availability of a highly sensitive and specific laboratory test. The acquisition of new breeding stock for herds free of the infection should include a period of quarantine and two serological tests 3 weeks apart. Only seronegative animals should be introduced into the herds. A seropositive animal should be considered a potential carrier. Field trials have shown that it is not possible to rear seronegative animals within a breeding and rearing herd heavily infected with serotype 2 of the organism.[156] Neither medication of the sows and piglets with trimethoprim–sulfonamides, nor a strictly applied all-in/all-out system reduced the percentage of seropositive animals.[156]

Management practices must emphasize the rearing of weaned pigs in pens separate from older stock which are carriers of the organism. Large breeding herds and finishing units should subdivide the total herd into separate units, which minimizes the spread of infection. Early weaning and segregation of gilts from infected stock have been used to develop a seronegative herd.

Herds can be classified into one of three categories depending on their infection status:

CATEGORY 1. Serologically positive for APP without a history of clinical disease. A majority of herds are serologically positive but do not have clinically apparent disease. Good management and environmental quality control can minimize the incidence of clinical disease. Good ventilation, the use of all-in/all-out management practices, and appropriate stocking densities are important.

CATEGORY 2. Serologically negative and clinically free of APP. These herds can be maintained free of infection with good biosecurity practices. New breeding stock must be obtained from herds free of infection. Artificial insemination can be used to limit the introduction of live pigs. Pigs sold from these herds to herds with endemic infection are highly susceptible to infection.

CATEGORY 3. History of clinical disease caused by APP, which has been pathologically and microbiologically confirmed. In these herds, acute disease outbreaks occur most commonly in pigs 9–20 weeks of age. Pigs are usually protected by colostral immunity for the first 8 weeks of life. The severity of outbreaks can be reduced by mass medication of the feed, treatment of individual pigs, and good management practices to insure adequate ventilation.

Eradication

The Danish SPF system was the first to try to eradicate APP.[157] Each month 20 serum samples were tested for APP 2 and 6 and were collected at the monthly clinical inspection. This happened every 3 months also for APP12 and annually for APP 1, 5, 7, and 10. Recurring outbreaks of pleuropneumonia is the most common reason for an eradication strategy. Eradication is done by depopulating the entire herd, followed by repopulation with animals from herds that are clinically and serologically negative. Eradication can be successful but the risk of introducing infections into the herd is high unless biosecurity measures are adopted and strictly implemented.

An alternative to depopulation is medicated early weaning, in which pigs are weaned at 10–15 days of age, treated with antimicrobials, and reared in isolation.[1] Transmission of infection between the sow and piglets does not occur before 11 days of age, about half of the piglets are infected at 16 days of age, and if

weaned at 21 days of age most of the piglets are infected.

The early weaning program can be expanded to the three-site system of rearing. Adults and nursing piglets are housed in one site. At weaning, piglets are moved to the nursery barn for growth to 25 kg, and then moved to a third site for the final growing period. The adults may be serologically positive for infection, but the nursery pigs, growing pigs, and finishing pigs are negative.

Age segregation, distance which prevents aerosol transmission, and adherence to strict biosecurity practices can reduce the prevalence of infection and the incidence of disease.

Vaccination

Natural or experimental infection with a serotype of APP induces a strong immunity to both homologous and heterologous serotypes. Vaccination has been attempted to prevent pleuropneumonia in pigs. However, the protection obtained by parenteral vaccination is serotype-specific and vaccines must, therefore, contain the serotype existing in the swine population. The mortality rate is lower in vaccinated animals, but they are still carriers of the organism.

Serotype 8 is closely related to serotypes 3 and 6, and parenteral revaccination using a capsular extract or killed APP serotype 8 provides a high degree of protection against challenge with serotypes 3 or 6. A tetravalent vaccine containing serotypes 1, 2, 5, and 7 stimulated titers to all four serotypes and an anamnestic response was induced by a second vaccination. This suggests that the serological and cross-protective properties of APP serotypes should be identified before they are used as antigen in the complement fixation test and in vaccines.

The protein associated with the capsule of APP is responsible for serotype-specific protection against mortality in mice. Further purification and characterization of this protein antigen is needed to determine if it is the specific antigen responsible for protection against mortality in swine or if it is a necessary carrier for a serotype-specific capsular disaccharide antigen.

The vaccines that have been evaluated are killed vaccines with an adjuvant. In one experimental trial, two and three vaccinations using a bacterin containing serotypes 1 and 5 prevented mortality following an aerosol challenge with the same serotypes as present in the vaccine. However, all vaccinated pigs had severe signs of respiratory disease and the vaccine did not prevent the development of lung lesions. The use of a formalin-inactivated alum-precipitated vaccine containing serotype 1 was effective in decreasing the morbidity and mortality rates from naturally occurring pleuropneumonia. The adjuvanted vaccines have caused considerable tissue reaction, resulting in abscesses and granulomas.[158] The mineral oil adjuvants are highly irritant and cause granulomas, which are present 8 weeks after vaccination but result in high titers. The aluminum hydroxide adjuvants are less irritant, but result in lower titers.[158] Vaccines containing a lecithin-base oil at 5% are non-irritating and stimulate high complement fixation titers.

Subunit vaccines containing purified or partially purified antigens provide better protection than whole cell vaccines. Capsular antigens, outer membrane proteins, lipopolysaccharide, and soluble toxic factors are immunogenic in pigs. An acellular vaccine containing multiple virulence factors provided complete protection from mortality and significantly reduced morbidity to homologous challenge.[159] Pigs vaccinated with the cell extract had fewer clinical signs of pleuropneumonia than pigs vaccinated with three other commercial vaccines and challenged with serotype 1.[160] A vaccine containing the LiCi cell extracts and a crude hemolysin isolated from serotype 1 provided protection against both mortality and morbidity in vaccinated pigs challenged by intratracheal inoculation.[161] An experimental vaccine using bacterial 'ghosts' which are empty cells produced by bacteriophage lysis appears to be successful.[162] A better cellular response was observed to inactivated bacteria than to ghost vaccines.[163] Bacteria grown in conditions resulting in high in vitro adhesin levels induced better protection than those grown in NAD rich medium.[164] An APP type 2 vaccine has been described with deletions in the Apx IIA gene which can then function as a negative marker vaccine, which appears to be capable of protecting pigs without shedding.[165]

Antigenic variation within a capsular serotype, for example in subtypes 1A and 1B, due to antigenic variation within the lipopolysaccharide, can result in the failure of whole cell bacterins to provide protection against the same capsular serotype.[166] This lack of cross-protection within a capsular serotype provides a partial explanation for vaccination failures observed under field conditions.

A polyvalent bacterin containing serotypes 1, 3, 5, and 9 provided satisfactory protection against homologous challenge 14 days after the second vaccination.[167] Mortality was reduced, and lung lesions, pleural adhesions, and isolations of the organism from the tonsils and lungs were reduced.

Diseases associated with bacteria – V

20

Diseases associated with *Fusobacterium* and *Bacteroides* spp.

Infection with *Fusobacterium* spp. especially *F. necrophorum* is common in all species of farm livestock. *F. necrophorum* is a non-spore-forming obligate anaerobe of the family Bacteroidaceae and a normal inhabitant of the alimentary tract (particularly the rumen), the respiratory tract, and the genital tract. There are four biovars, three of which – biovars A, AB, and B – are important in livestock disease. The fourth, biovar C, is not a pathogen. Two of these have been given subspecies status: *F. necrophorum* subsp. *necrophorum* (biovar/ biotype A) and *F. necrophorum* subsp. *funduliforme* (biovar/ biotype B). The subspecies vary in their production of leukotoxin, in the quantity and composition of endotoxin and probably in virulence, but the full significance of this to individual diseases in livestock is not yet fully determined as both are isolated from the diseases associated with this infection.[1,2] The leukotoxin carries epitopes that can induce protective immunity to experimental infections.[3]

The specific diseases dealt with here as being associated with primary infection with *F. necrophorum* are foot rot of cattle, oral necrobacillosis, foot rot of pigs, and foot abscess of sheep. In foot rot of sheep the causative organism (*Dichelobacter nodosus*) occurs in association with *F. necrophorum*. In foot rot of pigs a species of *Fusobacterium* and spirochetal organisms are commonly found together.

In many infections the organism is present as a secondary invader rather than as a primary cause of disease. Some of the common conditions in which *F. necrophorum* is found as a secondary invader are navel ill and hepatic necrobacillosis in sheep and cattle, pneumonia of calves and in the secondary infections of covering epithelium. These include necrotic enteritis associated with *Salmonella* spp. in pigs, necrotic rhinitis and atrophic rhinitis of pigs, most diseases in which vesicular eruption and erosive lesions of the buccal mucosa and coronary skin of cattle and sheep occur, and in vulvitis, vaginitis, and metritis.

Fusobacterium spp. have been associated with stomatitis, enteritis, and granulocytopenia in calves, summer mastitis in cattle, hematogenous metaphyseal osteomyelitis in a 6-month-old calf, and endocarditis of swine examined at slaughter.[4]

The factors which contribute to the pathogenicity of *F. necrophorum* include a potent endotoxin, a polysaccharide capsule, an exotoxin (a leukocidin), and a hemolysin. The biochemical and functional properties of a leukocidin produced by different strains of *F. necrophorum* have been described.[1,5,6]

Extensive studies have been directed towards the immunity of the organism and the possibility of vaccination against the several diseases associated with *F. necrophorum*. However, the main virulence factors of *F. necrophorum* are only weakly immunogenic and the experiments give only limited encouragement for an effective necrobacillosis vaccine[1,7] although trials with a vaccine against liver abscess in cattle show positive results.[8]

Other organisms are commonly present in infections with *F. necrophorum* and it is thought that this is a pathogenic synergy where facultative pathogens utilize oxygen and lower the redox potential to create an anaerobic environment for growth of *F. necrophorum*. In turn the leukotoxin of *F. necrophorum* protects other organisms from phagocytosis.[1]

An enzyme-linked immunosorbent assay (ELISA) for the detection of *F. necrophorum* antibodies in the serum of cattle

and sheep has been developed[9] as has a PCR that can differentiate *F. necrophorum* subsp. *necrophorum* from *F. necrophorum* subsp. *funduliforme*.[10]

NECROBACILLOSIS OF THE LIVER (LIVER ABSCESS)

Synopsis

Etiology *Fusobacterium necrophorum* subsp. *necrophorum* (biovar/biotype A) is the most common isolate and is usually present in pure culture. *F. necrophorum* subsp. *funduliforme* (biovar/biotype B) is less common and usually isolated as a mixed infection with *Arcanobacterium pyogenes*
Epidemiology Greatest importance in grain-fed cattle where it occurs secondary to rumenitis
Clinical findings May be associated with abdominal pain but most infections are subclinical. Importance is in slaughter condemnation of affected organs
Clinical pathology Inflammatory response
Diagnostic confirmation Ultrasound. Slaughter examination
Treatment Not commonly conducted Control. Feed management to avoid ruminal acidosis, prophylactic antibiotics, vaccination

ETIOLOGY

Fusobacterium (*Sphaerophorus*) *necrophorum* is commonly found in pure culture in hepatic abscesses in ruminants. *F. necrophorum* subsp. *necrophorum* (biovar/biotype A) is the more common type isolated and is usually present in pure culture. *F. necrophorum* subsp. *funduliforme* (biovar/biotype B) is less common and usually isolated with other bacterial species, commonly *Arcanobacterium* (*Actinomyces, Corynebacterium*) *pyogenes Bacteroides* spp., *Streptococcus* spp. and *Staphylococcus* spp. *A. pyogenes* is the most common species isolated; it acts synergistically to promote growth of *F. necrophorum* by utilizing oxygen to create an anaerobic environment and provide iron for growth through its hemolytic activity. The leukotoxin of *F. necrophorum* is believed to protect *A. pyogenes* against phagocytosis.[1,2]

EPIDEMIOLOGY

Occurrence

The disease occurs in all ages and types of cattle and sheep but achieves the greatest economic significance in **grain-fed cattle** where it occurs secondary to **rumenitis**. In feedlots in the United States the prevalence varies widely between feedlots but ranges from 12–32% in most;[3] equivalent rates occur in 'barley beef' cattle in the United Kingdom. Sporadic cases or occasionally outbreaks of liver abscess occur in the **neonate** from **umbilical** infection.

Pathogen risk factors

F. necrophorum is a common **inhabitant of the intestine and rumen** in normal cattle and a common inhabitant of the **environment** of farm animals. It uses lactate as the major sugar substrate and its numbers in the rumen increase with a **change from roughage** to high grain diets.[4] *F. necrophorum* is not capable of prolonged survival outside the animal body; 1 month is the probable maximum period under favorable conditions. Infection to the liver requires a **predisposing injury** at a primary site of infection. The disease can be reproduced experimentally by intraportal inoculation of *F. necrophorum*.[5]

Risk factors in grain-fed cattle

Rumenitis, resulting from **rumenal acidosis**, is the primary site of infection in grain-fed cattle. The risk for liver abscess is increased by factors that predispose rumenitis such as low roughage and **high-energy diets** and the incidence increases as roughage in the diet decreases.

Management

Introducing hungry cattle to high-energy diets, rapidly increasing dietary energy and poor feedbunk management with irregular periods and amounts of feeding is associated with higher rates of liver abscess.

Diet

The type of grain and the use of processed, including gelatinized, grain can influence risk of abscess as can the physical nature of the diet if it allows feed sorting by the animal during feeding. Cattle hair in the rumen may exacerbate the ruminal lesion and promote the invasion of *F. necrophorum* and may account for a higher incidence of liver abscess in the spring, when cattle are grooming coats that are shedding.[1]

Breed

Holsteins are at greater risk than beef breeds because they are fed longer and have higher feed intakes and the prevalence in steers is marginally higher than in heifers, probably also related to higher feed intake.[2]

Risk factors in other farm animals

In lambs, infection usually occurs through the **navel** at birth or through **ruminal ulcers**; the infection originates from infected bedding grounds or barn bedding. Liver abscess can be a sequella to other disease such as traumatic reticulitis and peritonitis.

Economic importance

In feedlot cattle there is considerable financial loss due to **condemnation of use of livers** in abattoirs. Cattle that are more severely abscessed (with very large abscesses or multiple small abscesses) have a significant depression of weight gain and decrease in feeding efficiency.[3]

PATHOGENESIS

Vascular drainage from the primary lesion, omphalitis or rumenitis, leads to localization in the liver. The pathogenesis of rumen acidosis in grain-fed cattle is described under that heading.

It is postulated[6] that the ruminal wall in rumenitis is colonized by the bacteria in the rumen including both biotype A and biotype B *F. necrophorum*. Most of the ruminal wall lesions heal without penetration, especially if they contain only the less virulent biotype B. The more virulent biotype A strains persist longer and possibly penetrate the portal system with the help of leukotoxin. The lower virulence biotype B requires helper organisms to penetrate the defense mechanisms and leads to a mixed infection. There are differences in the biological activities of *F. necrophorum* isolated from liver abscesses and those of the general population in the rumen, and many of the ruminal inhabitants are probably not capable of invasion to cause disease.[7]

The experimental inoculation of viable cultures of *F. necrophorum* into the hepatic portal veins of cattle results in the development of diffusely distributed microabscesses within 30 min up to 2 h.[6] Gross abscesses develop in 3–36 h. Neutrophils are the predominant phagocyte in lesions of 8 h or less, and macrophages are the predominant phagocyte in lesions of 12 h duration or more. The **leukotoxin** is postulated to be responsible for allowing the bacteria to withstand the phagocyte cell response and enable the infection to persist. If there is sufficient hepatic involvement, a toxemia develops from the bacterial infection, and causes a chronic or acute illness.

In most infections, the lesions are too small to produce clinical signs. **Hematogenous spread** from hepatic lesions, including rupture into the caudal vena cava, may result in multiple lesions in many organs, severe pulmonary disease with hemoptysis, and rapidly fatal termination.

CLINICAL FINDINGS

In the majority of cases of hepatic abscessation in feeder cattle there are **no clinical signs** of illness. Abscesses that are very large may result in an acute or chronic illness.

In **acute cases** in dairy cattle there is fever, anorexia, depression, fall in milk production, and weakness. Abdominal pain is evidenced on percussion over the posterior ribs on the right side and affected cattle show arching of the back, and reluctance to move or lie down. The liver may be so enlarged that it is readily palpable behind the costal arch. The abdominal pain may be sufficiently severe to cause grunting with each breath. In **chronic cases**, there are no localizing signs but anorexia, emaciation and intermittent diarrhea and constipation occur.

Animals infected through the navel show signs at about 7 d of age and omphalophlebitis is usually present.

CLINICAL PATHOLOGY

A high leukocytosis with a marked neutrophilia may be present with large or multiple abscesses. Clinical chemistry and liver function tests have been found to be **poor indicators** and of little diagnostic value in predicting the presence of liver abscesses[8] but hepatic dysfunction can be detected by these means in the acute stage of hepatic injury. **Ultrasound** and centesis may aid in diagnosis.[8,9]

NECROPSY FINDINGS

Usually, multiple hepatic abscesses are present. The hepatic lesions may be deep in the parenchyma or under the capsule, especially on the diaphragmatic surface. Extension to the diaphragm or perirenal tissues is not unusual.

In bovine rumenitis cases, the anterior, ventral sac is most commonly affected. There are local or diffuse mucosal lesions with thickening of the wall, superficial necrosis and the subsequent development of ulcers. In lambs there may be lesions at the cardial end of the esophagus. The histologic appearance of acute to subacute necrobacillosis lesions consists of a zone of necrosis bordered on one edge by mats of filamentous rods and on the other by a band of karyorrhectic leukocytes.

Samples for confirmation of diagnosis

- **Bacteriology** – swab of abscess or tissue sample from deep edge of lesion (ANAEROBIC CULT)

DIFFERENTIAL DIAGNOSIS

Acute cases in cattle resemble cases of traumatic reticuloperitonitis and differentiation can only be made on localization of the pain, ultrasonography, and by exploratory rumenotomy. The latter is essential if traumatic hepatitis is a possible diagnosis.

- Other causes of liver abscess
- Caseous lymphadenitis in sheep

TREATMENT

F. necrophorum is sensitive to B-lactam antibiotics, tetracyclines, the macrolide and lincosamide antimicrobials but is resistant to aminoglycosides and ionophores with no difference in sensitivity between the two subspecies except for clindamycin and lincomycin.[10]

Liver abscess in feedlot cattle is not clinical and not routinely treated as a clinical disease. In clinical disease associated with liver abscess, prolonged treatment with high doses of antimicrobial or sulfonamides is required if therapeutic concentrations are to be achieved at the site of infection. **Relapse** is common because of incomplete control of the localized infection.

CONTROL

Control procedures in feedlot cattle include prevention of rumenitis by feed management and the use of prophylactic antimicrobials.

Feed management

Feed management aims to prevent the occurrence of rumen acidosis and rumenitis and requires controlled dietary energy step up, attention to the grain type and content of the diet and correct feedbunk management.[11] The control of rumen acidosis is discussed elsewhere under that title.

Prophylactic antibiotics

The addition of antimicrobials to the feed can significantly reduce the incidence of liver abscesses and is a routine practice in most feedlots. The site of action may be in rumen or the liver or possibly in both, but is probably the rumen as tylosin and virginiamycin, which are both effective in prevention, are not absorbed into the circulation.[8] Tylosin has been shown to inhibit the increase in ruminal *F. necrophorum* numbers that occur in association with feeding high-grain diets.[2]

In the United States, bacitracin, chlortetracycline, oxytetracycline, tylosin, and virginiamycin are approved for feed inclusion for the control of liver abscess in feedlot cattle. Tylosin appears highly effective[2] and a summary of trials feeding tylosin at 11 g/t of feed or 90 mg/animal/d showed a 73% reduction in the occurrence of liver abscesses.[2] Antimicrobial feed additives also increase average daily gain and feed conversion efficiency, but the inclusion level for these effects and prevention of liver abscess is not necessarily the same.[12]

Vaccination

Vaccination with leukotoxoid vaccines has shown some protection against intraportal challenge[13] and has reduced the abscess rates in a study of naturally occurring disease in a feedlot.[14] A trial of the efficacy of a high antigenic-mass-combined *Arcanobacterium pyogenes-Fusobacterium necrophorum* bacterin-toxoid in preventing naturally occurring liver abscess in feedlot cattle showed a significant effect of vaccination with a reduction of the prevalence and severity of abscesses that was equivalent to that achieved by the incorporation of tylosin in the feed.[15] The reduction in prevalence in two trials comparing vaccinated and non-vaccinated cattle was 48.4% (31% of controls and 16% of vaccinates with liver abscess) and 37.5% (48% of controls and 30% of vaccinates with liver abscess).[15]

Control in young lambs

In young lambs, the disease can be controlled by disinfecting the navel at birth and providing clean bedding or bedding grounds.

BOVINE INTERDIGITAL NECROBACILLOSIS (FOUL IN THE FOOT, FOOT ROT, INTERDIGITAL PHLEGMON)

Synopsis

Etiology Biotypes A and B of *F. necrophorum*. Other organisms can facilitate infection
Epidemiology All ages susceptible. Infected feet are source of infection. Transmission highest where conditions are wet underfoot and in wet humid seasons
Clinical findings Sudden onset of fever, lameness, drop in milk production with typical fissuring, necrotic, lesion in the skin at the top of the interdigital cleft
Clinical pathology Not routinely done
Diagnostic confirmation Clinical findings. Culture may be done
Treatment Antimicrobials
Control Avoidance of abrasive under-foot conditions. Footbaths, antimicrobials, vaccination

ETIOLOGY

Foot rot is usually described as being associated with *F. necrophorum*. Other bacteria such as *Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*) are also present and may be important in cause. Experimentally, the subcutaneous inoculation of only *F. necrophorum* into the interdigital skin of cattle will result in typical lesions of interdigital necrobacillosis.[1] The majority of isolates of *F. necrophorum* obtained from the feet of cattle and sheep belong to biotypes A and AB; they produce a soluble exotoxin, a leukocidin, and are pathogenic experimentally in cattle and mice.[2] The isolates obtained from lesions which are not classified as interdigital necrobacillosis and from clinically normal feet are predominantly biotype B (*F. necrophorum* subsp. *funduliforme*), and cause few experimental lesions and produce little or no leukocidin.

Strains of *Bacteroides nodosus*, that are associated with the non-progressive form of ovine foot rot, can also be isolated from the feet of cattle and cause mild interdigital dermatitis. It is possible they may predispose to the much more severe dermatitis that characterizes bovine interdigital necrobacillosis.

EPIDEMIOLOGY

Occurrence

The disease is common in most countries and accounts for 5–15% of cases of lameness in dairy cattle.[3,4]

Usually the disease is sporadic but under favorable conditions, as many as 25% of a group may be affected at one time. An epidemiological study of foot rot in pastured cattle in Denmark over a 12-year period revealed that incidence rates annually ranged from 0.1–4.8% but in most years it was below 1%.[5] The incidence rates were higher in some breeds than others, higher in some geographical areas than others (usually where the fields were smaller and soil higher in pH), and 4–8 weeks after periods of high rainfall.

Transmission

Discharges from the feet of **infected animals** are the probable source of infection. Duration of the infectivity of pasture or bedding is unknown. Infection gains entrance through **abrasions** or damage to the skin in the interdigital cleft. Introduction of the infection to a farm by transient cattle is often observed but again the disease may not develop on some farms in spite of the introduction of the infection. Contaminated footbaths can be a source of infection.

Environmental risk factors

In many[6] but not all[3] regions, the incidence is much higher during **wet, humid weather** or when conditions are **wet underfoot**. Stony ground, lanes filled with sharp gravel and pasturing on coarse stubble also predispose to the condition. A high incidence can occur with beef cattle at high stocking densities on irrigated pastures. The observation that the disease is common on some farms and does not occur at all on others suggests that there may be factors which limit the persistence of infectivity in certain soils or environments.

Abrasions to the skin of the feet are more likely to occur when the skin is swollen and soft due to continual wetting. The increased incidence in wet summer and autumn months may be so explained in part, although wet conditions may also favor persistence of the infection in pasture. In housed cattle the incidence is higher in **loose-housed** cattle than tied cattle.[6] Unhygienic cubicle passageways and poorly maintained straw beds may predispose to infection.

Host risk factors

Cattle of all ages, including young calves, may be affected but the disease is much more common in adults. The highest incidence occurs in cows in the **first month of lactation**.[6] A field observation is that *Bos indicus* cattle are much more resistant to infectious foot rot than *Bos taurus* breeds and variations in prevalence have been observed among dairy breeds.[6] The occurrence of the foot disease digital dermatitis on a farm or infection with bovine virus diarrhea has been suspected as predisposing to more severe foot lesions.[7]

Economic importance

Foot rot is of greatest economic importance in dairy cattle, in which it reaches the highest level of incidence, because of the intensive conditions under which they are kept. In beef cattle at range the incidence is usually low but many cases may occur in purebred herds and in feedlot cattle. Lame cows will lie down for longer and eat less, have difficulty rising and are at greater risk for teat trampling and mastitis. Loss of production occurs and an occasional animal may suffer a serious involvement of the joint and other deep structures of the foot necessitating amputation of a digit. The disease is not fatal but some cases may have to be slaughtered because of joint involvement.

PATHOGENESIS

The pathogenesis is not completely understood, but with the experimental SC inoculation of the virulent biotype of *F. necrophorum* into the interdigital skin of cattle the typical lesion of foot rot develops in approximately 5 d.[1] This suggests that any injury or constant wetting of the skin of the cleft which interferes with its integrity will allow the organism to invade the tissues. There is acute swelling and necrosis of the skin and SC tissues which may spread to adjacent tendon sheaths, joint capsules and bone if treatment is delayed or ineffective.

CLINICAL FINDINGS

Severe foot **lameness** appears suddenly, usually in one limb only and may be accompanied by a moderate systemic reaction with a **fever** of 39–40°C (103–104°F). There is temporary depression of milk yield in cows and affected bulls may show temporary infertility. The animal puts little weight on the leg although the limb is carried only when severe joint involvement occurs. Swelling of the coronet and **spreading of the claws** are obvious.

The typical lesion occurs in the skin at the top of the **interdigital cleft** and takes the form of a **fissure** with swollen, protruding edges which may extend along the length of the cleft or be confined to the anterior part or that part between the heel bulbs. Pus is never present in large amounts but the edges of the fissure are covered with **necrotic material** and the lesion has a **characteristic odor**. Occasionally in early cases no external lesion may be visible but there is lameness and swelling of the coronet. Such cases are usually designated 'blind fouls' and respond well to parenteral treatment.

A more severe form of the disease which is peracute in onset and refractory to conventional therapy has been termed 'super foul' or '**super foot rot**'.[8] With this type there is sudden onset of acute lameness, severe interdigital swelling and rapid progression to necrosis and

deep erosion of the interdigital space with swelling of soft tissue above the coronary band. The hindfeet or all four feet may be affected.[7] It may be predisposed by the foot disease digital dermatitis. Septic arthritis is a common sequella if this type is not treated early in its course.

Spontaneous recovery is not uncommon but if the disease is left untreated, the lameness usually persists for several weeks with adverse effects on milk production and condition. The incidence of **complications** is also higher if treatment is delayed and some animals may have to be destroyed because of local **involvement of joints and tendon sheaths**. In such cases the lameness is severe, the leg is usually carried and the animal strongly resents handling of the foot. Swelling is usually more obvious and extends up the back of the leg. There is poor response to medical treatment and surgical measures are necessary to permit drainage. **Radiological examination** may be of value in determining the exact degree of involvement of bony tissue.

Long continued irritation may result in the development of a wart-like mass of fibrous tissue, the **interdigital fibroma**, in the anterior part of the cleft and chronic mild lameness. Interdigital fibroma occurs commonly without the intervention of foot rot, the important cause being inherited defects in foot conformation in heavy animals.

CLINICAL PATHOLOGY

Bacteriological examination is not usually necessary for diagnosis but direct smears of the lesion will usually reveal large numbers of a mixture of *Fusobacterium* and *Bacteroides* spp. Routine differentiation between virulent and non-virulent bovine isolates of *F. necrophorum* can be done by assessment of the cultural characteristics of the colonies grown on blood agar.[2]

DIFFERENTIAL DIAGNOSIS

The characteristic site, nature, and smell of the lesion, the pattern of the disease in the group and the season and climate are usually sufficient to indicate the presence of true foot rot.

NECROPSY FINDINGS

Necropsy examinations are rarely carried out in cases of foot rot. Dermatitis is followed by necrosis of the skin and SC tissues. In complicated cases there may be suppuration in joints and tendon sheaths.

Interdigital dermatitis/stable foot rot

This infection occurs commonly in cattle which are housed for long periods. Although the condition occurs most commonly when the cattle are kept under unsanitary conditions, it is also seen in well-managed herds. The causative agent has not been established but *Bacteroides nodosus* can be isolated.

The initial lesion is an outpouring of sebaceous exudate at the skin–horn junction, particularly at the bulbs of the heel. There is a penetrating foul odor and the lesion is painful to touch, but there is little swelling and no systemic reaction. More than one foot is commonly affected. In longstanding cases there is separation of the horn at the heel bulb and this is followed by secondary bacterial infection of the sensitive structures of the foot. Often there is a purulent dermatitis of the interdigital space. Stable foot rot does not respond satisfactorily to the standard parenteral treatments used in foot rot but local treatments as set out as follows are effective.

Verrucose dermatitis

Verrucose dermatitis is a proliferative inflammatory lesion of the **skin of the plantar surface** of the foot extending from the bulb of the heels to the fetlock joint. The condition is seen particularly in feedlot cattle that are overcrowded in wet muddy conditions and may occur in outbreaks. **All four feet** may be affected, there is considerable pain and lameness and, on smear of the lesion, *F. necrophorum* is present in large numbers. The treatment of verrucose dermatitis consists of washing the affected skin with a disinfectant soap, followed by daily applications of 5% copper sulfate solution. When many animals are affected, a daily walk through and soaking in a foot bath containing the copper sulfate solution is very effective.

Traumatic injury

Traumatic injury to bones and joints, puncture by foreign bodies, bruising of the heels and gross overgrowth of the hoof can usually be distinguished by careful examination of the foot. **Laminitis** is the major cause of lameness in most herds but with this condition there are no skin lesions present.

TREATMENT

Parenteral administration of antibiotics or sulfonamides and local treatment of the foot lesion are necessary for best results. **Immediate treatment** as soon as possible after the onset of swelling and lameness will give excellent recovery in 2–4 d. In the experimental disease, when treatment was delayed for a few days after the onset of signs, severe lesions developed and recovery was extended. Under field conditions, the disease may be present in cattle at pasture for several days before being recognized, making it necessary to confine them for daily treatment until recovery is apparent.

Antimicrobials

Ceftiofur, 1–2 mg/kg (BW) IM, or procaine penicillin G, 22 000 iu/kg BW IM twice daily, or once daily for three consecutive days are effective.[9] Oxytetracycline, 10 mg/kg BW IV, or long-acting tetracycline IM may also be used but injection site tolerance and withdrawal period is less favorable than ceftiofur. When a high incidence of foot rot is experienced in a herd, treatment of all animals simultaneously has been carried out.[10]

Sodium sulfadimidine (150–200 mg/kg BW) solution given by IV injection is highly effective. Sulfabromomethazine at the rate of 30 g/kg grain was given for two consecutive days to calves weighing 150 kg and results were excellent. Sulfonamides are not approved for use in lactating dairy cattle in many countries. **'Super foot rot'** has been effectively treated by parenteral tylosin or a single dose of long-acting tetracycline.[8]

Local treatment

Local treatment necessitates restraint of the affected leg and this procedure is greatly facilitated by a restraint table or the administration of a very small dose of xylazine. The foot is scrubbed, all necrotic tissue curetted away and a local dressing applied under a pad or bandage. Any **antibacterial**, and preferably **astringent**, dressing appears to be satisfactory. A wet pack of 5% copper sulfate solution is cheap and effective. Any suitable antibacterial ointment preparation may be applied and secured with a bandage, which may be left on for several days. The main advantage of local treatment is that the foot is cleaned and kept clean. If conditions underfoot are wet, the animal should be kept stabled in a dry stall.

In cattle running at pasture, or in the case of large numbers of feedlot cattle, examination of the foot and local treatment are often omitted because of the time and inconvenience involved. However, identification of the animal with a marker is considered necessary in outbreaks to avoid unnecessary confusion in the days following, and examination of the foot is deemed necessary to insure that foreign bodies are not involved. Local treatment may not be necessary in the early stages of the disease if the animal can be prevented from gaining access to wet, muddy areas.

Surgical drainage

Surgical drainage may be necessary in refractory cases or when complications with spread to deeper tissues have occurred. **Amputation** of the digit may be necessary.

CONTROL

Prevention of foot injuries by filling in muddy and stony patches in barnyards and lanes will reduce the incidence of the disease. Lanes and bedding should be kept clean and dry. The incorporation of biotin in the diet, while reducing the incidence of lameness caused by white line lesions, has no effect on the incidence of interdigital necrobacillosis.[11]

Footbaths

Provision of a footbath containing a 5–10% solution of formaldehyde or copper sulfate, in a doorway so that cattle have to walk through it twice daily, will practically eliminate the disease on dairy farms. A mixture of 10% copper sulfate in slaked lime is often used in the same manner. Similar measures can be adopted for small groups of beef animals.

Antibacterials

Feeding chlortetracycline to feedlot cattle 500 mg/head/d for 28 d, followed by 75 mg/d throughout the finishing period has been recommended but controlled comparative trials have not been carried out. The feeding of organic iodides (200–400 mg) of ethylene diamine dihydroiodide (EDDI) in the feed daily has been used for many years as a preventive against the disease in feedlot cattle. Feeding EDDI in an ad libitum salt mixture at a level of 0.156% EDDI (0.125% iodine) is also effective in reducing the incidence of foot rot. Dosing cattle daily with zinc sulfate by including it in the feed has no prophylactic effect.

Vaccination

Commercial vaccines against bovine interdigital necrobacillosis are available but their efficacy has not been established in controlled comparative trials.[12] A mineral-oil adjuvant vaccine containing whole cells or fractions of *F. necrophorum* provided about 60% protection from experimentally induced interdigital necrobacillosis. A similar vaccine containing *Bacteroides nodosus* appeared to reduce the severity of lesions but not the incidence rate compared to non-vaccinates.

BOVINE DIGITAL DERMATITIS, PAPILLOMATOSIS DIGITAL DERMATITIS OF CATTLE (MORTELLARO'S DISEASE) (FOOT WARTS, HAIRY FOOT WARTS, 'HEEL WARTS')

Papillomatous digital dermatitis (PDD) is a painful, erosive, papillomatous-like lesion of the skin of the feet of cattle. The region proximal and adjacent to the interdigital skin midway between the heel bulbs of the plantar surface of the foot is most frequently affected. Early lesions are circumscribed, with a red, granular appearance and variable degrees of proliferation of filiform papillae. Mature lesions tend to be more proliferative and may have long papillary fronds. Lameness is severe, and economic losses are due to decreased milk production and reproductive performance.[1]

ETIOLOGY

The etiology is uncertain. A mixed population of Gram-negative bacteria including anaerobes, microaerophilic organisms, and spirochetes have been demonstrated in or isolated from PDD lesions. Histologically, invasive spirochetes have been isolated from the tissues of cattle with typical lesions, but their significance is uncertain.[2] The humoral response to spirochetes in cattle with the disease is different from that in cattle without detectable lesions.[1] At least five different spirochetal phylotypes within the genus *Treponema* have been identified in lesions and *Treponema denticola*-like spirochetes were most common.[3] DNA analysis of the spirochetes recovered from typical lesions revealed that the organisms were closely related to *Treponema denticola*.[4] A combination of spirochetes and *Campylobacter faecalis* has also been found in typical lesions.[5]

A spirochete isolated from cases of severe virulent ovine foot rot (SVOFR) in Australia[6] and the UK[7] and Ireland[8] is closely related to a treponeme isolated from human periodontitis and bovine digital dermatitis. This suggests the possibility of cross-species transmission, and that a number of spirochetes could be involved in the pathogenesis of either PDD or SVOFR.

EPIDEMIOLOGY

Occurrence and prevalence of infection

The disease was first described in 1974 as Mortellaro's disease. It occurs ... yearly estimated cumulative incidence primarily in dairy cattle and has been reported as a cause of lameness in cattle worldwide.[9] Beef cattle are also affected. Surveys of dairy farms in California in the United States found that 25–75% of farms have had the disease and about 10% of cows have been affected with a range from 1–99% of cows in affected herds.[10]

The disease has occurred in a herd of dairy bulls in New Zealand.[11] Lesions similar to PDD have been recognized in cattle in Australia, occurring during periods of high rainfall and being responsive to topical and parenteral therapy, but not associated with the presence of spirochetes in the lesions.[12]

The National Animal Health Monitoring System (NAHMS) Dairy 1996 assessed the incidence of digital dermatitis in US dairy herds.[13] The study design was a population-based cross-sectional survey of US dairy herds with at least 30 cows in 20 states, representing 79% of US dairy cows. PDD was reported in the previous 12 months from 43.5% of dairy herds. Within affected herds, 18.9% of cows were affected and 81.9% of affected cows and 85.9% of affected heifers were lame. Regions of the US with the highest percent of herds affected included the Southwest, Northwest, and Northeast. Factors associated with high incidence (>5%) included region, herd size, type of land lactating cows accessed on a daily basis, flooring type where lactating cows walked, percent of cows born off the farm, use of a primary hoof trimmer who trimmed cows' hooves on other farms, and lack of washing of hoof-trimming equipment between cows.

People providing a hoof-trimming service report that 97% of dairy farms in California have the disease but, mysteriously, some farms have none. Regional differences in the prevalence occurred but reasons for the incidence were not examined. Seasonal differences occur and may be due to a combination of weather, housing, and management. The incidence may be higher during the winter months, when the weather is cold and wet, and cows are kept in confined housing than during the summer months when cows are on pasture.

Based on examination of the feet of cattle at an abattoir, 29% of culled dairy cattle and 4% of beef cattle had gross lesions of PDD, and spirochetes were present in 61% of the lesions.[14]

In a commercial dairy farm in Mexicali, Mexico, 33% of cows were affected during lactation and 1% during the dry period; 68% of cows that had lesions in the previous lactation had lesions in the current lactation.[15] The highest risk occurred during the first month of lactation. The ...

risk was 35% and the incidence density rate was 44.6 cases per 1000 cow-months. More animals were affected in summer and fall than in winter and spring. Purchased animals were 3.4 times more likely to be affected than animals born on the farm. Healthy cows conceived 93 days after calving (median), but affected cows conceived 113 days after calving.

In 214 dairy herds in two main dairy areas in Chile, 91% of herds were affected and a median of 6% of cows had PDD.[16]

Risk factors

Host risk factors

A cross-sectional study of prevalence and risk factors of digital dermatitis in female dairy calves between 2.5 and 12 months of age in the Netherlands revealed a mean prevalence of 67%.[17] The prevalence increased with age and by 1 year of age almost all animals had lesions in at least one claw. The clinical disease is much more common in first calf heifers and young cows. First-parity cows have the highest odds of PDD, and the odds decrease, in a dose-effect manner, as parity increases.[18] The odds of PDD increase with increasing days in lactation.

The plantar and palmar regions of the foot may be more conducive to the development of PDD because these anatomical sites are exposed to more moisture. Epidemiologic observations indicate that the risk of PDD is associated with environmental conditions that cause moist feet in commercial dairy herds. The greater incidence of the lesions in the hindfeet is considered to be associated with more exposure to deeper slurry during feeding times than the forelimbs. The plantar and palmar regions of the interdigital cleft are, therefore, more susceptible to being continually moist. compared with the more open dorsal locations. The anatomic location of PDD lesions also has an effect on the efficacy of topical treatment with antibiotics.[19]

Immune mechanisms

Treponema phagedenis-like spirochetes isolated from active PDD lesions in dairy cattle are associated with serum IgG_2 antibodies and most react with lipopolysaccharide.[20,21] Both the antibody and blastogenic responses were reduced in convalescent dairy cattle, suggesting the immune response to the spirochetes has short duration. The presence of IgG_2 spirochete antibodies detected by ELISA does not necessarily describe an active immune protective response by affected cows but reflects prior infection and repeated exposures to treponemes.[22]

Cattle and sheep with PDD and severe virulent ovine foot rot, respectively, and which may be infected by the same group of treponemes, have increased seropositivity rates to both treponeme isolates, with different patterns of reactivity between farms.[7]

Environmental and management risk factors

Case–control studies in dairy farms indicate that the odds of having a higher proportion (>5%) of affected cows were about 20 times more likely in dairy farms with muddier corrals than in farms with drier ground surfaces in corrals.[10] The disease appears to be more common in freestall confined herds where feet are constantly expose to moisture and manure conditions. The feet often become coated with a layer of dried feces which may provide the anaerobic conditions necessary for bacterial growth.

Buying replacement heifers was associated with a 4.7-fold increase in the odds of a higher occurrence of disease than in herds which did not purchase heifers. In dairy herds in Chile, cows on farms that bought heifers in the previous 10 years had a 3-fold increase in the odds of PDD compared to those on farms that never bought heifers. Cows in dairy herds that used a footbath were less likely to have PDD than those herds not using one. There also may be a positive relationship between risk and the number of heifers purchased. Animals housed in a straw yard were 3.2 times less likely to be affected compared to cattle on slatted floors. Herd size was positively associated with the presence of the disease. Feeding with a larger variety of dietary components (hay, milk, concentrates plus silage) was a protective measure.

Pathogen risk factors

Several spirochete strains have been isolated from PDD lesions in dairy cattle in Iowa and compared with strains previously isolated from dairy cattle in California.[20] All strains are *Treponema phagedenis*-like and exhibit genetic and antigenic diversity.

Molecular typing of PDD-associated *Treponema* isolates have found some genetic relatedness to those of the related human-associated *Treponema* spp. associated with human periodontal disease.[23,24] These *Treponema* strains have adhesion properties and produce high levels of chymotrypsin-like protease and high levels of proline iminopeptidase which are major virulence factors.

Economic importance

The economic losses associated with the lameness associated with PDD in lactating cows include loss in milk production,[25] the effects on reproductive performance, and the costs of treatment including the time required to recognize the lesions and the costs of individual medication of affected cows if necessary, and the costs of construction and maintenance of a foot bath. Lameness has an important effect on milk yield. In a data set including 8000 test-day milk yields from 900 cows on five farms in the UK collected over 18 months, the total mean estimated reduction in milk yield per 305-d lactation was 360 kg.[25]

In a 600-cow dairy herd in Mexico, cows with PDD produced a mean of 268 lb less milk than healthy cows.[26] Using Dairy Herd Improvement Association Records in the dairy herds in Florida, interdigital phlegmon was associated with a 10% decrease in milk production. Cows with PDD produced less milk than healthy cows but the difference was not significant.

Lameness has an important effect on reproductive performance.[27] Dairy cows with claw lesions have a higher calving to conception interval, and a greater number of services per conception.

PATHOGENESIS

PDD is an acute or chronic ulcerative lesion of the skin of the bulbs of the heel or interdigital cleft. In the early stages of the lesion there is loss of superficial keratin, with a concurrent thickening of the epithelium by both hyperplasia and hypertrophy of epithelial cells. Superficial layers are eosinophilic and undergo necrotic change with the appearance of small holes. Large numbers of spirochetes are present around the holes. Loss of superficial layers of keratin stimulates epidermal proliferation and hyperplasia. In advanced cases, large numbers of spirochetes infiltrate the eroded dermis and may destroy the epidermis.[28] PDD is characterized by erosion of the superficial layers of the epidermis, epithelial hyperplasia and hypertrophy, pain, swelling, and a foul odor. Lesions usually occur on the hind feet and are prone to bleeding. Early lesions are circumscribed with a red, granular (strawberry-like) appearance and variable degrees of proliferation of filiform papillae. Mature lesions are more proliferative and may have long wart-like projections, thus the term 'hairy-wart' disease.

CLINICAL FINDINGS

PDD typically occurs in dairy cattle as lameness episodes of variable severity. Affected cattle are lame and reluctant to move. The affected limb is often held trembling in partial flexion as if the animal is in pain. Less severely affected limbs are rested on the toes and animals may walk on their toes, which become markedly worn and may even expose the sensitive laminae. Affected cattle lose weight and may not eat normally if they have to walk some distance to obtain feed. Milk production may decline if the lesions are severe enough.

Lesions are confined to the digits and do not occur above the dewclaws. The feet of the hind limbs are most commonly affected. The plantar surface of the feet are most commonly affected but the palmar aspects may also be involved.

The majority of lesions are medium to large, measure 2–6 cm across at their largest dimension and are **located on the skin at its junction with the soft perioplic horn of the heel and midway between the two claws.** Most lesions are situated proximal and adjacent to the plantar/palmar interdigital space and rarely involve the interdigital skin. The surface of the lesions is moist, prone to bleeding and intensely painful to the touch. The lesions are circular to oval in shape, raised and variable in color and in degree of papillary proliferation. The washed surfaces are typically red and granular or a composite of white-yellow, gray, brown, or black papillary areas mixed with red granular areas (strawberry-like) with a very strong pungent odor. Filiform papillae commonly protrude from the surface of the lesions. Most lesions are circumscribed or delineated by a discrete line of raised hyperkeratotic skin with long wart-like projections. The lesions are restricted to the skin and do not extend into the deeper soft tissues. If untreated, PDD can persist for months associated with persistent lameness, reduced milk production, and impaired reproductive performance, and premature culling. More advanced lesions may lead to progressive separation of horn from the sensitive laminae, resulting in a typical underrun sole which may extend forward from the heel to reach half-way to the toe. Outbreaks of the disease may occur in dairy herds in which up to 75% of all cows may be affected over a period of several months.[29]

A screening method for the detection of lesions of dairy cattle has been described.[16] At the milking parlor and once the cows are in place for milking, a water hose is used to wash the cows' feet. Then using a powerful flashlight, the digits are carefully inspected for PDD lesions. A PDD case is defined as a cow with a circular-to-oval, well-demarcated, alopecic, moist, erosive foot lesion, surrounded by a white hyperkeratotic ridge or hypertrophic hairs. Lesions bleed easily and are very painful. When impacted by a concentrated jet of water from a hose, the animal frequently reacts by pulling the foot away and sometimes shaking it. Lesions can be classified into one of three stages based on their morphology: early, classical, and papillomatous. The screening method has a sensitivity of 0.72 and a specificity of 0.99.

CLINICAL PATHOLOGY

Detection of organism

Smears of the exudate and scrapings of the surface of the lesions are submitted for culture and for staining for spirochetes. Dark-field microscopy of the scrapings may reveal profuse motile spirochetes with vigorous rotational and flexing movements. Biopsy specimens of the lesions can be submitted for histological examination and special silver staining to identify the spirochetes.

Serology

Using an ELISA, in cattle with PDD, there is a significant humoral response to certain strains of spirochetes isolated from lesions.[1,21] Animals without PDD lesions show little or no response.

PATHOLOGY

The majority of lesions are 2–6 cm across their largest dimension, circular to oval, raised, and variable in color.[30] Washed surfaces are typically either extensively red and granular or a composite of white-yellow, gray, brown, and/or black papillary areas interspersed with red granular areas. The surface of the lesions is covered by filiform papillae, 0.5–1 mm in caliber and 1–3 mm in length. Most lesions are characteristically circumscribed or delineated by a discrete line of raised hyperkeratotic skin often bearing erect hairs 2 to 3 times longer than normal. The surfaces are also partially to completely alopecic, moist, prone to bleed and intensely painful to touch. Histologically, active lesions are characterized by zones of acute degeneration, necrosis, and inflammatory cell infiltration within the stratum corneum, usually associated with focal thinning.[14] Using immunocytochemical staining and PCR of lesion biopsies, *Borrelia burgdorferi*, *Treponema denticola*, and *Treponema vincentii* have been identified.[31]

DIFFERENTIAL DIAGNOSIS

Digital dermatitis must be differentiated from:

- Interdigital dermatitis: moist, gray thickening of the skin, with focal areas of shallow ulceration and hyperkeratosis. It is less painful and rarely has a granular, tufted or papillomatous surface
- Heel erosion (slurry heel) – occurs commonly in dairy cows standing for long periods in slurry.[32] The intact smooth horn of the heel develops deep, black fissures which may become totally eroded. There is no liquefaction necrosis of keratin characteristic of digital dermatitis[32]
- Interdigital necrobacillosis (foot rot) – a necrotizing infection of the interdigital skin. There is marked painful deep swelling of the tissues of the interdigital cleft; cracking of the skin may occur with release of a foul-smelling discharge. Response to treatment with antimicrobials is good unless the lesion is advanced
- Verrucose dermatitis – occurs in cattle kept in deep muddy yards and is characterized by marked painful proliferative dermatitis of the plantar surface of pastern from the bulbs of the heels to the fetlocks. *Fusobacterium necrophorum* is usually present in the lesions. Affected cattle are lame and respond to topical treatment and use of a footbath with a suitable antimicrobial
- Interdigital fibroma (corn) – develops from the fold of skin adjacent to the axial wall of the hoof in the interdigital space. The lesion consists of firm fibrous tissue and may extend the entire length of the interdigital cleft. Lameness is caused by the presence of the corn in the interdigital cleft; advanced corns must be removed surgically.

TREATMENT

Antimicrobials parenterally and topically

Antimicrobial therapy is indicated and effective and various methods of administration have been used including parenteral and topical application in individual animals, and foot baths for medication of large numbers of animals.

Parenteral antimicrobials

Procaine penicillin, at 18 000 U/kg BW IM twice daily for 3 days, or ceftiofur sodium at 2 mg/kg daily for 3 days was highly successful for the treatment of PDD in dairy cattle in California.[30] However, the use of parenteral antimicrobials on an individual basis is labor intensive, costly, and not feasible when large numbers of animals are involved. In addition, drug residues in the milk are more likely when animals are treated parenterally. Recurrence after treatment may also occur. In one report, the lesions recurred in 18% of cows treated with antibiotics parenterally.[30]

Cleaning the surface of the lesion

It is very important to wash and clean the surface of the lesion with a disinfectant soap before the topical administration of any medication. Treatment failures are commonly associated with failure to adequately wash and clean the surface of the lesion.

Topical antimicrobials

Topical antimicrobial sprays or ointments are used on individual animals after the lesions have been cleaned. Direct spraying of the lesions with oxytetracycline at 25 mg/mL in 20% glycerine in deionized water once daily for 5 d using a garden-

type spray applicator was effective.[33] Only affected cows and individual lesions should be treated.[34]

The anatomic location of PDD lesions has an effect on the efficacy of topical treatments. The use of oxytetracycline solution (25 mg/mL in distilled water) as a topical spray on cows with PDD lesions was most effective on lesions located on the heels or dewclaws compared to those in the interdigital cleft.[19] Application of oxytetracycline and bandaging the affected part has been effective but not practical when large numbers of animals are affected.

Oxytetracycline solution (100 mg/mL), acidified ionized copper solution, acidified sodium chlorite, or placebo given as a topical spray three times daily, after washing the lesions, for 3 weeks was effective in decreasing the lameness associated with the disease.[33] In a Swedish dairy herd, topical oxytetracycline was more effective for the treatment of PDD in cattle with heel-horn erosion than hoof trimming alone and than glutaraldehyde.[35]

The use of an oxtetracycline solution topically at doses of 15 mL of a solution containing 100 mg oxtetracycline/mL sprayed twice daily for 7 days, or a one-time application of a bandage of cotton soaked with 20 mL of a solution containing 100 mg oxtetracycline/mL had a low risk of causing violative antibiotic residues in milk.[36]

Lincomycin at a dose of 25 mL of a solution containing 0.6 mg lincomycin/mL or valnemulin at a dose of 25 mL of a solution containing 100 mg/mL valnemulin, given as an individual topical spray for two treatments 48 hours apart resulted in significant improvement within 14 days after the first treatment.[37]

Nonantibiotic formulations

The efficacy of oxytetracycline has been compared with nonantibiotic solutions, a commercial preparation of soluble copper, peroxide compound and a cationic agent, 5% copper sulfate, acidified ionized copper solution, hydrogen peroxide-peroyacetic acid solution, and, tap water, for the treatment of PDD.[38] The commercial formulation of soluble copper, peroxide compound, and a cationic agent appeared to be as effective as oxytetracycline. A non-antimicrobial cream containing soluble copper with peroxide and a cationic agent was compared with topical lincomycin.[39] The efficacy of the treatments was not different for decreasing pain or lesion activity but lincomycin was more effective in decreasing lesion size and preventing recurrence. Cows with ≥3 lactations were more likely to have a healed lesion at 29 days, compared with first and second lactation cows.

A nonantibiotic formulation based on a reduced soluble copper solution, peroxide compound, and a cationic agent (Victory), was most effective for the treatment of PDD, once daily for 5 days, compared to other similar formulations and oxytetracycline.[40]

A nonantibiotic paste, Protexin Hoof-Care, containing formic acid (6.8%), acetic acid (3.74%), copper (3.29%), and zinc sulfate (0.40%), essential oils (peppermint /eucalyptus, 0.16% and a pH of 3.5 has been compared under controlled conditions with topical oxytetracycline and is considered an effective alternative to the antibiotic for the treatment of PDD.[41] Only one topical application is required after cleaning the lesion. Advantages include no prescription is required, no withdrawal time is required, and it does not result in any concerns about antibiotic residue in meat or milk.

Bandaging the lesion

Whether or not the lesion should be bandaged after cleaning and medicating is controversial. Bandaging requires additional restraint to handle the leg and foot, it is labor intensive, and is an additional cost. However, field observations indicate topical treatment under a bandage is particularly effective with most cows showing remarkable improvement in 24–48 hours. Futhermore, when properly applied the bandage and the topical medication have the potential of reaching lesions in the interdigital cleft.

Footbaths

Footbaths containing antimicrobials and germicides have been used for treatment of groups of animals and for control of the disease. The most important benefit of using footbaths is that all animals are treated for PDD at the same time. Types of footbaths include walk-through and stand-in (stationary). The walk-through footbath, commonly located in milking-parlor exit lanes, is most popular in loose housing systems. Portable walk-through footbaths constructed of rubber, fiberglass, or hard plastic are also available and can be relocated as needed.[42] The portable footbath is also the most convenient type for individual treatment situations that may involve bathing two, or possibly all four feet, for prolonged periods.

Most walk-through footbaths are at least 1 m wide, 2 to 3 m long, and 12 to 15 cm deep. Proper construction includes systems for efficient drainage, cleaning and refilling. The capacity of a rectangular footbath varies according to its dimensions, which can be calculated using the formula: width × length × depth 7.46 = capacity in gallons. (Multiplying the number of gallons by 3.8 will provide capacity in liters – US.) The size of the footbath needed will depend on the number of feet which will be treated with the system. Footbaths must be carefully monitored for excessive contamination with dirt and feces and solutions should be changed after every cow passes.[34]

The maximum number of cows which can be treated with a footbath varies according to the cleanliness of the cows, size of the bath, type and concentration of the medication used, housing system, weather conditions, and cow flow patterns. One recommendation suggests one footbath is sufficient for 150 to 200 cows and that PDD may be controlled with a single monthly passage through a footbath containing 5 to 10 g/L of oxytetracycline or 1 to 3 g/L of lincomycin in 200 L of water or erythromycin at a rate of 50 g/150 L of water.[42] A common recommendation is that a foot bath can treat 150 to 200 cows per change of solution, used three times per week in outbreaks, once every week or two for maintenance.

Other observations however, suggest that as few as 30 to 50 cows through a footbath may cause major shifts in pH and solids loading, and the largest increment of change in pH occurred with the passage of the first 32 cows through the bath.

In summary, footbaths make biological sense for the treatment and control of PDD. However, most of the recommendations regarding their use, frequency of use, optimum number of cows, are based on uncontrolled field observations.

Antibiotics in footbaths

Antibiotics are commonly used in footbaths for the treatment and control of PDD.[42] Antibiotics in footbaths are rapidly neutralized in the presence of excessive contamination from mud and manure. This is a significant limitation in large herds or in housing situations in which muddy conditions are present.

Tetracycline in 6–8 g/L of water has been used in a footbath for treatment of PDD. Tetracycline powder (324 g/lb) at 20 to 40 g per gallon (US) to deliver 0.5 to 1%. Lincomycin mix at 0.5 to 4 g/gallon US is also used. A mixture of lincomycin and spectinomycin in 150 g/200 L of water for treatment and 125 g/200 L of water for control was also effective. Walking cows through a footbath containing erythromycin, at a concentration of 35 mg erythromycin/L, after two consecutive milkings is effective.[43] Four days after treatment, four of the measured signs (exudation, reddening, creaminess, and pain) were all significantly improved.

Most of the antibiotics used require a veterinary prescription and must be used according to specific recommendations and compliance with withdrawal periods as necessary.

Non-antibiotics in footbaths

Copper sulfate has been used widely in footbaths to control PDD but is considered ineffective.[42] Copper sulfate and zinc sulfate combine with organic matter and become neutralized.

Formalin (37%) diluted to a 3–5% concentration has also been used extensively worldwide in footbaths for the control of lameness in cattle. However, it is not recommended for use in footbaths for the treatment of PDD.

A 7-day footbath of 6% formalin, 2% copper sulfate or 1% peracetic acid can be as effective in controlling PDD as erythromycin at 210 g/L for two days.[44]

In a dairy herd with heel-horn erosion, a foot bath containing acidic ionized copper through which the cows walked twice daily after milking for a total of 47 days was effective in controlling PDD.[35]

Treatment failure

The possible causes of treatment failure include inconsistent application of treatments and/or failure to periodically retreat all feet of all cows in the herd every 2 to 3 months with a topical spray, improper formulation of the medication, the neutralization of the antibiotics by manure, and the inaccessibility of the medication when the lesion is in the interdigital cleft.[45] In addition, ideally lesions should be washed and cleaned thoroughly before applying the medication.

Protocol for evaluation of treatment

A uniform protocol to evaluate the results of treatment and control of PDD has been described.[46] The protocol includes herd information including history and facilities, animal identification and production and clinical information about the lesions, the trial design which includes the duration of the trial, the positive and negative controls, how the lesions will be described and scored, the lameness score, the evaluation of pain, and the different treatments being evaluated.

CONTROL

Because the risk factors which predispose to the lesions are uncertain, specific environmental control strategies have not been examined using controlled field trials. Recurrence rates of PDD vary from 40 to 52% after 7 to 12 months.[45] Thus it makes biological sense to have an infectious disease control system in place in the herd to provide optimum control.

- **Housing, environment, and management.** The high incidence of the disease in dairy cattle in drylot and freestall housing suggests that a high infection rate may be associated with high population density and contamination of bedding and the environment. Providing environmental conditions which promote clean and dry ground surfaces and bedding appears to be a logical strategy. Improving cow comfort by providing clean stalls, corrals, and alleys, dry and comfortable bedding, reducing the stocking rate, and improving ventilation to allow drying of stalls and alleys may decrease the incidence and severity of clinical cases. Hoof trimming, mobile tilt tables, and livestock trailers should be thoroughly cleaned and disinfected to prevent potential transmission of the agent of PDD.
- **Biosecurity.** For herds which are free of PDD, the most important control consideration is the purchase of herd replacements. According to the NAHMS survey of 1996 in the US, the odds of PDD infection were 8 times greater in herds which purchased replacements from outside sources compared with those that did not.[45] Herd replacements should be purchased from herds known to be free of PDD. Quarantine procedures may be applicable but often impractical.
- **Footbath.** Successful control is possible by single passage of cattle through a footbath containing 5–6 g/L oxytetracycline or 150 g lincospectin 100 in 200 L water.[47] For optimum results the heels of affected cows should be spray washed prior to entering the footbath. Repeating the footbath treatment in 4–6 weeks is recommended. Regular footbaths with 5% copper sulfate solution and formalin 3–5% solution once weekly, according to the incidence of the disease may be necessary in certain circumstances. Regular inspection of the feet of cattle is recommended to monitor the occurrence of the lesions.
- **Vaccination.** There is no evidence that a vaccine is effective for the control of PDD.[45]

INFECTIOUS FOOT ROT IN SHEEP

Synopsis

Etiology *Dichelobacter nodosus*. Strains vary in virulence to produce benign and virulent foot rot

Epidemiology Source of infection is lesion discharge from other infected sheep. The survival of *D. nodosus* in the environment is short. Highly contagious

disease with high attack rate in warm wet conditions. Lesions are present on both claws of the foot and commonly in more than one foot. Significant effect on productivity
Clinical findings Inflammation of the skin at the skin–horn junction in the interdigital area with underrunning of the soft horn in benign (non-progressive) foot rot. Progresses to underrunning of the hard horn and inflammation of the sensitive laminae in virulent (progressive) foot rot and severe lameness
Clinical pathology Protease test for strain virulence
Diagnostic confirmation Clinical
Treatment and control Topical treatment with bactericides in footbaths at time of transmission to minimize new infections, parenteral antibiotics for treating virulent footrot, vaccination, culling

ETIOLOGY

Dichelobacter (*Bacteroides*) *nodosus* is the essential causal pathogen. It is a highly specialized organism in the small taxonomic group, the Cardiobacteriaciae. *F. necrophorum* aids *D. nodosus* in the invasion of the foot and contributes in the inflammatory reaction. Two other bacteria, a treponeme originally known as *Spirochaeta* (*Treponema*) *penortha*, and a motile fusiform bacillus, are commonly present in affected feet but are believed to have no primary etiological importance.

The type IV fimbriae of *D. nodosus* are recognized as a major virulence factor, are highly immunogenic, and provide the basis for the classification of *D. nodosus* strains into two major classes based on the genetic organization of the fimbrial gene region, with class I containing strains of serogroups A, B, C, E, F, G, I, and M and class II consisting of serogroups D and H. The serological diversity observed in the fimbriae is due to sequence variation in the fimbrial subunit protein and the fimbriae are the major immunoprotective antigens, although protection is serogroup-specific.[1–4]

Within this typing scheme there are strains that have major and minor prevalence in the disease. A strain-specific typing system based on genetic analysis of the *fimA* locus and combined with DNA sequencing is suggested for the characterization of *D. nodosus* strains.[5]

EPIDEMIOLOGY

Geographical occurrence

Foot rot of sheep is common in all countries where there are large numbers of sheep, except that it does not occur in arid and semi-arid areas unless the sheep have access to wet areas such as sub-irrigated swales.

Host occurrence

Sheep are the species principally affected but goats are also susceptible. Infection has been identified in farmed red deer,[6] in cattle and is considered the cause of overgrown and deformed claws in wild mouflon in Europe.[7] With environmental conditions of moisture and warmth, the disease in sheep has a high attack rate and a large proportion of a group of sheep can be affected within 1 to 2 weeks. Both claws of a foot and more than one foot (usually all) on the sheep will be affected. The disease is common and in high-risk areas the prevalence of infected flocks is high.

Source of infection

The source of infection of *D. nodosus* is discharge from the active or chronic infection in the feet of affected animals. The major **reservoir** of infection for virulent strains of sheep is other sheep as the isolates from cattle and deer generally produce the benign form of foot rot in sheep. The organism does not survive in the **environment** for more than a few days, 2 weeks at the most, but it can survive virtually indefinitely in lesions on chronically infected feet. Two classifications of foot rot have made based on the site of survival and perpetuation of the organism in a flock and the importance of this to control strategies:

1. **Virulent foot rot (progressive foot rot) and intermediate foot rot** – strains survive between foot rot transmission periods in pockets in previously underrun ovine hoof
2. **Benign foot rot (non-progressive foot rot)** – strains survive in the interdigital skin and the organism can be demonstrated in interdigital skin of a high proportion of asymptomatic sheep.[8,9]

Methods of transmission

Infection is usually introduced into a flock by the introduction of **carrier sheep**. Infection into a flock can also occur from the **environment** when foot rot-free sheep use yards, roads, or trucks that have been used by foot rot-infected sheep in the immediate past. Transmission has occurred to sheep held for 1 hour in a yard that 4 hours previously had contained a flock of sheep in which less than 1% had foot rot.[10] Spread within a flock is facilitated by the flocking nature of sheep and heavy environmental contamination around communal drinking and feeding areas.

Host risk factors

Age

Foot rot occurs in sheep of all ages. In a flock outbreak, the age-specific incidence and severity of lesions in ewes increases with age.[11] Older lambs have more severe lesions; young lambs and lambs from maiden ewes have less severe lesions than lambs from higher parity ewes. Prior natural infection does not engender immunity to a subsequent challenge that have had the disease. However, sheep do vary in their resistance or susceptibility to footrot infection. This appears to be, in part, immunologically mediated with the ability of some sheep to mount a strong T-cell response and to produce agglutinating antibodies to *D. nodosus* fimbriae an important factor in conferring resistance to severe infection.[5]

Breed

Sheep of the Merino type are the most susceptible to foot rot. British breeds, particularly Romney Marsh, are less susceptible and suffer from a milder form of the disease; they respond better to vaccination by suffering fewer subsequent attacks of foot rot but have worse reactions to the vaccination than Merinos.[12] In the natural disease some animals never become infected, a few become infected but recover and most become infected and persist as chronic cases. There is developing evidence that this variation is **genetically determined** and selection for resistance, based on exposure to the disease and rigorous culling of affected individuals, has been demonstrated in the Targhee, Romney, Merino, Corriedale, and Perrendale breeds.[13,14] Genetic markers can be identified and the SY1b histoglobulin may be associated with this resistance.[13]

Environmental risk factors

Climate

Moistness of the pasture and environmental temperature are major determinants for the transmission of foot rot. Conditions of **wetness** and **warmth** favor persistence of the bacteria in pasture and increase susceptibility of the feet to injury and dermatitis, thus facilitating spread of the disease from carrier sheep. The wetness has to be of considerable duration; short, heavy rainfalls are not significant – persistent rain over several weeks is, as there must be continued moistness on the ground for transmission to occur. Warmth is also required and moisture in winter in colder climates exerts no effect on foot rot – the daily mean temperature must be above 10°C (50°F) for transmission to occur. There is a linear relationship between the prevalence of farms with foot rot and yearly rainfall.[15]

Season

The requirement for both moisture and a warm environmental temperature determines that most serious outbreaks in sheep at pasture occur in the spring or in autumn and the transmission period is usually 4–6 weeks of each of these

seasons. Transmission and outbreaks occur in winter in housed sheep when conditions underfoot are wet and in summer with sheep on irrigated pastures.

Management

Any practice that concentrates sheep in small areas will favor spread of the disease when environmental conditions favor transmission. Routine foot trimming may increase risk of infection and clinical disease.[16]

Failure to isolate introduced sheep until their foot rot status has been determined is a risk factor.

Pasture type

Foot rot is commonly associated with lush or improved pastures, irrigated pastures, and clover-dominant pastures. Long mature grass may result in interdigital abrasions as it is dragged through the interdigital space and facilitates infection, as may penetration of interdigital skin by barley grass seeds (*Hordeum murinum*).[10,11] Skin penetration by larvae of the nematode *Strongyloides* spp. may also predispose to infection.

Pathogen factors

The major *D. nodosus*-encoded virulence factors that have been implicated in the disease are type IV fimbriae and extracellular proteases and the fimbrial subunit gene, *fimA*, is essential for virulence.

There is considerable variation in the virulence of strains of *D. nodosus*. Some produce benign foot rot whereas others produce deep lesions that facilitate their survival and confound eradication programs.[17–19] As a result they have traditionally been subdivided into **benign, intermediate, and virulent** strains to conform with the types of clinical foot rot they are associated with in the field.[20] The virulence of each strain depends on its **keratinolytic capacity**; virulent strains produce more extracellular protease, and an earlier production of elastase, than benign strains.[20,21] The separation of the hard horn of the claw from the germinal layer, which is a characteristic of virulent foot rot, has been associated with infection with strains that produce a **heat-stable protease** with a single isoenzyme pattern, whereas benign strains have thermolabile protease.[18,22] Infection associated with more than one strain is reported and up to five serogroups including up to eight strains have been reported from a single foot.[5,19]

Economic importance

Benign foot rot is generally considered to cause little if any economic effect and its occurrence is confined to the wet season. However, even benign foot rot infections are reported to depress body weight, wool growth, and wool quality in some countries.[7]

In contrast, virulent foot rot certainly results in severe loss of bodily condition and this, combined with a moderate mortality rate, a reduction in wool production, the disruption of the general routine of the farm, and the expense of labor and materials to treat the disease adequately, makes foot rot one of the most costly of sheep diseases. In addition there are welfare concerns, societal pressures encountered by owners of foot rot-infected flocks and, in control areas, the community costs of statutory foot rot control programs.

In controlled studies severe underrunning foot rot has resulted in an 11% depression in body weight and an 8% reduction in clean fleece weight of affected sheep.[3] The magnitude of the loss can be related to the virulence of the infecting organism and the severity of the disease.

The effects on body weight are most severe during the active transmission period of the disease and there may be compensatory growth during the recovery period. Both greasy and clean fleece weight are significantly depressed by foot rot with a linear association between the extent of the depression and the severity of the disease. Wool fiber diameter is also decreased, which could partially compensate for fleece weight decrease in the final price for wool. Some sheep with severe disease may develop a break in the wool.

Feet of sheep affected with foot rot are attractive to blowfly strike. Necrotic exudate with accompanying maggots from affected feet can be deposited on the fleece to result in a focus of body strike.

PATHOGENESIS

Maceration of the interdigital skin from prolonged wet conditions underfoot allows infection with *F. necrophorum*. This **initial local dermatitis** associated with infection with *F. necrophorum* at the skin and the skin–horn junction may progress no further, but the hyperkeratosis induced by this infection facilitates infection by *D. nodosus* if it is present. The preliminary dermatitis has been named '**ovine interdigital dermatitis**' and is also called '**foot scald**'.

Ovine interdigital dermatitis, foot scald

This disease is commonly seasonal and occurs when moist conditions under-foot, or trauma from pastures or frost, produces maceration of the interdigital skin and allows invasion by *Fusobacterium necrophorum*, a ubiquitous organism in feces and soil.

Lesions are in the interdigital space where there is hyperemia, or swelling and blanching, and wetness of the interdigital skin. There is no, or only minimal, separation at the skin–horn junction. Lambs are more commonly affected, particularly in spring, but the disease can involve all ages of sheep. Most or all feet on a sheep are affected and it is present in a large proportion of the age cohort of the flock.

In Australia and New Zealand the disease is not usually associated with lameness and is often found incidentally when examining sheep for other reasons.

In Britain it is reported as a common cause of lameness[23] but this might reflect a lack of cultural differentiation from the less virulent forms of infectious foot rot that can present with identical clinical findings.[24,25]

Control is by avoiding grazing lambs on long grass and where there are muddy conditions. The disease will regress spontaneously when the pasture dries up but can be treated with topically applied oxytetracycline or by walking through a foot bath containing 3% formalin or standing (10 minutes) in one containing 10% zinc sulfate.

Ovine interdigital dermatitis can predispose to infectious foot rot, or to foot abscess.

Benign and virulent foot rot

It is assumed that the pili of *D. nodosus* facilitate attachment of the organism to the epithelium of the foot. When the feet of sheep with interdigital dermatitis are colonized with a strain of *D. nodosus* that has little keratinolytic ability, there is underrunning of the soft horn but no further progression and this infection has been given the name of **benign foot rot** or **non-progressive foot rot**. Benign foot rot cannot be easily distinguished on clinical examination from ovine interdigital dermatitis. Colonization with keratinolytic and virulent strains leads to the clinical disease of **virulent foot rot**. The underrunning lesion is the result of keratolytic activity and the associated inflammation is a consequence of a combined activity of *D. nodosus* and *F. necrophorum*. A designation of intermediate foot rot has been used by some to provide a mid-classification of severity between benign and virulent foot rot and the classification of infected sheep into these categories is based on a foot lesion scoring system (see below). There is much difficulty in specifying exactly the characteristics of these clinical forms in natural outbreaks, in part because commonly more than one strain is involved, the more so because the severity of the lesions is also modulated by geographic and climatic conditions.[8–11,26]

CLINICAL FINDINGS

Sheep

Virulent foot rot

In a flock, a sudden onset of **lameness** of several sheep is the usual presenting sign

of foot rot as the disease is not detected before this occurs. The pain associated with infection is severe and affected sheep will limp or carry the affected leg. Usually more than one foot is affected and affected sheep may graze on their knees.

On close examination the earliest sign of virulent foot rot is swelling and moistness of the skin of the interdigital cleft and a parboiled and pitted appearance at the skin–horn junction in the cleft. This inflammation is accompanied by slight lameness which increases as necrosis underruns the horn in the cleft. The **underrunning** starts as a separation of the skin–horn junction at the axial surface just anterior to the bulb of the heel and proceeds down the axial surface and forwards and backwards. There is destruction of the epidermal matrix beneath the hard horn, which is subsequently separated from the underlying tissues. In severe cases both the axial and the abaxial wall and the sole are underrun and deep necrosis of tissue may lead to the shedding of the horn case. The separation may not be obvious on superficial visual examination but can be detected with a knife blade or by paring of the feet. There is a distinctive, **foul-smelling** exudate, which is always small in amount. Abscessation does not occur.

Both claws of the one foot will be involved and commonly more than one foot is involved. When extensive underrunning has occurred lameness is severe. A systemic reaction, manifest by anorexia and fever, may occur in severe cases. Recumbent animals become emaciated and may die of starvation. Secondary bacterial invasion and/or fly strike may result in the spread of inflammation up the legs.

Benign foot rot

Benign foot rot is manifest with interdigital lesions, a break at the skin–horn junction and separation of the soft horn, but the disease does not progress beyond this stage to severe underrunning of the hard horn of the foot. The interdigital skin becomes inflamed and covered by a thin film of moist necrotic material; the horn is pitted and blanched.

It is difficult to distinguish between an established infection with benign foot rot and the early stages of virulent foot rot. With virulent foot rot it is common to find all stages and severity of the disease in the same flock. A large number of sheep should be examined in order to differentiate benign from virulent foot rot and it may be necessary to re-examine the flock after a period of time to determine if the disease has progressed to the virulent type.

Scoring systems

Several scoring systems, based on severity and persistence, have been devised to aid in epidemiological and control programs and can be used to categorize the severity of disease, and the virulence of associated strains of *D. nodosus*, within a flock.[27] In the Australian system, a score of 0 to 4 is allocated to each foot but the score is used to classify the flock or a cohort, as to the severity of disease. Feet scored 0 have no evidence of necrosis or inflammation or cleavage of horn. Scores of 1 and 2 are confined to sheep with interdigital lesions whereas a gradation of scores from 3 to 4 reflect progressive underrunning and separation of horn from the underlying laminar with 3 representing underrunning of the soft horn. In this score system benign foot rot cases score 0 with some allowance for scores of 3. Intermediate foot rot in a cohort is defined when 1 to 10% of the cohort have a score of 4. Virulent foot rot is defined by greater than 10% of the cohort with a score of 4.[28] It has been suggested that the score system is not valid as the severity of disease can be influenced by climate but one study suggests that score systems are strain specific rather than climate specific. It found that a cohort of sheep with scores defining intermediate foot rot maintained that clinical classification when moved to a climate that would promote the development of more severe disease.[28]

Symptomless carriers

These carriers may be affected for periods of up to 3 years. Most such animals have a misshapen foot and a pocket of infection beneath underrun horn can be found if the foot is pared. A less common form of the chronic disease is an area of moist skin between the claws without obvious involvement of the claw.

Goats

Foot rot is associated with *D. nodosus* and is manifested by severe interdigital dermatitis; there may be some separation of the skin–horn junction at the axial surface but rarely is there an underrunning of the horn of the sole or the abaxial surface of the foot as in sheep.[29]

Cattle

Infection with *D. nodosus* is also associated primarily with a severe interdigital dermatitis and there may be lameness. There is fissuring and hyperkeratosis of the interdigital skin with pitting and erosion at the skin–horn junction in the cleft. There is also fissuring, pitting, and erosion on the horny bulbs of the heel. There may be underrunning at the heel but it is usually minimal.

Contagious ovine digital dermatitis (CODD)

CODD is an apparent new disease recently described in the UK.[30,31]

It is manifest with severe, rapidly spreading, lameness and is more common in adults than lambs. Commonly there is a history of poor response to conventional methods of footrot control. The initial lesion is a proliferative or ulcerative lesion at the coronet, with subsequent extensive under-running of the hoof horn and, in some cases, complete separation. Interdigital lesions are absent. It may affect only one claw on one foot. A spirochete, morphologically different from *Spirochaeta penortha* but with similarities to the spirochete associated with digital dermatitis (hairy foot wart) in cattle has been isolated.[31,32]

F. necrophorum and *D. nodosus* may also be present in some flocks but their contribution, at present, is unclear.

Response to formalin and zinc sulfate footbaths is poor but the disease is reported to respond to topical lincomycin and spectinomycin solutions.[30]

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

In countries that do not have a large sheep industry identification of *D. nodosus* in most laboratories, is made by examining a smear made of exudate taken from underneath some underrun horn at the advancing edge, and stained with Gram's stain. This is potentially inaccurate and to increase the validity of a decision, a fluorescein-stained antibody can be used. A highly sensitive polymerase chain reaction (PCR) can be used.[20,33] PCR tests can be used to detect gene sequences and identify particular strains and are used in eradication schemes in Australia.[17,19]

Examinations of protease type, gene probe category and nucleotide sequence to differentiate virulent from benign strains are used in regions with eradication programs for virulent foot rot and in epidemiological studies.[20,21] Of the protease tests, the gelatin gel protease thermostability test allows clear-cut and rapid differentiation between virulent and benign strains.[34]

Serum antibody following natural infection develops as early as 2 weeks after infection and the level obtained is proportional to the severity of the early clinical disease. The antibody response is not long lasting and falls to pre-infection levels within a few months after resolution of the foot lesions.[35,36] An ELISA for serological detection of infected sheep has some value for diagnosis of flock infection but lacks specificity and is inaccurate in older sheep.[35]

Necropsy of sheep for diagnosis of foot rot is not needed.

DIFFERENTIAL DIAGNOSIS

Diagnosis of virulent foot rot is clinical, is based on a whole flock approach, and postmortem examination is not necessary.

Because of the rigorous control measures required sometimes by law to control or eradicate infectious foot rot of sheep, it is imperative that the diagnosis be made with great care. The greatest problem is in the identification of carrier sheep in the non-transmitting periods. A number of conditions may be confused with foot rot, especially when they occur under the same environmental conditions (Table 20.1).

Foot abscess – a major differential and can be present in several sheep in a flock at the same time. It usually affects only one foot, is not contagious and is characterized by extensive suppuration. The abscess occurs in a single claw on the foot and there is obvious local heat and pain on palpation.

Contagious ovine digital dermatitis.

Shelly toe – the name given to a condition where there is separation of the wall of the foot in Merino sheep and occasionally in other breeds on improved pasture. The abaxial wall of the hoof separates from the sole near the toe and the crevice formed becomes packed with mud and manure. The hoof in the region is dry and crumbly. The cause is not known but it is probably a form of laminitis.

Suppurative cellulitis – associated with *F. necrophorum*, commences as an ulcerative dermatitis of the pastern above the bulb of the heel, and extends up the leg to the knee or the hock and more deeply into SC tissues.

Other diseases with foot lameness include:

- Contagious echyma
- Bluetongue
- Foot and mouth disease
- Ulcerative dermatosis
- Strawberry foot rot
- Laminitis
- Lameness associated with *Erysipelothrix insidiosa*, and occurring after dipping

TREATMENT AND CONTROL

The time-honored method of treatment of foot rot has been the application of topical bactericidal agents to the foot. These are most effective early in the transmission period, prior to any extensive underrunning of the horn. When there is underrunning of the horn, the underrun horn must be removed so as to expose the infection to the topical agent. This approach has been used successfully for treatment, control, and eradication purposes. However, it requires extensive paring of affected feet, which is labor intensive, time consuming and distressing both to the operator and to the sheep. Recent years have seen the advent of treatment methods that minimize the need for extensive paring of the feet. These include the use of topical zinc sulfate, the use of parenteral antibiotics and the recognition of vaccination as an adjunct to treatment as well as a strategy for control.

Topical treatment

Most topical treatments require that all underrun horn be carefully removed so that the antibacterial agent to be applied can come into contact with infective material. This necessitates painstaking and careful examination, and paring of all feet. Incomplete paring will leave pockets of infection. With severely underrun feet, it is impossible to expose all of the underrun areas without causing hemorrhage as it may be necessary to remove all of the sole and the wall of the claw. Very sharp instruments including a knife and hoof secateurs are necessary to do the job properly and they should be disinfected after each use. The parings should be collected and burned. Sheep restraint cradles lessen the labor of paring of the feet.

With small numbers of sheep topical treatment may be applied by brush, by spray, or aerosol. Topical treatments are likely to be washed off the feet and their efficacy under wet conditions is a determinant in selecting the agent to be used. Local applications include chloramphenicol (10% tincture in methylated spirits or propylene glycol), oxytetracycline (5% tincture in methylated spirits), cetyltrimethyl ammonium bromide or cetrimide (20% alcoholic tincture), zinc sulfate (10% solution), copper sulfate (10% solution) and dichlorophen as a 10% solution in either diacetone alcohol or ethyl alcohol.

Chloramphenicol is expensive but efficient under both wet and dry conditions. Its use with food animals is prohibited in many countries. Oxytetracycline must be used as a 5% tincture for optimum results and is not as efficient as chloramphenicol under wet conditions, but gives excellent results when the weather is dry. Cetrimide is a relatively cheap product and appears to be as effective as chloramphenicol under all conditions. It is possible that in different countries with different climates and environmental conditions, the efficiency of particular treatments will vary. When only a few sheep are affected, bandaging may help maintain local concentrations of the topical preparation. In general, parenteral treatment with antibiotics, without paring of the feet, has replaced topical antimicrobial treatment of individual or small numbers of sheep.

Footbathing for treatment and control

Footbathing is a more practical approach to topical treatment, and for control during transmission periods, when dealing with large numbers of sheep. All sheep are passed through the footbath but it is usual to divide the flock into affected and unaffected groups by examination prior to the initial footbathing, and to pasture them separately following footbathing to minimize subsequent infection of uninfected sheep. After several footbaths and inspections the majority of the flock should be free of infection and the residual infected sheep are culled.

Preparations suitable for footbaths include 5% copper sulfate, 5% formalin and 10% zinc sulfate with or without a surfactant to aid wetting of tissues. Regardless of the agent used, it is recommended that the sheep be kept standing on concrete, on wooden slats, or on dry ground for a few hours after treatment.

The relative merits and disadvantages of the various preparations used are as follows.

Copper sulfate solution (5%)

Copper sulfate solution colors the wool, deteriorates with pollution, corrodes metal, and may cause excessive contamination of the environment with copper. The feet of the sheep must be pared and all infected areas exposed before treatment. Copper sulfate footbathing appears to harden the horn, which can be an advantage but also a disadvantage if further paring is required at a later date. A patented copper salt preparation (not copper sulfate) has efficacy in treatment without the disadvantages of copper sulfate.[37]

Formalin solution (5%)

Formalin solution does not deteriorate with pollution but causes extreme discomfort to sheep that have heavily pared feet and its use for sheep with severe lesions is discouraged on humane grounds. The feet of the sheep must be pared and all infected areas exposed before treatment. Formalin is unpleasant to work with in enclosed areas, has toxicity for humans and its use may be banned in some countries for this reason. Sheep should be passed through the footbath weekly for 4 weeks or weekly during periods of high risk for transmission.

The use of solutions containing more than 5% formalin or dipping at intervals of less than 1 week may cause irritation of the skin. Farmers can be neglectful in maintaining proper concentrations of formalin in footbaths, and frequent use of the bath combined with hot weather can result in a concentration of 30% formalin. Such concentrations cause extensive cellulitis around the coronets, and a

Table 20.1 Differential diagnosis of lameness accompanied by foot lesions in sheep

Disease	Epidemiology	Foot lesions	Other lesions	Other clinical signs	Response to treatment	Diagnostic microbiology
Infectious foot rot	Serious outbreaks in wet, warm weather. High morbidity. Few chronic lame sheep in dry seasons	Interdigital dermatitis, underrunning of horn medial aspect of claw. Strong smell of necrotic horn	–	Very severe lameness. Walk on knees	To penicillin and streptomycin, erythromycin excellent	*Dichelobacter nodosus* on smear, or fluorescent antibody test
Benign foot rot (scald)	High morbidity in wet warm weather. Disappears with dry weather	Interdigital dermatitis, no smell, almost no underrunning of horn	–	Mild lameness	Not treated	*D. nodosus* avirulent strains not distinguishable microbiologically
Infectious bulbar necrosis	Adult sheep, usually less than 10% affected. Serious in wet seasons	Toe abscess usually in front feet. Heel abscess in hind feet. Swelling, pain, discharge of pus	–	Very severe lameness	Good to sulfonamides or penicillin-streptomycin	*F. necrophonum* and *Actinomyces* (*Corynebacterium pyogenes*)
Contagious ecthyma	Lambs mostly or non-immune adults. Dry summer	Raised proliferative lesions with tenacious scabs on coronet skin	Lesions around mouth almost always	Rarely lambs have septicemia. Lameness mild only	–	–
Ulcerative dermatitis	Spread by physical contact at mating. Morbidity usually 20%	Raw granulating ulcers in interdigital space and on cornet. No pus	Around mouth and genitalia usually	Moderate lameness	–	–
Bluetongue	Insect-borne disease. Variable morbidity	Coronitis, separation of horn. Are late in syndrome	Severe erosions around mouth and nasal cavities	High fever, salivation. Severe lameness and recumbency	–	Virus isolation
Strawberry foot rot	In summer, high morbidity, carrier sheep infect	Proliferative dermatitis, piled up scabs. Heal in 5–6 weeks. Coronet to knee or hock	–	No itching or lameness	–	*Dermatophilus congelensis*
Foot-and-mouth disease	May present like outbreak of contagious foot root	Vesicles at coronary band and skin of interdigital cleft	Vesicles in mouth	All ages	–	Virus demonstration
Infestation with *Strongyloides* or trombiculid mites	Wet summer conditions. Local distribution only	Non-specific dermatitis of skin of lower legs	–	–	Organophosphates for trombiculids	Parasites in scrapings

high proportion of animals may be so badly affected that they need to be destroyed. The safest precaution is to empty the vat and prepare a new mixture.

Zinc sulfate solution (10–20%)

Zinc sulfate solution is as effective as formalin, more pleasant to use and is generally the preferred topical chemical for the treatment of foot rot.[38] It has a superior ability to **penetrate** the hoof horn which is enhanced by the addition of the **surfactant** sodium lauryl sulfate to the footbath solution.[39] Significant cure rates can be achieved without prior paring of the feet which removes a significant labor cost from the treatment and control of the disease.[38–40]

Cure rates, without paring, are higher in sheep that have moderate rather than severe lesions in their feet. Some paring of chronically affected, overgrown feet may be required to allow the treatment access to pockets of infection in the anterior aspects of the sole, and also of feet that have underrunning that has progressed to the abaxial area of the digit. Sheep are stood for 1 h in a footbath containing a 10 to 20% zinc sulfate solution with 2% sodium lauryl sulfate with sufficient depth to cover the coronet. The treatment is repeated in 5 d and after a further 21 d the sheep are individually examined to determine their status and are retreated or culled depending upon the strategy of treatment and control in the flock. Zinc sulfate footbathing can provide protection to the foot against reinfection for periods of at least 2 weeks[41] and can be used effectively during periods of active spread of the disease[42] Repeated daily footbathing (10 min each day for 5 days) in a zinc sulfate solution with surfactant has eradicated (as opposed to controlled) virulent foot rot in sheep associated with some strains but was ineffective against a strain that produced severe underrunning.[17]

Thirsty sheep that drink from the footbath may die of acute zinc poisoning.

Antibiotic treatment

Foot rot can be treated with antibiotics without the necessity of paring of the feet. Treatment is considerably more effective if done during dry periods, and when the sheep are kept on dry floors for 24 h after treatment, as in wet conditions the concentration of antibiotic at the tissue level is much reduced.

D. nodosus is susceptible *in vitro* to penicillin, cefamandole, clindamycin, tetracycline, chloramphenicol, erythromycin, sodium cefoxitin, tylosin tartrate, nitrofurazone, tinidazole and has the least susceptibility to sulfonamides and the aminoglycosides. However, *in vitro* tests may have little relevance to field application due to differences in the penetrance of antibiotics to the affected part of the foot.

Antibiotics and their dosage shown effective against virulent foot rot are:

- **Penicillin/streptomycin.** Single IM dose of 70 000 U/kg procaine

penicillin and 70 mg/kg dihydrostreptomycin[43]
- **Erythromycin**. Single IM dose of 10 mg/kg[44,45]
- **Long-acting oxytetracycline**. Single IM dose of 20 mg/kg[44,46,47]
- **Lincomycin/spectinomycin**. Single SC dose of 5 mg/kg lincomycin and 10 mg/kg spectinomycin.[48]

Cure rates in sheep kept in a dry environment, preferably a shed, for 24 h following treatment are approximately 90% with all except penicillin/streptomycin, which may be slightly less efficacious.[49] Cure can occur even in severely affected sheep and extensive paring prior to treatment does not improve cure rates.[46,49] Cure rates fall to 60% if sheep are in a wet environment following treatment and in wet conditions cure rates improve slightly if sheep are footbathed at the time of antibiotic administration.[47,49]

Following treatment and holding, sheep are moved to a 'clean' dry pasture and inspected for cures 3–4 weeks later when clinically affected animals are culled. Reinfection will occur in foot rot spread periods and, in general, the use of antibiotics for control of foot rot should be confined to the summer period when there is no spread.[26]

All treatments are '**off label**' and some are not approved for use on sheep in some countries. Choice may be determined by the withholding period required before culled sheep can be sent to market. Lincomycin/spectinomycin in sheep may precipitate severe outbreaks of salmonellosis in some flocks.[49] Antibiotics are particularly valuable for the treatment of late-pregnant sheep that develop foot rot, where more drastic treatment could lead to problems such as pregnancy toxemia.

Antibiotics have no role in the prevention of foot rot.

Vaccination

Vaccination against foot rot can significantly increase short-term resistance to infection and is an important component of **control** strategies, especially in circumstances where climate and management practices make other control strategies difficult to apply. Vaccination also shortens the clinical course in infected sheep and can be used as a **treatment** strategy. In neither case is vaccination 100% effective.

Pilus antigens are the major host-protective immunogens and confer protection against challenge with homologous strains. Immunity is associated with circulating antibody but high levels of **pilus-specific** circulating antibody are required for adequate diffusion into the epidermis and protection against the disease. In groups of sheep, resistance is associated with the acquisition of flock mean agglutination titers of greater than 5000; there is a positive correlation between antibody titer and foot rot resistance in the first few months following vaccination. Immunity can be passively transferred with gammaglobulins from immunized sheep to naive recipients and from vaccinated ewes to their lambs via colostrum to provide protection for the first 8 weeks of life.[24,25]

Vaccines must contain adjuvants for an adequate antibody response and vaccination with oil-adjuvant vaccines is accompanied by significant **local reaction**, including local swelling at the injection site and abscessation in a proportion of animals.[50] This reaction is more severe in British breeds of sheep than in Merinos. In milk goats and sheep, vaccination can result in a significant drop in milk production. The potential gains from vaccination need to be weighed against this effect in a decision to use vaccination as a method of control rather than other control procedures.

Commercial vaccines have contained up to 10 strains of *D. nodosus* representative of the most common serogroups associated with foot rot. The extent to which these vaccines will give protection or will promote earlier cure depends upon the relationship of the vaccine pilus types to those associated with the foot rot problem. Vaccine failure is generally attributable to the occurrence of foot rot associated with strains of the organism not present in the vaccine or to which there is no cross-protection, and to individual animal variation in response.[1,25,51,52] However, more recently it is recognized that there is a limitation to the number of strains that can be incorporated in current vaccines due to antigenic competition.[51,53] Mixing different *D. nodosus* fimbriae in vaccines may lead to inadequate host responses to individual antigens and an alternative approach is to identify *D. nodosus* strains present in a given geographical region enabling the development of optimized and localized strain(s)-specific vaccines.[5,54]

Field trials have shown a wide variation in the therapeutic effect of vaccination with a reduction in foot rot incidence varying from 27–54% in sheep where there was no routine foot care to 69–91% in flocks in which vaccination was coupled with routine foot care such as trimming and footbathing.[12,25,53,55] The effect is to reduce both the incidence, severity, and duration of the infection. The improvement seems to be due to accelerated healing of the lesions with some protection against reinfection. For an optimum effect, two vaccinations are required and the duration of this effect depends upon the adjuvant and the breed of sheep. Even so the duration of the protection is limited to 4–12 weeks in most studies. It can be very effective in control when coupled with a culling policy of sheep that remain clinically infected.[54]

Whereas vaccination is of value for control of an existing flock infection, it may not be economic to use vaccination as a strategy to prevent infection of a foot rot-free flock.[25,55] The use of foot rot vaccines may be prohibited in areas where there are foot rot eradication programs.

Summary of control procedures in infected flocks

The objective of foot rot control in an infected flock is to maintain the prevalence of disease at a low level by reducing the incidence of new infections, to prevent the development of the debilitating and painful underrunning lesions of advanced foot rot, and to achieve this with strategies that are based on whole-flock control with minimal need for individual handling of individual animals. This approach is most likely to be adopted by sheep owners.[56] Routine footbathing, especially during transmission periods, coupled with vaccination can achieve this and sheep that are affected with severe underrunning are treated with parenterally administered antibiotics or culled.

Genetic selection

Whereas there are breed effects on susceptibility and an apparent high heritability coefficient for resistance,[13,14] genetic selection for resistance has not advanced sufficiently to be used practically in control programs. Resistance can be determined by direct challenge of a candidate ram.[14] Antibody response to vaccination cannot be used as a surrogate.

ERADICATION

Eradication of **virulent** foot rot is a desirable but not always feasible objective but it can be accomplished in climates where the transmission periods are short. Where rainfall is heavy and the ground moist most of the year, much greater difficulty may be encountered. Area eradication of virulent foot rot is a much more daunting task but is proceeding satisfactorily in several regions in Australia. Eradication of **benign** foot rot is not justified economically, nor is it possible with current knowledge as benign foot rot strains can be carried in the interdigital skin of asymptomatic sheep.[8,9]

Eradication programs are based on the following facts:

1. *D. nodosus* persists in the flock in infected feet
2. Infection in the foot can be detected and the infected sheep cured or culled
3. The organism does not persist in pasture for long periods and does not transmit in dry periods.

Fields kept free of sheep for 14 d can be considered free of infection. If all infected animals are culled or cured and infection removed from the pasture, eradication is achieved. Eradication of the disease should be undertaken during a dry summer season, but active measures must be taken to reduce the incidence of infection and spread during the transmission period in the preceding spring. Vaccination and footbathing may be part of this strategy.

In the eradication phase in the non-transmission period, all feet of sheep are examined and affected or suspicious sheep are segregated. When examinations are carried out during dry weather, the feet are likely to be hard and the disease at a quiescent stage. In such circumstances minor lesions may be missed, necessitating an extremely careful trimming and examination of all feet. Clean sheep are run through a foot bath (5% formalin or 10% zinc sulfate) and put into fresh fields, while the affected are isolated and treated with antibiotics and/or footbathing with one of the preparations described earlier. Footbathing treatments must be repeated weekly. Sheep that do not respond may be treated intensively, for example two 1-hour soaks in 10% zinc sulfate,[30] but preferably should be culled. In areas where flocks are small and there are insufficient fields to carry out this program completely, it has been found to be sufficient to treat all affected sheep weekly but to put all affected sheep back in the flock and the flock back onto the infective pasture, providing conditions are dry. Eradication of virulent foot rot from sheep and goats in an area of Nepal by a combination of treatment with parenteral antibiotics and a type-specific vaccine, routine vaccination with the type-specific vaccine and culling of non-responders is reported.[54]

Culling is an important strategy in foot rot eradication and if the number of infected sheep is small, immediate culling may be the most economic strategy. Culling can be an important strategy in the eradication of disease associated with moderately virulent strains if it is conducted in the climate periods of low transmission.[58]

Introduced sheep

Most breakdowns in eradication occur because of inefficient examination and treatment or the introduction of affected sheep without first insuring that they are free from the disease. Introduced sheep should be run as a separate group from the main flock until they have been proven to be foot rot-free in a climatic transmission period. Similar isolation of introduced sheep should also be practiced in flocks free of the disease. It should also be a management practice in flocks that have disease to minimize the risk of introduction of different strains of the organism.

FOOT ABSCESS IN SHEEP

Foot abscess includes two diseases: heel abscess and toe abscess, which will be discussed in turn.[1]

HEEL ABSCESS/INFECTIOUS BULBAR NECROSIS

Heel abscess is a sequel to damage to the interdigital skin. This damage may result from physical damage from sharp stones or stubble, or friction in the area produced by overgrown feet, but most commonly results as an extension from **ovine interdigital dermatitis** into the soft tissues of the heel and is associated with *Fusiformis necrophorum* and *Arcanobacterium* (*Actinomyces*; *Corynebacterium*) *pyogenes*.[2] In interdigital dermatitis, the organisms can invade deep into the interdigital skin. The joint capsule of the distal interphalangeal joint is extremely vulnerable to invasion on the axial interdigital area and this leads to abscessation.

Most flocks experience cases of heel abscess but the yearly incidence is usually less than 1%. Heel abscess occurs mainly during very wet seasons as does foot rot but the former is limited largely to adult sheep, especially ewes heavy in lamb, and rams. Interdigital dermatitis and heel abscess are frequently present in the flock at the same time. An increased prevalence in a flock of young rams may be due to close flocking and to increased muddying of pasture due to this high concentration of livestock.[1] Usually only one foot and one claw is involved, although in severe outbreaks all four feet may become affected. Most commonly, the **medial claw** of the **hindfoot** is affected.

In the initial stages the affected digit is hot and painful. There is an acute lameness – the affected sheep holds the foot off the ground while walking. There is swelling and inflammation of the interdigital skin and pain on pressure across the heel. Pressure in this area may result in the

discharge of pus from sinuses in the interdigital space. When the phalangeal joints are involved there is severe swelling at the back of the claw and the infection may extend to break out at one or more points above the coronet with a profuse discharge of pus.

Treatment of heel abscess

The treatment of foot abscess is by surgical drainage, parenteral treatment with sulfonamides or a combination of penicillin and streptomycin and the application of a local bandage. Therapy should be continued for several days. Recovery is not rapid. Because of the frequent involvement of the distal interphalangeal joints[3] with heel abscess, treatment with antibiotics without surgical intervention is unlikely to be successful but some cases heal spontaneously in 6–8 weeks.

TOE ABSCESS

Toe abscess is a lamellar suppuration with purulent underrunning of the horn at the toe. It results from damage to the sole, white line, or wall of the foot and is a common sequel to overgrown feet. Most commonly, it involves a digit on the **front** feet. The affected digit is hot and there is pain on pressure across the sole and toe. There is severe lameness, swelling of the coronet with pain and heat apparent, and usually rupture and purulent discharge at the coronet between the toes. Penetration to deeper structures may also occur.

Treatment of toe abscess

The only treatment of toe abscess is by surgical drainage and the response is rapid. **Toe granuloma** can be a sequel but more commonly toe granuloma is a response to overzealous foot paring.[4]

FOOT ROT IN PIGS (BUSH FOOT)

Foot rot in pigs is similar clinically to foot rot in other species and is included here for this reason, although the cause of the disease appears different and in most instances the disease is more analogous to foot abscess.

ETIOLOGY

The majority of cases appear to result from secondary infection of lesions that are traumatic in origin. The most common traumatic lesions are erosions of the sole and wall of the claw that occur in pigs reared on rough, abrasive flooring. By themselves these lesions do not usually produce lameness, unless they are extensive, but when pigs are also reared in dirty conditions, infection and subsequent lameness may occur.

Foot lesions are common in pigs of all ages[1,2] and bruising of the sole–heel junction, one of the earliest lesions observed can be seen in piglets less than 24 hours old. If the bruising is severe and further trauma is not prevented necrosis will follow quickly in the feet.[3,4] These studies have suggested that the cause may be a combination of factors including trauma, contact dermatitis, and subsequent infection. Wet conditions underfoot may cause maceration of the horn and exacerbate the abrasive effect of the flooring. Foot abscess in neonatal pigs is associated with being reared on woven-wire floors.[5,6] Dietary deficiency, especially biotin deficiency, may also result in foot lesions that predispose to secondary infection.

Fusiformis necrophorum, *Arcanobacterium* (*Corynebacterium*) *pyogenes*, staphylococci and an unidentified spirochete have been isolated from affected feet. In an outbreak of the disease on a semi-extensive pig farm, *Dichelobacter nodosus* and other anaerobic bacteria including *Prevotella*, *Peptostreptococcus*, *Fusobacterium*, *Porphyromomonas*, *Bacteroides*, and *Eubacterium* have also been isolated from affected feet.[7]

EPIDEMIOLOGY

The disease has been reported from several countries and is probably universal in occurrence. A study of the prevalence and distribution of foot lesions in finishing pigs in England found that 94% of pigs had at least one foot lesion.[8] The prevalence of the different lesions was: toe erosion (33%); sole erosion (62%); heel erosion (13%); heel flaps (14%); white-line lesions (55%); false sand cracks (24%); and wall separation (11%). The hind feet are more commonly affected than the front feet, and on each foot the lateral digits were significantly more frequently affected than the medial digits. Sole erosions, heel flaps, wall separation, and false sand cracks were observed more frequently on the lateral than the medial digit.

Erosive lesions on the foot are common and have been reported at an incidence as high as 65%. They have been reproduced experimentally and the nature of the flooring has a marked influence on claw wear in pigs. Recently poured alkaline concrete and poorly laid concrete with constituents leading to a rough abrasive surface lead to a high incidence. A slope inadequate to allow proper drainage may also be an important predisposing factor. All ages of pigs are susceptible, but clinical lameness is uncommon. In individual herds where the unfavorable predisposing factors prevail, a high incidence of infection and clinical lameness can occur. The disease may cause reproductive inefficiency due to reluctance to stand or mount for mating.

PATHOGENESIS

Perforation of the horn leads to infection of the sensitive laminae. The infection may track up the sensitive laminae to the coronary band and discharge to the exterior. Elastolytic activity is a virulence factor involved in the pathogenesis of foot rot in pigs associated with *Dichelobacter nodosus* and *Prevotella melaninogenica*.[7]

CLINICAL FINDINGS

Where the disease is due to abrasion of the horn by rough concrete surfaces, a number of characteristic lesions occur, including:

1. Erosion of the sole at either the toe or the heel
2. Bruising of the sole with hemorrhagic streaks in the horn
3. Separation of the hard horny wall from the heel or sole to produce a fissure at the white line, or
4. A false sand crack in the posterior third of the lateral wall of the claw.

In the majority of cases these do not produce lameness nor do they have any apparent effect on productivity. However, when they are extensive or where infection has occurred severe lameness is apparent. In most cases only the lateral digit of one foot is affected. Heat and obvious pain with only moderate pressure being applied to the affected claw are constant findings. Necrosis extends up between the sole and sensitive laminae and may discharge at the coronet, causing the development of a granulomatous lesion, or it may extend to deeper structures of the foot with multiple sinuses discharging to the exterior. A minimal amount of purulent material is present. Productivity is affected with this type of lesion. With deeply infected feet the recovery rate is only fair with treatment. A permanently deformed foot may result and destruction of the pig may be necessary in severe cases. Secondary abscessation in other parts of the body is an occasional sequel and may result in partial carcass condemnation.

Foot abscesses in neonatal pigs are characterized by necrotic pododermatitis, severe osteomyelitis, arthritis, and tenosynovitis.[6] The primary sites of injury are located at either[5] the point of the toe at the white line,[6] the bulb of the heel[7], or the haired skin around the coronet, including the interdigital area. The least severe lesions are superficial abrasions or ulcerations of the hoof wall, heel bulb, or interphalangeal skin, with only minimal inflammatory changes in deeper tissues. The most severely affected digits have focal superficial abscesses, or deep, diffuse,

purulent inflammation and fibrosis around tendons, joints, and bones.[6] The hind limbs are more commonly affected than the forelimbs, and in the hind limbs the medial claws are most likely to have lesions, whereas in the forelimbs the lateral claws are more likely to be affected. Approximately 6% of piglets develop foot abscess prior to weaning. About one-third of litters may be affected and most litters have only one or two affected pigs. Discharge of pus from the coronary band is common and the horny claw may slough, leaving sensitive laminae of one or more claws or accessory digits exposed. Skin necrosis may be present over the carpi, the fetlocks, hocks, coronary bands, and elbows in about 75% of pigs during the first week of life.

CLINICAL PATHOLOGY

Bacteriological examination of discharges from the lesions may aid in deciding the treatment to be used. In foot abscesses of neonatal pigs, bacteria isolated include:

- *Arcanobacterium pyogenes*
- *Staphylococcus* spp.
- Beta-hemolytic *Streptococcus* spp.
- *Actinobacillus* spp.
- *Escherichia coli*.

NECROPSY FINDINGS

Necrosis of the laminar tissue with indications of progression from an infected sole are the usual findings.

DIFFERENTIAL DIAGNOSIS

Most other causes of lameness in pigs are not manifested by foot lesions. In adult pigs housed indoors, an overgrowth of the hoof may occur and be followed by underrunning of the sole, necrosis and the protrusion of granulation tissue causing severe lameness and often persistent recumbency. The general appearance of these feet is not unlike that of canker in horses. Swelling of the hoof is caused by an extensive fibrous tissue reaction. Vesicular exanthema and foot-and-mouth disease are characterized by the presence of vesicular lesions on the coronets and snout.

TREATMENT

There are few published reports of treatment of foot rot in pigs. Broad-spectrum antimicrobials or penicillin given parenterally seems rational and the use of Nuflor was said to be a successful treatment.[9]

CONTROL

Prevention of excessive wear of the feet by the use of adequate bedding and less abrasive flooring in pig pens is suggested as a reasonable control measure. Any existing dietary deficiency should be corrected. Of particular interest is the response to biotin supplementation of the diet of pigs in the prevention of foot lesions of various kinds.

ORAL AND LARYNGEAL NECROBACILLOSIS

Synopsis

Etiology *Fusobacterium necrophorum*
Epidemiology Oral infection principally in calves less than 3 months old. Laryngeal involvement in older animals up to 18 months of age
Clinical findings
Necrotic stomatitis: Fetid breath and necrotic ulceration of mucosa of cheek
Calf diphtheria: Fetid breath. Inspiratory dyspnea, necrotic lesions on arytenoid cartilages
Lesions: Necrosis at site of lesion
Treatment Antimicrobials. Tracheostomy may be required to allow breathing with necrotic laryngitis
Control None specific

The term 'oral necrobacillosis' is applied to infections of the mouth and larynx with *Fusobacterium necrophorum*. It includes **calf diphtheria**, in which the lesions are largely confined to the larynx and pharynx, and **necrotic stomatitis**, in which the lesions are restricted to the oral cavity. They are considered together because the essential lesion and infection are the same in both instances.

ETIOLOGY

F. necrophorum is present in large numbers in the lesions and is considered to be the causative agent, probably aided by prior injury to the mucosa. In the case of the laryngeal disease, the point of entry is thought to be contact ulcers in the mucosa caused by repeated closure of the larynx.[1] Both *F. necrophorum* subsp. *necrophorum* (biovar/biotype A) and *F. necrophorum* subsp. *funduliforme* (biovar/biotype B) are associated with the disease.

EPIDEMIOLOGY

Occurrence

The disease has no geographical limitations but is more common in countries where animals are housed in winter or maintained in feedlots. In the United States, infections involving the pharynx and larynx appear to be more prevalent in the western states than in other sections of the country. It is a common disease in feedlots in yearling cattle, often in company with papillomatosis of the larynx.[1]

There is also a difference in age incidence, necrotic stomatitis occurring mainly in calves 2 weeks to 3 months of age, while laryngeal infections commonly affect older calves and yearlings. Although the disease is more common in housed or penned animals, it can occur in animals running at pasture.[2–4]

The disease is seen commonly only in cattle but has been observed in sheep and goats.[5,6] Laryngeal chondritis has been described in Texel sheep, which may be predisposed to the disease because of anatomical factors, namely the short head of the breed.[7] This may affect the shape of the larynx or its relationship to adjacent tissues.

Transmission

The causative bacterium is a common inhabitant of the environment of cattle and under unsanitary conditions the infection may be spread on dirty milk pails and feeding troughs. Entry through the mucosa is probably effected through abrasions caused by rough feed and erupting teeth. The difficulty of reproducing the disease and the irregularity of its occurrence, even when *F. necrophorum* is known to be present, suggests the possibility of etiological factors presently unknown.

Risk factors

Animals suffering from intercurrent disease or nutritional deficiency are most susceptible and the incidence is highest in groups kept in confined quarters under unsanitary conditions.

PATHOGENESIS

F. necrophorum is a normal inhabitant of the oral cavity and causes inflammation and necrosis following injury of the mucosa of the oral cavity, pharynx, and larynx. Edema and inflammation of the mucosa of the larynx results in varying degrees of closure of the rima glottidis and inspiratory dyspnea and stridor. The presence of the lesion causes discomfort, painful swallowing and toxemia. Extension of the lesion to the arytenoid cartilages will result in laryngeal chondritis.[7] Involvement of the cartilage will usually result in delayed healing or failure to recover completely.

CLINICAL FINDINGS

In describing the clinical findings, a distinction must be made between calf diphtheria characterized by involvement of the larynx and the more common necrotic stomatitis. In the former, a moist painful cough accompanied by severe inspiratory dyspnea, salivation, painful swallowing movements, complete anorexia, and severe depression are the characteristic signs. The temperature is high

(41°C; 106°F), the pharyngeal region may be swollen and painful on external palpation, and there is salivation and nasal discharge. The breath has a most foul rancid smell.

Examination of the pharynx and larynx by visual inspection through the oral cavity with the aid of a speculum positioned over the base of the tongue will often reveal the lesions. Visual inspection of the larynx is relatively easy and simple with the aid of a cylindrical plastic speculum placed over the base of the tongue in calves and adult cattle. The larynx can be viewed directly and illuminated with a strong source of light. A flexible fiberoptiscope is also useful when available and is necessary for examination of the equine larynx. The mucosa of the larynx and glottis are usually edematous, inflamed and a necrotic lesion is usually present and visible on one or both arytenoid cartilages. The opening of the larynx is commonly reduced due to the edema and inflammation. Careful visual inspection of the larynx during inspiration may reveal that the lesion extends into one or both vocal cords. The examination usually causes considerable discomfort, anxiety and the production of purulent or blood-stained saliva.

Death is likely to occur from toxemia or obstruction to the respiratory passages on days 2–7. Most affected calves die without treatment but only a small proportion of calves in a group are usually affected. Spread to the lungs may cause a severe, suppurative bronchopneumonia.

In calves affected with necrotic stomatitis, there is usually a moderate increase in temperature (39.5–40°C; 103–104°F), depression, and anorexia. The breath is foul and saliva, often mixed with straw, hangs from the mouth. A characteristic swelling of the cheeks may be observed posterior to the lip commissures. On opening the mouth this is found to be due to a deep ulcer in the mucosa of the cheek. The ulcer is usually filled with a mixture of necrotic material and food particles. An ulcer may also be present on the adjacent side of the tongue and cause severe swelling and protrusion of the tongue. In severe cases the lesions may spread to the tissues of the face and throat and into the orbital cavity. Similar lesions may be present on the vulva and around the coronets, and a spread to the lungs may cause fatal pneumonia. In other cases death appears to be due to toxemia.

CLINICAL PATHOLOGY

Bacteriological examination of swabs from lesions may assist in confirming the diagnosis.

Necropsy findings

Severe swelling, due to edema and inflammation of the tissues surrounding the ulcer, is accompanied by the presence of large masses of caseous material. Occasionally, lesions similar to those in the mouth, pharynx, and larynx may be found in the lungs and in the abomasum. Microscopically, areas of coagulation necrosis are bordered by large numbers of neutrophils and filamentous bacteria.

Samples for confirmation of diagnosis

- **Bacteriology** – anaerobic culture swab from deep within lesion (ANAEROBIC CULT)
- **Histology** – formalin-fixed sample of interface between ulcer site and normal tissue (LM).

DIFFERENTIAL DIAGNOSIS

Necrotic laryngitis is characterized by inspiratory dyspnea and stridor, toxemia, fever, edema, (inflammation) and necrotic lesions of the laryngeal mucosa.

- **Neoplasms of the larynx** – occur only rarely, usually in mature cattle, and cause chronic inspiratory dyspnea
- **Traumatic pharyngitis** – may resemble laryngitis but the lesions are obvious on visual inspection of the pharynx. In chronic cases of traumatic pharyngitis there may be peri-esophageal cavities containing rumen contents
- **Foreign bodies** – i.e. pieces of wire and small wooden sticks may become lodged in the mucosa of the arytenoid cartilages and cause clinical signs similar to necrotic laryngitis.

TREATMENT

The lesions of necrotic stomatitis will usually heal in a few days following debridement of the ulcers, application of a solution of tincture of iodine, and oral administration of sulfamethazine at a dose of 150 mg/kg BW daily for 3–5 d where this is labeled for use in food animals, or parenteral penicillin or broad-spectrum antimicrobials. Therapy should be at least for 5 days and therapy for up to 3 weeks may be necessary.

Successful treatment of necrotic laryngitis is dependent on early recognition and prompt therapy with antimicrobials daily for several days. Corticosteroids may be a beneficial adjunctive therapy, especially to reduce the edema. Tracheostomy may be necessary in some cases to relieve dyspnea. Failure to respond is usually associated with chronic suppurative chondritis, which requires subtotal arytenoidectomy.

CONTROL

Proper hygienic precautions in calf pens or feeding and drinking places together with avoidance of rough feed should prevent the spread of the disease. When the incidence is high prophylactic antibiotic feeding may keep the disease in check.

NECROTIC RHINITIS (BULLNOSE; PARANASAL ABSCESSATION)

Necrotic rhinitis is often confused with atrophic rhinitis. It occurs in young growing pigs and may occur in herds where atrophic rhinitis is present and even in the same pig, but there appears to be no relationship between the two diseases. There are a variety of other conditions of the face of the young pig that can be confused.[1] The common occurrence of *Fusobacterium necrophorum* in the lesions suggests that any injury to the face or nasal or oral cavities may lead to bacterial invasion, especially if the environment is dirty and heavily contaminated.[2] The incidence of the disease has diminished in recent years, due probably to a general improvement in hygiene in piggeries but possibly also to the declining occurrence of progressive atrophic rhinitis following vaccination and eradication of *P. multocida* toxigenic type D.

The lesions develop as a necrotic cellulitis of the soft tissues of the nose and face but may spread to involve bone and produce osteomyelitis. Local swelling is obvious and extensive lesions may interfere with respiration and mastication. Depression of food intake and toxemia result in poor growth and some deaths. Treatment by the local application of antibacterial drugs and the oral administration of sulfonamides is satisfactory in early cases. Oral dosing with sulfadimidine has been effective in young pigs.[3] Improvement of sanitation, elimination of injuries and disinfection of pens usually result in a reduction of incidence.

The disease differs from atrophic rhinitis by the presence of oral and facial lesions. Necrotic ulcer in pigs may involve the mouth and face but the lesions are erosive rather than necrotic.

Diseases associated with *Pseudomonas* and *Burkholderia* spp.

Pseudomonas aeruginosa is an occasional cause of infection in large animals. In cattle, there are occasional cases of generalized infection with *Pseudomonas aeruginosa*, usually following an attack of mastitis associated with this organism. Systemic invasion in cattle is manifested by fibrinous **pericarditis** and pleurisy and chronic **pyelonephritis**. *Pseudomonas* spp. are an occasional cause of **septicemia in foals, septic arthritis, vegetative endocarditis** in horses[1] and **placentitis** in mares,[2] and is isolated from cases of **pneumonia** in all large animal species. Infection in the urogenital tract is accompanied by infertility.

Outbreaks of **otitis media** in suckling calves and in sheep following dipping have been associated with pseudomonas infections.[3,4] The association of *Pseudomonas* spp. with **fleece rot** in sheep is covered elsewhere.

Pseudomonas spp. are commonly isolated from bacterial **corneal ulcers and keratitis** that develop after trauma to the corneal epithelium in horses[5,6] and the organism promotes rapid liquifaction of corneal stromal proteoglycans. Early cases respond to aggressive topical therapy with tobramycin or gentamicin[5] although there has been a significant increase in the resistance of isolates from ulcerative keratitis in recent years.[7]

Infections with *Pseudomonas* spp. are notoriously difficult to treat. Clinical isolates from animals are usually sensitive to tobramycin, polymyxin B, carbenicillin, and gentamicin.[8]

FLEECE ROT IN SHEEP

Synopsis

Etiology Dermatitis associated with growth of chromogenic *Pseudomonas aeruginosa* following prolonged wetting of the skin of sheep
Epidemiology Occurs with high incidence in sheep with susceptible fleece characters in wet seasons. Major risk factor for body fly strike
Clinical findings Dermatitis with fleece coloration over the backline
Diagnostic confirmation Clinical
Control Selection of sheep with resistant fleece characters

ETIOLOGY

Fleece rot develops as an **exudative dermatitis** following wetting of the fleece by rain. The growth of toxigenic strains of *Pseudomonas aeruginosa* is believed to be the major cause of the dermatitis, and the **fleece coloration** that usually accompanies it, but other *Pseudomonas* spp. including *Ps. maltophilia*, have been incriminated in the genesis of the condition.[1,2] The enzyme phospholipase C in *Ps. aeruginosa* is a virulence determinant for this disease.[3]

EPIDEMIOLOGY

Occurrence

The disease is common in most parts of Australia, occurs in South Africa and also in areas of New Zealand. Its occurrence is associated with **wet years** and in these circumstances the incidence in affected flocks varies from 40–100%.[2,4]

Environmental and host risk factors

Fleece rot occurs in sheep only in wet seasons and when the fleece is predisposed to wetting by its physical characters.

Prolonged rainfall, sufficient to wet sheep to the skin for a week, is required for this condition to occur. Young sheep are more susceptible than old, and **heritable differences in fleece characters** affect the susceptibility of individual sheep. These characters are probably related to the ease with which the skin can be wetted.

Fleece characteristics

The degree of 'grip' and body skin wrinkling are unimportant as factors affecting susceptibility but fleece weight, fiber diameter and variability, staple density and neck wrinkling are positively correlated with susceptibility.[5,6] These characteristics produce visible differences between fleeces. Resistant sheep have closely packed elliptical wool staples with blocky tips and even crimp. **Susceptible fleeces** have thin staples of unevenly crimped wool and with a fringe-tipped appearance due to the protrusion of thicker wool fibers above the top of the staple. This fringed appearance is visible along the back and sides. **Susceptible flocks** are characterized by fleeces with longer, heavier, thicker staples with lower crimp frequency and higher fiber diameter and variability.[6]

Fleeces with a **high wax content** are less susceptible probably because of the waterproofing effect of the wax. This view is supported by the observation that disruption of the sebaceous layer on the skin increases its susceptibility to wetting.[7]

Greasy fleece color has been found a good predictor of susceptibility to fleece rot in some studies[4] but not others.[5] Wool with a high suint content is highly susceptible.[8]

Experimental production

The disease can be reproduced experimentally by inoculating *Ps. aeruginosa* epicutaneously and wetting the fleece.[9]

Economic importance

Fleece rot causes considerable financial loss because of the depreciation in the value of the damaged fleeces. It also is the **major risk factor for body fly strike**.

PATHOGENESIS

With prolonged wetting, the conditions of high humidity in the fleece microenvironment, and the availability of rich nutrients from serous exudates and indigenous suint, allow the proliferation of opportunistic skin and fleece bacteria including *Ps. aeruginosa*, and result in dermatitis. The predominant bacterium is usually *Ps. aeruginosa*,[10] which inhibits the growth of other bacteria and its **pyocyanin** produces a green color. Its rapid growth is accompanied by the production of the **dermonecrotic toxin** phospholipase C, which exacerbates the dermatitis and initiates the inflammatory cascade that draws neutrophils and lymphocytes into the skin.[11]

In the experimental disease there is outpouring of serous exudate and infiltration of leukocytes into dermis but *Ps. aeruginosa* is localized as aggregates at the leading front of the seropurulent exudate and never penetrates the dermis.[12]

Other discolorations may occur depending upon the predominance of a particular **chromogenic bacterium**; many which belong to *Pseudomonas* spp. *Ps. maltophilia* can result in yellow coloration, and *Ps. indigofera*, blue coloration.

The **odor** produced by the bacteria and the serum protein on the skin surface is very attractive to blowflies, and most body strikes are due to pre-existing fleece rot lesions. To add a further complication, *Ps. aeruginosa* also proliferates in the presence of organophosphorus insecticides and facilitates its biodegradation.[13]

CLINICAL FINDINGS

Lesions occur most commonly over the **withers** and **along the back**. In active cases, the wool over the affected part is always saturated and the tip is more open than over unaffected areas. The wool is leached and dingy and in severe cases can be plucked easily. The skin is **inflamed** and serous exudate produces bands of matted and colored fibers across the staple. The **coloration** of the fibers is commonly green, but may be yellow, yellow-brown, or red-brown[1] and occurs

in fibers at skin level or extending the full length of the staple.

The **general health** of the sheep is unaffected in typical fleece rot but severe ulcerative dermatitis with mortality associated with *Ps. aeruginosa* can occur.

A chronic ulcerative and necrotic dermatitis associated with *Ps. aeruginosa*, occurring on the tail, udder, and legs of sheep and accompanied by green coloration of the surrounding fleece is recorded following excessive rain in the Mediterranean climate zone of Israel.[14]

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

Autopsy examinations are not carried out and laboratory examination of the living animal is not usually necessary.

There are differences in the inflammatory response and in peripheral blood lymphocyte subsets between fleece rot-resistant and susceptible sheep.[15,16]

DIAGNOSIS

Fleece rot resembles mycotic dermatitis in body distribution and predisposing factors but the typical scab is not present in fleece rot.

CONTROL

Treatment is unlikely to be of value but some degree of control may be effected by selection of **fleece rot-resistant sheep** for use in susceptible localities. In these same localities, shearing before the wet season should facilitate drying of the fleece and lessen susceptibility. The **heritability** of resistance to fleece rot has been estimated to be between 0.35 and 0.4 and selective breeding programs have been advocated[11] and genetically selected lines show increased resistance in high-risk environments.[17]

Chemical means of drying the living fleece have been shown to reduce wetness, fleece rot and blowfly strike. A mixture of zinc and aluminum oxides with sterols and fatty acids (the mixture identified as B26), applied at the rate of 100–200 mL per sheep as a mist-like simulated rain, caused significant reduction in fleece moisture for 10–12 weeks and this could be extended by further applications. Fleece rot was reduced by 60% and blowfly strike by 75%.

A vaccine containing killed *Ps. aeruginosa* has protected against the severe exudative form of fleece rot[1] and there is hope that a vaccine prepared against highly conserved outer membrane antigens of the organism may give more universal protection.[12]

MELIOIDOSIS

Synopsis

Etiology *Burkholderia pseudomallei.*
Epidemiology Ubiquitous soil saprophyte endemic to Southeast Asia, northern Australia and the South Pacific. Occurs primarily 20° north and south of the equator. Transmission is by inhalation of contaminated dust and cutaneous abrasion. Primarily a disease of sheep and goats and humans, occasional disease in horses and subclinical infection in pigs
Clinical findings Septicemia, weakness recumbency and death in sheep. Septicemia, pneumonia, and lymphangitis in horses
Clinical pathology Culture, serology, allergic skin test
Necropsy findings Abscessation of internal organs
Treatment and control General hygienic procedures. Little specific information available

ETIOLOGY

Burkholderia pseudomallei (*Pseudomonas pseudomallei, Malleomyces pseudomallei*) is the sole cause. There is considerable genetic variability and strains vary in pathogenicity.[1]

EPIDEMIOLOGY

Occurrence

The disease occurs almost exclusively in tropical countries 20° north and south of the equator and is endemic in South East Asia, Asia, and northern and sub-northern areas of Australia. Disease occurs in rodents, rabbits, pigeons, humans, animals in zoological gardens, dogs, cats, horses, pigs, sheep, goats, alpacas, and camels but rarely in cattle.[2,3] In domestic animals the disease has occurred in outbreak form in pigs, goats, and sheep in Australia,[3,4] in the Caribbean area and in Cambodia, in horses in Malaysia and Iran, in pigs and cattle in Papua New Guinea and Australia, in horses in France in 1976–1978[5] and in cattle in Argentina.[6]

Source and methods of transmission

In endemic areas the organism is a ubiquitous soil saprophyte and is present in moist soil and waterholes which are the primary reservoirs from which most infections are acquired. A variety of free-living amoebae including *Acanthamoeba* and *Hartmannella* spp. are potential hosts to *B. pseudomallei*.[7,8] The majority of cases in livestock are associated with the 'wet season' and exposure to surface water and mud. Infection occurs through inhalation, ingestion, in association with skin wounds via contaminated dust particles or water or by insect bites. Infected animals pass the organism in their feces and the disease in rodents runs a protracted course, making these animals important reservoirs of infection.

Pathogen risk factors

B. pseudomallei can survive in water at room temperature for up to 8 weeks, in muddy water for up to 7 months, and in soil in the laboratory for up to 30 months.[9] The organism can survive in contaminated injectable drugs and has ability to survive for some time in cetrimide 3% and chlorhexidine 0.3% solution.[3] Varying degrees of virulence are observed in different strains of the organism but starvation or other conditions of stress appear to increase the susceptibility of experimental animals to infection.

Experimental production

The disease can be produced experimentally in goats, sheep, rats, mice, hamsters, and pigs.[10]

Zoonotic implications

Humans are at risk for infection within endemic areas and while this can be zoonotic it can also occur without direct animal contact through inhalation. The disease of humans presents with various clinical pictures ranging from asymptomatic state, localized infection such as pneumonia, to acute fatal septicemia.[11]

Veterinarians and animal owners are at risk from localized or generalized infection from infected animals. Pregnant women handling goats aborting with this infection have risk for infection and abortion.[3] Infected areas are often rural in nature and pasteurization of commercially sold milk should be ensured as should condemnation of infected carcasses at abattoirs.

Pathogenesis

There is initial bacteremia or septicemia and subsequent localization in various organs. Experimentally induced melioidosis in goats is characterized by septicemia with undulating fever, wasting, anorexia, hindlimb paresis, mastitis, and abortion. Necropsy lesions include widely scattered microabscesses after intraperitoneal

injection, and a chronic disease with abscesses in the lungs and spleen when the infection is administered subcutaneously.[12] In pigs experimental infection results in a generalized chronic infection.[10]

CLINICAL FINDINGS

Sheep

Signs consist mainly of weakness, respiratory disease and recumbency with death occurring in 1–7 d. In experimentally infected sheep, a severe febrile reaction occurs and is accompanied by anorexia, lameness and a thick, yellow exudate from the nose and eyes. Some animals show evidence of central nervous system involvement including abnormal gait, deviation of the head and walking in circles, nystagmus, blindness, hyperesthesia, and mild tetanic convulsions. The disease is usually fatal. Skin involvement is not recorded.

Goats

The syndrome may resemble the acute form as seen in sheep, but more commonly runs a chronic course with abscessation.[13] Mastitis is common in infected goats; one study finding mammary infection in 35% of infected goats.[3]

Pigs

Disease is usually chronic and manifested by cervical lymphadenitis, but in some outbreaks there are signs similar to those in other species. In such outbreaks slight posterior paresis, mild fever, coughing, nasal and ocular discharge, anorexia, abortion, and some deaths may occur.

Horses

The syndrome is one of an acute metastatic pneumonia with high fever and a short course. Cough and nasal discharge are minimal and there is a lack of response to treatment with most drugs. Other signs in horses include colic, diarrhea, and lymphangitis of the legs. Subacute cases become debilitated, emaciated, and develop edema.[5] Affected horses may survive for several months. A case of acute meningoencephalitis is described in a horse. The onset was sudden and manifest with violent convulsions.[14]

CLINICAL PATHOLOGY

The organism is easily cultured and may be isolated from nasal discharges. Injection into guinea pigs and rabbits produces the typical disease. An allergic skin test using melioidin as an antigen,[5] a complement fixation test (CFT), and an indirect hemagglutination (IHA) test are available. The IHA test is recommended for screening and the CFT for confirmation in cases of active melioidosis in goats[15] and pigs.[16] Affected horses may give a positive reaction to the mallein test.[17]

NECROPSY

Multiple abscesses in most organs, particularly in the lungs, spleen, and liver, but also in the subcutis and the associated lymph nodes, are characteristic of the disease in all species. In sheep respiratory infection is common and these abscesses in the lung contain thick or caseous, green-tinged pus similar to that found in *Corynebacterium pseudotuberculosis* lesions. Lesions in the nasal mucosa proceed to rupture with the development of ragged ulcers. An acute polyarthritis, with distension of the joint capsules by fluid containing large masses of greenish pus and acute meningoencephalitis have been observed in experimental cases.

A high incidence of lesions in the aorta of goats is reported in Australia. Nine out of 43 (21%) goats had aortic lesions at autopsy. Seven of these goats died as a result of a ruptured aortic aneurysm.[3]

DIAGNOSTIC CONFIRMATION

Culture of organism.

DIFFERENTIAL DIAGNOSIS

Sheep
- Caseous lymphadenitis
- Actinobacillosis.

Horses
- Glanders
- Strangles.

Pigs
- Tuberculosis.

TREATMENT

Treatment is unlikely to be undertaken in farm animals because of the nature of the disease and the risk of exposure to humans. Little information is available on satisfactory treatments of melioidosis in farm animals but recommendations for man are available.[18] Penicillin, streptomycin, chlortetracycline, and polymyxin are ineffective but *in vitro* tests suggest that oxytetracycline, novobiocin, chloramphenicol, and sulfadiazine are most likely to be valuable, with oxytetracycline the preferred drug. In horses chloromycetin has been shown to be an effective treatment.[5]

CONTROL

Prevention involves removing animals from the contaminating source. Water supplies can be chlorinated. This and the elimination of infected animals and the disinfection of premises should be the basis of control procedures. Housed animals can be removed from soil by raising them from the ground on wooden slats, concrete or paved floors.

GLANDERS

Synopsis

Etiology *Burkholderia mallei*
Epidemiology Contagious disease of solipeds
Clinical findings Acute or chronic form, and characterized by pneumonia and nodules or ulcers in the respiratory tract and on the skin. The disease is highly fatal
Clinical pathology Complement fixation test, mallein test, isolation of organism
Necropsy findings Extensive bronchopneumonia in acute cases. Miliary nodules in internal organs and ulcerated nodules in skin and respiratory tract
Treatment and control No effective treatment. Control is by slaughter of clinically affected and carrier animals detected by serological or mallein tests

ETIOLOGY

Burkholderia (*Pseudomonas*) *mallei* is the causative organism. It has close genetic and antigenic relatedness to *Burkholderia pseudomallei*.[1,2] Isolates of *B. mallei*, recovered from three continents over a period of 30 years have identical allelic profiles.[1]

EPIDEMIOLOGY

Geographical occurrence

Glanders is restricted geographically to Eastern Europe, Asia Minor, Asia, and North Africa. It was more widespread but has been **eradicated** from most countries.[3] Glanders was an important disease when there were large concentrations of horses in cities and armies, but now has sporadic occurrence, even in infected areas.

Host occurrence

Horses, mules, and donkeys are the species usually affected. Humans are susceptible and the infection is usually fatal. Carnivores, including lions may be infected by eating infected meat and infections have been observed in sheep and goats.

Source of infection and transmission

B. mallei is an obligate parasite and is readily destroyed by light, heat, and the usual disinfectants and is unlikely to survive in a contaminated environment for more than 6 weeks.

Infected animals or **carriers** that have made an **apparent recovery** from the disease are the important sources of infection. **Chronic nodular lung lesions**, which have ruptured into the bronchi, infect upper airway passages and nasal or oral secretions. Spread to other animals occurs mostly by **ingestion**, the infection spreading on fodder and utensils, particularly **communal watering troughs**, contaminated by nasal discharge or sputum. Rarely the cutaneous form appears to arise through contamination of skin abrasions by direct contact or from harness or grooming tools. Spread by inhalation can also occur but this mode of infection is probably rare under natural conditions.

Experimental reproduction

An experimental model for disease has been reproduced by intratracheal inoculation of horses with cultures of *B. mallei*.[4] Horses showed fever within 24 to 48 hours of challenge followed by the progressive development of signs of respiratory distress with epistaxis and purulent nasal and ocular discharge. On post-mortem there was lymphadenopathy, ulcerative lesions in the nasal septa and pneumonia.

Host and pathogen risk factors

Horses tend to develop the chronic form, **mules and donkeys** the acute form, but all types of equid and all ages are susceptible. The disease is more likely when animals are in a **stressed state** from heavy work and animals that are poorly fed and kept in a poor environment are more susceptible.

The stress associated with movement of a large number of horses can precipitate an outbreak with high mortality rates. In the few animals that recover, there is a long convalescence with the frequent development of the '**carrier**' state. Animals rarely make a complete recovery.

Economic importance

The disease has little current economic importance, although the threat of horse movement reintroducing glanders into countries that have eradicated it is a concern.[5]

Zoonotic implications

While humans are not highly susceptible, the infection may gain access through skin abrasions to produce granulomatous disease and pyemia. Infection can also occur from inhalation of infectious material. The case fatality is high. Horse handlers in general are at risk and veterinarians conducting postmortem examinations without proper precautions are at particular risk. The organism is identified as a possible agent of bioterrorism.

PATHOGENESIS

Invasion occurs mostly through the intestinal wall and a septicemia (acute form) or bacteremia (chronic form) is set up. Localization always occurs in the lungs but the skin and nasal mucosa are also common sites. Other viscera may become the site of the typical nodules. Terminal signs are in the main those of bronchopneumonia, and deaths in typical cases are caused by anoxic anoxia.

CLINICAL FINDINGS

Acute disease

There is a high fever, cough, and nasal discharge with rapidly spreading ulcers appearing on the nasal mucosa, and nodules on the skin of the lower limbs or abdomen. Death due to septicemia occurs in a few days.

Chronic disease

Three major manifestations are described:

1. Pulmonary
2. Skin
3. Nasal, although the chronic nasal and skin forms commonly occur together.

Pulmonary form of disease

The **pulmonary** form manifests as a chronic pneumonia with cough, frequent epistaxis, and labored respiration.

Nasal form of disease

In the **nasal form**, lesions appear on the lower parts of the **turbinates** and the cartilaginous **nasal septum**. They commence as nodules (1 cm in diameter), which ulcerate and may become confluent. In the early stages there is a serous nasal discharge which may be unilateral and which later becomes purulent and blood stained. Enlargement of the submaxillary lymph nodes is a common accompaniment. On healing, the ulcers are replaced by a characteristic **stellate scar**.

Skin form of disease

The **skin** form is characterized by the appearance of subcutaneous nodules (1–2 cm in diameter), which soon **ulcerate** and discharge pus of the color and consistency of dark honey. In some cases the lesions are more deeply situated and discharge through fistulous tracts. Thickened **fibrous lymph vessels** radiate from the lesions and connect one to the other. Lymph nodes draining the area become involved and may discharge to the exterior. The predilection site for cutaneous lesions is the medial aspect of the hock, but they can occur on any part of the body.

Animals affected with the chronic form are usually ill for **several months**, frequently showing improvement but eventually either dying or making an apparent recovery to persist as occult cases.

CLINICAL PATHOLOGY

Disease is accompanied by a low hemoglobin content of the blood, a low erythrocyte count and packed cell volume, and a moderate leukocytosis and neutrophilia. The principal tests used in the diagnosis of glanders are the mallein test, the complement fixation test on serum, and demonstration of the organism.

Mallein test

The intradermopalpebral test has largely displaced the ophthalmic and SC tests. Mallein (0.1 mL) is injected intradermally into the **lower eyelid** with a tuberculin syringe. The test is read at 48 h, a positive reaction comprising marked edema of the lid with blepharospasm and a severe, purulent conjunctivitis.[5] Some infected animals exhibit a general hypersensitivity reaction after inoculation.

Serological tests

The CFT is the most accurate of the serological tests available, and the usual official test, but some strains of *B. mallei* give cross-reactions with *B. pseudomallei*. Other tests used are an indirect hemagglutination test using mallein as the antigen[6] and the conglutinin complement absorption test.[7] The accuracy of the complement fixation test may be improved by the simultaneous testing with the indirect hemagglutination test. CFT may be unsuitable in mules and asses because of anticomplement activity. A dot enzyme-linked immunosorbent assay (ELISA) test has been developed that is suitable for use in all soliped species.[8] It is reported to have high sensitivity and can be used as a field test without specialized equipment. All serological tests may be inaccurate for periods up to 6 weeks following the mallein test.

Demonstration of organism

If pus is available, from either open ulcers or necropsy material, the organism can be **cultured** or the pus injected intraperitoneally into male guinea pigs to attempt to elicit the **Strauss reaction**. This is a severe orchitis and inflammation of the scrotal sac but it is not highly specific for *B. mallei*.

Gene sequencing can be used for rapid identification and differentiation from *B. pseudomallei*.[9]

NECROPSY FINDINGS

In the **acute** form there are multiple petechial hemorrhages throughout the body and a severe catarrhal bronchopneumonia with enlargement of the bronchial lymph nodes.

In the more common **chronic** form, the lesions in the lungs take the form of **miliary nodules**, similar to those of miliary tuberculosis, scattered throughout the lung tissue. **Ulcers** are present on the mucosa of the **upper respiratory tract**, especially the nasal mucosa and to a lesser extent that of the larynx, trachea, and bronchi.[10] Nodules and ulcers may be present in the **skin and subcutis** of the limbs, which may be greatly enlarged. Local lymph nodes receiving drainage from affected parts usually contain foci of pus and the lymphatic vessels have similar lesions. Necrotic foci may also be present in other internal organs. *B. mallei*, and sometimes *Arcanobacterium pyogenes*, are isolated from infected tissues, and this is main means of confirmation of diagnosis at necropsy.

DIAGNOSTIC CONFIRMATION

In live animals that could be carriers, the complement fixation test is used as the official test in most countries. The mallein test is used in those horses whose sera is anticomplementary.

DIFFERENTIAL DIAGNOSIS

- Epizootic lymphangitis
- Ulcerative lymphangitis
- Sporotrichosis
- Melioidosis
- Other causes of pneumonia.

TREATMENT

There is little information on treatment. However, it is unlikely that treatment would be an option in most countries. Penicillin and streptomycin have no detectable effect on the progress of the disease but sodium sulfadiazine has been highly effective in the treatment of experimental glanders and melioidosis in hamsters. Treatment for a period of 20 d was necessary to effect 100% recovery. Combinations of a formalized preparation of *B. mallei* and sulfadiazine, or mallein and sulfadimidine, are reported to be effective in the treatment of affected horses.

CONTROL

Although clinical and serological recovery from glanders occurs occasionally, recovered animals are not solidly immune and attempts to produce artificial immunity have been uniformly unsuccessful.

Complete quarantine of affected premises is necessary. Clinical cases should be destroyed and the remainder subjected to the mallein test at intervals of 3 weeks until all reactors have been removed. A vigorous disinfection program for food and water troughs and premises generally should be instituted to prevent spread while eradication is being carried out. Restriction of the movement of horses should be instituted and the mallein test carried out in horses which may have had contact with the infected group.[11]

Diseases associated with *Campylobacter* and *Lawsonia* spp.

ETIOLOGY

Several species of the genus *Campylobacter* are known to cause disease in farm animals; some are potentially zoonotic and the role of some is uncertain. *Campylobacter fetus* var. *venerealis* is the cause of infertility and abortion in cattle and the reader is referred to a textbook in theriogenology for more details. *C. fetus* subsp. *fetus* causes sporadic abortion in cattle and enzootic abortion in sheep and has been associated with bacteremia in man.[1] The organism has also been isolated from the intestines of healthy sheep and cattle and from enteric lesions in cattle with enteritis, but its significance as the causative agent is uncertain.

EPIDEMIOLOGY

Prevalence of infection

Campylobacter jejuni* and *Campylobacter coli can be isolated from the intestines of healthy farm animals, poultry, pets, zoo animals, and wild birds.[2] *C. jejuni* and *C. hyointestinalis* can be found in the rumens and intestines of normal adult cattle and calves. *C. jejuni* and *C. coli* were isolated from rectal swabs of dairy cows in New Zealand where the prevalence was 24%, 31%, and 12% in the summer, autumn, and winter, respectively. *C. jejuni* and *C. coli* were present in the feces of slaughter-age cattle and sheep in Australia with median prevalences and ranges for dairy cattle, 6% (0–24%), feedlot beef cattle, 58% (12–92%), pasture beef cattle, 2% (0–52%) mutton sheep, 0% (0–4%), and prime lambs 8%.[3] The cattle production system being used may be an important risk factor. The organism may be present in about 15% of cattle at the time of slaughter. *C. jejuni* is widely distributed among northwestern US dairy farms, while *C. coli* is more narrowly distributed, more particularly in calf rearing farms.[4]

Approximately 60% of the specimens of healthy slaughter pigs may yield *C. jejuni*.[2] *C. coli* has been isolated from the intestinal contents of 99% of pigs at slaughter. A high prevalence of *C. coli* in the stomach of pigs at slaughter in France is recorded, and a high proportion of the strains were resistant to tetracyclines and erythromycin.[5] *C. jejuni*, *C. coli*, *C. lari* can be isolated from pigs on commercial swine herds.[6] Piglets probably become colonized with *Campylobacter* within a few hours of birth.

The prevalence of *Campylobacter* infections in both diarrheic and non-diarrheic calves, piglets, lambs, and goat kids may average around 50% but there is no correlation between the occurrence of the organism in the feces and the presence of diarrhea. However, the presence of these organisms constitutes a potential zoonosis among animal handlers. The details of surveys of the incidence of campylobacters from the tissues of cattle at slaughter and from fresh and frozen meat and poultry collected at slaughter are available.[3] An adaptation of the ELISA test is available for the detection of antibodies to *Campylobacter* sp. for use in seroepidemiological studies in herds of cattle and sheep. Wild birds probably constitute the main natural reservoir of infection.

Individual single-visit farm prevalence of intestinal *Campylobacter*, predominantly *C. jejuni*, in lactating dairy cows from various regions of the US ranges from 0 to 10%, and there was no difference geographically.[7] This low prevalence compares favorably with the rates of 5% for beef cattle on pasture,[8] with 7% of dairy cows in the UK,[9] and with 6–7% of adult cattle in the US.[8] Using a PCR assay of the feces for *C. jejuni*, 80% of dairy herds were positive, and 38% of individual cows were positive.[10] Possible risk factors for *C. jejuni* were application of manure with broadcast spreaders, feeding of whole cottonseed or hulls, and accessibility of feed to birds.

In feedlot beef cattle, 100% of the animals may shed campylobacters over a period of several months.[11] In surveys of feedlot cattle in Ireland over a period of several months, 54% of the animals shed *Campylobacter* and *Campylobacter coli*, 69 and 30%, respectively.[12] Of environmental pen samples, 29% were positive, and *C. jejuni* and *C. coli* accounted for 35 and 59%, respectively. *Campylobacter* was not isolated from any of the dressed carcasses.

Abortions in beef cattle herds have been attributed to *C. jejuni*.[13] The abortion rates were 19% and 10% in two herds on

neighboring ranches in Saskatchewan. Abortions occurred in late gestation and were accompanied by retention of fetal membranes and weight loss. Necrotizing and suppurative placentitis and fetal bronchopneumonia along with culture of large numbers of *C. jejuni* from the placental and fetal tissues were present. The organism was also isolated from the feces of aborting and healthy cows, and diarrheic and healthy calves. It is suggested that the source and mode of transmission of the organism was fecal contamination of water supplies and feeding grounds by carrier cows or wildlife. *C. coli* alone and *C. jejuni* and *C. fetus* subsp. *fetus* together have been isolated in epidemics of abortion in sheep. The IV inoculation of *C. jejuni* into pregnant sheep results in abortion 7–12 days later. A purulent endometritis and vasculitis were present.

C. jejuni has been isolated from an aborted fetus from a goat and the fetus of a heifer which aborted.

Risk factors

Pathogen risk factors

Campylobacter jejuni is adapted to the intestinal tract of warm-blooded animals and does not normally replicate outside this environmental niche.[14] The single polar flagellum and corkscrew shape facilitates motility in the viscous intestinal mucus. The bacterium gradually dies outside the host's intestinal tract. *C. jejuni* strains could not be isolated from water after 3 weeks but may survive for up to 60 days in unstirred water. The distribution and diversity of campylobacters in a large-scale farming environment in the UK was determined by systematic sampling of feces, soil, and water.[15] The organism was widespread, there were low levels of antibiotic resistance, high genetic diversity, and a strain of *C. coli* which may have become adapted to survival or persistence in water.

The organism is not normally pathogenic in farm animals. In humans, the infectious dose is considered to be <1000 *Campylobacter* organisms.[14]

Antimicrobial resistance. Increasing antimicrobial resistance in *Campylobacter* is being recognized worldwide, and resistance to the quinolones is most common in isolates of both *C. jejuni* and *C. coli* from food-producing animals, especially poultry.[16,17] Resistance of *C. jejuni* from poultry increased to 30% within several years after its approval for use as mass water medication in poultry.[18] The antimicrobial susceptibilities of *Campylobacter* spp. isolated from organic and conventional dairy herds in Wisconsin, US, were not different.[19] Thus the restricted use of antimicrobials on organic dairy farms had no effect on antimicrobial resistance to ciprofloxacin, gentamicin, erythromycin, and tetracycline in *Campylobacter* spp. From dairy farms in Washington State, *C. coli* isolates were more frequently resistant than *C. jejuni* to ciprofloxacin, nalidixic acid, erythromycin, and doxycycline.[4] Of *C. coli* isolates from dairy calf rearing farms, 89.3% and 72.2% from feedlots were resistant to quinolone antimicrobials, respectively. Multidrug resistance was more common among *C. coli* than *C. jejuni*.

Zoonotic implications

Campylobacter is the leading bacterial cause of diarrhea in humans in many industrialized countries. In the United States, disease caused by *C. jejuni* or *C. coli* has been estimated to affect 7 million people annually, causing 110–511 deaths.[20] Data from population-based studies indicate that the most important cause of indigenous foodborne disease is contaminated chicken.[21] Red meat (beef, lamb, and pork) also contribute to illness despite the lower risk.

C. jejuni is ubiquitous in areas contaminated with cattle feces but the intensity of infection varies considerably. Humans can be exposed to *Campylobacter* spp. in a range of sources via both food and environmental pathways. In dairy farm areas in which there are also outdoor recreational activities, *Campylobacter* spp. have been isolated from a range of environmental samples by use of a systematic sampling grid.[22] *C. jejuni* was the most prevalent species in all animal species, ranging from 11% in samples from nonavian wildlife to 36% in cattle feces, and from 15% of water samples. *C. coli* was most commonly found in water (17%) and sheep (21%). *C. lari* was commonly found in water and in birds. Many of the *C. jejuni* genotypes isolated from cattle, wildlife, and water were indistinguishable from those recovered from human clinical cases.[22]

The annual increase in *Campylobacter* infections in England and Wales begins in early May and reaches a peak in early June. This seasonal incidence may be associated with transmission of the organism by flies.[23]

An estimated 20% of cases of illness associated with *C. jejuni* are due to vehicles of infection other than food, including water. *Campylobacter* spp. have been found to cause waterborne outbreaks worldwide, especially where people drink untreated water from streams and other sources.[20] Untreated surface water has been implicated in *Campylobacter* outbreaks in New Zealand, Finland, England, Wales, Australia, the United States, and Canada. The Walkerton, Ontario, waterborne outbreak of 2000 resulted from entry of *Escherichia coli* 0157:H7 and *Campylobacter* spp. from neighboring cattle farms into the town water supply.[20] The bacteriologic, epidemiologic, and hydrogeologic data indicated that the bacteria from cattle manure were able to enter groundwater after heavy rains and contaminate a well serving the town of Walkerton, subsequently infecting those consuming the water. Some investigations consider that beef cattle represent a limited threat to water supplies and subsequent transmission of *Campylobacter* to humans.[24]

Raw milk contaminated by infected cows is a major cause of food-borne human campylobacteriosis in the United States and United Kingdom.[14] *C. jejuni*, along with other food-borne pathogens such as shiga-toxin producing *E. coli*, *Listeria monocytogenes*, *Salmonella* spp., and *Yersinia enterocolitica* can be found in the bulk tank milk supply of dairy herds in Canada and the United States.[25] Drinking raw cows' milk is commonly related to illness due to *C. jejuni*.[2] Raw goats' milk may transmit *C. jejuni* infection from animals to humans.[2] There is a strong association of *Campylobacter* infection in humans with residence on a farm[14] and contact with diarrheic animals is a major risk for *Campylobacter* enteritis in humans. Fecal contamination, rather than udder infection, is considered to be the means by which campylobacters enter milk and thereby infect humans. *C. jejuni* has been isolated from the bulk milk supply of goats whose milk was associated with *Campylobacter* infection in a human.

Along with other food-borne bacteria, such as *E. coli*, *Salmonella* spp., *Campylobacter* spp. can be found in retail raw meats (chicken, turkey, pork, and beef) sampled in supermarket chain stores.[26]

There is good evidence that isolates of *C. jejuni* from human disease and farm animals are very similar. The use of multilocus sequence typing is being used to compare the genotypes of *C. jejuni* from farm animals and the environment with those from retail food and human disease.[15,27]

PATHOGENESIS

The role of *C. jejuni* as primary pathogens in farm animals is uncertain. The organism was originally thought to be the causative agent of winter dysentery in cattle but reliable evidence for this relationship has not been found. Experimentally, the organism will cause a mucoid diarrhea, often with dysentery and a fever in calves.

C. jejuni or *C. coli* can cause a mild self-limiting enteritis and bacteremia when inoculated orally into newborn calves. The organism has been isolated from the feces of diarrheic calves and lambs, which suggests that it may be a causative agent

in some outbreaks of diarrhea but this has not yet been substantiated. The oral inoculation of pure cultures of *C. fetus* subsp. *intestinalis* into young calves will also result in an enteritis similar to that associated with *C. jejuni*. The oral inoculation of *C. jejuni* into gnotobiotic pigs results in diffuse edema and neutrophil infiltration of the mucosa of the cecum and colon. An episode of diarrhea in calves 5–12 weeks of age has been attributed to *C. hyointestinalis*. A *Campylobacter*-like organism has been isolated from young sheep about 1–2 months after weaning, when they were about 6 months of age, affected with weaner colitis. The morbidity rates in flocks ranged from 20–75% and the case–fatality rate was about 3%. *Campylobacter* spp. can be found in a high proportion of foals on horse farms where persistent non-responsive diarrhea has been a problem. Outbreaks of severe gastroenteritis in fattening lambs have been attributed to *C. jejuni*, these outbreaks were treated successfully with daily injections of erythromycin followed by a single injection of long-acting oxytetracycline.

Campylobacter fetus* subsp. *fecalis has been isolated from intestinal lesions of cattle and experimentally will cause a diarrhea and dysentery in calves.

***Campylobacter coli* (formerly *Vibrio coli*)** has been isolated from the small intestines of diarrheic piglets and experimentally can cause colitis in young piglets. The organism may be the cause of naturally occurring diarrhea in nursing piglets and weaned pigs in certain circumstances.

CLINICAL FINDINGS

The disease may be so mild as to be unapparent, without fever, and may be manifested only by mild depression and soft feces with occasional strands of mucus.

CLINICAL PATHOLOGY

The information on the various methods used for the detection and identification of *Campylobacter* in laboratory samples has been reviewed.[28] Because of the unique growth characteristics of *Campylobacter*, isolation of these organisms from field samples requires the use of special media and culture conditions, and is generally laborious and time-consuming. However, isolation of *Campylobacter* from feces is possible with high success rates. Recovery of *Campylobacter* from environmental samples can be difficult because the organism does not propagate in the environment.[28] The use of molecular detection methods has greatly facilitated the specific and rapid detection and identification of campylobacters, but has not replaced the gold standard of traditional culture methods. Detection and quantification of *C. jejuni* in the feces of naturally infected cattle is possible using real-time quantitative PCR.[29]

The laboratory methods used to distinguish epidemic-associated *Campylobacter* strains isolated from animals and humans have been examined.[7]

NECROPSY FINDINGS

At necropsy, there may be a diffuse catarrhal to severe hemorrhagic enteritis of the jejunum and ileum.

CONTROL

Control depends on sanitation and hygiene in livestock barns to reduce the bacterial populations in the environment of the animals. The numbers of organisms can be reduced and controlled in meat processing plants by using Hazard Analysis of Critical Control Points including the washing, handling and freezing of carcasses. Improvement of food-handling skills in restaurants and in the home kitchen will reduce transmission of the organism and adequate cooking of raw meat such as poultry to an internal temperature of 82°C will eliminate the organism.[14]

ILEITIS (REGIONAL ILEITIS, PORCINE PROLIFERATIVE ENTERITIS COMPLEX, PORCINE INTESTINAL ADENOMATOSIS, PORCINE PROLIFERATIVE ENTEROPATHY, NECROTIC ENTERITIS, REGIONAL ENTERITIS, PROLIFERATIVE HEMORRHAGIC ENTEROPATHY OF PIGS)

Synopsis

Etiology *Lawsonia intracellularis (ileal symbiont intracellularis)*
Epidemiology Four to 8 weeks after weaning, feeder pigs, and young gilts, sows and boars. Risk factors not known
Signs Diarrhea, weight loss, inappetence, and may recover. Outbreaks of bloody diarrhea and rapid death may occur in feeder pigs, young gilts, and boars
Clinical pathology Demonstrate organism
Lesions Proliferative ileitis. Proliferative hemorrhagic enteropathy, fibrinous casts, blood clots
Diagnostic confirmation Demonstrate organism in tissues
Differential diagnosis list
- Esophagogastric ulceration
- Intestinal hemorrhage syndrome
- *Clostridium perfringens* type C hemorrhagic enteritis

Treatment Antimicrobials in feed
Control No reliable strategies. Medication of feed

ETIOLOGY

The causative agent is *Lawsonia intracellularis* (LI), which was isolated in 1993.[1] It was described about 60 years earlier and first reported in 1974.[2] Koch's postulates for the disease were fulfilled in 1993.[3] It is an obligate intracellular bacterium[4] or in other words host cell dependent. It was also known as *ileal symbiont intracellularis*. Recent classification of DNA from infected enterocytes indicates a close relationship to *Desulfovibrio* species.[4] It has also been shown to be closely related to *Bilophila wadsworthii* which is a known inhabitant of the human colon and may be associated with appendicitis and is widely found in pigs in Australia.[5] Molecular typing of the organism has recently been described.[6] The isolates of *Lawsonia intracellularis* from the United States are similar to the European isolates.[7]

Formerly, the intracellular organisms, *Campylobacter sputorum* subsp. *mucosalis* and *Campylobacter hyointestinalis* were considered to be the causative agents because they could be isolated from the intestines of pigs with proliferative ileitis. Both pure cultures and mucosal homogenates of LI will produce clinical signs, lesions, and shedding.

The disease complex, often just called ileitis, occurs in two forms; a chronic form usually referred to as porcine intestinal adenomatosis (PIA) or necrotic enteritis occurs from 6–20 weeks and an acute form called porcine hemorrhagic enteropathy or regional ileitis occurs earlier from 4–12 weeks.

EPIDEMIOLOGY

Occurrence

The worldwide occurrence has been described [8]

The porcine proliferative enteropathy complex affects pigs from weaning age to feeder pigs and also young gilts, sows, and boars. It is characterized clinically by diarrhea, loss of body weight and inappetence in recently weaned pigs, and sudden death in feeder pigs, young gilts, and boars. The essential lesions are proliferative and there seems to be an etiological and pathological relationship between **porcine intestinal adenomatosis, necrotic enteritis, regional enteritis, and hemorrhagic enteropathy.** A study in Belgium suggested that 24% of slaughtered pigs had a thickened ileum with a range in farm batches from 10–49%.[9] In Denmark 94% of herds were infected with a mean within herd prevalence of 30%.[10] In Canada, there is a widespread distribution between 50–100% of herds in the provinces with 5–89% of pigs affected.[11] In the USA it was found using the IPMA test to study antibodies that 75% of growing herds had antibodies and within the herd the prevalence was 11–91%. Of the breeding herds 78% had antibodies with two peaks at the time of infection and 9–18 weeks later[12] and with an overall prevalence of 5–61%.

In Canada, studying 96 cases of porcine proliferative enteropathy,[13] it was found that 15% were in weaners (8–10 weeks), 36% in growers from 10–18 weeks and 14% amongst finishers of 18–26 weeks. A further 16% were in mature pigs of >26 weeks.

Estimation of the incidence of disease is complicated by the difficulties in making an accurate clinical and pathologic diagnosis. Surveys of pig farms in Australia indicate that 56% had either observed the disease or the veterinarian had made the diagnosis.[14] Non-hemorrhagic proliferative enteritis occurred most commonly in pigs 6–24 weeks of age. Proliferative hemorrhagic enteropathy usually affects pigs over 16 weeks of age but occurs in pigs as young as 6 weeks and as old as 4 years of age.[14]

Proliferative hemorrhagic enteropathy is one form of the proliferative enteropathy complex and has been reported from the United Kingdom, Europe, Australia, Asia, and the United States, and appears to occur in most countries. It probably has a worldwide distribution[8] with 30–60% of herds affected depending on the country. In Germany 82.7% of finishing herds had seroconversion.[15] It is especially common in hysterectomy-derived or specific pathogen-free (SPF) herds and has a higher prevalence in the hot summer period. In some countries its prevalence is increasing and it is emerging as a major syndrome in SPF herds.

The disease in all ages is frequently associated with the concurrent occurrence of porcine intestinal adenomatosis, but it is unknown whether the hemorrhagic syndrome results from some insult to the intestine which also predisposes to a proliferative enteropathy or whether it is simply an acute manifestation of this disease. The related syndromes of necrotic enteritis and regional ileitis can be found in apparently healthy pigs examined at slaughter. Because the disease is common in pigs, suboptimal growth of pigs in nutritional studies may be due to the disease complex.[16] It has been suggested that it can live extracellularly within the environment for two weeks[17] at 5–15°C. It appears highly resistant to a lot of cleaning agents such as pevione–iodine, or K permangosulfate but may be susceptible to 3% cetrimide. In one study transmission occurred despite cleaning, use of footbaths, and dedicated boots, etc.[18]

It has been suggested that it normally lives in organic matter in weaner units awaiting the arrival of batches of susceptible pigs with the resultant sudden increase in shedding 4–12 weeks after weaning.[19] The recent finding of LI in the tonsil may be a coincidental finding in that they have just been trapped in the crypts after licking of infected material[20] as they were only found in this site in 2/32 pigs. Mixed infections are found in 10% of growers and there is a strong association between diarrhea and prevalence of *B. hyodysenteriae* and *B. pilosicoli*.[21]

Economic effect

The potential economic effect can be quite severe with estimates of $1.48–3.42 for mild infections and $11.50–22.19 for severe infections.[22]

Prevalence of infection

Surveys of fecal samples from swine herds in Taiwan revealed an overall prevalence of infection of *Lawsonia intracellularis* in 30% of herds and 5.5% of pigs.[23] They have looked for it in wild pigs in Sweden but not found it.[24]

Morbidity and case fatality

The disease can occur in all ages of post-weaned pigs, but it has a high incidence in young replacement gilts and boars at 6–9 months of age and in pigs approximately 4–8 weeks after weaning. The high incidence in replacement gilts may be due to suppression of the disease by low-level feeding of antibacterial agents during the growing period, but frequently the syndrome appears first in gilts and some time later in the growing pigs. In gilts, outbreaks may be explosive, but generally are short-lived with morbidity rates of up to 50% of the group occurring within a 2- to 3-week period. The case–fatality rate does not usually exceed 10%. In large herds with continual addition to the replacement gilt herd and in herds where the disease occurs in grower pigs, outbreaks may be more prolonged. The disease in growers generally has equivalent morbidity and case–fatality rates, but is more severe in that runting of surviving and contemporary pigs may occur necessitating further economic loss through culling.

When given experimentally at a high level of 10^9–10^{10} LI per pig mortality in the untreated groups varied from 10–50% which is considered much higher than in the natural outbreak.[25,26]

Risk factors

There may be two patterns of infection. One is an early infection and the second is a delayed infection which is seen in farms which have separation of pigs at weaning and all in/all out methods of production.[8]

Very little is known about the risk factors. A gene has been discovered which encodes for a surface antigen (LsaA) which is believed to be associated with attachment to and entry into cells and which is synthesized during infections.[27] A study of recorded outbreaks of proliferative hemorrhagic enteropathy indicated the disease often occurred within 12 months after repopulation of the herd, and following withdrawal of antimicrobials from the feed.[28] It has been proposed that the introduction of breeding stock from herds where the disease is endemic may be a risk factor but this is not documented. In a study in the UK[29] there seemed to be a higher risk where there were over 500 sows. An older parity structure in the sow population seemed to reduce infection. There seemed to be a higher risk if buying in boars. Fully slatted or fully meshed floors also carried a higher risk of infection compared with solid floors or straw. A higher risk was seen in those herds where large numbers of pigs entered the finishing units simultaneously. Pigs on concrete slats may also be predisposed. Intensive systems were more severely affected than outdoor systems. There was a reduced risk if there was thorough cleaning and disinfection (all in/all out) before the next group of pigs arrived.[30] Seroconversion usually occurred as the

pigs entered the finishing site suggesting that the exposure takes place in the nursery.[31] A recent study in the USA[32] identified five major types of risk factor. These were co-mingling, temperature fluctuations (overheating/ chilling), transportation, depopulation and new buildings. Sows may have low levels of antibody and are capable of passing on colostral protection to the piglets. Maternal antibodies have usually declined by 3–5 weeks of age but may be extended to 42 days by repeated sow vaccination[33] by which time exposure may have occurred and therefore there may be both active and passive antibodies.[31]

Methods of transmission

The organism is found in hamsters, ferrets, foxes, hares, deer, emus, ostriches, and primates. The significance of these alternative hosts has not yet been ascertained. Most significant host is the pig. The organism can be spread by both growing pigs and adults. Gilts can be shedders and carriers. It can probably survive in the extra-cellular world for 1–2 weeks at 5–15°C.[17]

The method of transmission between pigs is assumed to be the fecal–oral route but no information is available to support this.

PATHOGENESIS

The infection process appears to go ileum to colon, to cecum and finally rectum. The histological lesions may have cleared from the ileum by day 29 following inoculation.[34]

Proliferative enteropathy is characterized by the hyperplasia of the epithelial cells of the intestinal crypts, particularly in the ileum and colon. The presence of non-membrane bound, curved bacteria free in the cytoplasm of the affected enterocytes is a consistent feature of the disease.[35] These bacteria have been cultured in a rat enterocyte cell line[36] and the disease has been reproduced in hamsters by inoculation of a pure culture of the organism derived from pigs.[37] The disease has been reproduced experimentally by inoculation of conventional pigs with the organisms.[38,39] The organisms infect the immature cells of the mucosal glands and stop them from maturing. This causes them to multiply without leaving the gland and they then degenerate and the glands continue to proliferate. Gross and microscopic lesions typical of acute proliferative enteritis can be reproduced by inoculation of cell-cultured *Lawsonia intracellularis* into pigs 3 or 7 weeks of age.[39] The incubation period is about 7–14 days with the early lesions appearing in the terminal ileum. Fecal shedding usually occurs about 7 days post-challenge and the animals seroconvert about 14 days post-challenge. The disease peak is about 21 days post-infection. The clinical signs decrease and the lesions begin to resolve after 28 days. The disease process results in a 2 week delay in marketing. Inoculation of gnotobiotic pigs does not cause the disease. It now seems certain that *Lawsonia intracellularis* is the causative agent of the disease complex.[40] Infection of intestinal epithelial cells is causally linked to marked hyperplastic proliferation of affected tissue.[41]

Lawsonia intracellularis is an obligate intracellular bacterium which causes hyperplasia of intestinal tissues; this eventually reverts to normal. The organism internalizes and multiplies within the cells and it is proposed that the organism is capable of affecting, directly or indirectly, the cell cycle within the intestinal epithelium. This may or may not be concerned with the role of cyclin kinase p27 which regulates differentiation of immature crypt cells into the differentiated form.[42] The changes in the experimental disease are similar to those in the natural disease. Following experimental infection there is almost complete replacement of normal ileal mucosa by adenomatous mucosa. Affected crypts are enlarged and branched, with loss of goblet cells and marked proliferation of crypt epithelial cells. Hyperplastic lesions may develop 2–3 weeks after challenge and persist for several weeks. In older animals, the lesions may be complicated by acute mucosal hemorrhage or necrosis. In the progressive stage of the disease, 3 weeks after infection, numerous organisms are consistently present within affected intestinal epithelial cells but not elsewhere.[41] In the developed and recovering stage of the disease, 7–9 weeks after infection, ultrastructural features in affected intestinal tissues consist of pale, swollen, protruding epithelial cells and shrunken epithelial cells. This is followed by the appearance of apoptotic bodies in both epithelial cells and macrophages, the reappearance of normal goblet cells and reduced numbers of organisms within the lesions. Bacteria are released from cells via cytoplasmic and cellular protrusions into the intestinal lumen and can be found in fecal samples.

In the experimental disease in pigs, seroconversion to the organism does not occur, confirming the weak response characteristic of the natural disease.[43]

The proliferative lesion may result in suboptimal performance in otherwise normal pigs or unthriftiness, or be manifested as acute intestinal hemorrhage during the recovery stages of intestinal adenomatosis. The hemorrhagic lesions are more difficult to explain but there may be direct or indirect toxic damage to the endothelium of the blood vessels.

It has been suggested that there is a close association between the presence of LI and reduced T- and B-cell numbers. This provides evidence of an immunosuppressive effect operating in this disease. It seems also that macrophages have an important function with activated macrophages accumulating in the infected hyperplastic glands.[44] At day 14 post-infection there were a few pinpoint lesions and the percentage of infected crypts was minimal but at the same time the number of $CD3^+$ cells was reduced and the number of intra-epithelial $CD3^+$ cells was also reduced whilst the CD8 and CD4 cells showed no changes. Apparently there is an induction of an immunosuppressive phenotype with down regulation of an adaptive immune response through the reduction in the $CD8^+$ T- and B-cells.

CLINICAL FINDINGS

This disease is one of the common causes of failure to grow, weight variation in batches of pigs and delay to market. Pigs may appear gaunt and may pass watery stools.

Regional ileitis is the most common differential diagnosis of the granulomatous enteritis that is seen in PCV2-associated enteric disease. In many cases both PCV2 and LI have been seen in the same case[45] as both target the ileum.[46]

Porcine proliferative enteropathy (PPE) or ileitis occurs in pigs 6–16 weeks of age. In the chronic form, a reduction in growth rate and failure to thrive are common. Affected pigs are afebrile and diarrhea occurs, but is unremarkable. Most cases recover spontaneously within 6 weeks of the onset of signs. When inflammation and necrosis have resulted in necrotic enteritis and regional ileitis, diarrhea and severe weight loss occur followed by death, often by ileal perforation in the case of regional ileitis.

Proliferative hemorrhagic enteropathy (PHE) occurs in older pigs such as young gilts and boars and is manifested primarily by bloody diarrhea and sudden death. Others within the group may show skin pallor and hemorrhagic feces with fibrin casts but otherwise appear clinically normal. In some pigs there is continual blood loss and death occurs within 48 h of the onset of hemorrhage, but in the majority the hemorrhage is transient. In outbreaks, up to 70% of pigs affected with dysentery may die within 24 h after the onset of signs.[28] Fever is not a feature and the majority of pigs suffer only a minor setback for a 2-week period. A small percentage develop chronic illthrift.

In grower pigs the disease is economically more severe. As in gilts, acute death with marked skin pallor and without premonitory signs can occur but survivors

show illthrift and as the outbreak progresses contemporary pigs may show a chronic syndrome of illthrift with the periodic passage of bloody feces.

The most staggering advance in clinical diagnosis may be by use of ultrasonics,[47] where it is said that it is possible to diagnose the condition by measuring the thickness of the ileal mucosa. It was said to increase from 0.27–0.36 cm in normal animals to 0.30–0.70 in affected animals.

CLINICAL PATHOLOGY

Detection of organism. The organism can be detected in the feces of healthy 10- to 25-week-old growing/finishing pigs, which is probably the age group of pigs serving as the main source of infection for younger nursery pigs.

A polymerase chain reaction assay is highly reliable for the detection of the organism in feces and intestinal tissues.[48,49] It may detect as few as 2×10^2 bacterial cells per gram of feces[50] but more likely is that the PCR detects shedding of 10^3 or greater per gram of feces.[51,52]

Positive results with the PCR are only present in animals with active lesions of proliferative enteropathy.[53] Shedding as detected by PCR may start as early as 6–8 weeks and continue to 28 weeks. From seroconversion to first shedding was 2–8 weeks.

A fluorescent in situ hybridization technique targeting 16S ribosomal RNA using an oligonucleotide probe successfully identified LI.[54]

Seroconversion may commence between 12–27 weeks. The range for positivity from first detection was 7–23 weeks.

NECROPSY FINDINGS

The immediate impact is of a thickened ileum and cecum and less frequently a spiral colon. Not all cases have lesions. Some may be so mild as to be overlooked. Obvious gross lesions occur in severe cases but in the less severe, histology is needed. The pathology is related to the dose.[55] As long as you remember these facts you can monitor LI in the abattoir.[56]

A complex gross, histological and immunohistochemical study of LI has been made[57] in which the pigs showed complete recovery and were IHC –ve by 35 days post-infection. The antigen was detected in the intestine, lymph node (macrophages) and in the tonsils (free living in the crypts). They were found in the rectum and in several portions of the large intestine. The first site of colonization was the jejunum and ileum and then the lower intestinal segments. On day 29 there was nothing in the small intestine but the LI were still observed in the cecum, proximal colon, and rectum. Mucosal IgA was first detected on day 15 and was still detectable on day 29 but in all cases the titers varied from only 1:4–1:16.

The macroscopic lesions of proliferative enteropathy were first detected at 11 days post-infection which is the same time as histological identification with enterocyte hyperplasia and reduced goblet cells. Immunohistochemical identification can be seen at 5 days post-infection and continues until day 29.

In porcine intestinal adenomatosis, the prominent lesions are in the terminal ileum and proximal portion of the large intestine. There is gross thickening of the mucosa and submucosa of the terminal ileum and the colonic mucosa may also appear congested and slightly thickened.

In both forms of the disease the mucosal surface may be eroded and may look granular with abundant adherent material in the form of fibrinonecrotic debris. There may also be a fibrinonecrotic core filling the lumen. In PHE the only difference may be that the surface of the mucosa may be covered by large undigested blood clots.

Histologically, the mucosal change consists of marked proliferation of immature epithelial cells and a suppurative cryptitis.

In regional ileitis (called hosepipe gut) the distal ileum is rigid due to thickening of the intestinal wall caused by muscular hypertrophy and granulation tissue formation. The initiating mucosal damage is often somewhat masked due to colonization of the ulcerated mucosa by secondary bacterial invaders.

In proliferative hemorrhagic enteropathy, the carcass is usually very pale and massive amounts of blood are often present within the intestinal tract. The mucosa and submucosa of the ileum are thickened and may be coated in fibrin. Fibrin casts are also sometimes present. Although the intestinal wall is dark red and hemorrhagic, there may be no obvious points of hemorrhage. Histologically, there is evidence of vascular congestion, fibrin thrombi, increased permeability of blood vessels and necrosis of the intestinal mucosa. The character of the vascular lesion resembles an acute bacterial infection and type I hypersensitivity reaction. Again, the key microscopic feature is the presence of proliferating immature epithelial cells with basophilic nuclei, which line the greatly elongated crypts. There are no goblet cells in this site. In an analysis of histological lesions crypt abscesses were seen in 20% of pigs, decreased goblet cells in 90%, hypertrophy and hyperplasia in 3%, hypertrophy of both muscle coats in 78%, increased eosinophils in 34% and lymphoid hyperplasia in 90%.

In chronic cases the lesions described above are nearly all replaced by fibrous connective tissue and the diagnosis may rely on seeing just isolated pieces of mucosa.

Lawsoniana are also a common cause of colitis. In 70% of cases of colitis LI are also found in the colonic mucosa. In three cases, LI were found only in the colon and in these infected large bowels there was an excess of mucus on the surface.[58]

Staining of smears of ileal mucosa with modified acid-fast stains may reveal typical curved bacterial rods in the apical cytoplasm of the infected proliferating enterocytes, permitting a presumptive diagnosis. It is not always specific for Lawsoniana. They are not always present in necrotic debris or autolysed tissue. Immunohistochemistry or silver stains (Warthin/Stary)[59] of formalin-fixed gut are usually sufficient to detect the intracellular organisms in all forms of proliferative enteritis. *Lawsonia intracellularis* can also be identified using a PCR assay.[49,53] It is possible to find bacterial antigen in the lamina propria and draining lymph nodes of the ileum and this is a result of the natural process of infection clearance.[57]

Samples for confirmation of diagnosis

- **Bacteriology** – distal ileum, proximal colon (DIRECT SMEAR, PCR). The organism needs to grow on tissue cell lines at oxygen and CO_2 concentrations that mimic the small intestine. It is not really an option because these techniques are difficult and the organism is an obligate intracellular organism.

There has been a considerable development of PCR techniques for feces as an antemortem technique.[60,61] This is a variable sensitivity which is affected by sample quality and the presence of inhibitory factors in feces, but the specificity is around 97%. It appears to be very useful in the clinically ill but not so reliable in the subclinically affected. The PCR is more specific when applied to the ileal mucosa rather than to feces. It has been reported that fecal samples are more likely to be PCR positive in herds with PHE rather than in PIA herds. It is more sensitive than either WS staining or IFAT.[62] Shedding commences around 7 weeks and is observed most between 13–16 weeks.[63,64] A one tube nested-PCR has been developed which is very sensitive and less prone to false positives compared to a standard nested-PCR.[65] A 5′ nuclease assay has been developed with a detection limit of 1 LI cell per PCR tube.[66] A real-time PCR has been designed[67] as a high-throughput test for use on feces. It is as specific as a conventional PCR but is more sensitive. It can be quantified and can be carried out with pure cultures, tissue homogenate or bacteria shed in feces.

A multiplex PCR has also been described for *B. hyodysenteriae, pilosicoli,* and *L. intracellularis.* It has a 100% specificity for the three species and does not generate false positives.[68]

There is also an indirect fluorescent technique but this requires expertise and a reliable Lawsoniana specific antibody and again is not 100% for subclinically affected animals.[69,70] The percentage of agreement between IFAT and IPMA was 98.6%.[71] It has been suggested that IFAT is more sensitive than PCR in antemortem testing.[50]

- **Histology** – distal ileum, proximal colon (LM, IHC). Immunohistochemistry was described[72–75]
- **Serology** – current methods utilize LI grown in enterocytes or LI prepared on slides as the antigen. These assays are specific because cell cultures or slides are examined microscopically and specifically stained bacteria can be distinguished from any background. Staining of bacteria is either by a fluorescent (IFA) or peroxidase-labeled IPMA. The IPMA test is highly specific (100%) and fairly sensitive (90%) in experimentally infected animals.[71,76] It is an appropriate diagnostic test for herd screening but not for diagnosing PPE on an individual animal basis. The IgG antibodies may be only short lived and found only between 18–24 weeks. These have proved useful for routine PPE diagnosis, although the humoral response is often weak and short lived. Titers of 1:30 to LI appear about 2 weeks after infection and 90% become positive by about 3 weeks after challenge with 5% having titers of 1:480 or above. They are however already decaying by about 4 weeks after challenge. Antibody was not detected until 16 weeks of age and often not until 19–22 weeks[71]
- **A cell-mediated response** can be detected in the research laboratory using an (enzyme linked immunospot assay) Elispot-T-cell assay that measures the LI specific secretion of IFN-γ by lymphocytes. It appears to follow the same pattern as the humoral response and it also starts to decay from about 3 weeks although more slowly.

Both humoral and cell-mediated responses can still be detected 13 weeks after challenge or vaccination.[71,76]

DIFFERENTIAL DIAGNOSIS

Porcine intestinal adenomatosis. Characteristic clinical findings are inappetence, loss of weight and mild diarrhea in recently weaned pigs. Must be differentiated from postweaning coliform gastroenteritis – clinically much more severe and death rapidly occurs. The postweaning drop in average daily gain (postweaning check) occurs within several days after weaning and recovery occurs within several days following consumption of a normal daily intake of feed.

Proliferative hemorrhagic enteropathy. Occurs in feeder pigs, young gilts, and boars and is characterized by sudden death and extreme pallor of the skin. Must be differentiated from fatal hemorrhagic esophagogastric ulceration, acute swine dysentery, and intestinal hemorrhage syndrome.

Esophagogastric ulceration. Occurs in all ages of pigs but especially in growers. The necropsy finding of ulceration in the non-glandular portion of the stomach at the esophageal entrance along with hemorrhage into the stomach with passage into the intestines provides easy differentiation. Acute death with intestinal hemorrhage occurs occasionally in swine dysentery. More common in adults affected with the disease and at the onset of an outbreak, skin pallor is not as marked and hemorrhage is restricted to the large intestine, and is associated with the characteristic lesions of swine dysentery in this area. Contemporary pigs show clinical and necropsy findings typical for this disease and the diagnosis can be confirmed with laboratory studies.

Intestinal hemorrhage syndrome. More difficult to differentiate from the proliferative hemorrhagic enteropathy. Occurs most commonly in 3–6-month-old pigs that are well-nourished and many but not all outbreaks have been associated with whey feeding. Typically associated with abdominal distension and evidence of abdominal pain preceding death and the presence of marked intestinal tympany on postmortem examination. In many cases, hemorrhage in the intestine appears to result from torsion which occludes the mesenteric veins. It occurs in all areas of the intestine except the proximal duodenum and stomach, which have separate drainage. Owing to intestinal distension the torsion may be easily missed but it is best determined by the abnormal cranial direction of the blind end of the cecum and palpation of the mesentery. This distribution of hemorrhage may occur without the occurrence of torsion and the etiology in these cases is unknown.

Other diseases
Infectious necrotic enteritis associated with *Clostridium perfringens* type C. May cause hemorrhage into the intestine but they are easily differentiated on clinical, epidemiological and laboratory findings.

TREATMENT AND CONTROL

Biosecurity to prevent the entry of infection is the key to control. Beware of carrier pigs, isolate for 30–60 days, use preventive antibiotics as outlined below, use laboratory diagnostics and vaccinate using the new water vaccine.

Eradication using early weaning is not a possibility, but using medication and vaccination is a possibility.

It has been said[77] that pigs between 30–50 kg shed fewer LI in the feces when they are fed non-pelleted and non-heated (home-mixed) feed.

An eradication scheme for LI used in Denmark following the use of antimicrobials (tiamulin, lincomycin, and tylosin) failed.[78]

A control program was tried in the UK using PCR to identify affected animals and medication with chlortetracycline and tiamulin for control.[79] The number of PCR-positive animals declined from 50–70% to 0%. In pigs over 14 weeks there were some PCR positives derived from treated groups. Another farm used tylosin phosphate and these remained clean.

Antimicrobials

In acute disease, water medication and particularly individual medications are more effective than treatment through in-feed medication.[80]

Continuous medication for LI can prevent infection but is frowned upon because it can prevent the development of immunity and extend susceptibility to infection. In fact the timing of any medication can affect the immune response, subsequent fecal shedding and the development of lesions.

There is no published information available on the treatment of individually affected pigs. The disease is usually treated on a herd basis by medication of the feed.

There appears to have been no changes in the in vitro MICs since the 1980s/1990s. There are probably four reasons why medication does not work: (i) underdosing; (ii) concurrent infections; (iii) some other disease or nutrition problem, i.e. misdiagnosis; (iv) antibiotics given too late to be effective.

If you are going to use antimicrobials it is a good idea to start at least 3 weeks before the anticipated acquisition of the infection.

The antimicrobial susceptibility of the organism isolated from pigs with proliferative enteropathy was determined in a tissue culture system. Penicillin, erythromycin, difloxacin, virginiamycin, and chlortetracycline were the most active compounds tested.[81] Tiamulin and tilmicosin were the next most active, and the aminoglycosides had the highest minimum inhibitory concentrations. Both lincomycin and tylosin were relatively inactive against the strains of the organism tested.

In the field bacitracin, virginiamycin and salinomycin are useless as are penicillins and fluoroquinolones.

Chlortetracycine, one of the oldest drugs is still used; at 300 or 600 mg/kg it can prevent challenged pigs from developing clinical disease. Chlortetracycline at 300 ppm and tylosin at 600 ppm have prevented the clinical signs of PE.[82,83]

Tylosin is ideal for treatment by injection, in-feed or through the water and was successfully used for treating PPE at 100 ppm.[80] For effectiveness, the antimicrobial would have to accumulate in the cytoplasm of the intestinal cell and block bacterial protein synthesis. The macrolides, tetracyclines, and virginiamycin act by selectively blocking protein synthesis in ribosomes. The oral administration of tylosin phosphate at a dose of 100 or 40 ppm in the feed to pigs for 4 days before experimental challenge and continued for 16 days when the dose was reduced to 40 and 20 ppm was effective in preventing the clinical signs and lesions of proliferative enteropathy.[81] It does not appear to block the pattern of seroconversion to LI. Tylosin at 110 ppm significantly reduced fecal shedding of LI and histologic lesions consistent with PPE.[84] Injection of tylosin produced an improved diarrhea score, and clinical impression score and thereby weight gain.[85] Tylosin tartrate in drinking water for the treatment of ileitis was effective in reducing clinical signs , lesions and reduction in growth rate.[86]

Lincomycin is ideal for injection, water treatment, and in-feed treatment. Lincospectin at 80 ppm used consecutively was shown to be useful for treatment of PPE.[87,88] Lincomycin at 44 and 110 ppm for 21 consecutive days[89] was effective in controlling the clinical signs of PPE and at 110 ppm also reduced the mortality associated with PPE. Lincomycin water soluble powder at 250 mL/gal is also effective.[90]

Aivlosin was found to be useful at concentrations 25% less than those used for tylosin.[91]

Valnemulin was also shown to be effective at 75 ppm in the feed.[92,93]

Tiamulin is useful for in-feed medication and water administration. Tiamulin given 50 ppm, 2 days before experimental challenge and kept for 3 weeks prevented the clinical disease.[94] In addition, pigs given 150 ppm tiamulin 7 days after challenge remained clinically normal and had no specific lesions of proliferative enteropathy at necropsy. Tiamulin in water is very useful[95] but a study showed that in water it interfered with seroconversion whereas administration in feed did not.[96]

The use of zinc-bacitracin in the feed of growing/finishing pigs at 300 or 200 ppm from weaning up to 100 d of age; or 200 or 100 ppm from 100–125 days of age; and 100 or 50 ppm from 125–156days of age was effective in controlling the effects of proliferative enteropathy in pigs on a farm with a previous history of the disease.[97]

Carbadox might have some effect against LI as might zinc oxide.[98] It has been shown to be useful if fed in the final 2 weeks in the nursery. It reduces fecal shedding, clinical signs and no IHC+ve or PCR+ve animals were found in one study.[99]

Hyperimmune chicken eggs for controlling LI infection in growing swine has been described.[100]

Vaccines

The main difference between respiratory and alimentary diseases in the last few years has been the development of vaccines for the former but not the latter. The recent development of an ileitis vaccine is the first of these for the enteric diseases.

It is a safe, labor-saving, efficient, and easy method of vaccinating pigs through the administration of drinking water using the water proportioner. In the presence of feed medication, vaccinated pigs performed better than the non-vaccinated pigs when exposed to LI challenge. The percentage morbidity was reduced, the feed conversion better and the average daily gain increased by about 6%. There was also a 23% reduction in culls. It is best given in a 7-day antibiotic-free period. The present vaccine is given in water to 70–90 lb gilts. It can be dispensed with antimicrobials and produce protective immunity.[101] There is a reduction in gross and microscopic lesions in the complete absence of antimicrobials when the gilts are vaccinated as finishers and the animals receive a booster vaccination every 6 months.[102]

PROLIFERATIVE ENTEROPATHY IN HORSES

ETIOLOGY

The disease is associated with *Lawsonia intracellularis*, an obligate intracellular Gram-negative bacterium associated with proliferative enteropathy in pigs, horses, hamsters, dogs, deer, rabbits, rats, and ratites.[1] There is close similarity in DNA among isolates from a variety of species.[2] Isolates derived from pigs are infective in hamsters but there is no information regarding infectivity of porcine strains for horses, or vice versa.[1] The organism from pigs is viable and able to produce disease in pigs when stored in feces at room temperature for up to 2 weeks.[14]

EPIDEMIOLOGY

The disease was initially reported from North America and has recently been diagnosed in Australia and Europe.[4,5,15] Nine of 164 randomly selected weanlings in the Hunter Valley of Australia had serum antibodies to *L. intracellularis*.[5]

The disease in foals occurs as isolated cases and as outbreaks on breeding farms.[4] There is evidence that outbreaks begin after introduction of foals or weanlings to farms with no history of the disease, although whether this is coincidence or represents the mechanism of introduction of infection to the farm is unknown.[4] Morbidity among foals and weanlings on affected farms is 20–25%, although this is based on disease outbreaks on only two farms.[4] Case fatality rate is 15–20%.[4]

Affected foals are usually 3–13 months of age and disease in adults is rare. There is insufficient information to determine if there is a breed predisposition to the disease. The disease is presumably transmitted by the fecal–oral route, as in pigs, but there are no reports of experimental induction of the disease in foals.

PATHOGENESIS

The pathogenesis of the disease in foals has not been determined, but it is probably similar to that of the disease in pigs.[6] Infection results in development of an enteropathy characterized by proliferation of intestinal crypt epithelial cells and infiltration of the lamina propria with mononuclear inflammatory cells.[4,7–9] Subsequent malabsorption of small intestinal contents and protein loss from diseased intestine cause weight loss and hypoproteinemia characteristic of the disease in foals. However, there was no evidence of decreased absorption of glucose in three foals in which this was examined.[4] Colic and diarrhea result from intestinal dysfunction and malabsorption. Hypoproteinemia and the subsequent decrease in plasma oncotic pressure result in edema and signs of hypovolemia. Death is associated with severe hypoproteinemia, inanition, and colic.

CLINICAL SIGNS

The disease may present as one with a short course characterized by rapid weight loss, colic and death within 2–3 days of onset of clinical signs or as a more chronic disease characterized by gradual development of weight loss and depression.[4,7,8,10] Weight loss and poor body condition are consistent findings among foals affected by the chronic disease. Most affected foals have diarrhea that ranges in severity from acute profuse watery diarrhea to, more commonly, excessively soft feces. Foals are often depressed although they continue to nurse. Edema of the ventral abdomen and intermandibular space is common. Fever is not a consistent feature of the disease.

Ultrasonographic examination of the abdomen reveals multiple loops of mildly distended small intestine with thickened walls. Loops of intestine can have walls of 5–8 mm thick (normal < 3 mm).

Many affected foals, and especially those that die of the disease, have concurrent diseases including parasitism and pneumonia.

The incubation period in pigs is 2–3 weeks but that in horses is unknown. Foals that recover from the disease may take several weeks to regain normal body weight. There do not appear to be long-term consequences of the disease in recovered foals.

CLINICAL PATHOLOGY

Hypoproteinemia with moderate to severe hypoalbuminemia is present in most affected foals. Serum albumin concentrations can be as low as 0.6 g/dL (6 g/L).[8] Hyperfibrinogenemia and mild anemia are common but not consistent findings.[4] White cell count is elevated (>14 $\times$ 10^9 cells/L) in most foals. Serum sodium and chloride concentrations are lower than normal and serum creatinine concentrations higher than normal in about 50% of affected foals. PCR examination of feces for *L. intracellularis* is specific for detection of organism in affected foals. An indirect immunofluorescent assay detects serum IgG antibody to *L. intracellularis* in foals, although the specificity of this finding for detection of the disease in foals is unknown.[4,5] Foals with proliferative enteropathy have titers of 1:30 or greater.[5] Antemortem diagnosis in pigs is based on positive serology and detection of *L. intracellularis* DNA in feces by PCR.[11]

NECROPSY

Gross lesions are mainly thickening and irregular corrugation of the small intestine.[4,7,8] There is proliferation of intestinal crypt epithelium with projection of crypt cells into the intestinal lumen. The lamina propria is infiltrated by mononuclear inflammatory cells. Silver staining of intestinal sections reveals numerous short, curved bacteria in apical cytoplasma of crypt epithelial cells.[4]

Samples for confirmation of diagnosis[12]

- **Histopathology** of small intestine
- **Silver staining** of small intestine to demonstrate intracellular bacteria associated with hyperplastic cryptic cell
- **Bacteriology** – culture (which can be difficult as it requires cell cultures) and PCR examination of small intestinal tissue.

DIFFERENTIAL DIAGNOSIS

Antemortem diagnosis of proliferative enteropathy in foals should be based on the presence of characteristic clinical, hematological and biochemical signs, positive serology and detection of *L. intracellularis* DNA in feces by PCR.

The primary differential diagnosis is **parasitism** by *Parascaris equorum*, Cyathostomes, and large strongyles (in older foals). Examination of feces for

helminth ova is diagnostic in cases with patent infections, but parasite infestations are often not patent in young foals. A history of an adequate parasite control program makes parasitism less likely, but does not rule it out. **Malnutrition** due to inappropriate or inadequate feeding practices or agalactia should be ruled out as a cause of failure to thrive.

Protein-losing enteropathy secondary to **enteritis and colitis** may be associated with *Salmonella* sp., *Rhodococcus equi*, or *Cryptosporidium* sp. Other intestinal diseases that cause enteritis but less commonly cause protein loss include the intestinal clostridioses, equine granulocytic ehrlichiosis, and *Bacteroides* sp. infection. Intra-abdominal abscesses associated with *R. equi* or *Streptococcus* sp. can cause chronic weight loss and hematological signs similar to proliferative enteropathy.

Hypoproteinemia can occur secondary to gastrointestinal ulceration. Neoplasia is rare in foals of this age but intestinal lymphosarcoma can cause hypoproteinemia and weight loss. Intoxication by **non-steroidal anti-inflammatory** drugs can cause a protein-losing enteropathy.

Diarrhea and ill thrift caused by colitis and typhlitis associated with *Brachyspira* sp. (a spirochete) is reported from Japan.[13]

TREATMENT AND CONTROL

Principles of treatment are eradication of infection and correction of hypoproteinemia. Administration of **antibiotics** is curative in many foals.[4,16] Isolates of the organism from pigs are sensitive in vitro to a wide range of antimicrobials including penicillin, erythromycin, difloxacin, virginiamycin, and chlortetracycline.[14] Antibiotics used to treat *L. intracellularis* infection in foals include oxytetracycline (6.6 mg/kg q 12 h IV),[16] doxycycline (10 mg/kg q 12 h, orally),[16] chloramphenicol (50 mg/kg, q 6 h, orally), or erythromycin estolate or similar product (15–25 mg/kg q 6–8 h orally), sometimes in combination with rifampin (5–10 mg/kg q 12 h orally). Erythromycin or oxytetracycline/doxycycline appear to be effective in treatment of affected foals.[4,16] Chloramphenicol is used in place of erythromycin in foals that develop intractable or severe diarrhea when treated with erythromycin, but its use is illegal in some countries and is not recommended because of the risk of aplastic anemia in people exposed to the drug. Enrofloxacin might be effective, based on MIC values, but should be reserved as a drug of last resort because of the arthropathy associated with its use in foals.

Mildly or moderately affected foals require only administration of antimicrobials and nursing care. More severely affected foals may need intensive supportive care including intravenous administration of plasma and/or hetastarch to restore plasma oncotic pressure and minimize edema formation, fluid and electrolyte supplementation because of hypovolemia and abnormalities in serum electrolyte concentration, calorie enhanced diets or parenteral nutrition, and antiulcer medications if signs of gastric ulceration are present.

Specific **control measures** to prevent spread of the disease among horses have not been developed. Given the putative fecal–oral cycle of infection and association of outbreaks of the disease in pigs after introduction of new stock or mingling of groups, hygiene measures that minimize fecal contamination of the environment by potentially infected foals is sensible. The organism from pigs can survive in feces for up to 2 weeks. Foals with the disease should be isolated from healthy foals, although the duration of this isolation is not known, and should not be transported to other farms until clinical and hematological signs of the disease have resolved. The role for wildlife hosts, if any, in the disease of foals is unknown. There is currently no vaccine for the disease in foals.

Diseases associated with *Leptospira* spp.

LEPTOSPIROSIS

Synopsis

Etiology *Leptospira interrogans* (many distinct serovars). *Leptospira borgpetersenii* (many distinct serovars)
Epidemiology Worldwide distribution, most commonly in warm, wet climates. Occurs in cattle, sheep and goats, pigs, and horses. Host-adapted (maintenance or reservoir) and non-host-adapted (accidental or incidental) leptospirosis dependent on response of each species to particular serovars. Prevalence of infection greater than incidence of clinical disease. Transmission by urine of infected animals; some wildlife species may transmit to cattle. Ground surface moisture most important factor for persistence of organism. Major zoonosis
Signs Acute, subacute, and chronic forms. Fever, acute hemolytic anemia, changes in milk, stillbirths, abortion in all species (especially pigs), weak neonates, infertility, milk drop syndrome, periodic ophthalmia (recurrent uveitis in horse)
Clinical pathology Demonstration and/or culture of organism in blood, urine, cervico-vaginal mucus, body fluids, and tissues; serological tests, primarily macroscopic agglutination test. ELISA and DNA probes
Lesions Anemia, jaundice, hemoglobinuria, serous hemorrhages, autolysis of aborted fetuses, fetal hepatitis, and nephritis.
Diagnostic confirmation Culture or demonstrate organism in body fluids or tissues; high serum titers
Differential diagnosis list:
Cattle
- Acute leptospirosis: anaplasmosis; rape and kale poisoning; postparturient hemoglobinuria; bacillary hemoglobinuria
- Chronic leptospirosis: all other causes of abortion in cattle (Table 18.6). Milk drop syndrome

Pigs
All other causes of abortion, mummification and stillbirths in swine (Table 20.2)
Sheep and goats
Chronic copper and rape poisoning; anaplasmosis
Horses
Abortion, stillbirths, perinatal deaths of foals due to: *Streptococcus zooepidemicus*; *Salmonella abortivoequina*; *Escherichia coli*; *Actinobacillus equuli* (*Shigella equuli*). Equine herpes virus; equine viral arteritis. Weak neonatal foals due to isoimmunization hemolytic anemia. Periodic ophthalmia from other causes of iridocyclitis of horses, and conjunctivitis, keratitis and hypopyon
Treatment Antimicrobials to treat acute infection and eliminate leptospiruria
Control Antimicrobials to eliminate carriers. Vaccination with vaccines containing serovars which are causing the disease in that geographical area

ETIOLOGY

The pathogenic leptospires are classified into one species of *Leptospira interrogans* containing over 212 serovars arranged into 23 serogroups,[1] for example, *L. interrogans* serovar pomona. Differentiation between serovars, formerly serotypes, belonging to a particular serogroup is by cross-agglutination tests. Two strains are considered different if, after cross-absorption with adequate amounts of heterologous antigen, 10% or more of the heterologous titer regularly remains in either of the two antisera.[1] Because this system is subjective, the restriction endonuclease analysis (REA) of leptospiral DNA is used as a genotyping taxonomic tool[2] which is less

Table 20.2 Diagnostic summary of common causes of abortion, mummification, and stillbirths in swine

Disease	Epidemiology	Clinical features	Laboratory diagnosis	
			Isolation of agent	*Serology*
Leptospirosis (*L. interrogans* serovar pomona) possibly also *muenchen* and bratislava	Abortion last 2–3 weeks of gestation. Follows introduction of infected boar or sow or contamination of water supply or rodent infestation	Abortion, vulval discharges, sow systemically normal. Weak piglets sometimes.	Fetal tissues and urine of sow.	Positive or rising titers in aborting sows. Antibody in thoracic fluids in stillborn fetuses is diagnostic
Brucellosis (*B. suis*)	Abortion may occur any time during gestation. Spread by coitus (early abortion)	Embryonic death infertility, abortion. Orchitis in boars	Culture from lymph nodes	Positive titers in herd (cross-react with *Yersinia*). Many animals seronegative
Porcine parvovirus infection	Herd outbreak when introduced for first time. Subsequently herd immunity develops and problem sporadic, affecting primarily gilts. May be continual low-grade problem in piggeries where sows are stalled. Due to incomplete spread	Abortion outbreaks possible. Mainly mummification, stillbirth and infertility. Sow clinically normal. Failure to farrow. Small litters. Returns to estrus	Virus detectable by hemagglutinating antibody or fluorescent antibody in fetuses less than 16 cm crown–rump (C–R) length. PCR for antigen in fetuses. ELISAS for fetal antibody	Antibody present in fetuses greater than 16 cm C-R length. Antibody in high titer in sow. Variety of tests including ELISA
SMEDI virus	Poorly defined. Similar to parvovirus. Sporadic, affecting gilts primarily	Small litter size, uneven pigs and poor piglet viability, stillbirth and mummification. Infertility	Virus difficult to isolate from affected fetuses. Lung from fetuses or stillborn best site	Antibody in fetus, greater than 16 cm C–R length and paired samples from sow with 1:32 increase in titer
Porcine reproductive respiratory syndrome (PRRS) (Lelystad virus)	Epidemics of reproductive failure. Possibly even death (Sams syndrome)	Abortion, mummified stillbirths, fetuses, weak piglets, increased preweaning mortality	Virus isolation from lung, tonsil, serum or lymph node. RT-PCR and nPCR, ISH, IHC, etc. can be used	Serology (wide variety of techniques; ELISAs, indirect ELISAs, IFA, SNT) (pre-colostral, colostral, active Abs)
Aujeszky's disease (pseudorabies)	Abortion usually 10–20 days after clinical illness. At any time but especially first 2 months of pregnancy. Concurrent or preceding clinical disease in young pigs in herd	Sows may show mild clinical disease at time of infection, anorexia, depression, transient pyrexia. Abortion or stillbirth or mummified fetuses at term	Difficult. Histology, with inclusions, IHC of CNS and lungs of fetus best. Also FAB, for virus in tonsil or CNS and vaginal swab sow, brain, spleen or lung for culture	Positive titers in herdmates. Variety of tests now ELISAs
Hog cholera (classical swine fever) and African swine fever	Usually signs of clinical disease within piggery. Low virulence strains may produce reproductive/ teratogenic effects only. New herd entrants? Waste food feeding? Contact wild boar?	Abortion of sows during or following acute clinical disease. Also embryonic death, small litter size, stillbirth and mummification. 'Trembling pigs' at birth may be only manifestation.	Fetal pigs and affected pigs within herd. Variety of antigen techniques-isolation, PCR, RT-PCR, IHC, ISH, FAB for antigen, antigen capture ELISA. Transmission studies	Positive titers in herds. Wide variety of tests (SN, CF, ELISAs, blocking ELISAs

Other agents such as Erysipelothrix, Japanese encephalitis virus, Japanese hemagglutinating virus, fungi, nutritional deficiency may produce abortion or reproductive inefficiency. Any infectious agent may produce abortion because of pyrexia in the sow. Many outbreaks of abortion in sows remain undiagnosed and there must be important agents as yet unrecognized producing this syndrome. An example of agents in this category include Chlamydophila and Arcobacter.

time and labor consuming than cross-agglutination absorption and gives highly reproducible results. This method allows observations between strains of the same serovar which can be correlated with differences in the epidemiology of the strains and, possibly, the pathogenicity of the strains. It has also found instances in which strains have been incorrectly identified by conventional typing methods.

Serological typing has revealed many groups, some of which share antigenic configuration. The serovar is the serologically least divisible recognized type. It is accepted as the basis of taxonomy as the subspecific level. The serovar name is spelled with a lower case initial letter, e.g. serovar pomona. The name of the serovar was previously italicized but this is no longer recommended.

Serovars which share antigens can be identified after controlled absorption and agglutination. They are grouped into serogroups, which have no taxonomic status, but are convenient for application such as diagnosis and epidemiology. The name of the serogroup is spelled with an initial capital letter, e.g. serogroup Pomona. Within some serovars further subgroups can be identified by genomic analysis. These groups are types of the serovar, and are not serologically distinguishable from one another (e.g. serovar hardjo, types hardjoprajitno and hardjobovis).

Nomenclature of leptospires

For efficiency, in this text, the specific leptospire serovars will be abbreviated, for example, *L.* pomona for *Leptospira interrogans* serovar pomona, or the serovar only will be used, e.g., pomona.

EPIDEMIOLOGY

Animal risk factors

Serovars and species susceptibility. The epidemiology of leptospirosis is most easily understood by classifying the disease into two broad categories: **host-adapted** and **non-host-adapted** leptospirosis. An animal infected with a host-adapted serovar of the organism, is a '**maintenance**' **or** '**reservoir**' **host**. Exposure of susceptible animals to non-

host-adapted serovars results in **accidental** or **incidental disease**. Each serovar is adapted to a particular **maintenance host**, although they may cause disease in any mammalian species.

A serovar behaves differently within its maintenance host species than it does in other, incidental or accidental hosts. A **maintenance host** is characterized by:

1. A high susceptibility to infection
2. Endemic transmission within the host species
3. Relatively low pathogenicity for its host
4. A tendency to cause chronic rather than acute disease, producing insidious economic loss through reproductive losses
5. Persistence of the serovar in the kidney and sometimes the genital tract
6. A low antibody response to infection, with difficulties in diagnosis
7. Low efficacy of vaccination in prevention of infection.

Examples of this relationship are serovar bratislava in swine, and serovar hardjo type hardjo-*bovis* in cattle. In contrast, an **incidental host** is characterized by:

1. Relatively low susceptibility to infection but high pathogenicity for the host
2. A tendency to cause acute, severe rather than chronic disease
3. Sporadic transmission within the host species and acquisition of infection from other species, sometimes in epidemic form
4. A short kidney phase
5. A marked antibody response to infection, making for ease of diagnosis
6. More efficacious vaccines for preventing infection.

An example of this relationship is serovar pomona (*kennewicki*) infection in cattle.

Some common leptospiral serovars and their maintenance hosts are as follows:

Serovar	Maintenance hosts
hardjo-bovis (North America):	cattle
hardjo-prajitno (Europe):	cattle, pig,
bratislava:	horse
pomona (kennewicki):	pig, skunk, racoon, opossum
grippotyphosa:	racoon, opossum, squirrel
icterohemorrhagiae:	brown rat

Some common leptospiral serovars and their accidental hosts are as follows:

Serovar	Accidental hosts
hardjo:	sheep, man
pomona:	sheep, cattle
grippotyphosa:	sheep, cattle
icterohemorrhagiae:	cattle, pig

Calves and lambs are highly susceptible to infection and septicemia is likely to occur.

Occurrence and prevalence of infection

Most leptospiral infections are subclinical[3] and infection is more common than clinical disease. *L.* pomona is the commonest infection in all farm animals but its international distribution is unpredictable; it had not been present in the United Kingdom until recent years and then only sporadically. The number of serovars of concern in domestic animals has been increasing and serovars and their antibodies have been detected which were thought previously to be exotic.

L. canicola infection has been recorded in cattle and in pigs and specific antibodies have been detected in horses. *L.* icterohaemorrhagiae is a rare isolation in large animals but has been reported in cattle and pigs, and serological evidence of infection has been found in the horse. *L.* hyos (*L.* mitis) has been isolated from cattle and pigs, *L.* grippotyphosa from cattle and goats, and positive serological tests have been obtained in horses. *L.* sejroe, *L.* hebdomadis and *L.* australis infection have been observed in cattle. *L.* szwajizak is thought to be the predominant serovar in Israel.

Serological surveys of cattle in the African continent reveal evidence of antibodies against numerous leptospiral serovars[4] and some previously not described strains of serovars. In West Africa, serosurveys of dairy herds revealed 45% of cattle were positive to one or more serovars, which probably represented natural infection because vaccination had not been practiced.[4]

Leptospirosis is common in farm animals in Portugal.[5] Outbreaks of clinical disease have been recorded in cattle and pigs, and also in sheep and goats, and in horses to a lesser extent. In Italy, serological surveys indicate that sheep, horses, pigs, and dogs have the highest number of positive responses.[6]

CHARACTERISTICS OF LEPTOSPIROSIS IN SPECIES OF ANIMAL

Leptospirosis affects all farm animal species and the epidemiological characteristics of the infection, some of which are unique with a species and important in the diagnosis, treatment and control strategies, are outlined here.

Cattle

Leptospira interrogans is divided into seven genospecies of leptospires, two of which are *L. interrogans* and *L. borgpetersenii*.[7] *L. borgpetersenii* serovar genotype hardjo-bovis formerly *L. interrogans* serovar hardjo-*bovis* occurs worldwide[3] and in many areas outranks *L.* pomona in cattle. It is now the commonest serovar in cattle in some parts of Australia, New Zealand, the United States, and Canada. *L. interrogans* serovar genotype hardjo-prajitno so far has been recovered only in the United Kingdom, Nigeria, India, Malaysia, Brazil, Mexico, and the United States. *L.* hardjo is a common cause of abortion in dairy cattle in Brazil.[8] New serovars occur occasionally, as for example, serovar *ngavi*, in the serogroup Tarassovi isolated from oxen in Zimbabwe.[9]

L. interrogans serovar hardjo (type hardjoprajitno) and *L. borgopetersenii* (type hardjo-*bovis*) are serologically indistinguishable but genetically distinct.[10] The former has been isolated primarily from cattle in the UK, while the latter is common in cattle populations throughout the world.

L. hardjo-prajitno has not yet been identified as a pathogen of North American cattle.[11] Because this genotype, instead of hardjo-*bovis* is used in vaccines it may explain the lack of complete protection of animals against hardjo-*bovis* and the difficulties in laboratory diagnosis. In addition, there are at least two variations of the hardjo-prajitno genotype. These differences may be associated with differences in pathogenicity of hardjo strains, and although the cross-agglutination absorption test cannot distinguish these strains as separate serotypes, the degree of cross-protection conferred by these heterologous genotypes in vaccines is not known.

Cattle are the maintenance host for *L.* hardjo and are the only reservoir. *L.* hardjo is an important cause of bovine abortion[3] and is the commonest leptospiral infection in man. It is a common infection in Australian sheep and may affect up to 40% of the population.

Seroprevalence surveys found 34–65% of sera obtained from cows at slaughter in parts of the United States had antibodies to leptospira serovars.[3] Approximately 30% of all sera were positive when tested for *L.* hardjo, the host-adapted serovar of cattle. This seroprevalence is similar to reports from Europe, Australasia, and South America, in which 25–65% of all cows tested for *L.* hardjo were positive. The morbidity rate for clinical disease may vary from 10–30%, depending on the clinical manifestation of infection, and the case–fatality rate is usually low at about 5%. The case–fatality rate in calves is much higher than in adult cattle. A high rate of abortions (up to 30%) and loss of milk production are the major causes of loss but deaths in calves may also be significant.

Serovar hardjo-*bovis* is the most common serovar of cattle in the UK,[3] Australia, New Zealand, and North America. Abattoir surveys of sera and

kidneys of beef cattle in Quebec found a high prevalence of infection and nephritis associated with hardjo-*bovis* in contrast to pomona, which occurs more frequently in dairy cattle in that area. It is also possible that hardjo-*bovis* infection may be more common in feedlot cattle because they originated from Alberta, where the prevalence of infection with that serovar is prominent.

In serological survey of dairy cows in herds with suboptimal reproductive efficiency in a region in Spain. *L.* bratislava and *L.* grippotyphosa were the most prevalent serovars.[12] The risk of seroconversion against *L.* grippotyphosa was higher during the spring season while *L.* bratislava did not differ among seasons. The prevalence of *L.* hardjo was low which indicates that the reproductive inefficiency was unassociated with hardjo. In surveys of dairy and beef cattle in Spain, *L.* bratislava is the most frequently detected serovar while hardjo is at a relatively low seroprevalence compared with similar studies in western European countries.[13] In Spain, serovars grippotyphosa, *tarassovi* and copenhagi are more frequent in dairy herds, probably related to management practices and geographical location of these herds which facilitate the contact with maintenance hosts for these serovars.

A serological sampling of adult dairy cows in Brazil, not vaccinated for leptospirosis, and from herds with lowered fertility, 47% were positive for *L.* hardjo.[14] The major risk factor associated with seropositivity was co-grazing with other species, mainly pigs.

L. pomona and *L.* hardjo-*bovis* are responsible for most bovine leptospirosis in Australia.[11] Serovar pomona is a pig pathogen for which cattle are an accidental host and is a cause of bovine abortion, and fatal hemolytic disease in calves. Serovar hardjo-*bovis* is adapted to cattle as a maintenance host, is maintained in the bovine population but has a relatively low pathogenicity.[11] It is responsible for epidemics of agalactia, **the milk drop syndrome**, and a major cause of infertility. However, diagnostic surveys in Australia suggest that hardjo-*bovis* is not responsible for any substantial proportion of bovine abortion in contrast to the situation in Northern Ireland, where the genotype hardjo-prajitno is present. In beef cattle in Queensland, Australia, the major serovars in order of decreasing crude seroprevalence were hardjo (15.8%), tarassovi (13.9%), pomona (4.0%), and szwajizak (2%).[15] Vaccinates were not included in the hardjo and pomona seroprevalence; and the seroprevalence for hardjo and pomona tended to increase with age of the animals. The data indicate that serovars other than hardjo, pomona, and tarassovi, are unlikely to have a significant role in bovine infertility, and cattle are unlikely to be a source of human infection in central Queensland.

Seroprevalence surveys in Ontario, found hardjo-*bovis* was most commonly found in beef cattle, whereas pomona was most commonly found in dairy cattle. In Prince Edward Island, 14% of dairy cows were serologically positive for serovar hardjo. Serological surveys of cattle farms in Alberta found infection with hardjo-*bovis* was widespread across the province and the prevalence has increased. In contrast, pomona reactors were found usually on single premises within a locality as compared to the clustering of hardjo reactor herds. This is an expression of the difference between host–parasite relationships in which cattle are well-adapted reservoir hosts for hardjo, generally inducing a weak agglutinin response to natural infection and remaining capable of transmitting infection for months or years.

With pomona infection, cattle tend to develop high agglutinin titers with or without clinical disease, and not remain long-term carriers. Thus, pomona infections can remain limited to a single herd unless cattle are dispersed to other herds at the height of infection. In addition, reservoir hosts such as skunks may become infected and contaminate other premises, or a water supply common to a number of premises becomes contaminated when the water is near neutral pH (about 15–25°C) and of appropriate volume to deliver infectious numbers of organisms to cattle downstream.

As a measure of the loss associated with *L.* hardjo-*bovis* in beef cattle, the percentage of cows which are serologically positive has been related to the proportion of the herd affected with lactation failure, and there is a greater wastage in reactor cows.

Seroprevalence surveys of mature cattle in the United States found antibodies of hardjo-*bovis* were most common, followed by pomona and copenhagi.[16] This confirmed earlier observations that the nationwide seroprevalence of hardjo-*bovis* was greater than pomona. The isolation rates were also higher in beef cattle than in dairy cattle and higher in bulls than in cows. Combined culture and immunofluorescence results found that 2% of mature cattle were renal carriers of leptospires.[16]

In Greece, the seroprevalence in pigs, goats, sheep, cattle, and dogs is 17.8%, 16.2%, 5.7%, 12.6%, and 11.4%, respectively.[17] The overall prevalence is high, and against multiple serovars, indicating a considerable level of infection in each animal species, and that the zoonotic risk is considerable. In Turkey, *L.* hardjo is the dominant serovar identified in serological surveys of cattle, but *L.* grippotyphosa is the dominant serovar causing clinical disease in cattle while the disease in sheep is uncommon.[18]

The distribution of isolates and prevalence of serovars varies according to regions of the country.[16] Both isolation rate and seroprevalence are higher in the south eastern, south central, and Pacific coast regions than for other regions of the United States.[16] The isolation rate is related more to regional temperature than to amount of precipitation. This suggests that high levels of precipitation are not required for transmission of leptospirosis; oases in arid lands and deserts may become well-defined endemic zones by introduction of carrier animals.

Farmed deer

Leptospirosis is a well-established clinical disease in farmed deer in New Zealand.[19] Slaughterhouse surveys of farmed deer in New Zealand found serological evidence of serovar hardjo in 73.6%, pomona in 41.5%, copenhagi in 11.3%, and tarassovi in 15.1% of farms. Antibodies to serovars australis, ballum, and *balonica* were present in three, one, and four of six herds studied, respectively. The titer prevalence to hardjo was higher than that of pomona and other serovars within farms. Renal lesions were characteristic of subclinical leptospirosis, and spirochetes were present in renal tubules. Cultures were positive in 10 stags from six lines with similar prevalence across age groups. On-farm surveys found a 10 to 30% within-herd prevalence of pomona and hardjo titers in 56% of 3-month-old deer herds; by 11 months of age, 100% of herds were titer-positive with high prevalences to one or both serovars.

Sheep and goats

The disease in sheep has been reported in many countries and in goats in Israel. Leptospirosis in sheep can cause lamb losses due to congenital infections, starvation of lambs because of the acute agalactia of hardjo infection of the ewes, and fatal infection of feedlot lambs infected with grippotyphosa. Deaths of animals and loss of condition in mildly affected animals are the main causes of loss.

Although few outbreaks are recorded, an infection rate of 75% is not uncommon in sheep and case–fatality rates usually average about 20% in this species and up to 45% in goats. *L.* pomona is the common infection and the cause of most clinical leptospirosis in sheep. Infection with *L.* hardjo occurs but is unlikely to be a source of infection for cattle herds. Sheep are not natural maintenance hosts for pomona or hardjo and are likely to have infections of relatively short duration,

producing severe pathological effects. However, persistent leptospiruria due to hardjo in sheep where no contact with cattle has occurred suggests that sheep may be a maintenance host for this serovar.[20] This could complicate control of hardjo infection in cattle which are free of this serovar, and infected sheep are a potential zoonotic risk to abattoir workers, sheep farmers, and shearers which previously had not been considered. Infection with serovar hardjo is widespread in Merino stud rams in South Australia.[21]

Pigs

In infected herds the prevalence of positive serological reactors is high, and in large infected pig populations is about 20%. Economic losses are about equally divided between abortions and deaths of weak and unthrifty newborn pigs. In Iowa, 38% of sera from National Animal Health Monitoring System herds were positive to one or more of 12 serovars. Infection of pigs at slaughter is associated with multifocal interstitial nephritis, which results in condemnation of kidneys.[2] *L.* pomona (genotype *kennewicki*) has been the predominant infection in pigs but with the widespread use of bacterins against it, other infections are assuming importance. *L. tarassovi*, copenhageni, ballum, bratislava, muenchen, and hardjo are now isolated more frequently.

Swine are affected by several leptospiral serovars and the clinical signs often associated with these infections include poor reproductive performance.[22–24] Seropositive sows have a greater risk of weak newborn pigs and having more weak newborn piglets per litter.[23] In some areas suboptimal reproductive performance was associated with certain serovars such a grippotyphosa and not others such as autumnalis, bratislava, pomona, and icterohemorrhagiae.[24]

The most common serovar antibodies found in pigs in Prince Edward Island swine herds were *L.* icterohemorrhagiae, *L.* bratislava, *L.* autumnalis, and *L.* pomona.[25] Only herds with a higher prevalence of *L.* bratislava had more infertility as measured by non-productive sow days per parity.

Pigs in intensive housing present a different problem from those in more conventional housing or at pasture. In large pig units the possibility for cross-infection is high because of high population density. The movement of pigs from pen to pen, and access to effluent from other pens are the critical means of spread in these circumstances. The spread of infection within piggeries is encouraged by mixing infected with uninfected pigs, which results in epidemics within the pens. Transmission from infected to susceptible grower pigs occurs continuously in grower houses, with a constant proportion of pigs becoming infected each week. Introduction onto a farm may be via an imported boar who frequently is found to harbor leptospires in the genital tract. Lepospira were found commonly in the kidneys of slaughter fattening pigs in Vietnam but are not considered to be the cause of the white spotted kidneys of pigs.[26]

The Australis serogroup of leptospires is now important because of an increasing awareness that antibodies to bratislava are widespread in the pig populations of many countries, the recovery of *lora*, *muenchen*, and bratislava from pigs, and the involvement of bratislava and *muenchen* in reproductive problems of swine herds. All of the pig isolates of the Australis serogroup have been identified as either bratislava or *muenchen*, and there are also differences at the subserovar level which may be important in understanding the epidemiology of the Australis serogroup, the development of efficacious vaccines, and the pathogenesis of disease. Certain genotypes are associated with abortion and stillbirths in pigs, while another genotype may be responsible for meningitis in piglets.

House mice on swine farms may be serologically positive to *L.* bratislava, which suggests a possible source of the organism.

Horses

- **Recurrent uveitis**. Leptospirosis is relatively mild in the horse, except for blindness due to recurrent uveitis or periodic ophthalmia. When groups of horses are infected, up to 30% of the adult horses may be serologically positive with a higher prevalence in tropical areas. The dominant serovar varies widely between localities. A high seroprevalence of bratislava occurs in healthy horses in Ireland and in horses in Ohio. The high seroprevalence to bratislava suggests that the horse may be a maintenance host for this serovar.
- **Nonulcerative keratouveitis**. A case of nonulcerative uveitis associated with leptospira infection in a 2-year-old horse in Japan has been described.[27] The horse was seropositive to three serovars of *L.* interrogans (*pyrogenes*, canicola, and icterohemorrhagiae
- **Neonatal foal disease**. A severe rapidly fatal illness in foals characterized by massive pulmonary hemorrhage and kidney disease has been associated with serological evidence of bratislava and serogroup Australis serovar lora
- **Abortion and stillbirths**. Leptospirosis is an important cause of abortions and stillbirths in the horse population of central Kentucky in the United States. *L. kennewicki*, grippotyphosa, pomona, and bratislava were isolated from aborted fetuses.[28] Leptospirosis has also been diagnosed as a cause of abortions, stillbirths, neonatal illness, and neonatal death on a horse farm involved in a flooding incident.[29] Serological surveys of thoroughbred and standardbred horses in Ontario revealed a higher prevalence of bratislava, which increased with age. In a survey of horses in Alberta, titers to *L.* icterohemorrhagiae, bratislava, copenhagi, and autumnalis were common (94.6%, 56.6%, 46.5%, and 43.5%, respectively). The prevalence to other serovars ranged from 0.8–27.2%.[30] The probability of being seropositive increased by approximately 10% with each year of life. Horses managed as individuals (e.g. racetrack horses) were about half as likely to be seropositive as those managed in groups (e.g. rodeo horses). A giant cell hepatitis in four aborted foals has been associated with the presence of pomona (*kennewicki*).

The risk factors associated with the likelihood of seropositivity to *L.* pomona, *L.* autumnalis, and *L.* bratislava in horses in New York State have been quantified.[31]

Rodent exposure was associated with risk of exposure to all serovars. Management was associated positively with the risk of exposure to serovars pomona and bratislava, but not with risk of exposure to autumnalis. Soil and water had a positive association with risk of exposure to pomona and autumnalis but not to bratislava. The wildlife index value and the population density of horses turned out together were associated with risk of exposure to autumnalis.

A bacteriological survey of kidneys from abattoir horses in Portugal found serogroups *L.* australis and *L.* pomona, which were identified as *L.* bratislava, and *L.* kirschneri serovar Tsaratsovo, respectively.[32] Leptospiral antibodies were more than 1:10 in 37% of the horses.

Methods of transmission

The source of infection is an infected animal which contaminates pasture, drinking water, and feed by infective urine, aborted fetuses, and uterine discharges. All of the leptospiral types are transmitted within and between species in this way. A viable infected neonate can harbor the infection for several weeks after birth. The semen of an infected bull may contain leptospirae and transmission by natural

breeding or artificial insemination can occur but is uncommon. In rams, the semen is likely to be infective for only a few days during the period of leptospiremia; in boars there is no evidence of coital transmission. *L. interrogans* serovar hardjo is excreted from the genital tract of aborting cows for as long as 8 days after abortion or calving and is detectable in the oviducts and uterus for up to 90 d after experimental infection and in naturally infected cows. It may also be present in the genital tract of bulls and venereal spread of the infection is possible. Young pigs may act as carriers for 1 year and adult sows for 2 months. Because of the high intensity and long duration of the infection in pigs, they play an important role in the epidemiology of leptospirosis.

Leptospiruria

Urine is the chief source of contamination because animals, even after clinical recovery, may shed leptospirae in the urine for long periods. All animals which have recovered from infection may intermittently shed organisms in the urine and act as 'carriers'. In cattle, leptospiruria may persist for a mean period of 36 d (10–118 d) with the highest excretion rate in the first half of this period. Sheep and horses are not common sources of infection because of low grade and intermittent leptospiruria. In any species, the leptospirae may persist in the kidney for much longer periods than they can be recovered from the urine by routine laboratory methods. Urine drinking by calves is not an uncommon form of pica in some dairy herds and is a means of transmission.

Wildlife as source of infection

Although surveys of the incidence of leptospirosis in wildlife have been conducted and the pathogenic effects of *L.* pomona on some species, particularly deer and skunks have been determined, the significance of wildlife as a source of infection for domestic animals is uncertain. Variable rates of seroprevalence to leptospires have been documented in white-tailed deer, mule deer, pronghorns, moose, red deer, and elk.[33] There is a high prevalence of infection in feral pigs, and in wild brown rats trapped on farms in the United Kingdom the prevalence of *L. icterohaemorrhagiae* and bratislava was about 14%.[34] *L.* canicola is known to spread from domestic dogs and jackals to cattle and, when hygiene is poor, even from humans to cattle. The serovar bratislava has been associated with severe interstitial nephritis in raccoons in a recreational area in Quebec which were also serologically positive to pomona, hardjo, and grippotyphosa.[35]

Portal of entry of organism

Entrance of the organism into the body occurs most probably through cutaneous or mucosal abrasions. Transplacental transmission is uncommon but neonatal infection in utero has occurred. Oral dosing is an unsatisfactory method for experimental transmission as compared to injection and installation into the nasal cavities, conjunctival sac, and vagina.

Environmental and management risk factors

Survival of the organism in the environment depends largely upon variations in soil and water conditions in the contaminated area. The organism is susceptible to drying, and a pH lower than 6 or greater than 8 is inhibitory. Low urinary pH in cattle fed with brewer's grains may inactivate leptospires in animals with leptospiruria.[36] Ambient temperatures lower than 7–10°C (44.6–50°F) or higher than 34–36°C (93–96°F) are detrimental to its survival.

Ground surface moisture and water is the most important factor governing the persistence of the organism in bedding or soil; it can persist for as long as 183 days in water-saturated soil but survives for only 30 min when the soil is air-dried. In soil under average conditions, survival is likely to be at least 42 d for *L.* pomona. It survives in free, surface water for long periods; the survival period is longer in stagnant than in flowing water although persistence in the latter for as long as 15 d has been recorded. Contamination of the environment and capacity of the organism to survive for long periods under favorable conditions of dampness may result in a high incidence of the disease on heavily irrigated pastures, in areas with high rainfall and temperate climate, in fields with drinking water supplies in the form of easily contaminated surface ponds, and in marshy fields and muddy paddocks or feedlots. Because of the importance of water as a means of spreading infection, new cases are most likely to occur in wet seasons and low lying areas, especially when contamination and susceptibility are high. A differential distribution has been observed in the prevalence of seropositives in cattle in Australia. *L.* hardjo antibodies have a high prevalence through all rainfall areas, but *L.* pomona is much more common in low rainfall areas.

Certain management factors have been identified which pose risks of *L.* hardjo infection being introduced into dairy herds:[37]

- Purchase of infected cattle
- Co-grazing or common grazing with infected cattle or sheep
- Purchase or loan of an infected bull
- Access of cattle to contaminated water supplies such as streams, rivers, flood or drainage water.

Economic importance

Leptospirosis is a major cause of economic loss in farm animals. The majority of leptospiral infections are subclinical and associated with fetal infections causing abortions, stillbirths, and the birth of weak neonates with a high death rate in cattle, sheep, horses ,and pigs. In cattle, epidemics of abortions, infertility, and increased culling rate cause major economic losses. Epidemics of agalactia in dairy herds, the **milk drop syndrome**, are associated with infection with *L.* hardjo.

Zoonotic implications

In the past decade, leptospirosis has emerged as a globally important infectious disease in human medicine.[38,39] It is uncommon in developed countries but the incidence is increasing in travelers returning from endemic countries. The epidemiology has undergone major changes, with a shift away from the traditional occupational disease in developed countries, to a disease associated with recreational exposures.[39] It is now recognized as an emerging, potentially epidemic disease associated with excess rainfall in tropical settings, representing a significant public health hazard. Mortality in humans with leptospirosis remains significant because of delays in diagnosis due to lack of diagnostic infrastructure and adequate clinical suspicion when patients are presented for medical diagnosis and care. The differential diagnosis of febrile illness in returning travelers should include leptospirosis. Pulmonary hemorrhage is increasingly being recognized as a major, often lethal, manifestation of leptospirosis in humans, the pathogenesis of which is unclear. Treatment consists of tetracyclines and beta-lactam/cephalosporins. No vaccine is available for the prevention of leptospirosis in humans.

Leptospirosis is an important zoonosis and is an occupational hazard to butchers, farmers, and veterinarians.[40] The high prevalence of leptospiral infection (serovars pomona and hardjo) in Texas cattle represents potential threats to human health and agricultural economics.[41] The incidence of positive agglutination tests in humans in contact with infected cattle is surprisingly low and clinical cases in humans in which the infection is acquired from animals are not common. Human infection is most likely to occur by contamination with infected urine or uterine contents. Veterinarians may become infected by handling the tissues and urine of sows which have aborted from pomona infection. Although leptospirae may be

present in cow's milk for a few days at the peak of fever in acute cases, the bacteria do not survive for long in the milk and are destroyed by pasteurization. However, farm workers who milk cows are highly susceptible to *L. interrogans* serovar hardjo infection and one New Zealand survey found 34% of milkers were seropositive, mostly to *L. interrogans* serovar hardjo, but a high proportion also to *L. interrogans* serovar pomona. This has aroused alarm and leptospirosis became known as 'New Zealand's No. 1 dairy occupational disease'. A campaign of vaccination of dairy cattle across the country resulted in a marked decrease in the incidence of the disease in humans. In most situations, dogs, cats, and horses are unlikely to contribute to human infection.[40]

Leptospirosis is New Zealand's most common occupationally acquired infectious disease, and the incidence of the disease is high compared with other temperate developed countries.[42] The epidemiology of leptospirosis in New Zealand has been changing. The annual incidence of human leptospirosis in New Zealand from 1990–98 was 4.4 per 100 000. Incidence was highest among meat processing workers (163/100 000), livestock farm workers (91/100 000) and forestry-related workers (24/100 00). The most commonly detected serovars were *L. borgpetersenii* sv. ballum (11.9%). The annual incidence of leptospirosis declined from 5.7/100 000 in 1990–92 to 2.9/100 000 in 1995–98. The incidence of *L. borgpetersenii* sv. hardjo and *L. interrogans* sv. pomona infection declined, while the incidence of *L. borgpetersenii* sv. ballum infection increased. The increasing incidence of *L. borgpetersenii* sv. ballum suggests changing transmission patterns via direct or indirect exposure to contaminated water. The risk of transmission of leptospirosis from dairy cattle infected with *L.* hardjo to dairy workers in Israel was low.[43]

Leptospirosis is a risk factor for swine producers and slaughterhouse workers. An epidemiological investigation of people exposed to infected pigs from a university-owned swine herd found 8% of the workers were confirmed to have leptospirosis.[44] Risk factors included smoking and drinking beverages while working with infected pigs. Washing hands after work was protective. Leptospirosis is infrequently diagnosed by human physicians in the United States and veterinarians have often informed physicians of the potential of leptospirosis in humans. The disease can be prevented through appropriate hygiene, sanitation, and animal husbandry.[44] It is essential to educate people working with animals or animal tissues about measures for reducing the risk of exposure to such zoonotic pathogens as leptospira.

Veterinary students may be exposed to leptospirosis by taking courses in food inspection and technology, on-farm clinical work experiences, contact with pets especially carnivores, and contact with animal traders.[45] In a one-year period, the seroprevalence of leptospirosis in veterinary students in a veterinary school in Spain increased from 8.1% to 11.4%. The incidence of the disease during the study was 0.0394.

PATHOGENESIS

Leptospirosis manifests itself as a disease in several different ways. Leptospires invade the host across mucosal surfaces or softened skin. They have the ability to bind to epithelial cells and attach to the constituents of the extracellular matrix through an active process involving surface proteins. Pathogenic leptospires are found extracellularly between cells of the liver and kidney. Release of lymphokines such as tumor necrosis factor (TNF-alpha) from monocytes through the endotoxic activity of the leptospiral LOS may be an important virulence mechanism. Induction of TNF-alpha release may help explain the damage to endothelial cells with resultant hemorrhage seen in severe leptospirosis.

Leptospirosis can occur as an acute and severe disease due to septicemia with evidence of endotoxemia such as hemorrhages, hepatitis, nephritis, meningitis; as a subacute moderately severe disease with nephritis, hepatitis, agalactia, and meningitis, or as a chronic disease characterized by abortion, stillbirth, and infertility. In the occult form there is no clinical illness. The form of the disease that occurs depends largely on the species of the host as set out in Table 20.3. Variations between serotypes of *L. interrogans* in their pathogenicity also affect the nature of the signs which appear. For example, in *L.* pomona infections, intravascular hemolysis and interstitial nephritis are important parts of the disease. However, *L.* hardjo does not produce hemolysin and does not cause interstitial nephritis. But it does cause clinical infection in **sexually mature, lactating or pregnant females**. Thus infection occurs in the pregnant uterus and lactating mammary gland resulting in septicemia, abortion, and mastitis. The pathogenesis of the disease associated with *L.* pomona is set out as follows.

Acute form

After penetration of the skin or mucosa, the organisms multiply in the liver and migrate to, and can be isolated from, the peripheral blood for several days until the accompanying fever subsides. At this time serum antibodies begin to appear and organisms can be found in the urine.

Septicemia, capillary damage, hemolysis, and interstitial nephritis

During the early period of septicemia, sufficient hemolysin may be produced to cause overt hemoglobinuria as a result of extensive intravascular hemolysis. This is an unlikely event in adult cattle, but is common in young calves. If the animal survives this phase of the disease, localization of the infection may occur in the kidney. Hemolysis depends on the presence of a serovar which produces hemolysin. Capillary damage is common to all serovars and during the septicemic phase, petechial hemorrhages in mucosae are common. Vascular injury also occurs in the kidney and if the hemolysis is severe, anemic anoxia and hemoglobinuric nephrosis may occur. There is some evidence that leptospires produce a lipopolysaccharide endotoxin which may exacerbate the vascular lesions. The infection localizes in the renal parenchyma, causing an interstitial nephritis and persistence of the leptospirae in these lesions results in prolonged leptospiruria. The renal lesion develops because the infection persists there long after it has been cleared from other tissue sites. In the acute phase of the disease, the animal may die from septicemia or hemolytic anemia or both. Subsequently, the animal may die of uremia caused by interstitial nephritis.

Focal chronic interstitial nephritis, also called 'white spotted kidney' is a common finding in clinically healthy cattle at slaughter and has frequently been assumed to be related to current of prior infection with *Leptospira* spp. However, studies of

Table 20.3 Forms of leptospirosis in the animal species.

	Acute form	Subacute form	Chronic form
Cattle	+ (Calves only)	+	+ (Abortion)
Sheep and goat	+ (Includes abortion)	–	–
Pig	+ (Rarely and only in piglets)	–	+ (Abortion)
Horse	–	+	+ (Abortion and periodic ophthalmia)

'white spotted kidney' in cattle at the abattoir indicate that neither *Leptospira* spp. nor active infection by other bacteria are associated with the lesions.[46]

Abortion

Following systemic invasion, abortion may occur due to fetal death, with or without placental degeneration. Abortion usually occurs several weeks after septicemia because of the time required to produce the changes in the fetus, which is usually autolyzed at birth. Abortion occurs most commonly in the second half of pregnancy, due probably to the greater ease of invasion of the placenta at this stage, but may occur at any time from 4 months on. Although abortion occurs commonly in both cattle and horses after either the acute or the subacute form of the disease, abortion without prior clinical illness is also common. This is particularly the case in sows and occurs to a less extent in cows and mares; this may be due to degenerative changes in the placental epithelium. Leptospirae are rarely present in the aborted fetuses, however if the aborted fetus has survived the infection long enough to produce antibodies, these may be detectable.

Experimental infection of serologically negative pregnant cattle with a north-Queensland strain of *L. borgpetersenii* serovar hardjo resulted in seroconversion and shedding of the organism in the urine.[47] Elective cesarean sections were done 6 weeks after challenge. No evidence of *L.* hardjo infection of the fetuses occurred. Some of the fetuses had histopathological lesions consistent with *Neospora* sp. infection.

Encephalitis

Localization of leptospirae in nervous tissue is common in sheep and goats and may result in the appearance of signs of encephalitis.

Subacute and occult forms

In the subacute form, the pathogenesis is similar to that of the acute septicemic form, except that the reaction is less severe. It occurs in all species, but is the common form in adult cattle and horses. Occult cases, with no clinical illness but with rising antibody titers, are common in all animals. These are difficult to explain but may be associated with strains of varying pathogenicity. But with leptospirosis, characteristically, differences between groups may be associated with prior immune status, environmental conditions, or number of carriers in relation to severity of exposure.

Periodic ophthalmia (recurrent uveitis) in the horse

There is some evidence of a causal relationship between leptospiral infection and periodic ophthalmia in the horse.[48] The incidence of serologically positive reactors is higher in groups of horses affected with periodic ophthalmia than in normal animals. Agglutinins are present in the aqueous humor in greater concentration than in the serum. Serological surveys indicate that leptospira infection is not a major factor in the etiology of equine anterior uveitis in the United Kingdom, but serological evidence of pomona is associated with uveitis in horses in the United States. The opacity in both cornea and lens is a consequence of the antigenic relationship between leptospires and components of the ocular tissues and does not require the presence of living bacteria. A 52-kDa protein appears to be involved in the antigenic relationship between the leptospires and equine ocular tissues and is located inside the bacterium. The uveitis alters the composition of the aqueous humor and impedes the nutrition of the ocular structures, leaving sequelae such as iris atrophy, synechiae, and corneal opacity.

Retinal immunopathology in horses with uveitis has been described and may be a primary immunological event in equine uveitis, providing evidence that leptospira-associated uveitis may be a distinct subset of equine uveitides.[48]

Immune mechanisms

Following infection, specific antibodies are induced which opsonize leptospires, facilitating their elimination from most parts of the body. However, leptospires which reach the proximal renal tubules, genital tract and mammary gland appear to be protected from circulating antibodies. They persist and multiply in these sites, and may be excreted and transmitted to susceptible, in-contact animals, primarily by urine. Furthermore, and of major importance, the level of serum antibody commonly declines to undetectable levels in animals which are persistently infected.

The first serological response with *L.* hardjo infection is the production of immunoglobulin M (IgM) antibodies. These rise rapidly but commonly decline to undetectable concentrations by 4 weeks after infection. Within 1–2 weeks of infection, IgG1 antibodies appear, and at 3 months they represent 80% of antibodies detected in the microscopic agglutination test (MAT). The MAT titer peaks 11–21 d after infection but may vary from 3200 to an undetectable concentration. The MAT titer declines gradually over 11 months but the persistence is variable. Vaccination induces antibodies that are mainly of the IgG class with levels peaking at 2 weeks after a two-dose vaccination but decreasing rapidly to levels lower than those after natural infection. **Approximately 95% of vaccinated heifers do not have MAT antibodies 20 weeks after the second of two vaccinations given 4 weeks apart and the absence of titers is not necessarily an indication that protection has waned**. Vaccinated animals are protected from natural challenge for many months after their MAT titers become undetectable. The serological response of calves vaccinated at 3 months of age is lower than those vaccinated at 6 months of age because of the presence of maternal antibody. Transfer of passive immunity antibodies to newborn calves occurs via the colostrum and the antibodies persist in the calves for 2–6 months.

While antibodies against leptospiral lipopolysaccharides (LPS) give passive protection in some animal models, cattle vaccinated against serovar hardjo with pentavalent vaccines are vulnerable to infection with serovar hardjo despite the presence of high titers of anti-LPS antibody. It is now known that peripheral blood mononuclear cells (PBMC) from cattle vaccinated with an *L. interrogans* serovar hardjo vaccine which protects against serovar hardjo proliferated in vitro in response to hardjo antigens. Thus a cell-mediated immune response to serovar hardjo may be necessary for protection.[10] A protective killed vaccine against serovar hardjo induces a strong antigen-specific proliferative response by PBMC from vaccinated cattle 2 months after the first dose of vaccine. This response was absent from unvaccinated cattle. The mean response peaked by 2 months after completion of the two-dose vaccination regimen, and substantial proliferation was measurable in vitro cultures throughout 7 months of the study period. Up to one-third of the PBMC from vaccinated animals produced gamma interferon (IFN-γ after 7 days in culture with antigen. One-third of the interferon gamma producing cells were (gamma delta lymphocytes, with the remainder cells being $CD4^+$ T-cells.[10] Thus a very potent Th1-type immune response was induced and sustained following vaccination with a killed bacterial vaccine adjuvanted with aluminum hydroxide and the involvement of gamma delta T-cells in the response. The induction of this Th1-type **cellular immune response** is associated with the protection afforded by the bovine leptospiral vaccine against *L. borgpetersenii* serovar hardjo.[10]

The immune response of naïve and vaccinated cattle following challenge with a virulent strain of *L. borgpetersenii* serovar hardjo has been examined.[49] Beginning at 2 weeks after challenge, gamma interferon was measured in antigen-stimulated PBMC cultures from nonvaccinated animals, although the

amount produced was always less than that in cultures of PBMC from vaccinated animals. IFN-γ^+ cells were also evident in antigen-stimulated cultures of PBMC from vaccinated but not from non-vaccinated animals throughout the post-challenge period. Naïve and vaccinated animals had similar levels of antigen-specific immunoglobulin G1 (IgG1) following challenge; vaccinated animals had two-fold more IgG2. It is evident that while infection may induce a type 1 response, it is too weak to prevent establishment of chronic infection.

CLINICAL FINDINGS

The clinical findings in leptospirosis are similar in each animal species and do not vary greatly with the species of *Leptospira* except that infection with *icterohaemorrhagiae* usually causes a severe septicemia. For convenience the various forms of the disease are described as they occur in cattle, and comparisons are made with the disease in other species. In all animals the incubation period is 3–7 d.

Cattle

Leptospirosis in cattle may be **acute**, **subacute** or **chronic** and is usually associated with **pomona or hardjo**.

Acute leptospirosis associated with pomona

Calves up to 1 month old are most susceptible to the acute leptospirosis. The disease is manifested by septicemia, with high fever (40.5–41.5°C; 105–107°F), anorexia, petechiation of mucosae, depression, and acute hemolytic anemia with hemoglobinuria, jaundice and pallor of the mucosae. Because of the anemia, tachycardia, loud heart sounds and a more readily palpable apex beat are present: dyspnea is also prominent. The case–fatality rate is high and if recovery occurs, convalescence is prolonged. In adult cattle, abortion due to the systemic reaction may occur at the acute stage of the disease. Milk production is markedly decreased and the secretion is red-colored or contains blood clots, and the udder is limp and soft. Mastitis as part of leptospirosis has often been described in cattle and a high somatic cell count in grossly abnormal milk suggests mastitis, but these changes are due to a general vascular lesion rather than local injury to mammary tissue. Severe lameness due to synovitis is recorded in some animals and a necrotic dermatitis, probably due to photosensitization, in others.

Subacute leptospirosis associated with *L.* pomona

The subacute form of leptospirosis differs from the acute form only in degree. Similar clinical findings are observed in a number of affected animals but not all of the findings are present in the same animal. The fever is milder (39–40.5°C; 102–105°F), and depression, anorexia, dyspnea and hemoglobinuria are common but jaundice may or may not be present. Abortion usually occurs 3–4 weeks later. One of the characteristic findings is the marked drop in milk production and the appearance of blood-stained or yellow-orange, thick milk in all four quarters without apparent physical change in the udder.

Chronic leptospirosis associated with *L.* pomona

The clinical findings in the chronic form of leptospirosis are mild and may be restricted to abortion. Severe 'storms' of abortions occur most commonly in groups of cattle which are at the same stage of pregnancy when they are exposed to infection. The abortions usually occur during the last trimester of pregnancy. Apart from the abortion, there is no depression of reproductive efficiency in cattle affected by leptospirosis. Many animals in the group develop positive agglutination titers without clinical illness.

There are occasional reports of leptospiral meningitis in cattle. In coordination, excessive salivation, conjunctivitis and muscular rigidity are the common signs.

Leptospirosis associated with *L.* hardjo

Infertility and milk drop syndrome occurs only in pregnant or lactating cows because the organism is restricted to proliferation in the pregnant uterus and the lactating mammary gland. There is a sudden onset of fever, anorexia, immobility and agalactia. The milk is yellow to orange and may contain clots. The udder is flabby, there is no heat or pain, and all four quarters are equally affected. The **sudden drop in milk production** may affect up to 50% of cows at one time and cause a precipitate fall in the herd's milk yield. The decline may last for up to 8 weeks but in individual cows milk production will return to normal within 10–14 days. The milk may have a high leukocyte count which subsides over a period of about 14 days as milk production returns. In some cases, there is no evidence of mastitis, no change in the consistency of the milk and no changes in the udders of affected cows, but leptospiruria may be present in up to 30% of affected cows. In endemically infected dairy herds, there may be no relationship between seropositive and seronegative cows in different lactations, nor at different stages of lactation and total lactation milk yield.[50]

The **herd fertility status** incorporating the **first service conception rate, the number of services per conception for cows conceiving, the calving-to-conception interval, and the culling rate** usually reveals a low reproductive performance, especially during the year of the diagnosis.[51] The effect is also temporary and not easily detected. Exposure of nonvaccinated dairy cows to *L.* hardjo can be associated with a subsequent reduction in fertility, as indicated by a greater time from calving to conception and a higher number of breedings per conception.[52]

Abortion may occur several weeks after the initial infection and may also occur as the only evidence of the disease; in some areas or circumstances it is the principal clinical manifestation of leptospirosis due to hardjo, and the principal cause of abortion in cattle. In others it is thought to be an uncommon cause of abortion. This may be related to different strains of the serotype, or to the degree to which the disease has become enzootic. Thus outbreaks of milk yield drop and systemic illness appears to be the characteristic clinical picture when the disease first appears in an area. However, as natural immunity develops in adult cows, only heifers become newly infected, and the only sign is abortion. Furthermore, many cows have subclinical infections with hardjo in which only a fall in milk yield may be detectable.

Leptospirosis associated with *szwajizak*, produced experimentally, is characterized by a short bout of fever, listlessness and anorexia, and diarrhea in some. The illness lasts for 24 h.

Pigs

Pomona is the common infection, *tarassovi* is the other common infection, and chronic leptospirosis is the commonest form of the disease in pigs. It is characterized by abortion and a high incidence of stillbirths. Failure to conceive is not usually observed in leptospirosis but has been reported in infections with canicola. In an infected herd the rearing rate may fall as low as 10–30%. An abortion 'storm' may occur when the disease first appears in a herd but abortions diminish as herd immunity develops. Most abortions occur 2–4 weeks before term. Piglets produced at term may be dead or weak and die soon after birth. Hardjo may be a sporadic cause of reproductive disease and muenchen and bratislava are occasional isolations during investigations of porcine abortion and stillbirths. In a survey of swine farms in Canada, those herds with a high serological prevalence of serovars bratislava and pomona had more infertility as measured by non-productive sow days per parity.[25] There was no association between infertility and antibodies to serovars autumnalis and icterohemorrhagiae.[25]

Rarely the acute form as it occurs in calves also occurs in piglets in both natural field outbreaks and in experimentally produced cases. *Icterohaemorrhagiae* infection causes septicemic leptospirosis with a high mortality rate.

Sheep and goats

The disease is rare in these species so that good descriptions of the naturally occurring disease in them are lacking; most affected animals are found dead, apparently from septicemia. Affected animals are febrile, dyspneic, snuffle, and hang their heads down. Some have hemoglobinuria, pallor of mucosae and jaundice, and die within 12 h. Lambs, especially those in poor condition, are most susceptible. The chronic form may occur and is manifested by loss of bodily condition, but abortion seems to be almost entirely a manifestation of the acute form when the infection is pomona. With hardjo, abortion has been recorded as the only clinical sign, and oligolactia and agalactia, similar to the bovine milk drop syndrome, have been observed in lactating ewes.

Horses

Abortion

Leptospira interrogans serovar pomona type *kennewicki* is a major cause of abortions and stillbirths in the equine population in Kentucky in the United States;[53,54] other serovars also occur. The gestational ages range from 140 d to full-term mean (250 d).[55] Horses in central Kentucky are exposed to multiple *Leptospira* serovars including bratislava, icterohemorrhagiae, grippotyphosa, pomona genotype kennewicki, hardjo and canicola.[56] In some years in Kentucky, leptospiral infection is a leading cause of abortion in which fetoplacental infections account for one-third of the abortions, stillbirths and perinatal deaths and in which 75% are due to bacterial infection.[57]

Periodic ophthalmia

Recurrent uveitis in horses (**periodic ophthalmia, moon blindness, recurrent iridocyclitis**) is a late complication of systemic leptospirosis in horses with signs beginning months to years after naturally acquired or experimentally induced infection. It is often associated with infection with *L. interrogans* serovar pomona. Clinically there are recurrent episodes of ocular disease including photophobia, lacrimation, conjunctivitis, keratitis, a pericorneal corona of blood vessels, hypopyon and iridocyclitis. Recurrent attacks usually terminate in blindness in both eyes. There is a strong relationship between uveitis and leptospiral seroactivity in horses. Seropositive horses with uveitis are at increased risk of losing vision, compared with seronegative horses with uveitis, and Appaloosas are at an increased risk of developing uveitis and associated blindness, compared with that in non-Appaloosas. The disease has been produced experimentally by producing infection with pomona. Infection with pomona in foals has been observed in association with *Rhodococcus equi* to cause a very heavy mortality. The foals died of a combination of interstitial nephritis and uremia, and pulmonary abscessation and chronic enteritis. Leptospirosis has been suspected as a cause of renal dysfunction in a horse[58] and hematuria and leptospiruria described in a foal.[59]

Nonulcerative keratouveitis associated with leptospiral infection has been described in horses.[27] Photophobia, epiphora, and blepharospasm are common. Hyperemia of the bulbar conjunctiva, edema of the paralimbal cornea, pupillary block and iris bombe are also present. As the disease progresses, there may be hyphema, hypopyon, and organized fibrin in the anterior chamber, myosis, dyscoria due to posterior synechiae and the cornea may become opaque and vascularized.[27] The cornea retains no fluorescein dye.

CLINICAL PATHOLOGY

General considerations

Laboratory procedures used in the diagnosis include culture or detection of leptospires in blood or body fluids, and detection and measurement of antibody in blood and body fluids such as urine, cerebrospinal fluid and cervico-vaginal mucus.[60] Culture of leptospires is laborious and can take up to 2 months. Serological and microbiological detection of chronically infected animals is difficult, as is the confirmation of leptospirosis as a direct cause of reproductive losses in a herd. A positive diagnosis of leptospirosis in individual animals is often difficult because of the variation in the nature of the disease, the rapidity with which the organism dies in specimens once they are collected and their transient appearance in various tissues. During the septicemic stage, leptospirae are present only in the blood and there may be laboratory evidence of acute hemolytic anemia and increased erythrocyte fragility and often hemoglobinuria. A leukopenia has been observed in cattle while in other species there is a mild leukocytosis. However, the only positive diagnostic measure at this stage of the disease is culture of the blood. If abortion occurs, the kidney, lung and pleural fluid of the aborted fetuses should be examined for the presence of the organism. Serological testing at the time of abortion is often unreliable because the acute titers have already peaked and are declining. In the stage immediately after the subsidence of the fever, antibodies begin to develop and the leptospirae disappear from the blood and appear in the urine. The leptospiruria is accompanied by albuminuria of varying degrees and persists for varying lengths of time in the different species.

The diagnosis of leptospirosis is much easier on a herd basis than in a single animal because in an infected herd, some animals are certain to have high titers and the chances of demonstrating or isolating the organism in urine or milk are increased with samples being taken from many animals. On the other hand, in a single animal, depending on when the infection occurred, the titer may have declined to a low level and be difficult to interpret. This becomes particularly important for the clinician confronted with a diagnosis of abortion due to leptospirosis in which the infection may have occurred several weeks previously and the serum may be negative or the titers too low for an accurate interpretation. Examination of the urine may be useful in these cases.

Serological and related tests

Acute and convalescent sera taken 7–10 d apart should be submitted from each clinically affected animal, or from those with a history of abortion, and sera should also be taken from 15–25% of apparently normal animals. Ten blood samples should be taken from each of the yearlings, the first-calf dams, the second-calf dams, and the mature age group in order to determine the infection status across the herd. If possible, wildlife or rodents which are known to inhabit the farm and use nearby water supplies should be captured and laboratory examinations of their tissues and blood carried out and the results compared with those obtained in the farm animals.

The Microscopic Agglutination Test (MAT) is the most commonly used serological test for the diagnosis of leptospirosis. In animals which survive infection, acute leptospirosis can readily be diagnosed on the basis of demonstrating a rising antibody titer in acute and convalescent sera.[60] Although paired sera are normally considered necessary so that a rise in titer can be detected, in cases of bovine abortion or stillbirth, infection may have occurred 1–4 weeks before the abortion by which time the MAT titers may be declining. Following infection, the IgM class of antibodies are first to appear followed by IgG antibodies, which persist for longer than IgM antibodies. The MAT detects both IgM and IgG antibodies. The MAT is particularly useful in diagnosis of disease associated with incidental, non-host-adapted serovars or acute disease associated with host-adapted serovars. It

is less useful in diagnosis of chronic disease in maintenance hosts since antibody response to infection may be negligible in chronic infections or may persist from subclinical infections. In pigs, MAT has an adequate sensitivity for some serovars, such as pomona, but is insensitive to infection associated with bratislava. The herd serological response to infection is often more helpful than the individual's response in chronic infections in maintenance hosts. Because agglutinating antibodies wane, the sensitivity of the MAT in detecting animals infected for more than 2 years is low, probably less than 50%. A major concern is the failure of the MAT to differentiate between titers after vaccination and those after natural infection since the titers may be of similar magnitude; however, titers after infection are in general, higher and persist longer than vaccination titers. Vaccinated cattle which subsequently become infected, may not mount an agglutinating antibody response.

A MAT titer of ≥100 is considered positive but there are several considerations in evaluating the MAT response. The MAT is a serogroup-specific test and serovars representative of all suspected serogroups should be tested. The test is a more sensitive detector of IgM antibody than IgG. It has a low sensitivity in chronic leptospirosis for detecting maintenance hosts. The test is inadequate for the detection of the carrier state in maintenance hosts, because titers ≥100 against host-adapted serovars have a low sensitivity but high specificity. The MAT is not a measure of immunity to infection because vaccination results primarily in an IgG response, with low (100–400) and transient (1–4 months) titers but immunity commonly persists in vaccinated animals long after MAT titers are negative. In cattle, titers of ≥100 are considered significant and a four-fold rise in titer on a paired sample taken 2 weeks apart is diagnostic. In abortion associated with incidental serovars, MAT titers against pomona and other incidental serovars are high, often ≥3000.

Paired sera are of limited value in chronic infections because abortion occurs after infection and titers are static or declining. In chronic hardjo infections, a recently aborting cow with a titer of ≥300 has about a 60%, of ≥1000 an 80%, and ≥3000 a 90% chance of fetal infection. If several aborting cows have high titers (≥300), this is evidence for the diagnosis of leptospirosis in unvaccinated herds. A semiautomated complement fixation test is available and is comparable in efficiency with the MAT.

The **ELISA test** is much more accurate than the others and has many advantages from the point of view of laboratory practice. It can be specific for IgM antibodies or IgG antibodies. A positive IgM-specific ELISA result can therefore indicate that infection occurred within the previous month. It has excellent diagnostic specificity and sensitivity, convenient technical features including automation, and can be used efficiently as a screening test for large numbers of serum samples. Some difficulty is encountered in interpreting the significance of titers of antibody in serum. For a diagnosis of leptospiral abortion in cattle, a reciprocal titer of 3000 is proposed as the threshold for pomona but no similar critical figure is available for hardjo. For a herd diagnosis of leptospirosis due to hardjo 10 animals from each of the yearling, first-calf heifer, second-calf heifer and adult cow groups should be tested.

An **indirect ELISA** has been developed for the detection of bovine antibodies to multiple *Leptospira* serovars including canicola, copenhagi, grippotyphosa, hardjo*bovis* pomona, and sejroe.[61]

An **antibody capture ELISA** is available to detect antibodies to a protective lipopolysaccharide fraction of *Leptospira borgpetersenii* serovar hardjo in cattle.[62]

A commercially available **ELISA** and the **Immunocomb Leptospirosis Kit** which detect *L.* hardjo antibodies have been compared with the **MAT**.[63] The Immunocomb and ELISA tests both exceeded the positive results obtained with the MAT.[63] The Immunocomb is very simple, and quick, requiring no sophisticated equipment.

Aqueous humor antibody. Measurement of aqueous humor antibody titers against leptospires in horses offers a more accurate means of establishing a diagnosis of leptospiral-associated uveitis than serology alone.

Serology in pigs. A comparison of diagnostic procedures for the diagnosis of porcine leptospirosis reveals that the apparent (maximum) sensitivities of diagnostic procedures for detecting infection were as follows: MAT (at a titer of 64 or 1024) 95%; IgM enzyme immunoassay 82%; culture of kidneys 61%; presence of white spots 55%; immunogold staining 52%; presence of large white spots 30%; and, Warthin–Starry silver staining 20%. An axial filament ELISA is a sensitive and specific test for the detection of antibodies against *L. interrogans* on a species rather than serovar level and has advantages over the MAT.

Demonstration or culture of organism or antibody

A number of tests are available to detect leptospires or leptospiral DNA in tissues or body fluids.[64]

Culture of urine. Of all the laboratory diagnostic tests for leptospirosis, the examination of urine samples for the organism probably offers the best opportunity to demonstrate the presence of infection. Following natural infection with *L.* hardjo, cattle may shed leptospires in the urine for between 28 and 40 weeks;[65] following experimental infection, shedding occurs for about 26–32 weeks. After the initial infection, large numbers of leptospires are shed in the urine for several weeks and thereafter there is a progressive decline in the numbers shed, which may be associated with a sharp increase in urinary anti-leptospiral IgG and IgA antibody levels.[66] Urine samples should be obtained from a cross-section of affected and non-affected (in-contact) animals. Furosemide can be given IV at 0.5–0.8 mg/kg BW and the second voiding of urine collected for culture. For maximum efficiency, one-half of each urine sample should be submitted with added formalin (1 drop to 20–30 mL of urine) and the other half submitted in the fresh state. The formalin prevents bacterial overgrowth and the fresh urine sample may be used for culture. Examination of urine using dark-field microscopy or fluorescent antibody test are useful tests. The fluorescent antibody test is more sensitive than dark field microscopy, detects degenerated as well as intact leptospires and may be serovar specific. Standard techniques for culture of leptospires have been described.[65]

Detection of organism in urine

Fluorescent staining of antibody in urine. A fast and accurate diagnostic method for detecting the presence of leptospirae and for identifying serotypes. Antibodies also appear in urine and milk and their measurement may have some significance in special circumstances.

Antibody in cervico-vaginal mucus. An ELISA has been used to detect specific antibody to *L.* hardjo in the cervico-vaginal mucus as early as 2 weeks after natural or experimental infection and may reach high levels after 8 weeks.[67] This may show some promise in diagnosis but has not yet been evaluated.

A comparison of a PCR assay with bacteriologic culture, immunofluorescence, and nucleic acid hybridization for detection of *L. borgpetersenii* serovar hardjo in urine of cattle found all were sensitive but a single technique was not the most sensitive for each animal tested.[68] Two techniques in combination are recommended for maximal sensitivity.

Detection of organism in tissues

DNA probes and PCR. Leptospires can be detected in tissues using a DNA genomic probe and DNA-based techniques will probably provide rapid and sensitive diagnostic techniques that are

serovar- and genotype-specific. Nucleic acid hybridization is a sensitive and rapid test for the detection of leptospires in the urine of cattle which become infected subsequent to vaccination, and is superior to bacteriological culture and fluorescent antibody testing. The polymerase chain reaction is also a promising test for the rapid detection of small numbers of leptospires in the urine of cattle infected with *L.* hardjo-bovis. A multiplex PCR is highly sensitive for detection of the organism in aborted bovine fetuses.[69]

Using a leptospira PCR assay, *L.* kirschneri has been identified as a potential cause of abortion in an fetal foal born on a farm with a history of repeated abortions.[70] Further confirmation of *L.* kirschneri was done by DNA sequence analyses of the PCR amplified DNA fragment.

Detection of organism in semen

In some countries, bulls destined for artificial insemination centers must be free of antibody to hardjo, grippotyphosa, canicola, pomona, sejroe, and *icterohaemorrhagiae* at a final serum dilution of 1:100 in the MAT. However, since animals with leptospirosis may not have a serum titer, it is possible that the semen of serologically negative but infected bulls may contain leptospires. Culture of leptospires is difficult, costly and time consuming. A polymerase chain reaction assay has been developed to detect pathogenic leptospires in the semen and urine of infected bulls.[71,72] PCR is a method of great potential for the detection of *Leptospira* spp. at bovine artificial insemination units.[54]

Detection in aqueous humor of horses with uveitis

Using PCR to detect the presence of *Leptospira* DNA, 70% of horses with uveitis were positive for *Leptospira* DNA, and 28% were culture positive for leptospires from the aqueous humor;[73] only 6% of horses free of uveitis used as controls were positive. The serologic results did not correlate well with the presence of *Leptospira* DNA or organisms in the aqueous humor.

NECROPSY FINDINGS

Acute bovine leptospirosis is characterized by anemia, jaundice, hemoglobinuria and subserosal hemorrhages. There may be ulcers and hemorrhages in the abomasal mucosa. Pulmonary edema and emphysema are also common in this species. Histologically, there is focal or diffuse **interstitial nephritis, centrilobular hepatic necrosis** and in some cases, vascular lesions in the meninges and brain in subacute to chronic infections. Leptospirae may be visible in silver-stained sections, especially in the proximal convoluted tubules ofthe kidney. In acute infections there may be minimal inflammation, with only **hemoglobin-filled renal tubules** and centrilobular hepatic necrosis evident microscopically.

In the later stages, the characteristic finding is a progressive interstitial nephritis manifested by small, white, cortical foci which are initially raised but become slightly depressed as the lesion ages. Many clinically normal cattle presented to abattoirs have these lesions, which may represent sequela to episodes of bacteremia from a variety of pathogens and should not be considered pathognomonic for leptospirosis.[74,75]

Aborted bovine fetuses are usually autolyzed to the point where no lesions or bacteria can be demonstrated. Even in a fresh fetus the positive identification of leptospirae in lesions is not an easy task. Culture of these organisms is difficult – *L. interrogans* serovar *hardjo* is particularly fastidious in its cultural requirements. The use of a fluorescent antibody technique assists in the demonstration of organisms but false-positives are common unless the test is interpreted by an experienced diagnostician. Dark-field microscopy may be attempted but is not well-suited to tissues collected at necropsy. PCR techniques show considerable promise, although sample processing requirements are stringent and the use of multiple primer sequences may be required in some cases.[46,76] Immunoperoxidase techniques are highly useful in the demonstration of leptospirae in formalin-fixed tissues, although this test is not serovar specific. Traditional silver-based staining of fixed material is also successful in a few cases. Antibodies to leptospirae are detectable in the serum of some aborted fetuses.[3]

Gross placental lesions in cases of **equine abortion and stillbirth** associated with leptospirosis include nodular cystic allantoic masses, diffuse edema, and areas of necrosis with a mucoid exudate on the chorionic surface. The liver is enlarged, mottled and pale-red to yellow. The kidneys are swollen and edematous with pale, radiating streaks in both cortex and medulla. Microscopic changes may include a suppurative and non-suppurative nephritis, dissociation of hepatocytes, a mixed leucocytic infiltration of portal triads, a giant cell hepatopathy, pneumonia and myocarditis. Thrombosis, vasculitis and a mixed population of inflammatory cells are evident in the placenta.[55] A variety of tests, as described for cattle, are available to try to confirm the diagnosis.

Aborted piglets are usually severely autolytic, with blood-stained fluid in the subcutis and filling the body cavities. Multiple necrotic foci, 1–4 mm in diameter and irregular in outline, are found in the liver of approximately 40% of aborted fetuses. Microscopic inflammatory changes may also be found in the kidneys. The fetal membranes are thick and edematous. Leptospirae can be demonstrated utilizing the battery of tests already mentioned for cattle.

Samples for confirmation of diagnosis

- **Bacteriology** – chilled kidney, liver, placenta (CULT (has special growth requirements), FAT, PCR)
- **Histology** – formalin-fixed kidney, liver, brain, heart, lung, placenta (LM, IHC)
- **Serology** – heart-blood serum or pericardial fluid from fetus (MAT).

The zoonotic potential of this organism should be noted when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The differential clinical diagnosis of the common forms of leptospirosis in each species is as follows:

Cattle

- Acute leptospirosis – must be differentiated from those diseases causing hemolytic anemia with or without hemoglobinuria (Table 20.4). They include: Babesiosis; anaplasmosis; rape and kale poisoning postparturient hemoglobinuria); bacillary hemoglobinuria
- Chronic leptospirosis causing abortion – must be differentiated from all other causes of abortion in cattle (Table 18.7). Most diagnostic surveys reveal that a specific cause is identifiable in only about 30% of fetuses submitted to a diagnostic laboratory. The vaccination history of the aborting cattle is a crucial part of the history since, for example, outbreaks of abortions due to infectious bovine rhinotracheitis occur primarily in unvaccinated cows. The specific causes of abortion in cattle vary depending on geographical location. Other common causes of abortion in cattle include: infectious bovine rhinotracheitis; protozoal abortion (*Sarcocytis* sp., *Toxoplasma gondii* and *Neospora caninum*). Less common causes are: brucellosis; bovine virus diarrhea; pine needle abortion; mycotic placentitis; campylobacter; *Actinomyces pyogenes*, ureaplasma
- Milk drop syndrome – characterized by a sudden drop in milk yield in up to 30–50% of the cows within several days. Must be differentiated from other causes of a decline in milk production of the herd including: (i) change of feed; (ii) change of management; and (iii) epidemic of infectious disease such as bovine respiratory disease.

Pigs

- Abortion in the last trimester – the common manifestation of leptospirosis in pigs and must be differentiated from all other causes of abortion, mummification and stillbirths in swine (Table 20.2). Other common causes of abortion in swine are: parvovirus; porcine reproductive respiratory syndrome. Less common causes are: brucellosis; pseudorabies; Stillbirth, Mummification, Embryonic death, Infertility (SMEDI) virus.

Sheep and goats

Chronic copper poisoning and poisoning caused by rape in sheep may present a clinical picture similar to that in leptospirosis but there will be no febrile reaction. Anaplasmosis associated with *Anaplasma ovis* may be accompanied by fever and hemoglobinuria but is more commonly a chronic, emaciating disease.

Horses

- Abortion, stillbirths, perinatal deaths of foals – *Streptococcus zooepidemicus*; *Salmonella abortivoequina*; *Escherichia coli; Actinobacillus equuli*. Other bacterial infections: Equine herpes virus; Equine viral arthritis; fungal infections. Diagnosis depends on laboratory examination of fetal tissues and fluids including bacterial culture, direct fluorescent antibody test for equine herpes virus and leptospires, serologic examination of fetal fluids for leptospiral antibodies using the MAT and special stains to demonstrate leptospires in fetal tissues
- Isoimmune hemolytic anemia – within 36 hours after birth, there is weakness, hemoglobinuria, pallor, failure to suck, tachycardia, high case–fatality rate and cross-matching blood tests
- Infectious equine anemia – chronic relapsing fever, anemia, weakness, jaundice, edema, oral mucous membrane hemorrhages, Coggins serological test
- Exertional rhabdomyolysis – acute onset of stiff gait, weakness, sweating, distress, myoglobinuria, creatine kinase test
- Periodic ophthalmia differentiate from other causes of iridocyclitis of horses, and conjunctivitis, keratitis and hypopyon which may occur in equine viral arthritis.

Table 20.4 Differential diagnosis of diseases of cattle characterized by acute hemolytic anemia with or without hemoglobinuria

Disease	Epidemiology	Clinical findings	Laboratory findings
Leptospirosis	All ages, cattle on pasture	Acute fever, red-colored milk. Hemoglobinuria abortion. May die in 24–48 hours	Leptospira titers
Postparturient hemoglobinuria	High-producing lactating cows 4–6 weeks postpartum	Acute. No changes in milk. No fever. Die in 12–48 hours. Marked hemoglobinuria	Hypophosphatemia
Bacillary hemoglobinuria	Usually mature cattle on summer pasture in enzootic area	Acute fever, abdominal pain. May die in 2–4 days. Hemoglobinuria	Leukopenia or leukocytosis
Babesiosis	Enzootic areas, tick-borne, young animals	Acute fever, jaundice, abortion, course of 2–3 weeks. Marked hemoglobinuria	Blood smear, complement fixation test, transmission tests
Anaplasmosis	Yearling and mature cattle, common in summer,insect-borne, common in feedlots	*No* hemoglobinuria, jaundice common, fever	Anaplasms on blood smear, complement fixation test
Chronic copper poisoning	Follows long-term oral administration of medicines or feeds containing copper	Severe jaundice. No fever. Hemoglobinuria	Toxic levels of copper in blood, liver and feces
Cold-water haemolytic anemia of calves	Following consumption of large quantities of cold water after period of limited intake	Sudden onset within 1 hour after ingestion. No fever. May die in few hours. Hemoglobinuria	Acute hemolytic anemia
Rape and kale poisoning	All ages of cattle on rape crop grown for fodder in fall	Peracute hemolytic anemia, may die in few hours after onset. No fever. Hemoglobinuria	Acute hemolytic anemia
Drug-induced	Some drug preparations when given intravenously	Mild hemoglobinuria. No hemolytic anemia	Nil
Blood transfusion reaction	Using blood from same donor more than 1 week after initial transfusion	Sudden onset, dyspnea, hiccoughs, trembling, responds to adrenalin	Nil

The common causes of hematuria in cattle are pyelonephritis and cystitis due to Corynebacterium renale, non-specific cystitis and enzootic hematuria.
Myoglobinuria occurs occasionally in young cattle affected with enzootic-nutritional muscular dystrophy and may be confused with hemoglobinuria.

TREATMENT

Antimicrobial therapy. The primary aim of treatment is to control the infection before irreparable damage to the liver and kidneys occurs. Treatment with dihydrostreptomycin preferably, or one of the tetracyclines, as soon as possible after signs appear is recommended. The results of treatment are often disappointing because in most instances animals are presented for treatment only when the septicemia has subsided. The secondary aim of treatment is to control the leptospiruria of 'carrier' animals and render them safe to remain in the group.

Parenteral antimicrobials. For infections due to pomona, dihydrostreptomycin (12 mg/kg BW IM twice daily for 3 d) is effective in the treatment of the systemic infection. For the elimination of leptospiruria in cattle and pigs, a single dose of dihydrostreptomycin (25 mg/kg BW IM) is recommended.[77,78] In an outbreaks in cattle the simultaneous treatment of all animals with dihydrostreptomycin at 25 mg/kg BW IM and vaccination has been successful in preventing new cases and abortion when pregnant cattle are involved. When the participation rate of dairy farmers in an area in the Netherlands was high, the combination of antimicrobial and vaccination was economical. A similar approach is recommended for outbreaks in swine. **Annual revaccination** and **regular serological testing** for new infections, combined with controlling the source of new infections, will usually successfully control further outbreaks. A surveillance system in the area is necessary, however, to detect the introduction of new serotypes. Streptomycin is no longer available for use in the United States and long-acting oxytetracycline at 20 mg/kg BW is an alternative.[64] Oxytetracycline, tilmicosin, and ceftiofur are also effective for resolving leptospirosis in cattle.[79] For the treatment of *L. hardjo*, amoxycillin is also an alternative to streptomycin.[80]

Dihydrostreptomycin G (25 mg/kg BW IM for 1, 3, or 5 d), or oxytetracycline (40 mg/kg BW IM daily for 3 or 5 d), tylosin (44 mg/kg BW IM daily for 5 d), or erythromycin (25 mg/kg BW IM daily for 5 d) are all effective for treatment of persistent leptospirosis due to pomona in swine.[81]

In vitro studies indicate that leptospires are highly susceptible to ampicillin, amoxycillin, penicillin G, cefotaxime, erythro-

mycin, fluoroquinoline ciprofloxacin and have a good susceptibility to streptomycin, tylosin and tetracyclines. Doxycycline and penicillin G are effective in treating acute leptospirosis.

For outbreaks of **leptospiral abortion in horses**, treatment of pregnant mares with dihydrostreptomycin (50 mg/kg BW) IM daily for 3–5 d can minimize further abortions[10]; this treatment regimen however has not been extensively evaluated.

For **equine periodic ophthalmia**, most recommended treatments have little effect on the course of the disease. A course of a suitable antibiotic systemically, and the administration of a corticosteroid, either parenterally in an acute episode, or subconjunctivally in a chronic case, is most likely to be satisfactory. Nonulcerative keratouveitis require long-term and intensive medication, and recur with tapering of treatment.[27] Topical and subconjunctival corticosteroids are recommended in controlling nonulcerative keratouveitis. Intravitreal implantation of cyclosperine is effective.[53] Atropine eye ointment is also usually applied three times daily to maintain dilatation of the pupil.

Antimicrobials in feed. In groups of pigs, the feeding of oxytetracycline (800 g/t of feed for 8–11 d) is claimed to eliminate carriers. Antimicrobial feeding should begin 1 month before farrowing to avoid the occurrence of abortion. Other experimental trials using long-acting tetracycline by injection or tetracycline in the feed have been inconclusive and the use of mass feeding techniques as control programs should not be recommended lightly. Antimicrobial feeding has also been suggested as a preventive measure in calves. The feeding of small amounts of tetracyclines (3 mg/kg/d BW) for 7 d before and 14 d after exposure, prevents the appearance of clinical signs but not infection as measured by the agglutination-lysis reaction.

Blood transfusions. Blood transfusions (5–10 L/450 kg BW) are indicated as treatment for the hemolytic anemia in acute leptospirosis in cattle. The clinical indications for a blood transfusion include obvious pallor of the mucous membranes, weakness and tachycardia.

CONTROL

Biosecurity and biocontainment

On an individual farm, leptospirosis can be eradicated or controlled by vaccination. With the diagnostic tests available, the success of antimicrobial therapy in eliminating the carrier state, and the vaccines, it is now reasonable to attempt eradication of the disease from individual herds, and possibly from areas. The major risk is the introduction of carrier animals of any species, or by reintroduction of the infection by rodents or other wildlife. It is because of this risk that most programs aim at containment rather than eradication. In these circumstances where only sporadic cases occur, it might be more profitable to attempt to dispose of reactors or treat them to insure that they no longer act as carriers.

The first step in control is to identify the source of the original source of infection and to interrupt transmission.[2] Sources of infection include clinically affected animals, aborted fetuses, placentas, carrier animals, wildlife, dogs and cats, and environmental sources such as water supplies. Education about leptospirosis is an effective method for reducing its incidence and its effects. Intensive well directed education and publicity campaigns in New Zealand, used in conjunction with a campaign for immunization of cattle, reduced the incidence of leptospirosis.[2] Groups to which educational efforts should be directed include professionals in human and veterinary medicine and public health, primary human and animal health care practitioners, wildlife and conservation scientists, water and sewage engineers and planners, health administrators and educators, and not least, the public at risk.

Risk-assessment and computer simulation models of the possible costs of infections due to *L.* hardjo have been developed to explore the risks and likely consequences to producers of the disease in dairy herds in the United Kingdom. Three main considerations are important when assessing the risks and likely financial implications of the disease to dairy producers:

1. Likelihood of a herd being infected
2. Likely effects of the disease on the dairy enterprise, both physically and financially, following the initial infection compared to a leptospirosis-free herd
3. Likely longer-term effects of the disease.[37]

The probability of infection of cattle by *L.* hardjo is increased by four factors:

1. Purchase of infected cattle
2. Co-grazing or common grazing with infected cattle or sheep
3. Use of natural service with an infected bull
4. Access of cattle to contaminated water such as streams, rivers, flood or drainage water.

Assessment of the risks facing different types of herds suffering losses from *L.* hardjo can then be used to help support decisions concerning control of the disease.

The major consequences of *L.* hardjo infection are milk loss and abortion in the dairy herd, and the risk of illness in man. The financial losses associated with disease in a herd according to the presence of different risk factors can be estimated using a static risk model.[37] The cost of various control strategies can then be considered in the light of these expected costs which result from doing nothing to control the disease. A dynamic simulation model can be used to consider how the disease might develop in a dairy herd following initial infection and over the next few years.

Producers with one or more of the main risk factors should consider strategies which (i) directly remove or diminish those risk factors or (ii) indirectly diminish their importance for the herd, for example, by vaccination. Strategies which successfully diminish one or more of the risk factors, but leave one other will yield little benefit due to the importance of each of the identified risk factors.

Vaccination is one strategy which can diminish all of the risk factors and provide some degree of assurance against potentially high and costly disease losses. Producers with high-risk herds are likely to choose vaccination. The dynamic simulation model estimates that the cost of endemic disease can be relatively high and that some form of vaccination strategy would be cost-effective. If a herd continues to have any of the risk factors, then whole-herd vaccination is likely to be the preferred option, since the disease could otherwise easily be reintroduced. Decision tree analysis of leptospirosis vaccination in beef cattle in Australia indicates that the beneficial economic effects of vaccination depend on the value of the calf and the probability of calf loss due to leptospirosis.

Artificial insemination centers. Bulls destined for artificial insemination centers must be free of antibody to hardjo, grippotyphosa, canicola, pomona, sejroe, and *icterohaemorrhagiae* at a final serum dilution of 1:100 in the MAT. However, since animals with leptospirosis may not have a serum titer, it is possible that the semen of serologically negative but infected bulls may contain leptospires. Culture of leptospires is difficult, costly and time consuming. A PCR assay has been developed to detect pathogenic leptospires in the semen and urine of infected bulls[71] (see Clinical pathology).

Eradication

Detection and elimination of carrier animals presents some difficulties. Positive reactors to the MAT do not necessarily void infective urine and to determine their status as carriers necessitates repeated examination of the urine for the organism. For practical purposes, serologically suspicious and positive reactors should be considered carriers and culled or treated as described above.

In groups of pigs, it should be assumed that infection is herd-wide and all pigs should be treated as though they were carriers. In these circumstances, the feeding of antimicrobials provides some protection, although it is not guaranteed to eliminate the carrier state. Leptospirosis has been eradicated from commercial pig herds by treating all pigs with dihydrostreptomycin at 25 mg/kg BW IM at one time. However, if the pigs have been exposed to heavy infection, not all of them are completely cleared of leptospiruria, and further treatment will be necessary.

In cattle herds, if the bulls are infected they should not be used naturally or for artificial insemination even though the antimicrobials in the semen diluent is sufficient to insure that no spread occurs. Elimination of infection can be difficult, especially in large commercial herds in an endemic area in which replacement cows and bulls are introduced from sales yards and cattle mingle with other herds on range. Eradication of **hardjo** is a possibility in purebred herds in which intensive measures are economically feasible and owners should be urged to undertake a program to eliminate leptospirosis from the herd and to prevent its entry. The following measures can be taken to eliminate hardjo infection:

1. Judicious combination of group serological testing
2. Segregation of age classes
3. Selective vaccination
4. Possibly artificial insemination
5. Determination of the cause of reproductive failures
6. Isolation of the herd from outside sources of infection.

Bulls suspected of spreading infection should be treated to reduce the level of urinary shedding regardless of subsequent vaccination. Exposure of cattle to herds, heavily infected with leptospirosis, for example, on communal grazing pastures should be avoided. The herd should be monitored periodically, coincident with other serological testing. In endemic areas, all cattle over 6–9 months of age should be vaccinated, and vaccination should be continued for up to 5 years to minimize the number of susceptible cattle until no long-term shedders remain in the herd.

Simple management procedures to limit the infection in beef cows until their second calves are born, and the culling of older carriers can greatly decrease and possibly eradicate the infection from a herd. Virgin yearling bulls are used on virgin yearling heifers, and young cows are segregated from older cows until 38–39 months of age, when they go to pasture after being bred, with their second calf. This delays direct exposure of heifers to infected cattle until their third breeding. These practices must be combined by monitoring infection by serological and other laboratory methods.

If eradication is attempted and completed, introduced animals should be required to pass a serological test on two occasions at least 2 weeks apart before allowing them to enter the herd. Urine examination for leptospirae should be carried out if practicable.

Occupational hygiene

Occupational hygiene is important for prevention of leptospirosis wherever the disease is known to occur predominantly in certain occupational groups. Exposure to risk is unavoidable in people whose livelihoods depend on rice planting or farming, sugar cane cutting, work in tropical forests, keeping peridomestic pigs, building or maintaining drains or sewers, milking cows, and slaughtering or herding pigs or cattle. Occupational hygiene is concerned with means of minimizing the risks, by employing measures to reduce direct or indirect contact with animals which might be infected.

Control of the source of the organism is achieved by appropriate hygienic strategies. If the environmental sources of infection are identifiable, in the form of yards, marshes and damp calf pens, every attempt must be made to avoid animal contact with these infective surroundings. In dairy farming areas where human leptospirosis comes from cattle, milkers and transporters should be protected. The main measures available are immunization of cattle and pigs, education, and modification of work practices, including protective clothing. It is important to avoid urine splash. Cows should be handled calmly to minimize urination in the milking sheds. Sheds and yards should be hosed out so as to avoid aerosol and splash from urine on the floors. Herdspeople and milkers must be made aware of the risks of infection from mud contaminated with urine. Wet areas should be drained or fenced and pens disinfected after use by infected animals. The possibility that rats and other wild animals may act as a source of infection suggests that contact between them and farm animals should be controlled.

Meat industry workers are at high risk during the examination and dressing of carcasses. The dangerous parts of carcasses are the bladder, urine and kidneys. Handling bovine or porcine kidneys with bare hands is especially risky and rubber gloves should be worn. Wearing protective clothing in abattoirs is not well accepted because speed is paramount and gloves are an impediment. Nevertheless it offers protection.

Control of clinical disease by immunization

A control program to limit the occurrence of clinical disease is achieved by vaccination to maintain a high level of immunity in herd.

Vaccination

Vaccination against leptospirosis in cattle and swine is in general use and an effective method for control of the disease. In New Zealand, a publicity campaign to promote the widespread vaccination of cattle resulted in a marked reduction in the incidence of human leptospirosis. Most of the vaccines are formalin-inactivated bacterins containing one or more serotypes. Vaccines containing Freund's complete adjuvant induce higher serological responses but not necessarily superior protection. The immune response is serotype-specific and protection is dependent on the use of bacterins containing serotypes prevalent in the area. The bacterins induce a low titer to the MAT which appears early and declines after several weeks; however, protective immunity against the disease and renal infection persists for at least 12 months in cattle. Regular serological testing in herds vaccinated annually can be used to monitor new infections since these will induce a titer to the MAT. However, neither the CFT nor the MAT can reliably differentiate serological responses in cattle following leptospiral vaccination from those following natural infections.

Cattle

The difficulty of keeping purebred herds free of hardjo infection increases as the reservoir of infection increases. Several control measures can be applied especially in large herds which are at high risk. In endemic areas, transmission in commercial herds can be suppressed by annual vaccination of bulls, replacement heifers, and 2- and 3-year-old females a few weeks before release of the bulls. A cow which fails to carry a calf to term, or that produces a dead or weak calf, should be culled. Potential replacement heifer calves should be handled and raised in segregation from the adult herd after weaning and vaccinated a month before exposure to older cattle. Herd sires should be purchased from uninfected herds or at least purchased subject to a negative serological test.

Vaccination as part of a herd health program should start with the calves at 4–6 months of age, followed by revaccination annually. Such programs should provide significant rises in calving rates, but have little or no effect on perinatal or postnatal losses.

Bovine leptospiral vaccines and their efficacy

Many vaccines are available but there is conflicting evidence about their efficacy. A pentavalent leptospiral vaccine containing hardjo-*bovis* did not protect cows from experimental infection with hardjo-*bovis*. Vaccination of cattle with a pentavalent leptospiral vaccine containing either hardjo-*bovis* or hardjo-prajitno failed to protect cattle from experimental infection with hardjo-*bovis* 6 months after vaccination.[10] The hardjo-*bovis* vaccine is more antigenic than the hardjo-prajitno as measured by higher antibody titers in vaccinated animals. Calves as young as 4 weeks of age, vaccinated in the presence of maternally derived antibody can be fully protected against homologous virulent challenge.

Vaccine antigens. Most bovine leptospiral bacterins contain the reference strain hardjo-prajitno. However, North American cattle are predominantly infected with hardjo-*bovis*. DNA probe techniques can be used to identify animals infected with hardjo-*bovis* which enables diagnosticians to correctly diagnose infection in animals which have been previously vaccinated. Serovar hardjo-prajitno is used to prepare the hardjo component of pentavalent, whole-cell, leptospiral vaccines. The hardjo component of whole cell leptospiral vaccines is a weak immunogen, as evidenced by low-serum agglutinating antibody titers in vaccinated cattle and short duration immunity. Restriction endonuclease analysis of Australian and New Zealand isolates of *L.* pomona reveal that most closely resemble the serovar kennewicki reference strain, and all differed from the reference strain of serovar pomona. This suggests that vaccine manufactures should consider using the genotypes which are most prevalent in cattle and pigs. In New Zealand, a trivalent vaccine containing inactivated *L. borgpetersenii* serovar hardjo Hardjobovis, *L.* pomona and copenhagi has been developed and tested for efficacy and potency in cattle.

Leptospiral vaccines used in cattle in the United States are inactivated whole-cell vaccines containing *L. interrogans* serovar hardjo (type hardjoprajitno), canicola, pomona, and icterohemorrhagiae and L. kirschneri serovar grippotyphosa. These pentavalent vaccines provide adequate protection against disease associated with each of the serovars in the vaccine except serovar hardjo. They have failed to prevent abortion, stillbirth, and vertical transmission of infection when vaccinated cows were challenged with *L. borgpetersenii* serovar hardjo during pregnancy, and the infection rates for control and vaccinated cattle did not differ. Attempts to improve the protection against *L. borgpetersenii* serovar hardjo by including *L. borgpetersenii* serovar hardjo in a pentavalent vaccine or by increasing the quantity of serovar hardjo antigen in a monovalent serovar hardjo vaccine failed. However, monovalent vaccines with a field isolate of *L. borgpetersenii* serovar hardjo and another with *L. interrogans* serovar hardjo found these vaccines prevented infection and colonization following challenge with *L. borgpetersenii* serovar hardjo strains from the United States and Europe.[10]

A protective killed vaccine against serovar hardjo induced a strong, sustained Th1 or cell-mediated response.[10] The vaccine is composed of a whole-cell bovine isolate of *L. borgpetersenii* serovar hardjo and aluminum hydroxide and is given as two doses subcutaneously 4 weeks apart.[49] Following vaccination, a type 1 (Th1) cell-mediated response occurred characterized by the production of gamma interferon cells including $CD4^+$ and WC1 gamma delta T-cells. Vaccinated animals had twofold-more IgG2.

A monovalent *L. borgpetersenii* serovar hardjo (type hardjo-bovis) vaccine commercially available in Australia, New Zealand, Ireland, and the UK, given as two doses, 4 weeks apart, protected heifers against renal colonization and urinary shedding when challenged with *L. borgpetersenii* serovar hardjo strain 203 four months after vaccination.[82] None of the animals shed leptospires in their urine, or kidneys at necropsy. In contrast, all nonvaccinated control heifers became infected with serovar hardjo and shed organisms in their urine. A monovalent US reference hardjo vaccine failed to prevent infection, renal colonization, and urinary shedding in cattle challenged with *L. borgpetersenii* serovar hardjo.[82] The reference vaccine was prepared with *L. borgpetersenii* serovar hardjo (type hardjo-bovis) rather than *L. interrogans* serovar hardjo (type hardjoprajitno), which is used in many cattle leptospiral vaccines available in the US, because *L. borgpetersenii* serovar hardjo is the organism which infects cattle in the US.[82]

Two monovalent Hardjo vaccines provided protection from infection against *L. borgpetersenii* serovar hardjo while a pentavalent vaccine containing the Hardjo organisms did not.[76] The protective monovalent vaccines produced strong cell-mediated immune responses in vaccinated cattle as demonstrated by proliferation of lymphocytes and production of IFN-gamma by their peripheral blood mononuclear cells in response to culture with serovar Hardjo antigens. This response is generally much lower or absent in antigen-stimulated cultures of PBMC from cattle vaccinated with the pentavalent vaccine and nonvaccinated cattle.

In conclusion, protective immunity to serovar Hardjo correlates with induction of a substantial immune response that is characterized by antigen-specific IFN-gamma-producing T-cells, IgG1 and IgG2 antibodies which react with antigens common between serovars as well as antibodies that are largely serovar-specific and agglutinate leptospires through reactivity with surface lipopolysaccharide. These results contrast with those induced by pentavalent vaccines that have a superior ability to induce antibodies that agglutinate all the serovars of leptospires included in their formulation with the exception of serovar hardjo.

There is no cross-immunity between *L.* pomona and hardjo, and in areas where both diseases occur, a bivalent vaccine is used routinely. If separate vaccines are used the *L.* pomona vaccine should be administered at least once annually, but the *L.* hardjo vaccine provides some protection against *L. szwajizak*.

Vaccination of calves less than 3 months of age is unlikely to be effective and is not recommended, but vaccination of cows in late pregnancy gives effective immunity to their calves.

Swine. Vaccination of sows and gilts before breeding with a bivalent vaccine, containing pomona and *tarassovi*, protects them against infection and the development of leptospiruria and is widely practiced, especially in large intensive piggeries. In the United-States, vaccination of gilts and sows with two doses of a bacterin containing five or six leptospiral serovars, one of which contained bratislava, before the first breeding and thereafter before each breeding improves reproductive performance. *L.* bratislava is an important cause of abortions in sows in North America and Europe and vaccination is effective. Vaccination of pregnant gilts and sows can provide protection to the piglets for the first several weeks after birth.

Vaccination and antimicrobial strategies. Whether or not to vaccinate depends upon the cost of the procedure relative to the losses which can be anticipated. If the disease is spreading rapidly, as evidenced by the frequent appearance of clinical cases, a high range of titers or rising titers in a number of animals, (i) all clinical cases and positive reactors should be treated; (ii) the negative animals vaccinated; and (iii) the herd moved on the first day of treatment to a clean field. Retesting a group to determine the rate of spread would be an informative procedure but active measures must usually be commenced before this information is available. Another variation

of this program, and a highly practical one, is the vaccination of all cattle in the herd, and the treatment with one dose of dihydrostreptomycin (25 mg/kg BW IM) of all pregnant cows to eliminate renal infection and leptospiruria. However, antimicrobial therapy is not highly efficacious, especially in cattle infected with hardjo.

A successful control strategy has been described for hardjo infection in a large, closed beef herd. All animals were treated with dihydrostreptomycin at 25 mg/kg BW IM once followed by removal to a clean pasture to prevent new cases, and annual vaccination of the whole herd for 5 years. All cattle introduced into the herd were treated with the antimicrobial and quarantined; at the end of the trial the entire herd was treated prophylactically with the antimicrobial to minimize the risk of residual infection. By the end of the trial all young stock entering the breeding program were seronegative. There was serological evidence of a high level of control and bacteriological monitoring at the end of the trial indicated that hardjo had been eliminated from the herd.

Vaccination is also recommended to protect animals continuously exposed to infection from wildlife, other domestic species, and rodents. The serological status of these groups can also be determined as necessary before a decision is made to vaccinate.

If only sporadic cases occur, it may be more profitable to attempt to dispose of reactors or treat them to insure that they no longer act as carriers. A degree of immunity is likely to occur in pigs after natural infection and when the disease is endemic, 'herd immunity' may significantly decrease incidence of clinical disease.

One of the theoretical disadvantages of vaccination is the possible development of renal carrier animals which are sufficiently immune to resist systemic invasion but not colonization of the kidney, which leads to the development of a carrier animal with transient leptospiruria. This may occur but not sufficiently frequently to invalidate vaccination.

BORRELIOSIS (LYME BORRELIOSIS, LYME DISEASE)

Synopsis

Etiology Spirochete, *Borrelia burgdorferi*
Epidemiology Occurs in United States, Europe, Asia, Australia, in cattle, sheep, horses, dogs and humans. Transmitted from small wild animals which are reservoirs of organisms by *Ixodes* spp. ticks. Principal hosts are the white-footed mouse; the cottontail rabbit and jack rabbit are also known carriers. The adult tick feeds on deer, horses, cattle and dogs
Signs In horses: chronic weight loss, sporadic lameness, persistent fever, swollen joints, muscle stiffness, depression, anterior uveitis, neurological signs, abortion and weak foals. In cattle and sheep: polyarthritis, chronic weight loss, fever
Clinical pathology Serological tests (indirect immunofluorescent antibody test (enzyme-linked immunosorbent assay) (ELISA))
Lesions Polysynovitis, lymphadenopathy, emaciation, interstitial myocarditis, nephritis, meningoencephalitis
Differential diagnosis list
Other diseases causing muscle stiffness, lameness, polyarthritis, lymphadenopathy.
Treatment Tetracyclines and penicillin
Control No available methods

ETIOLOGY

B. burgdorferi, a spirochete, is the causative agent.[1]

EPIDEMIOLOGY

Occurrence and prevalence of infection

The disease has been described in cattle,[2] horses,[3] sheep,[4] dogs,[5] and is now considered one of the most common vector-borne infections in humans in the United States.[1] Lyme disease has been recognized in Canada,[6] Europe,[7] Asia, Australia, and in the countries of the former USSR.[1] In the United States, the infection is primarily found in three regions: the northeast (from Massachusetts to Maryland); the midwest (in Wisconsin and Minnesota); and the northwest (in California and Oregon). The disease occurs most commonly in areas with an appropriate density of the insect vector, intermediate hosts, and the environmental conditions favoring transmission. Much of the available information on borreliosis is based on serological studies which must be interpreted carefully because clinical disease is not common.

Cattle

Seroprevalence studies of cattle in the United Kingdom indicate that the seropositivity rate increased from 44% to 67% after the cattle were turned out to pasture[8] and the seropositivity rate was higher in cattle with digital dermatitis (71%) than in cattle without the lesions (7.3%). The proportion of seropositive cows increases with age and also following grazing. None of the housed cattle were seropositive. In Japan, the seroprevalence of infection varies from 8–15% and is higher during the summer months; cows with arthritis have higher titers to the organism than healthy cows.[9] Similar observations have been made in dairy cows in Minnesota[10] and Wisconsin in areas with endemic *B. burgdorferi* infections.[11] In Wisconsin, the peak seasonal incidence of clinical disease in horses and cattle occurs in May and June, and October which correlates with emergence of *I. dammini* in the spring, usually March and April, and again in September.[3]

Sheep

Seroprevalence studies in sheep infested with *Ixodes ricinus* in Scotland indicate an infection rate in lambs of 2.7%, 24–40% in young sheep and 0–6% in ewes.[12] There is also evidence for transmission of Lyme disease to sheep in Cumbria in the United Kingdom, grassland and heath communities where wild fauna are uncommon and sheep are believed to be the main host for all feeding stages of the tick.[13] However, there was no evidence of clinical disease associated with the infection. Serological surveys of infection in sheep in Norway indicate that 10% of animals tested are seropositive by the ELISA with a range of 0–20% between counties.[4] The distribution of seropositive animals correlated with the known distribution of *I. ricinus* with the highest proportion of seropositive animals being in southern coastal areas of Norway. The majority of animals appear to become infected during the first 2 years of life; the animals were all healthy at the time of sampling.

Horses

A large percentage of adult horses in the more eastern parts of the northeastern and mid-Atlantic United States are or may have been infected with *B. borgdorferi*.[3] In tick-infested areas of Connecticut in the United States, horses may have serum antibodies to both *B. burgdorferi* and *Ehrlichia equi*.[14] Serological surveys of horse populations in the United States revealed that in the New Jersey–Pennsylvania area, approximately 10% of horses have significant serum antibody titers to the organism.[15] Appearance of the organism appears to be uncommon in horses in Texas, where infection does not occur.[16] In Cape Cod horses, the seroprevalence was 35%, which is age-specific and considered to be a reflection of exposure because of the relative absence of disease.[17] It was found that 7–13% of horses admitted to a veterinary teaching hospital were seropositive to the organism and the frequency of antibody response varied according to the geographical origin of the horses.[18] Lyme disease in the horse is rare but it is clinically important in the United Kingdom.[19] In areas where the disease occurs in humans, the seroprevalence of infection in horses was 49% compared to 3–4% in horses from other areas.[20] Horses with unexplained lameness associated with fever and tick infestation had high levels of antibody to the organism. Within endemic areas, up to 60% of mares and yearlings on one farm were serologically positive. On such farms, there may be a clustering of clinical cases in foals after weaning. However, there is no evidence that abortion in mares is associated with infection.[21]

Wildlife

In Ontario, epidemiological studies indicate a widespread but low level or scattered distribution of infection in wildlife reservoirs in southern Ontario, with occasional spillover into human and canine populations.[6] Serologically, the organism was found to be circulating in populations of white-footed mice, field mice, and white-tailed deer.

Zoonotic implications

Lyme borreliosis was first recognized when a cluster of suspected juvenile rheumatoid arthritis cases occurred among residents of Lyme, Connecticut.[22] An arthropod-transmitted disease was suspected as the etiologic agent because in addition to recurrent, short-lived joint pain, patients had an expanding, red, annular rash resembling erythema chronicum migrans similar to a lesion identified in Europe in the early 20th century associated with tick bites and was responsive to penicillin. An infectious cause was confirmed when spirochetal bacteria isolated from *Ixodes* ticks and blood, CSF, and other tissues of patients were shown to be identical. Subsequently, *B. burgdorferi* was identified in ticks in numerous regions of the United States, and infection was associated with clinical disease in other animals including dogs and horses.

The disease has been recognized in man in most areas of the United States and in at least 20 countries spanning every continent.[23] The literature on lyme borreliosis in humans has been reviewed.[24,25] In the United States, the northeastern states of Connecticut, Massachusetts and New York; the midwestern states of Wisconsin, Minnesota, Michigan, Illinois, and Indiana; and the western states of California and Nevada are considered as the most endemic areas, especially in wooded and grassy parts of these regions.

Lyme borreliosis is the most common tick-transmitted disease of humans in the northern hemisphere.[24,25] In 2000, in the United States, 17 730 cases of Lyme borreliosis were reported nationwide.[22] The geographical prevalence of borreliosis in man and animals is related to the distribution of the various *Ixodes* spp. of hard ticks and the location of herds of deer, which are preferred hosts for the ticks. Geographical areas with dense vegetation and high humidity promote the development of the tick. Risk of infection is correlated with the opportunity of being bitten by an infected tick and dependent on the density of vector ticks in an endemic area, the proportion of ticks infected, and the duration and extent of the susceptible host's activities in that area.

Methods of transmission

The principal hosts for *B. burgdorferi* are rodents such as the white-footed mouse, *Peromyscus leucopus*. The cottontail rabbit in the eastern United States and the jack rabbit in California can also serve as hosts. It is suggested that migrating birds acting as carriers may account for the widespread nature of the infection in a country.

The spirochete is transmitted by *Ixodes* ticks including *Ixodes scapularis*, the deer tick, in the northeastern and midwestern United States, *Ixodes pacificus*, the western

black-legged tick, in the western United States,[22] *Ixodes ricinus* the sheep tick in Europe, and *Ixodes persulcatus* in Asia.[1,6] The lifecycle of the deer tick is 2 years and includes the stages of egg, larvae, nymph and adult. The white-footed mouse is the primary rodent which infects the tick. During the larval stage, the tick will feed on an infected mouse. Both immature stages of the tick feed on the white-footed mouse which makes the life cycle of the organism dependent on horizontal transmission from infected nymphs to mice in the early summer and from infected mice to the larvae in late summer. The white-footed mice are susceptible to oral infection and transmit the infection to each other by direct contact.[26] The white-footed mouse is thus linked to the transmission and maintenance of the organism. Infection with the spirochete does not cause clinical or pathological changes or alter the biological features of the mouse.[25] These combined factors indicate a longstanding relationship between the mouse and the spirochete. Furthermore, the mouse is an excellent reservoir host but an unsatisfactory laboratory model for the study of Lyme disease. When the tick becomes infected it is ready to feed on animals and humans. A nymphal tick will feed on small animals such as rodents, squirrels, birds, dogs and cattle. The adult tick feeds primarily on larger animals such as deer, horses, cattle, and dogs. All three stages of the tick will feed on humans.

The white-tailed deer is the preferred host for the adult stage of the tick and often harbors large numbers of adult ticks. Adult ticks are likely to be responsible for transmission of infection to horses and cattle.

The ticks, *Dermacentor variabilis* and *Amblyomma americanum*, tabanid flies and mosquitoes have also been shown to carry the organism.[2]

The organism can be found in the urine of infected animals and it is possible that transmission may occur through close contact without the bite of a tick. Infected cattle purchased from an endemic area could shed the organisms in the urine and transmit them to animals in a different herd. The resistance of the organism to heat is generally less at 50°C, and greater at 70°C than that of other non-spore-forming pathogens.[27] Heat treatments similar to that of high temperature, short time pasteurization of milk are expected to decrease the population of the organism but not eliminate it. When present in meats in large numbers, it is likely that the organism can survive heat treatments sometimes used to process these products.

Transplacental transmission of the organism from infected dams to their fetuses also occurs through in utero infection and can be a cause of mortality in foals[28] and calves.[3]

PATHOGENESIS

Borrelia are highly motile and invasive, and localize in selected tissues. They spread through tissues and can directly transcytose endothelial layers. Following infection there is multisystemic inflammation resulting in polyarthritis,[2] generalized lymphadenitis, pleuritis, peritonitis, interstitial pneumonia, encephalitis, and in utero infection resulting in fetal infection. In humans, the progression of Lyme borreliosis is divided into early localized, early disseminated, and late stages.[29] In humans, skin is the most frequently affected tissue. Erythema migrans, borrelial lymphocytoma, and acrodermatitis chronica atrophicans, neuroborreliosis, myocarditis, arthritis, and ocular disease are possible outcomes of infection.

Borreliosis has been reproduced in ponies by exposure to *Ixodes* ticks infected with *B. burgdorferi*.[30] Infection with *B. burgdorferi* was detected in skin biopsies and various tissues at necropsy by culture and PCR. The model can be used to evaluate chemotherapy and vaccines. Clinical signs were limited to skin lesions, all ponies seroconverted, and there were no significant other lesions.

Immune mechanisms

B. burgdorferi is able to persist in the mammalian host because of active immune suppression, induction of immune tolerance, phase and antigenic variation, intracellular seclusion, and incursion into immune privileged sites all as survival strategies.[29] Vaccination with outer surface protein A (OspA) from the organism could prevent *B. burgdorferi* infection in animal and human studies. Vaccination of 1-year-old ponies with recombinant OspA (*osp.A* gene derived from *B. burgdorferi* B31) with adjuvant (aluminum hydroxide), followed by challenge with *B. burgdorferi*-infected adult ticks (*Ixodes scapularis*), provided protection against skin infection compared to unvaccinated controls.[31]

CLINICAL FINDINGS

Because Lyme disease has been recognized only recently, the characteristic clinical findings in farm animals are not yet well described. The variety of clinical manifestations of the disease has made it difficult to obtain a definitive diagnosis in cases where the disease has been suspected. Based on serological surveys, subclinical infections are much higher than the incidence of clinical disease.

Horses

In horses, chronic weight loss, sporadic lameness, laminitis, persistent mild fever, swollen joints, muscle stiffness, anterior uveitis and neurological signs such as depression, behavioral changes, dysphagia, head tilting and encephalitis have been reported.[1,3] Polyarthritis and swelling of tendon sheaths in horses of all ages are commonly reported.[3,32] A confirmed case in a 20-year-old horse had a history of exposure to ticks, was depressed, had a temperature of 38.2°C, urticarial plaques, tendon sheath swelling and hindlimb lameness. This was followed by periodic episodes of fever, lameness with hindlimb stiffness, effusion of joints and tendon sheaths, and conjunctivitis. Acute bilateral blepharospasm, photophobia and excessive lacrimation are reported[3] followed by neurological signs of depression, compulsive walking, stupor, holding the head against a wall and quadripedal ataxia and eventual recumbency.[3] Infection of pregnant mares can result in abortion, and the birth of weak foals which die soon after birth.[28] An unexplained increase in early embryonic loss or failure of conception in mares has been associated with Lyme disease antibodies but not confirmed.[33]

Cattle

In cattle, polyarthritis, lameness, chronic weight loss, and a persistent mild fever have been reported.[2,34] In acute Lyme disease, fever, stiffness, swollen joints and decreased milk production are common.[1] Erythema of the udder or the skin between the digits has also been described.[1,22] Edematous lesions on the hairless skin of the udder, poor bodily condition, inappetence, and decreased milk production, stiff gait, and swollen joints have been described in cows with *B. burgdorferi* infection.[35]

Sheep

In sheep, lameness, swollen joints, unthriftiness, and a persistent fever occur.[29]

CLINICAL PATHOLOGY

Detection of organism

The organism is difficult to isolate because *B. burgdorferi* is found in low numbers in blood or tissues. Aseptically collected blood, cerebrospinal fluid, urine and colostrum can be examined under dark-field microscopy or in a culture. Cultures are difficult to maintain and require several weeks to grow.

Serology

Serological testing is the most practical method of making a diagnosis of *B. burgdorferi* infection.[1] Serum and synovial fluid samples may contain antibodies to the organism in horses.[20] The indirect immunofluorescent antibody (IFA) test has been used with reliable results in horses and cattle.[1] The ELISA is ideal for high-volume testing, the results are quantitative, and can detect total immunoglobulins or

class-specific IgM and IgM antibodies to the organism.[36] An ELISA and immunoblots using certain antigens of the spirochete are more specific for the diagnosis of Lyme borreliosis in horses.[37] An ELISA using a purified protein of the organism detects antibody in cattle and is useful as a screening method for borreliosis in cattle.[38] Western blotting techniques and the ELISA have been used for serological surveys and for examination of synovial fluids of horses in the United Kingdom where the incidence of infection is common in some areas.[39] The positive results in horses are not due to cross-reactions with *Leptospira* which has been suspected.

In cattle, the infection has been diagnosed by detection of *B. burgdorferi sensu strictu* DNA in samples of synovial fluid and milk of affected cows.[40]

A polyvalent ELISA, incorporating highly specific recombinant antigens of *B. burgdorferi* has been used to determine seropositivity to *B. burgdorferi* and *Anaplasma phagocytophilum* infection.[41]

Subclinical infections are common in domestic animals and the interpretation of serological results must be done in conjunction with the clinical findings. Positive antibody results are an aid to diagnosis but are not conclusive evidence of current infection or clinical disease. False-positive results may be due to infection with other *Borrelia* species.

NECROPSY FINDINGS

Polysynovitis, lymphadenopathy, and emaciation are present.[34] Multifocal interstitial myocarditis, glomerulonephritis, interstitial pneumonitis, and polysynovitis have been described in cattle.[34] In the horse, polysynovitis and meningoencephalitis have been reported.[3] Using PCR amplification of DNA, necropsy tissues may be positive for *B. burgdorferi* DNA.[3]

Samples for confirmation of diagnosis

- **Bacteriology** – kidney, joint synovium, lung, choroid plexus (PCR)
- **Histology** – formalin-fixed kidney, joint synovium, heart, brain, lung, lymph node (LM).

DIFFERENTIAL DIAGNOSIS

Diagnosis is dependent on recognition of clinical signs, a history of possible exposure to infection by the bites of ticks and identification of the spirochete in the affected animal. Because clinically normal animals have antibody to the organism, a positive antibody result is not conclusive of current infection or clinical disease. Other diseases causing muscle stiffness, lameness, polyarthritis, lympadenopathy, and fever must be considered in the differential diagnosis.

TREATMENT

Tetracyclines or penicillin has been recommended.[1] Procaine penicillin at 30 000–45 000 iu/kg BW IM daily for 10 d followed by benzathine penicillin every other day has been recommended for horses.[1] Doxycycline, 5–10 mg/kg BW orally/12 h for one month has been recommended but not based on any clinical trials.[3] Phenylbutazone has been used for the treatment of laminitis. Oxytetracycline at 6–12 mg/kg BW IV once daily for 3 weeks has also been used.[1] Oxytetracycline is reported to be successful for treatment of suspected borreliosis in an old horse.[20] Penicillin or oxytetracyclines daily for 3 weeks have also been recommended for use in cattle.

CONTROL

Prevention of Lyme borreliosis in domestic animals and humans is dependent on reduction of the risk of tick bites at the environmental or individual animal level.[22] A knowledge of the ecologic requirements for the tick-borne diseases which are present in an area is necessary for selection and implementation of the most effective integrated prevention strategies. Protective measures may include the avoidance of tick-infested areas, the use of protective clothing, repellents, and acaricides, tick checks, and modifications of landscapes in or near residential areas. After a tick bite has occurred in humans, the body of the tick should be grasped with medium-tipped tweezers as close to the skin as possible and removed by gently pulling the tick straight out, without twisting motions.[24]

A commercial adjuvanted vaccine is now available for use in dogs.[1,42] An experimental vaccine, composed of recombinant OspA protected ponies against *B. burgdorferi* infection and further studies are necessary to determine duration of protection after vaccination, safety and cross protection against the possible heterogeneous OspA structures which may be present among new *B. burgdorferi* strains isolated in the U.S.[31]

Two vaccines for Lyme borreliosis in humans, consisting of OspA in adjuvant, have been developed.[24] The Advisory Committee on Immunization Practice of the Center for Disease Control advises that vaccination for Lyme borreliosis should be considered for people older than 15–17 years who live in or visit high-risk areas and have frequent or prolonged exposure to *I. scapularis* ticks.[24]

SWINE DYSENTERY

Synopsis

Etiology Brachyspira hyodysenteriae
Epidemiology Major economic importance in growing pigs 8–16 weeks of

age. Transmitted by fecal–oral route. Crowding and high stocking density are risk factors. High morbidity and moderate mortality if not treated
Signs Mucohemorrhagic diarrhea, weight loss, commonly persistent if not treated
Lesions Colitis, typhlitis
Diagnostic confirmation Detection of organism in intestine. Serological diagnosis in herd
Treatment Tiamulin to individual pigs. Organic arsenicals in feed and water supplies. Carbadox, monensin in feed and water
Control Eliminate infection with treatment in the feed and water supplies. Prevent reinfection and avoidance of introduction of carrier animals into herd. Eradicate by depopulation and repopulation and biosecurity measures

Swine dysentery is a highly fatal disease characterized by mucohemorrhagic diarrhea and death if untreated for a few days.

ETIOLOGY

Brachyspira (formerly *Serpulina* and before that *Treponema*) *hyodysenteriae* (BH) a large strongly beta-hemolytic spirochete, is the principal causative agent.[1] It is supposedly indole positive but in a study in Belgium half were indole negative.[2] It will cause typhlocolitis in captive rheas[3] and rats and mice may act as reservoirs.

Two other spirochetes *B. innocens* and *B. pilosicoli*, which are weakly beta-hemolytic, cause porcine colonic spirochetosis, a mild disease of pigs.[4,5] Human intestinal spirochetes are distinct.

They are all anaerobic organisms but they are oxygen tolerant and will grow in the presence of 1% oxygen.

EPIDEMIOLOGY

Occurrence

Swine dysentery occurs in most major pig-producing countries and was an important disease of pigs in North America (11% in USA), Australia, and the United Kingdom.[6]

A postal survey suggested that 10.5% of herds were infected.[7] In Denmark 14% had BH.[8] However, in recent years with the increase in minimal disease herds, the incidence of the disease has decreased. It is most common in the 7- to 16-week-old age group but may affect older pigs to 6 months. Adult pigs are seldom affected, and rarely suckling piglets. The overall occurrence is probably around 10% with a considerable control through drugs, particularly growth-promoting antibiotics, in countries where these are allowed. A Swedish study,[9] showed that *Brachyspirae* species were isolated from 58.5% of all samples. Of these 25.4% were *B. hyodysenteriae*, 16.4% were *B. pilosicoli*, and 58.2% were *intermedia, innocens or murdochii.*

Morbidity and case–fatality rate

Morbidity within a group of pigs can range from 10–75% and if untreated the case–fatality rate can be as high as 50%.

Risk factors

Animal risk factors

Pigs from 8–16 weeks of age are most susceptible to swine dysentery. Most outbreaks occur in herds which have purchased infected animals from herds known to have the disease. Infection is spread within and between swine herds by carrier pigs.

Experimentally, a highly digestible diet can protect pigs from swine dysentery.[10]

Immune mechanisms. Clinical disease is associated with development of specific IgG, IgA, and IgM antibodies in serum and local production of IgA in gut mucosal tissues. Treated and untreated convalescent pigs develop elevated titers which are maintained as long as 150 days after infection. The relationship between the magnitude of the agglutinin titers and protective immunity is not clear. Carrier pigs shed *B. hyodysenteriae* while elevated agglutination titers against the organism are present.

Untreated pigs which recover from swine dysentery are resistant to experimental challenge for up to 16–17 weeks. In herds affected with swine dysentery, the disease may reappear at 3–4 week intervals following treatment and the more efficacious drugs may inhibit the development of immunity.

Pathogen factors

There are many latent infections without clinical signs. There is some evidence that the organism destabilizes the microbial community in the large intestine.[11]

The disease has been reproduced with pure cultures of *B. hyodysenteriae* in conventional and specific pathogen-free (SPF) pigs. Challenge of gnotobiotic pigs with pure cultures results in colonization of the organism but disease does not occur until other intestinal organisms are given, which suggests that the disease is the result of a mixed synergistic infection of the spirochete and other intestinal anerobic organisms. Experimentally, the oral inoculation of gnotobiotic pigs with a combination of *B. hyodysenteriae* and *Bacteroides vulgatus* or *Fusobacterium necrophorum* will result in the development of the characteristic clinical signs and lesions of swine dysentery. These results and others are consistent with the concept that *B. hyodysenteriae* is the primary causative agent of swine dysentery and that the presence of one or more other anerobes is a prerequisite for expression of pathogenicity of *B. hyodysenteriae.* This prerequisite can be met by a variety of anerobes.

Although closely related, the intestinal spirochetes isolated from pigs have been categorized into four groups based on phylogenetic studies.[12,13] Groups I and II are isolated only from pigs with dysentery or diarrhea. Group II was differentiated from Group I only by weak beta-hemolysis. In Sweden, members of Group II are often isolated from young weaned pigs up to 25 kg BW, in herds where a non-specific diarrhea, which is clinically distinct from swine dysentery, occurs frequently. These strains seem to be absent or rare in herds without such diarrheic pigs. Group III included the type strain for *Brachyspirae innocens.* Group IV included the pathogenic, weakly beta-hemolytic strain P43 shown to cause spirochetal diarrhea in pigs.

There is much antigenic heterogeneity among isolates of *B. hyodysenteriae.* At least nine serotypes and nine groups have been recognized.[14] They can be differentiated by pulsed field electrophoresis and multilocus electrophoresis and the former is particularly good at differentiating strains which are genetically 53–100% similar.[15,16] Strains of *B. hyodysenteriae* possess several antigens, some of which are shared by both species. Organisms have been described which are phenotypically characteristic of *B. hyodysenteriae* but their 23s RNA genetic signature and sequence are consistent with *B. innocens.*[17] Within the genus of *B. hyodysenteriae* there are some strains that are apparently non-virulent or of reduced virulence potential.[18]

Although *B. hyodysenteriae* is the primary etiological agent of swine dysentery, *B. innocens* has been isolated from healthy swine and those with postweaning diarrhea. Besides *B. innocens*, there are other groups of weakly beta-hemolytic spirochetes.[19] *B. pilosicoli* is the cause of porcine colonic spirochetosis originally known as spirochetal diarrhea.[4,19]

There is considerable variation in virulence among strains of different serotypes of *B. hyodysenteriae* when given orally to specific pathogen-free piglets or mice.[20] A virulent *B. hyodysenteriae* has been isolated from a herd free of clinical swine dysentery[21] which indicates that the organism can still be present in herds considered to be free of the disease.

Serotyping of isolates of the organism is important in terms of diagnosis and epidemiological evaluation.[22] The range of serologically distinct strains of the organism which exists is much wider than was previously realized. *B. hyodysenteriae* has heterogeneous antigens in the lipopolysaccharide portion of the outer membrane and several serotypes of

B. hyodysenteriae have been described on the basis of agar gel double immunodiffusion precipitation.[23] Some serotypes predominate in certain geographical areas.[23,24] Restriction endonuclease analysis is being used to type strains.[25,26]

The major polypeptides of *B. hyodysenteriae* are strong immunogens and present in the various serotypes but there is considerable diversity in the antigenicity of lipopolysaccharides between those same serotypes. A PCR-based DNA fingerprinting technique can analyze genetic profiles of isolates of the organism from cases of swine dysentery in different herds, which could be important epidemiologically.[22]

A hemolysin with cytotoxic activity extracted from a virulent strain of the organism causes severe epithelial damage when injected into ligated loops of the ileum and colon of germ-free pigs[27] and is a virulence factor in swine dysentery.[28] The organism can adhere to a culture of intestinal cells in vitro which may be one of its virulence factors. The organism is also highly motile, which provides it with the ability to move through mucus and facilitates penetration into the mucosa. This may be a very important virulence[29] factor. A wide variety of other virulence factors may be important. The organism probably does not attach to the epithelial surface of cells but instead colonizes the overlying mucus layer. Chemotactic attraction of the organism to sites containing mucus is also a potentially important factor.

Potentially pathogenic weakly beta-hemolytic intestinal spirochetes may be present in swine herds with a high incidence of diarrhea and can be distinguished from non-pathogenic strains by the hippurate hydrolysis test.[30] The prevalence of these strains is reduced in herds medicated with olaquindox.

Environmental and management risk factors

The usual source of infection is through the import of pigs. It is however difficult to control these because of asymptomatic carriers.

Investigation has shown that it may be the dirty truck that is important. In other words biosecurity has failed.

Overcrowding and the build-up of fecal wastes in pens contribute to an increased incidence of swine dysentery. The failure to clean solid floor pens on a regular basis results in an accumulation of fecal wastes, which increases the infection pressure. The contamination of pens with fecal effluent from adjacent pens or by open flush gutter systems allow pigs access to the flush water and can provide sources of infection and reinfection. The continuous introduction of young pigs into pens which have not been previously cleaned out and washed provide sources of infection. The mixing of weaner pigs from different sources is often a source of infection for susceptible pigs.

Several factors affect the survival of the organism from the feces of infected pigs.[31] The organism can survive for up to 48 days in dysenteric feces at 0–10°C (32–50°F); survival is reduced to 7 days at 25°C (77°F) and to less than 24 hours at 37°C (98.6°F). Dilution of dysenteric feces with tap water (1:10) enhances survival to 61 days at 5°C (41°F). Recently, it was found in feces after 112 days.[32] Drying and disinfection rapidly eliminates the organism from the environment. Phenolic and sodium hypochlorite disinfectants are most effective. The organism can survive in lagoons for up to 60 days; however, how long it will persist in an anerobic lagoon is unknown. In swine herd facilities with an open gutter-flush system which has housed dysentery-infected swine, the lagoon water is used to expel feces from the building thus allowing the pigs to drink the effluent as it flows through the gutter. Under these conditions the organism may survive for 5–6 days after the removal of infected shedders.[31] The organism has been isolated from the lagoon of a waste-handling system of a swine farm which could be partially responsible for maintenance of swine dysentery within a herd.

Recently, the study of the effects of dietary constituents on the commensal bacterial flora of the large intestine has become fashionable but the conclusions are not definite. This was based on the suggestion that non-starch polysaccharide was drawn into the distal parts of the colon and was then available for fermentation.[33,34] It was first suggested[35] that inclusion of wheat and soybean and/or addition of exogenous enzymes to pig diets influenced the large intestine microflora but did not prevent SD. The colonization of the gut by spirochetes[36] was highly related to soluble non-starch polysaccharide and the development of SD was influenced by the resistant starch content of the diet. Feed containing large amounts of soyabean meal and group housing of pigs were considered to be the major contributing factors in the experimental production of swine dysentery.[37] Feed containing high levels of soluble non-starch polysaccharides results in an increase in viscosity of gut contents, an increased amount of gut fluid, a low pH, and an increased number of coliforms in the intestines.[38] A recent experiment with feeding and SD showed no effect of feeding rice in the diet.[39] The feeding of rice was not able to prevent SD and neither was the increase of non-starch polysaccharide or resistant starch able to reduce the incidence or prevalence of SD[40,41] and in fact the clinical signs were worse.

Methods of transmission

The organism is present in the feces of affected pigs. Infection is by ingestion and transmission is enhanced by conditions leading to fecal–oral cycling. Spread of infection within a group is slow, taking up to 7–14 days, and may spread to other pens of pigs over a 2–3-week period. Pigs which have recovered from clinical disease with or without treatment may become carriers and still have the ability to shed the organism and infect in-contact animals for 50–90 days. Clinical disease may initially be precipitated by stress but infection subsequently spreads by direct contract. The frequency of shedding varies with time and only a small proportion of a convalescent population may be expected to be carriers.

The organism has been isolated from a dog on a swine farm where swine dysentery was present. Experimentally, mice are susceptible to the infection and may be a potential source of infection in a piggery. Direct evidence of transmission has been shown from mice[42] when eight farm mice were trapped and three were found which had BH which was of the same PFGE pattern as that of the pigs. This suggests that farm mice are a confirmed reservoir of infection. They are capable of carrying the organism for up to 180 days after inoculation.

Economic importance

The disease can cause heavy mortality in growing pigs but it is equally important for its effect on the efficiency of production. The economic losses from decreased feed efficiency are estimated at four times the cost of medication. The infection tends to be persistent within a herd and may have a cyclic occurrence, which is a problem in intensive pig-rearing enterprises and frequently control can be achieved only by costly continuous prophylactic medication.

PATHOGENESIS

B. hyodysenteriae is strongly beta-hemolytic and invades the intestinal crypts and disrupts the colonic epithelium causing a mucohemorrhagic colitis. The organism colonizes the intestinal mucosa by association with intestinal mucus in both the mucus gel covering the epithelium and the mucus-filled crypts. (On the other hand the weakly beta-hemolytic *B. pilosicoli* attaches by one cell end to the luminal surface of the colonic epithelium to form a dense carpet of adherent spirochetes.)

It is still not known if invasion is a necessary feature of infection for SD. Where it lives normally is unknown but in

the intestine it can obviously breed more quickly than it is evacuated. The pattern of colonization appears to be random.[43] The hemolysin lyses the intestinal mucosal cells which then supply the Brachyspirae with the vital sterols from the membranes. Several genes may be involved in virulence including thyA and Llya.[44] For infection to establish it seems that a gene for the production of NADH oxydase is required[45] as it protects against the effects of oxygen toxicity. Similarly there may be a *Brachyspira* iron transport system[46] and the presence of this may correlate with the pathogenicity of *B. hyodysenteriae*. Another gene of interest is the mglB gene which may eventually be shown to be of great importance.[47] Lipo-oligosaccharide production may also be a virulence factor.

Chemotactic- or motility-regulated mucus association appears to be the predominant mechanisms of mucosal association.[48] There is progressive erosion of superficial epithelium, excess mucus production, edema and hemorrhage of the lamina propria and pseudomembrane production. The erosive colitis is the cause of the diarrhea, dysentery and excessive quantities of mucus in the feces. Experimentally, the cytotoxic hemolysin of the organism affects intestinal epithelial cells.[49] The hemolysin produces some of the same changes as the whole bacteria.[50] Some $CD8^+$ cells may be associated with susceptibility to experimentally induced SD whereas monocytes and $CD4^+CD8^+$ T-cells appear to be the major responding leukocytes during the disease.[51] Death results from chronic dehydration and bacterial toxemia. In some animals, an acute shock syndrome results in rapid and sudden death. Early in the disease it activates IL-1 and IL-6 and stimulates macrophages. In the later stages T-cells play an important part in defence.[52]

CLINICAL FINDINGS

Swine dysentery. Most commonly, initially, only a few pigs are affected within a group but spread occurs over a period of a few days to 2 weeks to involve the majority. Affected pigs are slightly depressed, have a reduced appetite, and a moderate fever. The feces are only partially formed, usually of a porridge-like consistency and are passed without apparent conscious effort and splatter on contact with the pen floor. Affected pigs commonly defecate almost anywhere and on anything in the pen. The feces are light gray to black and on close inspection much mucus is present and flecks of blood and epithelial casts may be seen. In some pigs, the presence of larger amounts of blood will discolor the feces accordingly. The occurrence of blood in the feces generally occurs 2–3 days after the initial onset of diarrhea. Affected pigs become progressively dehydrated and their abdomens appear gaunt and sunken. Death usually occurs some days to weeks after the initial onset of signs and results primarily from dehydration and toxemia. Pigs with a severe hemorrhagic diarrhea die more quickly. Skin discoloration is not a feature except in the terminal stages.

In untreated pigs the disease may persist for 3–4 weeks before clinical recovery. Less commonly an outbreak may start with the sudden death of one or two pigs with no evidence of premonitory signs or a terminal hemorrhagic diarrhea. This occurs more commonly in market-age pigs and adults in herds where swine dysentery has been introduced for the first time. It also is a rare cause of sporadic death of gilts and sows in conventional herds.

The disease responds well to treatment but following withdrawal of treatment the disease may recur within the same group of pigs. A chronic form of the disease with persistent diarrhea and failure to grow occurs in some pigs with irreversible lesions of the colonic mucosa.

CLINICAL PATHOLOGY

Detection and culture of organism

The organism may be detected in the feces of affected pigs by dark-field microscopy as highly motile organisms with a characteristic serpentine motility or in dried smears with Giemsa or Victoria blue 4R staining. The best diagnosis is achieved by taking samples from the upper colon. Fecal samples submitted for laboratory examination should be diluted (1:10) in phosphate-buffered saline or rectal swabs placed in Amies medium to avoid death of the organisms which will occur when the samples are stored at room temperature or sent in the mail. Microagglutination tests (MATs), slide agglutination tests, and indirect and direct fluorescent antibody tests are also used to detect the organisms.[5]

The organism can be cultured on Trypticase Soy agar containing 5% defibrinated bovine blood under specific atmospheric conditions.[6]

Fluorescent antibody staining aids considerably in its demonstration, but may not distinguish non-pathogenic strains and false-positive and false-negative results are common.[53] The presumptive diagnosis from the fluorescent antibody test (FAT) can be supplemented with a variety of laboratory tests which serve to identify the spirochetes as pathogenic. The **slide agglutination test** is a useful and specific means of identifying an organism but requires an appreciable amount of growth of spirochetes on the surface of the agar to carry out the test.[54] The **microscopic agglutination test** is a rapid test for the definitive laboratory identification of *B. hyodysenteriae* but it cannot distinguish the avirulent strains of the organism.[54]

A major diagnostic problem has been the identification of carrier pigs which are infected with the organism and are a potential source of infection to other pigs. Indirect and direct FATs used to examine feces and colonic material from pigs for *B. hyodysenteriae* have not been sensitive or specific enough to identify individual infected pigs.

Any diagnostic test must be able to distinguish between the different *Brachyspira* spp.[55] Some are harmless commensals, while others are potentially pathogenic. *Brachyspira innocens*, a non-pathogenic inhabitant of the porcine large intestine, is very similar to *B. hyodysenteriae* in both morphology and growth characteristics and shares many of the same surface antigens. Numerous serological tests with sera from pigs that have recovered from *B. hyodysenteriae* infection have demonstrated the presence of cross-reactive antibodies between *B. hyodysenteriae* and *B. innocens*, which makes differentiation difficult.

Antigen detection methods. Detection methods based on the use of DNA probes or polymerase chain reaction PCR have recently been developed and show considerable promise.[33]

A PCR was developed that could detect 10^3–10^4 organisms and this was more rapid and detected more positive samples than did fecal culture and isolation.[56,57] The duplex PCR developed[58] was also more sensitive than the culture and biochemical tests which were shown to detect 10^2 bacteria per gram of.[59] A multiplex PCR has been developed that will differentiate *B. hyodysenteriae*, *B. pilosicoli* and *L. intracellularis*.[60]

In situ hybridization was also shown to work for BH.[61]

The most definitive method for differentiating *B. hyodysenteriae*, *B. innocens* and *B. pilosicoli* is the DNA–DNA relative reassociation method.[4]

Serological tests. Monoclonal antibodies against the serotype-specific lipopolysaccharide antigens of *B. hyodysenteriae*[62] can be used in ELISA, indirect immunofluorescence and immunoblot assays to differentiate between *B. hyodysenteriae* and *B. innocens*.[63,64]

A variety of serological tests have been used[65] and typically these tests have used whole-cultures or lipopolysaccaharides as the antigen. The former tends to increase false positives and the latter increases false negatives but gives fewer false positives. In general these techniques are useful for detecting infected herds but are unable to detect individual infected pigs

that may be acting as carrier animals. Recently a 30 kDa outer membrane lipoprotein (BmpB) which is specific to BH and is recognized in both experimentally and naturally infected pigs was identified and the gene cloned and sequenced and specific epitopes on BMPB are being identified.

Serological tests can assist in the identification of carrier pigs.[66] An evaluation of several serological tests for detection of antibodies against *B. hyodysenteriae* concluded that only the MAT detected antibodies to the organism.[64] The ELISA has been used to detect antibodies in individual pigs but cross-reactions between *B. hyodysenteriae* and *B. innocens* are common.[65] An ELISA using serotype 2 *B. hyodysenteriae* as antigen could not differentiate between stages of infection but could indicate if the pig had been infected.[66]

NECROPSY FINDINGS

Lesions are restricted to the cecum and colon. They vary from catarrhal to fibrinonecrotic to hemorrhagic typhlocolitis.

The carcasses of pigs that have died from swine dysentery usually show weight loss, dehydration and a microscopically visible typhlitis and colitis. The colitis is initially present in the apex of the spiral colon but subsequently spreads to involve the whole colon and the cecum. In the early stages, there is inflammation and necrosis with varying degrees of hemorrhage into the lumen. The submucosal glands are enlarged and frequently visible through the serosa of the colon as opaque spots. In advanced cases a fibrinonecrotic exudate is adherent to a reddened and granular mucosal surface. Intestinal contents may also adhere to the mucosa. The crypts are often thickened with edema. The draining lymph nodes are enlarged and congested. The small intestine is spared except for involvement of the terminal ileum in advanced cases. Spirochetes may be demonstrated in large numbers using Warthin/Stary stains in smears from the mucosal surface of these lesions, especially in early cases, but there is no systemic invasion.

Electron microscopic examination of the colon of pigs with swine dysentery reveals changes indicative of stasis in the microcirculatory vessels of the lamina propria. The earliest colonic lesion consists of superficial vascular congestion and dilatation, edema of the lamina propria and intercellular separation of the epithelial cells at the crypt shoulders. This lesion progresses to epithelial cell necrosis and extrusion with extravasation of red blood cells into the lumen. Degeneration, necrosis and extrusion of superficial colonic enterocytes follows progressively. Large spirochetes are present in the crypts, in the cytoplasm of damaged epithelial cells and in cavities around vessels of the lamina propria. The characteristic lesion of swine dysentery is necrosis of the superficial colonic epithelium. This feature may be difficult to appreciate in partially autolysed tissues, or if the animals sampled are recovering from the infection or being treated with antibiotics. In sub-acute lesions the crypt hyperplasia and goblet cell hyperplasia is more pronounced and the extensive mucus production distends all the crypts.

B. hyodysenteriae is difficult to culture, requiring anaerobic conditions and selective media. This has promoted the development of alternative diagnostic techniques such as the polymerase chain reaction (PCR) and immunohistochemical stains. Wet mount preparations from the colonic mucosa are often utilized to make a presumptive diagnosis and a fluorescent antibody test is also available.

Samples for confirmation of diagnosis

- **Bacteriology** – colon (CULT (has special culture requirements), DIRECT SMEAR (modified acid-fast stains), FAT, PCR)
- **Histology** – formalin-fixed colon, several sites (LM, IHC).

DIFFERENTIAL DIAGNOSIS

Swine dysentery must be differentiated from other diseases in which there is diarrhea in growing pigs.

Porcine colonic spirochetosis – associated with a mild diarrhea in wenlings and growing pigs.

Coliform gastroenteritis, salmonellosis and **hog cholera** – characterized by more rapid onset and spread within a group than with swine dysentery and death occurs earlier. In coliform gastroenteritis and salmonellosis, the initial sign may be sudden death or severely depressed and weak pigs with fever, skin discoloration, anorexia and a profuse watery diarrhea. Coliform gastroenteritis occurs within a few days after weaning whereas hog cholera occurs in all ages of pig. Swine dysentery is more insidious in onset, the appetite is rarely completely lost and the feces are soft and mucohemorrhagic. At necropsy the lesions of swine dysentery are confined to the large intestine whereas in coliform gastroenteritis, salmonellosis and hog cholera lesions are also present in the small intestine

Other diseases may result in the passage of bloody feces.

Intestinal hemorrhage syndrome – generally persists as a severe hemorrhagic diarrhea with rapid death rather than as a chronic syndrome but pathological differentiation may be necessary. Chronic hemorrhage due to an **esophagogastric ulcer** results in melena, the epidemiological findings are different, and the necropsy findings are characteristic. intestine and other organs.

TREATMENT

Antimicrobial therapy

Antimicrobials are usually administered by mass medication to all pigs within the affected group. Treatment by water medication rather than feed medication is preferable because it is generally easier and quicker to put into place and affected pigs usually continue to drink (but perhaps not in the same quantities as when unaffected) while they are anorexic. Pigs with severe hemorrhagic diarrhea and toxemia may not drink sufficient medicated water and must be treated initially by parenteral injection.

Medication of feed is most suitable for subsequent prophylaxis. When outbreaks occur, all severely affected pigs should be treated individually, and the drinking water medicated for several days at therapeutic levels, followed by possible medication of the feed for up to 3 weeks or longer at prophylactic levels.

Choice of antimicrobials. The susceptibility of different Brachyspirae to antimicrobials has been discussed.[67]

Several antimicrobials are suitable for the treatment and control of swine dysentery and the choice is largely dependent on availability, cost, efficacy and the regional withdrawal regulations. The antimicrobials and their dosages given here are used in treatment and control.

Currently, tiamulin, lincomycin and the nitroimidazoles (dimetridazole, ronidazole, and ipronidazole) are the most effective antimicrobials for treatment by water medication. In some countries, certain antimicrobials may not be approved for use in pigs. The most efficacious antimicrobials for use in the feed are carbadox, the nitroimidazoles, tiamulin and lincomycin.

A macrobroth dilution in vitro technique determined the antimicrobial sensitivity of a group of isolates of *B. hyodysenteriae* from Australia, the United States and Canada.[68] Dimetridazole and tiamulin were effective against most of the isolates. Lincomycin inhibited the growth of some isolates, and tylosin failed to inhibit most of the isolates tested.[69] A group of isolates of *B. hyodysenteriae* from the United Kingdom were all sensitive to tiamulin and there was no evidence that the organism was developing resistance to the drug.[70] A large number of strains of *B. hyodysenteriae* isolated in Hungary between 1978 and 1992 were tested against seven chemotherapeutic agents commonly used for the treatment of swine dysentery, and the changes in patterns of resistance were also monitored.[71] All strains remained sensitive to carbadox. The sensitivity to dimetridazole gradually decreased with about 50% of strains still sensitive. Most strains were resistant to tylosin. Resistance to lincomycin gradually

increased but about 50% remained sensitive. Tiamulin was most effective but some resistant strains have emerged.[70,72,73] Monensin was effective for prevention but resistance may evolve quickly. Sedecamycin, a macrolide antimicrobial was effective but the minimum inhibitory concentrations (MICs) were much higher than expected.[71] Isolates of *B. hyodysenteriae* in Denmark were sensitive in vitro to virginiamycin but medication of the feed at 20 ppm was ineffective for control.[74] A combination of tiamulin and salinomycin, and salinomycin alone in the feed for 105 days in diminishing doses is effective in controlling naturally occurring disease[75] and in the first 30 days (60 ppm salinomycin and 30 ppm tiamulin), in the next 60 days (30 ppm each) and the next, 15 days (30 ppm salinomycin). For salinomycin alone: the first 30 days (60 ppm), the next 60 days (30 ppm), and the next 15 days (30 ppm).

Tiamulin given once at a dose of 10–15 mg/kg BW IM is effective for the treatment of acute cases; recovery often occurs within 24 hours. Tiamulin in the drinking water of clinically affected pigs at a dose of 45 or 60 mg/L of water for 5 days is efficacious. Tiamulin at 20 ppm in the feed for 4–6 weeks is also effective for control and prevention.

Valnemulin, a more recent pleuromutilin was shown to be effective. At 50 ppm 62.5% of the pigs still had BH but only 12.5% of the 75 ppm group and none of the 100 ppm or 150 ppm groups.

Carbadox alone at 50 mg/kg of feed for 30 days or carbadox combined with sulfamethazine at 100 mg/kg of feed for 30 days is effective in preventing swine dysentery during the infection plus medication period and during the post-medication period.

Lincomycin at 11 mg/kg BW IM or tylosin at 8.8 mg/kg BW IM daily for 3 days for both drugs and up to 7 days for lincomycin are effective. A 1:1 mixture of lincomycin/spectinomycin given orally at a dose of 66 ppm in the feed for 8 days followed by a level of 44 ppm for 20 days was successful for the treatment of the disease in adult swine.

Monensin. The continuous administration of monensin in the feed of weaned piglets at a dose rate of 100 ppm for 56 days, followed by 50 ppm from 56–84 days, and 25 ppm until 112 days was effective in controlling swine dysentery.[76] Improvements occurred in mortality rates, diarrhea score/day, average daily gain, and feed conversion ratios.

Valnemulin. At 3 mg/kg the drug is highly effective for the treatment of SD[77] and also at 75 ppm in the USA.[78,79]

Organic arsenicals are the least expensive and are recommended as the first drug of choice when available. When given in either the feed or water, there is a risk of toxicity. The general recommendation is to administer the medication for a 7-day period and then withdraw it for a 7-day period before reintroduction. However, this is frequently impractical and continuous medication at 250 ppm in the feed is often used as follow-up therapy. Toxicity does not usually occur below levels of 500 ppm but it has occurred at levels as low as 200 ppm where continuous medication is practiced, and constant surveillance for signs of toxicity is necessary. While resistance to organic arsenicals has been suspected, it has not been documented. There has been a marked decline in the use of arsenicals for the clinical management of swine dysentery.

Failure to respond to therapy

The major problems with the treatment of swine dysentery are the failure of some outbreaks of the disease to respond favorably to treatment, and relapses or new cases which may occur following withdrawal of medication of the feed or water. Several drug-related problems have been postulated to explain these problems.

Drug-delayed swine dysentery occurs several days after withdrawal of medicated feed. It may be due to either an ineffective drug or inadequate dosage of an effective drug and failure to eliminate the causative organism from the colon. However, reinfection from other swine must also be considered. The nitroimidazoles at high levels will apparently prevent the delay or recurrence of dysentery.

In experimentally induced swine dysentery using colon from affected pigs as the oral inoculums, tiamulin in the drinking water at 45 or 60 mg/L for 5 days was also effective in treating clinical disease. However, diarrhea commonly recurred 2–10 days after withdrawal of the drug and repeated medication of the water with tiamulin was necessary to reduce the severity of diarrhea and prevent deaths. After one to three retreatments, the pigs were immune to experimental exposure and there was a significant increase in their serum anti-*B. hyodysenteriae* antibodies. This supports the observation that when certain antimicrobial agents such as dimetridazole, which are highly effective in preventing the development of diarrhea, are withdrawn, the affected pigs do not become immune.

Drug-diminished swine dysentery occurs when suboptimal levels of the drug are used. The severity of the diarrhea is reduced; deaths do not occur, but the disease is not eliminated. However, severe disease may follow withdrawal of medication.

The feeding of ronidazole at 60 ppm for 10 weeks, or carbadox at 55 ppm or lincomycin at 110 ppm for 6 weeks eliminated an experimental infection, and swine dysentery did not recur during a 9-week period after withdrawal of the medication. The feeding of sodium arsanilate at a level of 220 ppm for 3 weeks to pigs which had been fed ronidazole for only 6 weeks did cause the development of swine dysentery.

In both drug-delayed and drug-diminished swine dysentery, there are chronic lesions in the colon. In drug-resistant swine dysentery, medication of the feed is not effective and diarrhea and deaths occur. Certain outbreaks of the disease may be resistant to both tylosin and sodium arsanilate. Selection of an effective drug is necessary. The sensitivity of *B. hyodysenteriae* to dimetridazole has not decreased significantly following use of the drug over several years.

Drug-augmented swine dysentery is a more severe form of the drug-resistant disease in which affected pigs are more severely affected than non-medicated controls. The cause is unknown. The disease occurs in a severe form several days or weeks following withdrawal of successful medication for a previous outbreak of the disease. This form appears to occur most commonly in pigs which did not have clinical disease during an earlier outbreak, but received medication. The concentration of the drug administered was sufficient to prevent diarrhea, but not sufficient to eliminate the spirochetes from the colon. During the delay of the initial diarrhea by the drug, there may have been intraglandular recolonization of spirochetes throughout the colon. After withdrawal of medication, rapid intraglandular multiplication of the large spirochetes may occur and result in clinical disease. Drug-delayed augmented dysentery usually occurs only in those pigs that have been infected but did not develop clinical disease, which usually results in immunity. The occurrence of diarrhea is necessary for its development which occurs 4–13 weeks after infection. Treatment of swine dysentery with the more efficacious drugs has been shown to inhibit the development of this immunity and serum antibody to *B. hyodysenteriae*. However, the clinical significance of this is undermined and at present it is suggested that outbreaks of swine dysentery be treated vigorously.

It should be possible to minimize these drug-related problems of swine dysentery by the use of therapeutic levels of effective drugs in the drinking water for short periods followed by prophylactic levels in the feed for 3 weeks or more. This must be combined with proper management techniques and waste disposal systems which minimize or prevent re-exposure.

Regardless of the drug used, many pigs are reinfected following withdrawal of medication because of the continual presence of the organism in the environment. The sources of the organism include in-contact carrier pigs which are shedding the organism and survival of the organism in waste materials, which was presented under the heading epidemiology.

Cleaning and disinfection

After the institution of treatment, thorough cleansing of the contaminated pens is necessary to prevent reinfection or the transmission of infection to new groups of pigs. This is usually done after 3–6 days when all diarrhea has ceased. The decision to continue with prophylactic medication depends upon the hygiene and a knowledge of past patterns of the disease on the farm. It is generally recommended to continue prophylaxis for at least 2 weeks. Swine housing units with open gutter-flush systems in which swine dysentery-infected pigs have been maintained should remain idle for a longer period than 5 or 6 days to eliminate *B. hyodysenteriae*.[80]

CONTROL

Effective control of swine dysentery is dependent on the control of infection in the herd and the limitation of reinfection, eradication by depopulation and repopulation or mass medication without depopulation.

Control of infection/limitation of reinfection

Control of the clinical disease can be achieved by early treatment with adequate levels of antimicrobials for a sufficient length of time. This must be combined with adequate removal of fecal wastes to prevent reinfection. Pigs destined for market should be moved out as a group and their pens cleaned, disinfected and allowed to dry for a few days before pigs are restocked. Where possible the purchase of feeder pigs should be restricted to private sales from herds with no history of the disease. Communal trucks should not be used for transport. Where this is not possible pigs should be placed in isolation pens for 3 weeks and provided with medicated feed or water to eliminate the carrier state in infected pigs. Every effort should be made to avoid potential fecal–oral cycles and contamination by feces between pens. Preventing the build-up of fecal wastes is also of paramount importance. Pigs from different source farms should not be grouped in the same pen. It is also necessary to reduce the stress of transportation and overcrowding on the pigs.

In farrowing-to-market enterprises where the disease is always a threat, routine prophylactic medication may also be necessary. This is commonly carried out following weaning and during the early growing phase. In countries where withdrawal periods are in force, the use of certain microbials is precluded for this purpose.

The feeding of tiamulin at a dose of 20 mg/kg BW to pregnant sows beginning 10 days before farrowing and continuing until 5 days after farrowing when the piglets are weaned and transferred to an isolation unit has been successful in the prevention of infection of newborn piglets. This is known as the 'barrier method' which can be an efficient method of eradicating endemic infections. To reduce the risk of postnatal infection of the progeny, the piglets should stay with the latently infected sows for the shortest time possible. Furthermore, early weaning is necessary and strict isolation is an important condition to success. *B. hyodysenteriae* is spread primarily by carrier pigs, and contact between infected and uninfected pigs must be avoided.

The administration of tiamulin at 10 mg/kg BW IM daily for 5 days to all animals in a large herd, combined with cleaning, disinfection and rodent control was effective in controlling the disease and no further clinical signs occurred in the subsequent 2.5 years.

Mass medication and sanitation program without depopulation. With the strategic use of antimicrobials, effective sanitation, serial depopulation of possible carrier animals and the introduction of non-infected animals, it is possible to virtually eradicate the infection from a herd.

Elimination of infection from closed swine herds is possible using antimicrobials described under the treatment section. There are various options.

Dietary modification. Experimentally, modification of the diet can assist in the control of swine dysentery.[10] Feeding a highly digestible diet reduces fermentation in the large intestine and is associated with a failure of colonization by *B. hyodysenteriae* when challenged orally.[10] Pigs fed on a diet based on steam-flaked maize and steam-flaked sorghum had a decreased incidence of disease. Pigs fed on a diet based on cooked white rice were fully protected from experimental infection with *B. hyodysenteriae*.[81]

Eradication of infection

Depopulation and repopulation. The infection can be eradicated by depopulation of the entire herd and repopulation with breeding stock free of infection. However, this can be uneconomical unless it is part of the long-term plans for the herd and the producer.

The disease can be eradicated through the use of minimal disease or high-health-status herds which are free of several infectious diseases and maintain disease-free status. In such herds, diseases such as swine dysentery occur only rarely and almost never over a period of several years. Details are available in the current authors' book on health management.[82]

A control scheme for swine dysentery has been supervised by the Pig Health Control Association in Britain. To qualify, there must be no clinical signs of swine dysentery or, if any suspicious signs are noticed, laboratory tests for *B. hyodysenteriae* must be negative. In addition, a list of pharmaceutical compounds which might mask the disease or its laboratory diagnosis may not be used routinely after weaning, either for treatment or for control. Qualifying herds can import pigs only from other qualifying herds or by hysterectomy/hysterotomy or embryo-transfer methods; artificial insemination is also permitted. Over a period of 6 years the scheme has been highly successful.

Biosecurity. Strict biosecurity measures are necessary to prevent introduction of infected carrier pigs. This requires knowledge of the infection status of the herd of origin. It also requires a highly reliable test to detect the infected pig.

Vaccines

Pigs which have recovered from clinical swine dysentery may be protected against subsequent challenge, but attempts to immunize pigs with *B. hyodysenteriae* have been proven to provide incomplete protection and involve complex procedures which may have limited practical value. The development of effective vaccines will require attention to serospecificity of the organisms used to formulate the vaccines.

Effective vaccines are not widely available as yet. A commercial vaccine using a protein digested bacterin has shown efficacy in the reduction of disease due to *B. hyodysenteriae*.[83,84] It produced both a systemic and mucosal immunity. Both IFN gamma and lymphocyte blastogenesis responses were stimulated. A recombinant outer membrane lipoprotein has also been shown to be a hopeful vaccine.[85]

An inactivated, adjuvanted, whole-cell vaccine against *B. hyodysenteriae* has been tested experimentally.[86] The vaccine provided significant protection in two small trials but some of the vaccinated and unvaccinated pigs developed late-onset swine dysentery, which is unexplainable. Field trials to test the vaccine are required. An experimentally inactivated *B. hyodysenteriae* vaccine adjuvanted with mineral oil resulted in exacerbation of the clinical disease following challenge; a majority of the vaccinated pigs developed the disease earlier and to a more severe degree than the unvaccinated pigs.[80]

PORCINE INTESTINAL SPIROCHETOSIS (SPIROCHETAL COLITIS; PORCINE COLONIC SPIROCHETOSIS) AND NON-SPECIFIC COLITIS

INTRODUCTION

Porcine intestinal spiochaetosis is a non-fatal, colonic disease of recently weaned, grower and finisher pigs. The causative organism *B. pilosicoli* was first recognized in 1980.[1] It is a Gram-negative, anaerobic, but oxygen-tolerant spirochete found in the colon.

It is found in a wide variety of hosts including humans,[2] primates, dogs, opossums, commercial chicken production and various species of birds.[3,4]

Porcine colonic spirochetosis (PCS) and non-specific colitis may be two different syndromes.

PCS is certainly associated with *Brachyspira pilosicoli* formerly known as *Serpulina pilosicoli*. *B. hyodysenteriae* was described in 1971;[5] *B. pilosicoli* in 1997[6,7] and these are the only two confirmed pathogens in the Brachyspirae group. *B. innocens* described in 1992[8] and the other two *B. intermedii* and *murdochii* in 1997[9] are considered non-pathogenic.

Non-specific colitis (NSC) may be associated with any of the brachyspirae or any other of the common enteric bacteria but is also more likely to be associated with dietary disturbances of the large intestine. A large postal survey of enteric disease in grower-finisher pigs in England showed that colitis in some form occurred in 345 of farms.[10] Large, anaerobic weakly beta-hemolytic non-*B. hyodysenteriae* spirochetes have been associated with porcine colitis[11] and are capable of inducing disease in gnotobiotic pigs but their role as primary or opportunistic pathogens in colitis in conventional pigs is uncertain.[12] *B. innocens* has been considered as one member of a diverse group of non-pathogenic species which may be involved in a mild disease of the large intestine.[13]

ETIOLOGY

A specific colitis can be part of *Brachyspira, Salmonella, Lawsoniana, Trichuris* or *Balantidium* infections.

PCS

B. pilosicoli, a new species, has now been identified as the cause of porcine colonic spirochetosis (PCS).[14] Other species of weakly beta-hemolytic intestinal spirochetes are encountered less frequently and these may contribute to the non-specific colitis.[15] Three strains were investigated in the UK. The genetic relationships between brachyspirae were determined by pulsed field gel electrophoresis (PFGE).[16]

Swedish workers grouped the intestinal spirochetes isolated from pigs into four groups based on phylogenetic studies[17,18] although closely related. Groups I and II were isolated only from pigs with dysentery or diarrhea. Group II was differentiated from Group I only by weak beta-hemolysis. In Sweden, members of Group II are often isolated from young weaned pigs of up to 25 kg, in herds where a non-specific diarrhea which is clinically distinct from swine dysentery occurs frequently. These strains seem to be absent or rare in herds without such diarrheic pigs. Group III included the type strain for *B. innocens*. Group IV included the pathogenic, weakly beta-hemolytic strain P43 shown to cause spirochetal diarrhea in pigs. A PCR system is used for the detection and identification of Group IV spirochetes (*B. pilosicoli*).[19] Most farms have distinct *B. pilosocoli* genotypes and common genotypes between and among herds are rare.[20]

A complex investigation involving 85 pig units in Scotland over the period from 1992–1996 has provided much needed information on the occurrence of mixed infections.[21] All the pigs were within 20–40 kg (occasionally 50 kg), 8–16 weeks of age, and all had diarrhea

and grew slowly over the period of 2–3 weeks. *B. pilosicoli* was found on 25% of the units. Atypical brachyspirae on 7%; *B. hyodysenteriae* on 6%; with *S. typhimurium* on 4%; *Yersinia pseudotuberculosis* on 4% and *Lawsoniana intracellularis* on a mere 3%. Mixed infections of *B. pilosicoli* with yersinia, salmonella, other combinations and *B. hyodysenteriae* were found on 27%. On six of the 85 units nothing pathogenic was detected.

NSC

Non-specific colitis was first seen in the UK in intensive management systems. Pigs showed a sporadic diarrhea with soft, wet feces, in 18–35 kg pigs and with a morbidity of 20–30%. Most pigs continued to thrive but some grew poorly. Pigs had enlarged colons with frothy contents and most had a reddened mucosa. Microscopically they have a mild erosive colitis. Most of these cases were probably *B. pilosicoli* cases but there is now some evidence that would be better called dietary colitis. They could be diet related or diet induced and most often pelleted feed was implicated as a complicating factor. It has now been shown that some diets induce a colonic acidosis and enhance colonization by spirochetes. Many of these cases have no involvement of any of the brachyspirae and the possibility exists that there may be a syndrome of colonic dysfunction without direct spirochetal involvement. It is possible that any event that leads to disturbance of colonic microflora may lead to colonic lactic acidosis and damage to the colonic mucosa. You may then get a reduction in colonic fluid absorption and as a result of this diarrhea. At the moment the role of the various possible players is not clear. It might involve feed ingredients, feeding practices, pre-disposing viral enteritis, poor management, poor hygiene, or even sudden changes in husbandry.

Occurrence

The condition of PCS probably has a worldwide occurrence and has certainly been reported in Korea,[22] Italy,[23] Finland,[24] Sweden,[19,25] the UK,[21] Australia,[26] New Zealand,[27] Brazil,[28] Canada[29] and all the major pig producing states of the USA.[30–32] Recently, 428 pens were examined in Finland; none had *B. hyodysenteriae*, five had *B. intermedia*, *B. pilosocoli* were found in 14 and group III brachyspirae were found in 37. Herds using Carbadox had a lower prevalence of brachyspira species that the ones using olaquindox.

Risk factors

Transmission

It is likely that the common route of transmission is fecal/oral but there may be a role for mice and birds.

Managemental and environmental factors

There may be a close association between this agent and other non-specific factors in the gut. Changes in colonic microenvironment may pre-dispose to colonization and damage being associated with *B. pilosicoli*. There is a lower incidence if antibiotics are fed compared with no antibiotics.

Feed

Consumption of a rice-based diet but not vaccination delayed and significantly reduced the onset of excretion of *B. pilosicoli* after experimental challenge. In a recent set of experiments five diets were used in conjunction with *B. pilosicoli*.[33] They included pelleted feed, non-pelleted standard food, standard diet plus lactic acid, formulated liquid diet, and a diet based on cooked rice. The group that were fed rice did indeed excrete *B. pilosicoli* for less time in their feces and in fewer numbers than the other groups. The pigs on the pelleted diet were worse.

NSC

It may be associated with variations in a wide variety of factors including feed ingredients, feed formulations, feed availability, absence of fiber, or high salts in water.

PATHOGENESIS

The initial colonization of the colon appears to be mediated by the motility-regulated mucin association[34] in which there is a positive chemotaxis towards mucin.[35] Galactosamine and glucosamine are important constituents of intestinal mucin and *B. pilosicoli* uses both of these substrates when it is grown in vitro.[6,14] This is followed by the multiplication of the spirochetes in close proximity to the mucosal surface and inside the lumen of the crypts.[31,36] Intimate attachment of the of *B. pilosicoli* to the apical membrane of the colonic enterocytes, causes destruction of the enterocyte microvilli.[31] These lesions are only seen in the first 3 weeks postinoculation in the experiments that have been performed. There may be a specific spirochete ligand and host cell membrane receptor interaction.[32,37,38] *B. pilosicoli* can invade between the enterocytes and reach the lamina propria where it may remain extracellularly or be seen in macrophages.[37] *B. pilosicoli* can virtually eat its way through from the lumen to the lamina propria.[39–41] They spread extra-cellularly in the underlying lamina propria and are phagocytosed by the macrophages and also enter the capillary blood vessels.[30] They are taken up by a novel mechanism that has been called coiling phagocytosis in which the *pilosicoli* are localized and replicate in the endoplasmic reticulum of the infected cells which suggests intracellular trafficking.[42]

Penetration of the epithelium may involve disassociation of the intercellular junctional areas by the action of a subtilisin-like serine protease present in the outer membrane of the spirochete.[43]

CLINICAL FINDINGS

Porcine colonic spirochetosis is characterized by mild persistent diarrhea in pigs. Growth retardation and partial anorexia occur commonly. Morbidity and mortality data are not available.

The clinical signs of porcine intestinal spirochetosis (PIS) and NSC are difficult to distinguish from one another, and are similar to those seen in other forms of colitis, as well as those in the early stages of swine dysentery. Prevalence was found to be 5–15% in affected batches and the mortality 1%.[21]

It occurs in pigs from 4–20 weeks of age and is characterized by diarrhea and reduced growth rates in weanlings and growing pigs.[2,3,6,36] There is reduced feed conversion and more days to slaughter.

Typically, it occurs 7–14 d after weaning[6] or after they have been mixed. Morbidity is in the region of 5–30% and the signs last for 2–6 weeks. It is distinct clinically and pathologically from swine dysentery. Clinical findings include a mucoid non-bloody diarrhea, often soft and wet to start forming puddles like 'wet cement' and then becoming watery. During recovery and in chronic cases there may be large amounts of mucus. There is also reduced feed conversion, and reduced growth rate.[29] Affected pigs are usually alert and active but may become depressed, gaunt and found with stary, rough coats Affected pigs rarely die and eventually recover. Chronic infection and relapses are sometimes recorded. Mixed infections took longer to recover and had a more profound effect on growth rates and often persisted unless there was medication.[21]

Non-specific colitis

The clinical signs of non-specific colitis are mild and are characterized by mild persistent diarrhea in pigs 5 to 14 weeks of age.[29] Growth retardation and partial anorexia occur commonly. Morbidity and mortality data are not available.

PATHOLOGY

Gross lesions are usually subtle or not recognized. They are restricted to the large intestine in all species. The spiral colon is flaccid, and full of watery contents with a variable amount of mucus. Mucosal lesions are most obvious in the mid region of the spiral colon followed by the proximal spiral colon. The cecal mucosa is usually not involved or only mildly. The mucosa is

reddened or thickened by edema, and it may even form ridges. There are a variable number of erosions. If there are few there appears to be nothing visible but if they are many then the surface appears granular and it may be necessary to gently wash the mucosa with water to see these erosions. Fibrin may be mixed with mucus or blood and there may be variable amounts of either loose in the lumen of the colon. In mixed infections with *B. pilosicoli* then the lesions were more extensive and sometimes affected the cecum as well as the colon.

Microscopically, with time the surface epithelium becomes eroded and attenuated[21] but these changes are not specific to *pilosicoli*. There is a mild to moderately severe erosive colitis which can be multifocal or diffuse. The extent and severity of this is probably a function of the colonic microflora.[44,45] There is often adherent fibrino-necrotic exudates and feed particles. Goblet cell hyperplasia with distended mucus filled crypts, mucosal edema and lymphoplasmacytic infiltrates are also found.

The characteristic histological feature is a dense mat or false brush border of spirochete cells which are closely packed parallel to one another and are attached by one end to the colonic epithelium resembling a 'brush border'. This may be a feature only in the first 2–3 weeks of infection. With time the spirochetes persist in the lumen of the colonic glands which are dilated and filled with mucus.[21,36] The lesions of NSC resemble a mild form of swine dysentery.

IMMUNOLOGY

Recovered pigs may have serum immunoglobulins to several *B. pilosicoli* antigens[46] but in experimental infections there seems to be a lack of a systemic response.[47]

LABORATORY DIAGNOSIS

The laboratory diagnosis of PCS is similar to those used in swine dysentery. The identification of spirochetes in fresh wet smears of feces viewed by phase contrast microscopy may provide evidence of spirochetal infection but this method alone is not reliable and cannot differentiate between the various groups of pathogenic and non-pathogenic spirochetes. It can be combined with fluorescent labeled antibodies.[48,49]

Primary isolation is the technique of choice for confirmation of the disease and it is then necessary to show *B. pilosicoli* in the mucosa or feces by culture or PCR.[50] You can then demonstrate the weakly beta-hemolytic *B. pilosicoli* organisms and provisional identification is by hippurate hydrolysis[19] although there are organisms that are hippurate negative, but have been confirmed as *pilosicoli* by 16S ribosomal DNA analysis. Most have the hippurate cleaving capacity.[51] It is safer to remember that biochemical analysis is not definite as they can be both hippurate negative or positive.[52] For this reason it is worth checking on their reaction with beta-glucuronidase as they should be negative if they are *B. pilosicoli*.

Microscopic lesions are not diagnostic as they may be confused with salmonellosis or swine dysentery but you can see the organisms in HE sections and they may be confirmed in WS silver stained sections. Specific identification requires IHC staining with *B. pilosicoli* specific mouse monoclonal antibodies.[53] Fluorescent ribosomal RNA can also be detected in ISH.[54] Scanning electron microscopy shows degenerating epithelial cells and spirochetal colonization of the epithelium with *B. pilosicoli* but nothing with *B. intermedia*[54] The presence of *B. intermedia* can then be detected by PCR using 23SrDNA genes.[55]

POTENTIAL ZOONOTIC RISK

The human strains can cause colitis in pigs[14] and the wide species occurrence may cause concern for their being a zoonotic risk but this has not yet been confirmed. A cause of special concern is that in some parts of the world the level of infection in humans is quite high and this may be an indicator that spread is possible from some of the other species to humans.

TREATMENT

Treatment and control of PIS and PSC are achieved using the same principles as those used for swine dysentery. All USA isolates are susceptible to tiamulin and carbadox. Over 50% were resistant to gentamycin. With lincomycin 42% were susceptible, 15.8% resistant and 42% had an intermediate susceptibility.[56]

In experimental infections when given after challenge valnemulin significantly reduced diarrhea and colonization by spirochetes. More recently in-feed valnemulin has also been shown to be useful at 25 ppm for 14–27 days giving lower lesion scores and less widespread colitis.[57]

CONTROL

An effective rodent control policy and prevention of bird entry is probably essential for the control of PSC.

Treatment and control of PIS and PSC are achieved using the same principles as those used for swine dysentery. Control can produce significant savings where there is all in/all out management and multiple site production. Improving hygiene and reducing contact with feces are the essential ingredients for successful control. If there is a lot of contamination then it is always better to allow exposure for about a week before giving antibiotics as this allows at least some immunity to be produced. Since other species may be a source of infection it is necessary to control mice and birds. Rational use of antibiotics may be useful. Rotation of antibiotic usage may make the occurrence of resistance less likely. The three most likely successful treatments are vanemulin, carbadox and tiamulin, although carbadox cannot be used in many countries.

- Rations shown to contain 33 and 110 ppm of lincomycin provided an effective control
- In Finland the use of tiamulin at 200 ppm for 18–30 days combined with thorough cleaning removed PCS from a 60 farrow to finish operation
- Vanemulin at 25 ppm (1.25 mg/kg) was shown to be effective in controlling spontaneous PCS.

Vaccination

Vaccination seems to induce a primary and secondary serological response to *B. pilosicoli* but an experimental whole-cell bacterin was not protective when administered parenterally.[58]

ULCERATIVE GRANULOMA (NECROTIC ULCER; SPIROCHETAL GRANULOMA; ULCERATIVE SPIROCHETOSIS, ULCERATIVE DERMATITIS, GRANULOMATOUS DERMATITIS) OF PIGS

Ulcerative granuloma is an infectious disease of pigs associated with the spirochete, *Borrelia suilla*[1] (formerly *B. suis*), which is characterized by the development of chronic ulcers of the skin and subcutaneous tissues. It can be confused with necrotic ear syndrome[2] and more importantly with swine vesicular disease when there are granulating lesions at the coronary groove.

It occurs most commonly under conditions of poor hygiene in Australia and New Zealand[3] and is recorded in the United Kingdom.[4–6]

Lesions occur on the central abdomen of sows and on the mammary glands. The other important site is the face of sucking pigs, suggesting infection of cutaneous or mucosal abrasions as the portal of entry. In some instances these outbreaks have followed episodes of severe fighting.

Initially the lesions are small, hard, fibrous swellings which ulcerate in 2–3 weeks to form a persistent ulcer with raised edges and a center of excessive granulation tissue covered with sticky, gray pus. All you may see is a grayish, crusty, weeping lesion which may spread. It may follow infection with *Staphylococcus hyicus* or beta-hemolytic streptococci and the lesions may be contaminated by *Arcanobacterium pyogenes*.[7] The lesions expand, often to 20–30 cm in diameter, on the belly of the sow. They are usually single or in small numbers. In young pigs, usually within 2–3 weeks of weaning and whole litters may be affected. The lesions commence about the lips and erode the cheeks, sometimes the jawbone, and often cause shedding of the teeth. The disease has also been described in weaned pigs to affect the lower margin of both ears close to the junction with the neck, with extensive tissue destruction and sloughing. The lesions may continue to enlarge particularly those found on the central abdomen of sows and on the tail of suckling pigs. The major diagnostic problem is that the initial spirochetal lesions may be secondarily infected with environmental organisms such as *Fusobacterium* spp. or *A. pyogenes* and the underlying spirochetes may be missed unless smears are viewed. The pathology usually involves edema, erythema, necrosis, ulceration and purulent lesions.

In adult animals there is considerable inconvenience if the lesions are permitted to develop. In young pigs there may be heavy losses due to severe damage to the face.

In growing pigs, the lesions need to be differentiated from necrotic lesions resulting from the vices of snout rubbing in colored pigs and ear-biting, and those resulting from excessive self-trauma with mange infestation. Necrotic ulcers on the udders of sows may continue to develop and extend deeper into areas with fistulae, and sloughing may result.

Differential diagnosis may include abscesses, foreign bodies, granulomas, and pressure necrosis. It may be mistaken for lesions of actinomycosis and swabs should be taken from the ulcers for bacteriological examination. A fresh smear of the exudates usually shows the spirochetes and if necessary they can be stained by silver stains or viewed in histological sections. A course of potassium iodide given orally (1 g/35 kg up to 3 g), or a 5-day period of injections of penicillin are the methods of treatment. Topical tetracycline spray has been used effectively with early lesions[5] followed by tetracycline injection in the deeper seated and more chronic cases. Dusting with sulfanilamide, arsenic trioxide or tartar emetic has also been recommended. Removal of large granulomas surgically has also been tried. Fly repellants should be used to prevent flystrike.

The injection of 0.2 mL of a 5% solution of sodium arsenite into the substance of the lesion is reported to give good results. Improvement in hygiene particularly at the times of routine treatments and disinfection of skin wounds should reduce the incidence in affected piggeries.

Diseases associated with *Mycoplasma* spp.

The genera *Mycoplasma*, *Acholeplasma* and *Ureaplasma* form the family Mycoplasmataceae within the class Mollicutes. (Mollicutes: A class of Gram-negative bacteria consisting of cells bounded by plasma membrane. Its organisms differ from other bacteria in that they are deficient in cell walls. It contains a single order, Mycoplasmatales. Mollicutes: mollis = soft, cutis = skin.) More than 200 mollicutes, including 102 *Mycoplasma* species, have been named, although many more as yet unnamed species have been isolated.[1] A summary of the major Mollicutes of farm animals and the diseases associated with them is shown in Table 20.5.[2]

The *Mycoplasma* species that affect ruminants cause some of the most economically important diseases worldwide. Contagious bovine pleuropneumonia (CBPP) an Office International des Epizootes (OIE) List A disease is associated with *Mycoplasma mycoides* subspecies *mycoides* small colony type, and contagious carprine pleuropneumonia (CCPP), and OIE List B disease is associated with *Mycoplasma capricolum* subspecies *capripneumoniae*. The disease complex contagious agalactia, an OIE List B disease, is associated with a number of mycoplasma species, including *Mycoplasma agalactia*, *M. capricolum* subspecies *capricolum*, *M. mycoides* subspecies *mycoides* large colony and *Mycoplasma putrefaciens*.

Between 1990 and 2000, more than 1600 mycoplasmas and the related acholeplasmas were identified from ruminant animals by the Mycoplasma Group at the Weybridge Laboratories Agency, Weybridge.[1] Over the period, *Mycoplasma bovis* was the most commonly identified pathogen, with an overall mean

Table 20.5 Major pathogenic Mycoplasmas of ruminants, swine and horses

Animal host/Mycoplasma species	Disease
Bovine	
M. mycoides subsp. mycoides SC	Contagious bovine pleuropneumonia, CBPP
Mycoplasma sp. bovine group 7	Pneumonia and arthritis
M. bovis	Mastitis, pneumonia (calf), polyarthritis (calf) metritis, abortion, sterility
M. dispar	Pneumonia (calf)
M. californicum	Mastitis
M. canadense	Mastitis
M. bovocculi	Conjunctivitis
Ureaplasma diversens	Metritis, sterility, abortion
Mycoplasma (Eperythrozoon) wenyonii	Anemia
Sheep and goat	
M. capricolum subsp. capripneumonia	Contagious caprine pleuropneumonia
M. capricolum subsp. capricolum	Mastitis, arthritis
M. mycoides subsp. capri	Pneumonia, arthritis septicemia (goat)
M. mycoides subsp. mycoides LC	Pneumonia, mastitis, arthritis, septicemia (goat)
M. agalactiae	Infectious agalactia
M. ovipneumoniae	Pneumonia (lamb)
M. conjunctivae	Infectious keratoconjunctivitis (IKC) (sheep)
Pig	
M. hyopneumoniae	Enzootic pneumonia
M. hyorhinis	Pneumonia, arthritis
M. hyosynoviae	Arthritis
Mycoplasma (Eperythrozoon) suis	Anemia
Horse	
M. felis	Pleuritis
M. equirhinis	
M. equipharyngis	

of 52% of the isolates, mostly from pneumonic calves but also from cattle with mastitis and arthritis. *Mycoplasma canis* was first isolated in Britain in 1995 from pneumonic calves and the number of isolates increased 18% of the total mycoplasmas isolated from cattle in 1999. Other species isolated include *Mycoplasma dispar* from lungs of cattle with respiratory disease, and *Mycoplasma bovigenitalium* from the reproductive tract of cows with vulvovaginitis and infertility. *Mycoplasma bovirhinis* and *Acholeplasma* species were found commonly but are considered as opportunists. In sheep and goats, the majority of *Mycoplasma* species isolated were *Mycoplasma ovipneumonia* from pneumonic sheep. *Mycoplasma conjunctivae* from sheep with keratoconjunctivitis, and the ubiquitous *Mycoplasma arginini*.[1]

Molecular techniques such as denaturing gradient electrophoresis (DGGE) of a 16S ribosomal DNA PCR product have been used to differentiate almost all mycoplasmas within a host animal group.[3] The method can enable the rapid identification of many mycoplasma species for which there is no specific PCR available and which are currently being identified by culture and serological tests. This has demonstrated that *Mycoplasma* species are not necessarily host specific. Molecular epidemiological analysis of 53 *Mycoplasma bovis* isolates from pneumonic cattle collected in UK between 1996 and 2002, revealed two genetically distinct clusters (A and B).[4] There was no clear relationship between the geographic origin or year of isolation of the isolates and the profiles produced. Group B isolates were relatively more heterogeneous than isolates of the A group.

Mycoplasma bovis is a major pathogen causing respiratory disease, arthritis, mastitis, and other diseases such as otitis in cattle.[5] *M. bovis* is found worldwide and has spread into new areas, including Ireland and parts of South America, in the last decade. There is considerable antigenic variation in *M. bovis* associated with its variable surface proteins (Vsps) which differ from other mycoplasmas.[6] *M. bovis* is highly invasive and is not confined to the initial area of colonization, the respiratory tract. Consequently, organisms rapidly gain access to multiple organ systems.

Mycoplasma sp. bovine group 7 can cause substantial economic losses due to mastitis, polyarthritis and abortion in dairy cattle.[7,8] The disease may been spread from mammary gland infections, and neonatal calves were most likely infected by the consumption of milk contaminated with the mycoplasmas. Abortions probably occurred due to a systemic infection of mycoplasma.

Mycoplasmas are the smallest prokaryotes with autonomous replication. They are extracellular parasites with an affinity for mucous membranes, where they exist as commensals or pathogens. Pathogenic mycoplasma have a predilection for the respiratory system, urogenital tract, mammary gland and serous membranes. Most mycoplasmas are adapted to a main host in which they are commonly pathogenic. They may colonize other hosts without being pathogenic. As parasites of mucous membranes, they adhere firmly to epithelial cells and adhesion is a prerequisite for colonization and infection. Their mechanism of virulence is not well-understood and activation of the immune system of the host probably plays a major role in the pathogenesis of mycoplasmoses. In general, mycoplasmas are not highly virulent but rather induce chronic diseases. Most animal mycoplasmoses are herd problems with high morbidity and relatively low mortality and healthy carriers are an important part of the epidemiology of mycoplasmoses.

The most important pathogens are found in the *mycoides* cluster with six species, among them the pathogens of contagious bovine pleuropneumonia, contagious caprine pleuropneumonia, and the pathogens of pneumonia, arthritis and mastitis in goats and sheep. Another group of related mycoplasmas are *M. agalactiae* (contagious agalactia of goats and sheep) and *M. bovis* (mastitis, pneumonia and arthritis in cattle). *M. hyopneumoniae* is the agent of enzootic pneumonia of swine. Many other mycoplasma species, which occur commonly as commensals on mucous membranes, are sporadically associated with disease. They are often found along with bacteria or viruses.

Mycoplasmas lack a cell wall and are therefore resistant to β-lactam antimicrobials but sensitive to numerous other antimicrobials. The most active are macrolides (erythromycin, spiramycin, and tylosin), the tetracyclines, quinolines and chloramphenicol. The in vitro activity of danofloxacin, tylosin and oxytetracycline against field isolates of seven *Mycoplasma* species from cattle and pigs from five European countries were determined.[9] Danofloxacin, a fluorquinolone, has excellent in vitro activity against *M. hyopneumoniae*, *M. dispar* and *M. bovigenitalium* and similar activity to that of tylosin against *M. bovis*.[9] However, response to therapy is often unsatisfactory. In general, the antimicrobial sensitivity of mycoplasmas and ureaplasmas is greatest to tiamulin, then tylosin and least to oxytetracycline, but individual sensitivities vary sufficiently for it to be necessary to carry out laboratory tests of sensitivity on each isolate.

Those diseases in which mycoplasmas have been positively identified as the

causative agent are described separately: contagious bovine pleuropneumonia, bovine arthritis, bovine mastitis, caprine pleuropneumonia and enzootic pneumonia of pigs. Other diseases in which mycoplasmas play a contributory part are set out with a summary in Table 20.6. The comparative characteristics of the two most important mycoplasmas of cattle are summarized in Table 20. 7.

DISEASES OF THE GENITAL TRACT

Vulvovaginitis in cattle, sheep and goats may be associated with *M. agalactiae* var. *bovis*. The same infection when introduced with semen into the uterus can cause endometritis and salpingitis, resulting in a temporary infertility and failure to conceive.

Persistent infection in the genital tract of bulls has also been produced experimentally. Ureaplasmas have been isolated from the vulva of ewes with granular vulvitis and the disease was transmitted experimentally. However, the same organisms are present in the vulva of normal ewes and cows but *Ureaplasma* spp. are usually limited in their distribution to the vestibule and vulva of normal cows. In some areas, *Ureaplasma diversum* is commonly present in the lower reproductive tract of beef and dairy cattle, both cows and bulls, and is associated with granular vulvitis, which has been associated with infertility, sporadic abortions and neonatal mortality.[10] This infection adversely affects reproduction when it is either acute or chronic; it is capable of producing granular vaginitis and some strains can, if introduced to the upper reproductive tract, cause transitory endometritis and salpingitis.

Table 20.6 Summary of systemic mycoplasmoses of sheep and goats.

Bacterial species	Animals affected	Diseases caused	Pathogenicity
M. agalactiae	Sheep/goats	Contagious agalactia, arthritis, pneumonia, granular vaginitis, pinkeye	High
M. arginini	Sheep/goats	Pneumonia, arthritis, vaginitis, pinkeye, mastitis	Low
M. capricolum	Sheep/goats	Arthritis, mastitis, pneumonia	High
M. mycoides subsp. *capri*	Goats	Contagious caprine pleuropneumonia, pneumonia, arthritis	Moderate
M. mycoides subsp. *mycoides* (large colony type)	Sheep/goats	Contagious caprine pleuropneumonia, mastitis, arthritis, high mortality in young kids	Moderate
M. ovipneumoniae	Sheep/goats	Pneumonia	Commonly precursor to pneumonic pasteurellosis
M. putrefaciens	Goats	Mastitis and arthritis	High
Ureaplasma sp.	Goats	Vaginitis	Low
Mycoplasma strain F38	Sheep/goats	Contagious caprine pleuropneumonia	High pathogenecity

Table 20.7 Comparative properties of the two most important cattle mycoplasmas.

Properties	*M. mycoides* subsp. *Mycoides* SC	*M. bovis*
Diseases	Contagious bovine pleuropneumonia in cattle, occasionally in arthritis in calves	Calf pneumonia, mastitis, arthritis, abortion, keratoconjunctivitis
Distribution	Subsaharan Africa, probably in parts of Middle East, Central Asia	Worldwide
Hosts	Cattle, goats, (sheep)	Cattle
Histopathological	Fibrinous pleuropneumonima with necrosis	Interstitial pneumonia, lymphohistiocytic bronchitis, catarrhal bronchopneumonia
Clinical signs	Few signs, respiratory distress evident after exercise	Respiratory distress, mastitis, arthritis
Diagnosis	Isolation, serology, PCR, abattoir surveillance	Serology, isolation, PCR
Treatment	Chemotherapy not recommended because it encourages carrier status	Chemotherapy
Control	Vaccination, movement control, slaughter	Management, improved ventilation, reduced stocking density

Ureaplasms, *M. bovis* and *M. bovigenitalium* have been found the reproductive tract of bulls and their semen.[11] Using the PCR for the detection of mycoplasma in semen, *M. mycoides* subsp. *mycoides* SC has been found in semen of yearling bulls with seminal vesiculitis while negative to the complement-fixation test for CBPP.[11]

A combination of lincomycin–spectinomycin–tylosin has been shown to be most effective in the treatment of *Ureaplasma* spp. in bull semen. Chlortetracycline at 350 mg/h/d for 30 d in the prebreeding feed of virginal heifers, most of which had vulvovaginitis and from which 44% cultured positive for *U. diversum*, improved pregnancy rates and decreased the vaginal colonization of the organism.[12]

Parenteral vaccination of heifers with killed *U. diversum* induced antibodies to the mycoplasma but did not prevent subsequent infection or clear the ureaplasmas.[13] The use of the vaginal submucosal route for vaccination resulted in characteristic granular vulvitis in both vaccinated and control animals.[14]

Attempts to produce abortion in cows by the injection of mycoplasmas isolated from aborted fetuses and from weak calves has had varying success. *Acholeplasma* spp. have been isolated from aborted equine fetuses. *M. bovigenitalium* has been a frequent isolate from bovine genital tracts for many years, but its role in genital disease is still uncertain. It has been isolated from frozen bull semen and poses a threat to cows inseminated with infected semen. Mycoplasmas in semen can be transmitted through in vitro fertilization and infect embryos, and supplementation of culture media with standard antibiotics and washing embryos as recommended by the International Embryo Transfer Society are not effective in making IVF embryos free from *M. bovis* and *M. bovigenitalium*.[9]

Mycoplasma bovis in frozen semen can survive the antibiotic combination of gentamicin, tylosin, and lincomycin and spectinomycin.[15]

MYCOPLASMA MASTITIS IN DAIRY HERDS

Mycoplasma bovis, *Mycoplasma californicum*, and *Mycoplasma canadense* are causes of outbreaks of mastitis in cattle, and occasionally pneumonia, otitis media, or arthritis in calves of those dairy herds. The literature on mycoplasma mastitis in dairy herds has been reviewed.[16] The infection is highly contagious and is commonly introduced into a previously *Mycoplasma*-free herd by the purchase of infected heifers or cows. At least 11 other species of *Mycoplasma* have been isolated from

milk of cows with mastitis and the disease produced by each is similar. Cows of all ages and at any stage of lactation are susceptible. Typically, acute mastitis occurs which is resistant to treatment. Usually all four quarters are affected, there is a marked drop in milk production, and abnormal udder secretions vary from being like watery milk with a few clots to colostrum-like material. The affected cow is usually systemically normal. Chronically affected animals have a tan-colored milk secretion with sandy or flaky sediments which may become purulent-like over several weeks. However, the majority of milk samples which are positive for mycoplasma appear normal. In affected cows, milk production commonly declines, with normal appearance of milk but a high somatic cell count.

Mycoplasma mastitis in cattle is highly contagious and infections are transmitted at milking by means of fomites. Diagnosis is dependent on culture of milk samples from the bulk tank milk or individual cow milk samples. To identify cows with *M. bovis* mastitis, an indirect ELISA is available to detect antibodies to *M. bovis* in milk samples from cows with recently acquired *M. bovis mastitis*.[17] For mycoplasmal mastitis, individual cows milk sampling for culture and identification of *M. bovis* is time consuming and expensive. Some herds sample cows monthly with the dairy herd improvement (DHI) program but a preservative is added to the milk that kills *M. bovis*. A nested PCR procedure allows for rapid testing of preservative treated milk and is as sensitive as traditional culture.[18]

In herds where the diagnosis has been made, weekly monitoring of bulk tank milk is necessary to monitor the success of control procedures. Quality Milk Production Services, Cornell University, recommends the use of 1% iodine products to reduce the number of *Mycoplasma* on teat skin during mastitis outbreaks. There is no treatment for mycoplasma mastitis and vaccination has been ineffective. In affected herds, milk of all lactating animals should sampled, positive animals identified and culled or segregated from the mycoplasma-free animals. Waste milk from infected cows should not be fed to calves without pasteurization.[19]

Experimental vaccines against mycoplasma vaccines have been unsuccessful and may even exacerbate the mastitis.[5] It is best to segregate or cull carrier cows and to implement rigid sanitation procedures to prevent transmission from infected to non-infected cows.

Excellent vigilance and rapid culling of infected cattle are critical control factors affecting the spread of mycoplasma mastitis. Herds commonly become negative within the first year of the first case of mycoplasma mastitis.[20]

(Additional details on *Mycoplasma mastitis* in cattle are available in Chapter 15.)

DISEASES OF THE RESPIRATORY TRACT

Several different mycoplasmas have been isolated from pneumonic and non-pneumonic lungs of cattle, sheep and goats, but attempts to reproduce respiratory tract disease with them has resulted in inconclusive findings.

Sheep

In general, mycoplasmas cause a subclinical, mild pneumonia in gnotobiotic animals, but in combination with unidentified agents in lung homogenates administered intransally, 'enzootic' or chronic progressive pneumonia is produced in sheep. For example, *M. dispar* has a cytopathogenic effect and stops ciliary motility, and destroys ciliated epithelial cells in organ cultures. *M. ovipneumoniae* also has the capacity to colonize the sheep lung and produce mild pneumonic lesions, but in combination with pasteurellae in sheep, causes a proliferative exudative pneumonia. A similar disease in Icelandic sheep (kregda) has been identified as being associated with *M. ovipneumoniae*. Similar diseases are associated with *M. ovipneumoniae* and *M. arginini*.

Goats

Although contagious caprine pleuropneumonia has not been observed in Australia, a non-fatal respiratory disease of goats, characterized by coughing, fever and extensive pleurisy and pneumonia, has. A variety of mycoplasmas, including *M. agalactiae* and *M. mycoides* and *M. mycoides* var. *capri* have also been found in goats. The caprine *M. mycoides* var. *mycoides* (large colony type) is not pathogenic for cattle and has been associated with a variety of syndromes in goats including fibrinous peritonitis, pneumonia, arthritis, mastitis and abortion. It has been cultured from a goat with a subauricular abscess and mastitis.[21] The most common syndrome in goats associated with mycoplasma is a chronic interstitial pneumonia with cough, unthriftiness proceeding to extreme emaciation, chronic non-painful bony enlargement of joints and chronic indurative mastitis. The pneumonia in some cases progresses to the point where cor pulmonale develops with a subsequent appearance of the signs of congestive heart failure. *M. ovipneumoniae* has also been credited with causing pneumonia in goats. *M. adleri* has been isolated from a goat with a joint abscess.[22]

Cattle

Mycoplasma bovis is a major cause of calf pneumonia. *Mycoplasma dispar*, *Ureaplasma diversum*, *Mycoplasma bovirhinis*, and *Mycoplasma canis* have also been isolated from the lungs of pneumonic cattle but it is uncertain if they are primary causes of disease.[5] *M. dispar* is capable of producing a pneumonia without clinical signs in gnotobiotic calves, and in conjunction with *Ureaplasma* spp. it has been found commonly in 'cuffing' pneumonia of calves. It could, therefore, be a precursor to other infections causing enzootic pneumonia in calves or with pasteurellae producing fibrinous pneumonia of calves.

Horses

M. felis has been associated with outbreaks of lower respiratory tract disease of race-horses in training.[23,29,30]

DISEASES OF THE EYES

Mycoplasma bovoculi (*Acholeplasma oculi*) has been associated with, without necessarily being the cause in the field of, outbreaks of infectious keratoconjunctivitis of cattle, sheep and goats. The mycoplasmas are capable of producing keratitis experimentally and *M. bovis* has been isolated from the ocular discharge of young cattle affected with conjunctivitis.[24] The naturally occurring disease in goats is manifested by rapid spread and development with intense lacrimation, conjunctival hyperemia, corneal opacity and vascularization. A concurrent respiratory illness occurs in some goats. Response to treatment with oxytetracycline and polymyxin B is good. The disease is reproducible experimentally.

DISEASES OF THE BLOOD

Mycoplasma (Eperythrozoon) suis infection occurs worldwide in pigs causing fever and anemia in young animals and, occasionally, latent anemia in older animals. *E. suis*, originally classified as a *Rickettsia*, has now been shown to belong to the mycoplasmas based on phylogenetic analysis of its *rrs* (16S rRNA) genes and is now proposed to be known as *Candidatus Mycoplasma haemosuis*.

DISEASES OF THE JOINTS

Mycoplasma (*M. hyorhinis*, *M. hyosynoviae*) are associated with arthritis and polyarthritis in pigs and the disease is reproducible experimentally. Both organisms are carried in the respiratory tract. *M. hyorhinis* most commonly affects suckling and young pigs, especially after weaning or some stress, and may produce a polyserositis in addition to arthritis. The case–fatality rate is generally low, but residual fibrinous pericardial and pleural

cattle found *M. bovis* positive samples in 18%.

The chronic pneumonia–polyarthritis of cattle has been reported in Canada and the United States.[12,13] It occurs commonly in young feedlot cattle usually affecting many animals a few weeks after arrival and mingling in the lot. The morbidity ranges from 20–85% and the case–mortality rate from 3–50%. In Canada, the disease has been seen commonly in young cattle (6–8 months of age) following shipment from western rangelands to eastern feedlots, which suggests that long transportation and mixing of cattle of different origins may be important epidemiological characteristics. Calves affected with arthritis commonly have necropsy evidence of mycoplasma pneumonia and it is proposed that the pneumonia precedes the development of the arthritis. Calves sucking cows with experimental mastitis due to this organism may develop mycoplasmal arthritis, and a high incidence is recorded in calves in dairy herds where mycoplasmal mastitis was occurring.

In a group of feedlot cattle, from Alberta, Canada, with chronic unresponsive pneumonia and polyarthritis, *M. bovis* was the most common pathogen demonstrated, having been detected in 82% of cases, including 71% in lungs and 45% in joints.[14] All cases had been treated with antibiotics including tilmicosin, trimethoprim-sulfadoxine, ceftiofur sodium, and sulbactam and ampicillin.

In a series of cases of chronic, antibiotic-resistant pneumonia, sometimes with concurrent polyarthritis, in feedlot cattle in western Canada, *M. bovis* was present in the lung tissues of more than 90% of cases, and the BVDV was present in 60% of the cases suggesting a possible synergism between *M. bovis* and the BVDV.[12] Outbreaks of pneumonia and arthritis in beef calves associated with infection due to *Mycoplasma bovis* and *Mycoplasma californicum* have been described in a mixed dairy cattle and beef cattle herd kept under extremely poor housing and hygienic conditions.[15] During a 3-year period in Belgium, in calves with respiratory disease, the prevalence of *M. bovis* was 31.5%, *M. dispar* 45.5%, *M. canis* 10.7% and *Ureaplasma diversum* 14.8%, and in half the cases they occurred in association with *Pasteurella* and/or *Mannheimia* species.[16]

Because the clinical and pathologic findings of *M. bovis* pneumonia closely resemble those of contagious bovine pleuropneumonia (CBPP), it is very important to ensure the microbiological diagnosis when confronted with lesions resembling either infection. A serological and diagnostic microbiological and pathological survey of pneumonic cattle sampled on the farm followed by examination of heir lungs at slaughter in Hungary confirmed the presence of *M. bovis* as at causative agent of the pneumonia rather than due to *Mycoplasma mycoides* subspecies *mycoides* the cause of contagious bovine pleuropneumonia.[17]

Otitis media/interna in dairy and beef calves has been associated with *M. bovis* infection. It has been described in preweaned Holstein dairy calves in dairy herds which have expanded in size.[18,19] Affected calves were 2 to 5 weeks of age, morbidity was 3 to 10% and case fatality rates estimated at 50%. In a retrospective study of *Mycoplasma otitis* in calves submitted for necropsy in California, affected calves were 2 weeks to 4 months of age, 92% were from dairy herds, most cases occurred during late winter and spring.[20] *M. bovis*, *M. bovirhinis*, and *M. alkalescens* were isolated from the ears of affected calves. Outbreaks of suppurative otitis media and pneumonia associated with *M. bovis* have been described in calves on beef cattle farms in Japan.[21] Morbidity and mortality were estimated at 8 to 40% and 30 to 100%, respectively.

Pathogen risk factors

The virulence factors of *M. bovis* and mechanisms of pathogenicity are not well-known, but the organism's ability to vary the expression of a family of membrane surface proteins (Vsps) with high frequency is currently being investigated. The organism has 13*vsp* genes involved in antigenic variation which alter the antigenic character of its surface components, and may act to enhance colonization and/or adherence or evade the host's immune defense systems.[1]

M. bovis isolates from pneumonic cattle in the UK separated into two distinct groups based molecular epidemiological analysis.[22] The organism produces an immunosuppressive peptide which is able in vitro to inhibit mitogen-induced proliferation of bovine lymphocytes.[23] The peptide is a product of variable surface proteins which may have an immunosuppressive effect during infection of the lung.[24] The organism is also able to penetrate through lung epithelial junctions and cause systemic infections.[23] There is some evidence of variability of *M. bovis* strains to cause arthritis.[13]

Genetic fingerprinting of *M. bovis* strains isolated in Denmark over a 17-year period demonstrated remarkable genomic homogeneity which were likely epidemiologically related and have remained stable for many years.[25] The technique used allows the creation of databases for inter-laboratory use and comparison, and continued surveillance to monitor the spread of the organism as a prerequisite for effective control.

Methods of transmission

Clinically normal cattle harbor *M. bovis* in the upper respiratory tract with no apparent adverse effect and may shed the organism through the nasal discharge for months to years.[26] The methods of transmission of *M. bovis* as the causative agent of the pneumonia–polyarthritis syndromes, and related diseases, are unknown. It is assumed that direct contact between infected and susceptible animals is the primary mode of transmission but there is no supporting published evidence. *M. bovis* can be isolated from respiratory secretions such as nasal exudate which indicates at least one route of transmission. Serological surveys of feedlot cattle on arrival and 28 days later in Ontario, Canada, found an increase in titers to *M. bovis* and *M. dispar* which indicates that mixing of animals results in transmission of the organism.[27]

Calves fed discarded milk from cows with mycoplasma mastitis may develop pneumonia and otitis media.[18] Pasteurization of discard milk can eliminate transmission of the mycoplasmas to the calves.

PATHOGENESIS

The intra-articular injection of *M. bovis* into calves causes severe fibrinosuppurative synovitis and tenosynovitis, erosion of cartilage and its replacement by polypoid granulation tissue. Erosion of the cartilage is accompanied by chronic osteomyelitis and formation of pannus tissue. Histologically, there is extensive ulceration of synovial membranes of leukocytic infiltration of the subsynovium, congestion, hyperemia and thrombosis of the subsynovial vessels. Intratracheal inoculation of the organism results in pneumonia and severe lameness, which suggests that *M. bovis* is involved in pneumonia–arthritis syndrome.

As with many mycoplasmas, *M. bovis* is both immune reactive and immunosuppressive. Upon incubation with *M. bovis*, alveolar macrophages are activated and produce TNF-alpha and nitric oxide, two powerful initiators of immune activity.[24] *M. bovis* is also immunosuppressive by inhibiting neutrophil degranulation and oxidative bursts and proliferation of lymphocytes by mitogens. *M. bovis* also induces bovine lymphocyte death by apoptosis through the production of a protein which is different from other mycoplasmas both pathogenic and non-pathogenic.[28] The protein is an immuno-inhibitory peptide which can suppress Concanavalin A (ConA)-induced proliferation of bovine lymphocytes.[29] This represents a unique immunosuppressive peptide produced by the *M. bovis*.

Despite its deleterious effects on lymphocytes, infected cattle are able to generate measurable humoral and cellular immune responses against *M. bovis*. Serological analysis indicates that *M. bovis* stimulates increased production of antigen-specific IgG1 while very little IgG2 is produced.[27] Thus experimental lung infection of cattle with *M. bovis* results in a Th2-skewed immune response.

There is a systemic phase of *M. bovis* infection, including a potential interaction of the pathogen with endothelial cells. It is one of the most invasive bovine mycoplasmas capable of invading through lung epithelial junctions and causing systemic infections such as arthritis and mastitis following pneumonia. Localized lung vasculitis and the presence of thrombi within subsynovial vessels has been observed, both suggestive of interaction of *M. bovis* with epithelial cells.[23]

In otitis media/interna of calves there is facial nerve paralysis because of proximity of CNVII to the tympanic cavity.[19] Varying degrees of peripheral vestibulocochlear dysfunction occur because of the involvement of the vestibulocochlear receptors and nerve. The spontaneous regurgitation and dysphagia may be associated with lesions involving the glossopharyngeal nerve (CN IX) with or without the vagus nerve (CN X). These nerves may be affected by the inflammation associated with meningitis because both CN IX and CN X travel through the jugular foramen.[19]

CLINICAL FINDINGS

Chronic pneumonia–polyarthritis syndrome

The disease is most common in feedlot calves within a few weeks after arrival in the feedlot.[13] The morbidity rate may be up to 25%. Affected calves commonly have had a history of respiratory disease but have not responded to repeated antibiotic therapy. Auscultation of the lungs reveals areas of loud bronchial tones, crackles and wheezes and areas of muffled lung sounds indicating consolidation and occlusion of the bronchi with exudate. Depression, inactivity, inappetence, coughing, nasal discharge, fever, and progressive weight loss are common.

Concurrently affected calves commonly develop lameness. There is stiffness of gait, and lameness. Swelling of the large movable limb joints and distension of tendon sheaths, associated with fibrinous synovitis and synovial fluid effusions, are characteristic. Affected calves are reluctant to move and commonly are recumbent for long periods, continue to lose weight, and develop decubitus ulcers. Mildly affected cases recover spontaneously in 10–14 d, while severe cases become progressively worse and must be culled.

Pneumonia and polyarthritis associated with *M. bovis* may occur alone or together in cattle of all ages, including dairy and beef calves in their original herds, in growing dairy and beef cattle heifers, and in mature dairy and beef cows.

Otitis externa, otitis media/interna

Otitis externa is inflammation of the externa ear canal. Otitis media/interna is inflammation of the inner ear involving primarily the tympanic bullae which may extend to the meninges and the brain stem.[19,30] Clinical findings depend on the extent of the inflammation involving only the external ear or middle ear causing otitis media. Varying degrees of depression, coughing, nasal discharge and inappetence are common in affected groups of calves. Otitis extema is characterized by a drooping ear and purulent exudate in the external ear which can be detected by digital palpation of the pinnae which creates a fluid squishing sound. Deep palpation of the base of the ear may be painful.

A unilateral head tilt and paralysis of the lip, eyelid, and ear muscles on the same side are common. When the eye on the affected side is threatened, the eyeball may retract but there is no palpebral fissure closure.[19] An intermittent loss of balance on the affected side may be apparent when the animal attempts to walk.

Bilateral peripheral CN VII and VIII deficits (bilateral ear, lip, and eyelid paresis; bilaterally absent menace and palpebral reflexes; normal gait; balance loss to either side) are suggestive of bilateral otitis media/intema.[19,30] Dysphagia, spontaneous regurgitation of milk and difficulty in sucking from a bottle or prehending feed may occur.[19] Partially chewed feed may accumulate in the oral cavity along with difficult prehension and mastication. Bilateral vestibular disease (balance loss to either side) may occur. Endoscopy of the pharynx may reveal collapse of the nasopharynx, dorsal displacement of the soft palate, and a widely dilated, hypomotile esophagus.

In otitis media there may be no exudate in the external ear. Opisthotonus and nystagmus are common and ataxia, recumbency and death in several days may occur.

The mortality rate is about 50%.[19]

CLINICAL PATHOLOGY

Clinical and pathological signs are not characteristic for *M. bovis* so laboratory diagnosis is necessary for identification.[1] The organism can be detected by culture, DNA probe and PCR tests.

Detection of organism

Culture methods for the detection of *M. bovis* are restricted to culture and serology but both methods are time consuming, laborious, difficult and expensive. Bronchoalveolar lavage samples and nasal swabs can be used for the culture of *M. bovis* from cattle with respiratory disease; the lavage samples being more representative of the infection status of the lower respiratory tract disease.[31]

DNA probe and PCR

A DNA probe and semi-nested PCR test are now available to detect the antigen of the organism in milk samples and may be applicable to mucosal samples from conjunctivae, nasal and vaginal mucosae.[32] An arbitrarily primed PCR typing method provides genotypic epidemiological information to successfully characterize *M. bovis* from sequential sampling of outbreaks and different husbandry conditions.[33]

Immunohistochemistry

Immunohistochemical techniques can be used to detect the antigen of *M. bovis* in the tissues of cattle.[14] Histology and immunohistochemistry can be used to analyze the lesions and distribution of the *M. bovis* antigen in the lungs of cattle with pneumonia.[34]

ELISA

An ELISA can be used to detect the organism in lung tissue of animals with pneumonia.[35] To identify cows with *M. bovis* mastitis, an indirect ELISA is available to detect antibodies to *M. bovis* in milk samples from cows with recently acquired *M. bovis* mastitis.[36]

CLINICAL DIAGNOSTIC TESTS

Computer tomographic imaging for otitis media/interna in calves can provide detailed information of the bony structures of the middle and inner ear. Abnormalities of the tympanic bullae and petrous temporal bone may be visible with CT imaging which are not visible with conventional radiography.[19] CSF from affected calves may indicate the presence of a meningitis.

NECROPSY FINDINGS

At necropsy, the **fibrinous synovitis** is remarkable. There is severe thickening and edema of the synovial membranes and large quantities of fibrinopurulent synovial fluid. The tendon sheaths are similarly affected. Microscopically, large numbers of lymphocytes and plasma cells are found within the hypertrophic synovial villi. *M. bovis* can often be recovered from pneumonic lungs and causes **pulmonary foci of coagulative to caseous necrosis.**[14,37–39] *M. bovis* causes two patterns of pulmonary necrosis in cattle.[34] The first pattern is characterized by large irregular areas of coagulative necrosis surrounded by a dense zone of degenerated neutrophils. *M. bovis* antigen

is present in the center and periphery of the necrotic foci. The second pattern consists of rounded foci of caseous necrosis composed of granular eosinophilic material surrounded by a rim of granulation tissue. Large amounts of *M. bovis* antigen are present in the center and periphery of these necrotic foci.[34] Immunohistochemical techniques are used to detect the antigens of *M. bovis* in the tissues of feedlot cattle with chronic unresponsive respiratory disease and/or arthritis.[14] Immunohistochemical studies suggest that this organism may also briefly localize in the kidney and liver.[37] *Mycoplasma* spp. have been identified as an important cause **suppurative otitis** in dairy calves, often with concurrent mycoplasmal pneumonia.[20] *M. bovis* has also been associated with pleuritis and pericarditis and has been isolated from decubital ulcers of calves.[40]

Samples for confirmation of diagnosis

- **Histology** – lung, synovial membrane (LM, IHC)
- **Mycoplasmology** – lung, culture swab from joint cavity (MCULT).

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other causes of joint swelling and lameness in feedlot cattle.[13] There are usually several animals affected in a short period of time, which serves to distinguish it from other sporadic causes of arthritis in feedlot cattle. A diagnosis of infection by *M. bovis* should be considered when pneumonia and arthritis and synovitis occur at about the same time.

Other diseases causing lameness in feedlot cattle include:

- Interdigital necrobacillosis
- Laminitis (pododermatitis aseptic diffusa)
- Injuries in feedlot cattle
- Buller injuries
- Musculoskeletal injuries
- Lacerations

For a definitive diagnosis, joint fluid must be placed immediately into laboratory media specially prepared for *Mycoplasma* spp. The failure to isolate the mycoplasma from the fluid of joints which have been affected for more than 14 d does not preclude a diagnosis of mycoplasma arthritis because the organism may have been eliminated from the joint.

TREATMENT

Treatment is usually ineffective. Several antimicrobials, including tylosin, oxytetracycline, lincomycin and oleandomycin, have been used in naturally-occurring and experimental cases and while the isolates of mycoplasmas may be sensitive to these antibiotics in vitro, the response in affected animals has been unsatisfactory.

The published results of in vitro antimicrobial testing of isolates of *M. bovis* recovered from various locations are highly variable. The antimicrobial susceptibility of *M. bovis* strains, cultured from cases of pneumonia, arthritis, and mastitis of cattle, measured in vitro indicate that enrofloxacin was the only one which exhibited any measurable activity.[41] Spectinomycin has been evaluated for the treatment of experimental *M. bovis* pneumonia in 3-week-old calves and only decreased the level of *M. bovis* and *Pasteurella multocida* infection in the lung but did not alter the course of the illness.[42] The in vitro susceptibilities of Belgian field isolates of *M. bovis* to 10 antimicrobials found that tiamulin was the most active against the organism. The fluoroquinolones, danofloxacin, enrofloxacin, and marbofloxacin were effective against strains of *M. bovis*. Gentamicin was ineffective. Many strains were resistant to tyolsin, spectinomycin, lincomycin, tetracycline and oxytetracycline.[43] In a series of British isolates of *M. bovis*, most isolates were susceptible to danofloxacin, less susceptible to florfenicol. Oxytetracycline and spectinomycin had only a limited effect against the majority of isolates. Approximately 20% were highly resistant to spectinomycin, and tilmicosin was ineffective. There was no evidence of resistance to danofloxacin.[44]

In calves with a high incidence of respiratory disease associated with *M. bovis* and *Pasteurella* spp. the use of valnemulin in the milk of the calves for four days resulted in improved weight gains and fewer cases of *Mycoplasma* infection, required fewer treatments with antibiotics than those in the placebo treated group.[45]

CONTROL

Effective control of the disease is not yet possible. Some vaccines have been developed but have not been sufficiently efficacious or have yielded poor results. A quadrivalent inactivated vaccine containing BRSV, PI-3 virus, and *M. dispar* and *M. bovis* provided some protection against naturally-occurring outbreaks of bovine respiratory disease.[1] A vaccine containing formalin-inactivated strains of *M. bovis* and *Mannheimia haemolytica* from affected herds reduced losses from pneumonia and the cost of treatment in newly arrived feedlot calves.[1]

A single dose of vaccine for *M. bovis* pneumonia, inactivated with saponin, provided protection against experimental challenge of calves 3 to 4 weeks of age with a virulent isolate of *M. bovis*.[46] The vaccine also reduced the spread of *M. bovis* to internal organs. Attempts to vaccinate against *M. bovis* arthritis have been unsuccessful.[1] Experimental vaccines against mycoplasma vaccines have been unsuccessful and may even exacerbate the mastitis.

In dairy herds, pasteurization of mycoplasma mastitis milk at 65°C for 1 hour can kill mycoplasmas and reduce the incidence of respiratory disease in calves.[47] A temperature of 65°C killed *M. bovis* and *M. californicum* after 2 min of exposure, while *M. canadense* remained viable for up to 10 min. Exposure to 70°C inactivated *M. bovis* and *M. californicum* after 1 min, but *M. canadense* samples were positive for up to 3 min.

Biosecurity and **biocontainment** procedures should be implemented to prevent the introduction of infection into the herd and to minimize the spread of infection in the herd.

CONTAGIOUS BOVINE PLEUROPNEUMONIA

Synopsis

Etiology *Mycoplasma mycoides* subsp. *mycoides* (Small colony) (MmmSC)
Epidemiology A major plaque of cattle, endemic in eastern Europe, Asia, Africa, and has spread to Spain, France and Italy. Major concern in European Community because of relaxation of import controls and increase in international trade. Insidious nature of disease allows it to spread undetected for months
Signs Fever, agalactia, anorexia, depression, coughing, thoracic pain, back arched, dyspnea, expiratory grunting, pleuritic friction rubs, dull areas of lung, edema of throat and dewlap
Clinical pathology Complement fixation test. Detection of organism with polymerase chain reaction (PCR)
Lesions Remarkable pleuritis, marked consolidation and marbling of lung, pleural adhesions
Diagnostic confirmation Presence of organism in pleural fluid
Differential diagnosis list

- Pneumonic pasteurellosis
- Tuberculosis
- Other pneumonias (see Table 18.4)

Treatment Not usually done
Control Identification and slaughter of sick animals. Vaccination followed by test and slaughter. Establish disease-free areas. Control movement of cattle in control areas

ETIOLOGY

Mycoplasma mycoides subsp. *mycoides* Small Colony (SC) (MmmSC) is the cause of the disease in cattle.[1] The organism belongs to the '*mycoides*' cluster, which consists of six closely related mycoplasma. Members of the '*mycoides*' cluster are pathogens of cattle, sheep and goats but the agent of contagious bovine pleuropneumonia (CBPP) is not communicable to other species. It is very similar culturally and antigenically to the causative organisms of caprine contagious pleuropneumonia but the two can be differentiated culturally and biochemically. Large colony types are pathogenic for sheep and goats, but not for cattle. Small colony types have been isolated from the milk of sheep with mastitis and goats with pneumonia.[2]

Table 20.8 Members of the *Mycoplasma mycoides* cluster

Name	Main disease	Main (and other) hosts
M. mycoides subsp. *mycoides* SC variant	Contagious bovine pleuropneumonia	Cattle (goats, sheep, buffalo)
M. mycoides subsp. *mycoides* LC variant	Caprine pneumonia, contagious agalactiae	Goats (sheep, cattle)
Mycoides subsp. *capri*	Caprine pneumonia	Goats (sheep) but rare
M. capricolum subsp. *capricolum*	Caprine pneumonia, contagious agalactiae	Goats (sheep, cattle)
M. capricolum subsp. *capripneumoniae*	Contagious caprine pleuropneumonia	Goats (sheep)
M. bovine group 7 (Bg7)	Arthritis, also mastitis, calf pneumonia	Cattle

The organisms are pleomorphic and some forms are filterable. They can be maintained readily in special culture media and in embryonated hens' eggs. *MmmSC* is a member of the *M. mycoides* cluster which includes those listed in Table 20.8. The '*Mycoplasma mycoides* cluster' contains six important mycoplasma of ruminants. Only two of them cause disease in cattle, *MmmSC* which is the cause of CBPP, and Mycoplasma bovine group 7 (Bg7) which may cause arthritis and bovine mastitis. The four others, two subspecies within *Mycoplasma mycoides* species and two subspecies within *Mycoplasma capricolum* species are responsible for goat respiratory and other diseases.

EPIDEMIOLOGY

Occurrence and prevalence of infection

Under natural conditions, CBPP occurs in cattle of the species *Bos* and allied animals including buffalo, yak, bison and even reindeer.[3] While buffaloes can be infected by artificial means, and pulmonary lesions and the organism have been found in seropositive buffaloes which have been in contact with CBPP-infected cattle in Italy, it is uncertain if they can spread the disease to cattle.

CBPP is widespread in Africa and occurs in some countries of Asia and Europe. In 1995, the Office des International Epizooties (OIE) reported that CBPP in Africa was causing greater losses in cattle than any other disease including rinderpest. In 2001, 17 countries in Africa declared the presence of the disease and a potential threat for the world.[4] In Africa, it is found in an area south of the Sahara, from the Tropic of Cancer to the Tropic of Capricorn and from the Atlantic to the Indian Ocean.[1] Endemic infection extends throughout the pastoral herds of much of western, central and eastern Africa, with Angola and northern Namibia in southern Africa. Newly infected areas in the 1990s include Uganda, parts of Kenya, the Ituri Region of the Democratic Republic of the Congo, and most of the United Republic of Tanzania, where recently the disease has spread alarmingly. Rwanda in 1994, Botswana in 1995[2] but now free, Burundi in 1997, and Zambia in 1997 were recently re-invaded, but Lesotho, Malawi, Mozamique, South Africa, Swaziland, and Zimbabwe are currently free as of 2002.[1] An abattoir survey of the disease in Nigeria indicates CBPP is endemic and the campaign to control or eradicate the disease has been inadequate.[5] Reasons include inadequate and irregular vaccination programs because of the high cost of mass vaccinations, and the steady illegal introduction of infected cattle into areas across control barriers, and the presence of carrier animals which may not be detected clinically or serologically. Movement of cattle between Niger and Nigeria in the north and between Cameroon and Nigeria in the northeast have also been associated with spread.

The disease was present in most sub-Saharan countries and had reinfected countries such as Uganda and Kenya, where it had been eradicated in the 1970s.[6] Of more concern, countries which had been CBPP-free for many years were also reinfected. Epidemics occurred in Tanzania in 1990 and Botswana and Rwanda in 1995.[7] In addition, Angola, Benin, Cameroon, Chad, Eritrea, Ivory Coast, Ghana, Nigeria, Sudan, Togo and Zaire are infected.[6]

CBPP was first introduced into Tanzania in 1916 and was eradicated in 1964.[8] The disease re-emerged in the country in 1990 and since then it has

spread widely, threatening the entire national cattle herd. Because of lack of a clear disease-control policy, uncontrolled cattle movements, lack of public awareness and commitment, ineffective legislation, attempts to control and eradicate the disease between 1990 and 2000 failed.

The reasons for increase in incidence of CBPP in Africa are relate specifically to reduced funding for vaccination, possibly linked to the success of the rinderpest campaign, changes in vaccines and vaccine usage, cost recovery for CBPP vaccination, and reduced disease surveillance.[9]

In Asia, CBPP has been reported recently in Assam in India, Bangladesh, and Myanmar. Sporadic outbreaks have been recognized in the Middle East, probably derived from importation of cattle from Africa.

The status of CBPP in Europe is sharp contrast with that in Africa, because as of 1999, for the first time for over 20 years, no outbreaks were reported.[9] As of 2004, Europe is free from CBPP and the European Union rules prevent the importation of live animals from affected areas. CBPP is usually transmitted through movements of live animals; trade in animal products is not thought to be a significant risk. The disease was diagnosed in France and Spain in the 1960s, Portugal in 1983 and Italy in 1990. An abattoir based survey of CBPP in Turkey indicated the presence of the infection based on ELISA of blood samples and lung tissues of cattle examined in abattoirs but the organism was not identified.[10]

The disease was eradicated from the United States in 1892, South Africa in 1916, and Australia in 1973 after being introduced in 1858.[11,12] The disease was introduced into Australia in 1858 by dairy cattle imported into the colony of Victoria from England. It spread rapidly throughout Australia by cattle being driven to take up new pastoral lands everywhere, aided by the bullock teams, which provided the only form of transportation of goods and supplies in those days. One hundred years later, in 1958, a national eradication campaign was commenced and it took only 15 years before Australia was declared free from the disease, in Darwin in 1973.[11,12] An entire book, 'Clearing a Continent: The eradication of bovine pleuropneumonia from Australia'[11] documents a wonderful success story which resulted in the formation of several existing animal health agencies in Australia.[12]

In France, the recent epidemic was successfully eradicated. The disease is endemic in north western parts of Portugal but outbreaks have decreased significantly in recent years.[6]

Because of the method of spread, outbreaks tend to be more extensive in housed animals and in those in transit by train or on foot. In groups of susceptible cattle the morbidity approaches 90%, the case mortality may be as high as 50% and 25% of the infected cattle remain as recovered carriers with or without clinical signs.

Source of infection

The focus of infection is often provided by recovered 'carrier' animals in which a pulmonary sequestrum preserves a potential source of organisms for periods as long as 3 years. For many years, it was thought that conditions of stress due to starvation, exhaustion or intercurrent disease can cause the sequestrum to break down and convert the animal into an active case. Experimental evidence throws some doubt on this explanation, but droplet infection is usually associated with a donor lesion in the lungs. Renal lesions are not uncommon and large numbers of viable *M. mycoides* are passed in the urine of infected animals, and inhalation of urine droplets may be a route of infection. The organism has been isolated from the semen and preputial washings of two young bulls[13] which were the result of frozen embryos implanted into Portuguese cows and were being considered for entry into a breeding center.

Methods of transmission

Transmission occurs from direct and repeated contacts between sick and healthy animals. The principal route of infection is by the inhalation of infective droplets from active or carrier cases of the disease. Mediate infection by contamination of inanimate objects is unlikely under natural conditions, but it has been effected experimentally, the infected hay remaining infective for up to 144 h. A separation of 6 m between animals is usually considered to be sufficient, but transmission over 45 m has been suspected to occur. Spread of the disease may also occur by discharges from local tail lesions resulting from vaccination with virulent culture. Cattle may be exposed to infection for periods of up to 8 months before the disease becomes established and this necessitates a long period of quarantine before a herd can be declared to be free of the disease. Other inanimate objects such as placenta and urine can also remain infective for long periods.

A mathematical model of the effects of chronic carriers on the within-herd spread of CBPP in an African mixed crop–livestock system indicates that chronic carriers are less infectious than clinical cases.[14] Within-herd spread of CBPP occurs regardless of the measures such as isolation or the use of antibiotics.[15]

In 1990, a confirmed outbreak of CBPP was occurred in a dairy herd in Lombardy, Italy.[16] Italy had been free of the disease since 1899. Within 3 years of the index herd, an additional 94 outbreaks occurred within an area of 59 km^2. The disease was eradicated in 1993. Epidemiological investigations, especially tracebacks, during the outbreaks over a period of 3 years examined spatial segregation of infected and non-infected farms. In the high-risk area, infected and non-infected herds were spatially segregated. The high density of the cattle population within the study area and the possible intensive interactions between specialized cattle breeding farms, likely contributed to direct and indirect transmission of the infection. Both aerosol and indirect transmission of the infection could have occurred, as previously documented in Africa. It has been suggested that urine may be a mode of transmission especially in European countries with temperate climates where cattle are reared intensively in restricted geographical areas and many herds share the same watercourse.[17]

Risk factors

Animal risk factors

CBPP occurs only in cattle; rare natural cases have been observed in buffalo, yak, bison, reindeer and antelopes, and the disease has been produced experimentally in captive African buffalo and white-tailed deer. It has not been detected in other wildlife. In sheep and goats the injection of culture causes a local cellulitis without pulmonary involvement. There is no difference in the susceptibility of *Bos taurus* and *Bos indicus* cattle and both races respond equally to vaccination.

Immune mechanisms. A strong immunity develops after an attack of the natural disease in cattle and vaccination plays an important part in control. The exact nature of the immunity conferred by vaccination or by naturally occurring disease is not understood, although it can be transferred by the administration of serum from an immune animal. The lack of a cell wall and endotoxins may enable mycoplasmas to colonize the animal without inducing an immune response and the predilection for the mucosal membranes may also limit the humoral response. For these reasons it is suggested that the organism is a poor immunogen, which may account for the frequent lack of good circulating antibody responses in experimentally infected cattle. There is a poor relationship between complement fixation test (CFT) antibody titer and the severity of lesions; animals with high antibody titers may have no visible lesions and those with severe lesions may have low or undetectable titers.[7]

Management risk factors

The occurrence and incidence of CBPP is heavily influenced by management

systems, disease control policies and regulations of a country, knowledge of the disease by farmers and veterinarians, and livestock field officers. The diagnostic capability of veterinary laboratories, disease-surveillance and monitoring systems, adequacy of vaccination programs, government budgets allocated to control programs, the effectiveness of education programs, and the desire of cattle owners and traders to control the disease are critically important management factors which influence the effectiveness of control of the disease in a country. A serious commitment from all stakeholders in the cattle industry is necessary and the government has to provide sufficient resources.

Pathogen risk factors

M. mycoides subsp. *mycoides* is sensitive to all environmental influences, including disinfectants, heat and drying, and do not ordinarily survive outside the animal body for more than a few hours. A low incidence can be anticipated in arid regions because of the rapid destruction of the organism in exhaled droplets. Restriction enzyme analysis of strains of the organism found that European strains have different patterns than African strains.[6] This suggests that recent European outbreaks occurred from an established reservoir within Europe rather than as a result of importation from Africa. It also suggests that the African and Australian strains arose from strains no longer widespread in Europe.

The organism can be grouped into two major, epidemiologically distinct, clusters. One cluster contains strains isolated from different European countries since 1980 and a second cluster contains African and Australian strains collected over the last 50 years.[18]

The current European strains lack a substantial segment of genetic information which may have occurred by a deletion event.[18] The strains found in re-emerging outbreaks of CBPP, which occurred after the eradication of the epidemic in Europe in the middle of the 20th century, represent a phylogenetically newer cluster that has been derived from a strain of the older cluster of MmmSC which is still endemic on the African continent.[18] The genome of MmmSC type strain PG1^T has been sequenced to map all genes and to facilitate further studies regarding the cell function of the organism.[19] A variety of potential virulence factors have been identified, including genes encoding putative variable surface proteins and enzymes and transport proteins responsible for the production of hydrogen peroxide and the capsule which is thought to have toxic effects on the animal. The phylogeny of the *Mycoplasma mycoides* cluster according to sequencing of putative membrane protein genes has been examined.[20] Molecular epidemiology of CBPP by multilocus sequence analysis of Mmm biotype SC strains found a clear distinction between European, south-western African and sub-Saharan strains.[21] This indicates that the CBPP outbreaks which occurred in Europe were not due to introduction from Africa, and confirms true re-emergence. Strains of MmmSC isolated from recent outbreaks of CBPP in Africa have been compared to vaccine strains and older isolates.[22] A Botswanan field isolate differed from all other strains of MmmSC tested by a variety of criteria. The new isolate may possess a set of protective antigens different from those of other strains of MmmSC including vaccine strains. Such findings have implications for the control of CBPP in Africa.

The last strains isolated from an epidemic are usually of lower virulence than the first strains.[7] Strains are most virulent when first isolated and lose their virulence after subculture. Galactan is associated with pathogenicity of the organism but its mode of action is uncertain. Galactan can cause necrosis and a connective tissue response in cattle similar to the sequestra in chronically infected animals.

Economic importance

CBPP is the most economically important disease of cattle in Africa.[5] The direct losses are from mortality, reduced milk yield, vaccination costs, disease surveillance and research programs. The indirect costs are due to the chronic nature of the disease including:

- Loss of weight and working ability
- Delayed marketing
- Reduced fertility
- Losses due to quarantine
- Loss of cattle trade. In the affected countries, enormous losses are experienced each year from the deaths of animals and the loss of production during convalescence. The highly fatal nature of the disease, the ease of spread and the difficulty in detecting carriers also mean that close restriction must be placed on the movement of animals from enzootic areas. For example, in Australia many feeder cattle are reared on range country where the disease was endemic and, before the disease was eradicated, moving them into closely settled areas for fattening caused periodic outbreaks in these free areas. Losses were heavy and the costs of maintaining quarantine and eradication programs were also heavy.

PATHOGENESIS

Even after more than 100 years since CBPP was discovered the pathogenesis is not well understood.[9] The possible role of the carbohydrate cell capsule and hydrogen peroxide production in MmmSC has been reviewed.[6] The disease is an acute lobar pneumonia and pleurisy. The organism invades the lungs of cattle and causes a mycoplasmemia; this results in localization in numerous other sites including the kidneys and brain, resulting in high morbidity and mortality. An essential part of the pathogenesis of the disease is thrombosis in the pulmonary vessels, probably prior to the development of pneumonic lesions. The mechanism of development of the thrombosis is not understood, but there is no general increase in blood coagulability, and no generalized tendency to spontaneous thrombosis.

The isolation of MmmSC from the semen of yearling bulls with seminal vesiculitis has been reported.[23]

The production of hydrogen peroxide and other active oxygen species is widely believed to play an important role in mycoplasma pathogenicity, and has been demonstrated to result in lysis of erythrocytes, the peroxidation of lipids in *M. mycoides* infected fibroblasts and inhibition of ciliary movement in tracheal organ cultures infected with *M. mycoides* and *M. ovipneumoniae*.[9,24] European MmmSC strains appear to be distinguished from other *M. mycoides* strains by their lack of glycerol phosphate oxidase activity and ability to oxidize glycerol.[24]

Death results from anoxia and presumably from toxemia. Under natural conditions a proportion of animals in a group do not become infected, either because of natural immunity or because they are not exposed to a sufficiently large infective dose. These animals may show a transient positive reaction to the complement fixation test. Approximately 50% of the animals that do become infected go through a mild form of the disease and are often recognized as clinical cases.

CLINICAL FINDINGS

There is considerable variation in the severity of clinical disease from hyperacute to acute to chronic and subacute forms.

Acute form

After an incubation period of 3–6 weeks (in occasional instances up to 6 months) there is a sudden onset of high fever (40°C; 105°F), a fall in milk yield, anorexia and cessation of rumination. There is severe depression and the animals stand apart or lag behind a traveling group. Coughing, at first only on exercise, and thoracic pain are evident; affected animals are disinclined to move, standing with the

elbows out, the back arched and head extended. Respirations are shallow, rapid and accompanied by expiratory grunting. Pain is evidenced on percussion of the chest. Auscultation reveals pleuritic friction sounds in the early stages of acute inflammation, and dullness, fluid sounds and moist gurgling crackles in the later stages of effusion. Dullness of areas of the lung may be detectable on percussion. Edematous swellings of the throat and dewlap may occur and swelling of the large movable joints may be present. In calves, valvular endocarditis and myocarditis may occur. In fatal cases death occurs after a variable course of from several days to 3 weeks. In the **hyperacute form**, affected cattle may die within 1 week after the onset of respiratory distress.

Chronic and subacute forms

Recovered animals may be clinically normal but in some an inactive sequestrum forms in the lung, with a necrotic center of sufficient size to produce a toxemia causing unthriftiness, a chronic cough, and mild respiratory distress on exercise. These sequestra commonly break down when the animal is exposed to environmental stress and cause an acute attack of the disease. In Europe, the disease is characterized by low morbidity and the mortality and the majority of infected cattle have chronic lesions. In Italy during the 1990s, less than 5% of cattle in an infected herd had evidence of clinical disease, which may be due to the use of antimicrobials and anti-inflammatory agents which may mask the clinical findings and allow the formation of chronic lesions. In Africa, up to one-third of acute cases that recover become potential carriers, which may be even higher in Europe where there is a more widespread use of antimicrobials.[2]

CLINICAL PATHOLOGY

Isolation or detection of organism

Isolation of the organism is essential for the diagnosis. The organism is nutritionally very fastidious and special laboratory media is required for growth and identification.[6] Final identification of mycoplasmas is usually made by growth inhibition or immunofluorescence tests on agar.[6] The **polymerase chain reaction** (PCR) has been used to identify the specific organism and differentiate it from other members of the cluster. The test can be used to detect small numbers of organisms in nasal mucous, pleural fluid and pulmonary tissue. The PCR can identify the organism in bacterial isolates or clinical material within 2 d of extraction and is highly specific.[25] The organism can also be identified using the PCR on nasal filter strips placed into the nasal cavities of cattle to be tested.[26]

Latex agglutination test. A latex agglutination test (LAT) for the diagnosis of CBPP uses latex microspheres coated with anti-MmmSC IgG and based upon the detection of MmmSC capsular polysaccharide antigen in the serum of infected animals is useful for the detection of acutely infected animals compared to the CFT which is not highly sensitive in the early stages of the disease or for animals with chronic lesions.[27] In comparison to the CFT, the MmmSC IgG-coated LAT exhibited 62 and 61% correlation in diagnosis at 2 to 3 min of incubation, respectively.[27] The LAT combines low cost and high specificity with ease of application in the field, without the need for any specialist training or equipment, and allows rapid and primary herd screening prior to confirmatory laboratory diagnosis (PCR or ELISA).

Serological tests

The complement fixation test (CFT) on serum is still the most useful method of detecting infection. It is rapid, simple to perform and easy to interpret the results. It is more specific than the ELISA tests, it lacks sensitivity for serum samples having a very low antibody level.[28] ELISA tests detect late and persistent infections while CFT detects early infections. In a small proportion of animals the results may be deceptive. Early cases may give a negative reaction and some positive reactors show no lesions on necropsy. High levels of circulating capsular polysaccharide antigen can lead to false-negative diagnoses due to antibody'making', and in up to 36% of CBPP positive animals may be undetectable by the CFT. The test is particularly effective in detecting carriers. Animals recovering from the disease gradually become negative and vaccinated animals give a positive reaction for about 6 weeks, although this period may be much longer if severe vaccination reactions occur. A slide flocculation test and a rapid slide agglutination test have been used but their sensitivity is lower than that of the complement fixation test and they are recommended for herd diagnosis rather than for use in individual animals. A modified complement fixation test, the'plate CFT'is more accurate than the standard CFT and is much more economical of time and equipment. It has been very accurate and efficient in Australia and made eradication possible. With all of these tests there is a progressive loss of reliability if testing is delayed for very long after the clinical disease has passed.

A comparison of Western and dot blotting techniques with the CFT, indirect enzyme-linked immunosorbent assay (ELISA), mycoplasma culture and gross lung pathology to detect the organism found that the blotting techniques were more sensitive than the CF or ELISA.[29]

An indirect ELISA based on a recombinant protein, LppQ-NX, known as the complete ELISA kit 'CHEKIT-CBPP' has been developed and provides good sensitivity and specificity for the diagnosis of CBPP and is robust under harsh climatic conditions.[30]

The CFT, immunoblotting, indirect ELISA, and competitive ELISA for detection of antibodies to MmmSC were compared in naturally infected cattle in the 1995 outbreak in Botswana.[28] The percentage of seropositive sample in the iELISA (50%), and in the c-ELISA (43%) were similar but lower than those obtained by the IBT (57%) and the CFT (61%). The percentages of positive sera in the IBT and CFT were also similar and overall the efficacy of these tests were better than that of the two ELISA tests. There was 95% agreement between the IBT and the CFT, 85% agreement between the IBT and c-ELISA, 91% agreement between the IBT and i-ELISA, 88% agreement between the i-ELISA and CFT, 80% agreement between the c-ELISA and CFT and 90% agreement between the two ELISA tests.[28]

No single serological test is capable of detecting all CBPP affected animals in the field, and which are useful for diagnosis at the herd level only. In the absence of a 'gold standard' test for the serological diagnosis of CBPP, some uncertainties remain unresolved.[28] Suspicious CBPP cases identified by positive serology must be confirmed by further investigations which demonstrate the presence of antigen in the respiratory tissues of animals. In CBPP free countries like Botswana, CFT should be used in conjunction with other serological tests where possible, so that every stage of disease could be followed serologically should the disease enter the country.

NECROPSY FINDINGS

Lesions are confined to the thoracic cavity and lungs and the lesions are usually unilateral.[6] The pleural cavity may contain large quantities of clear, yellow-brown fluid containing pieces of fibrin. This fluid is ideal for culture of the organism. Caseous fibrinous deposits are present on the parietal and visceral surfaces of the lungs. The interlobular septae are prominently distended with amber-colored fluid surrounding distended lymphatics. This fluid distinctly outlines the lobules which vary in color with red, gray, or yellow hepatization. Consolidation of the lungs with a typically marbled appearance is characteristic. In chronic or advanced cases, a sequestrum of necrotic lung varying size from 1–10 cm in diameter is surrounded by a fibrous capsule. If these sequestrae rupture and are drained by a bronchus

they can be a source of aerosol infection to cattle. Such a mechanism accounts for epidemics in closed herds. In affected calves, exudative peritonitis, arthritis, bursitis and fibrinous arthritis of carpal and tarsal joints may be present.

Histologically, in the early stages the typical lesion consists of bronchiolar necrosis and edema, progressing to exudative serofibrinous bronchiolitis with extension to the alveoli, and adjacent lymphatics.[6] This process extends to the tracheobronchial lymph nodes and pleural lymphatics. The mediastinal, sternal, aortic and intercostal lymph nodes are enlarged, edematous and hemorrhagic. Lymphatics become thrombosed and fibrosed. The pulmonary lobules become consolidated with alveolar edema, fibrin and inflammatory cells. Coagulation necrosis is common and the organism can be demonstrated in these lobules by immunohistochemistry.

Perivascular organization foci or 'organizing centers' in the interlobular septa, are considered typical of CBPP. They consist of a center occupied by a blood vessel with proliferation of connective and inflammatory cells surrounded by a peripheral zone of necrotic cells. Type I foci contain more proliferative cells in the central zone, which is larger than the peripheral zone. In Type II foci, the proliferative cells are scarce and the peripheral zone is relatively larger. Immunoreactive antigen is visible in the central zone inside blood vessels. Immunocytochemical tests can be used to detect the organism in tissue sections and provide valuable confirmatory diagnosis after slaughter. Stained antigen is visible in the smaller bronchioles and alveoli and within the interlobular septa of the lung. Immunofluorescent staining of impression smears of lungs may be more sensitive and rapid than culture.[6]

Renal lesions are frequently detectable in CBPP in field and experimental cases.[17] In the acute phase of the disease, multiple renal infarcts are common. In subacute and chronic cases, the infarcts progress to form large areas of fibrosis accompanied by tubular dystrophic calcification, tubular atrophy, and lymphocyte interstitial infiltrates. Immunohistochemically, the MmmSC antigen is present in several renal structures.

A PCR test has also been developed.[25] Abattoir surveillance of lung samples and tracheobronchial lymph node tissues for culture and identification of MmmSC, immunohistochemistry with peroxidase anti-peroxidase system, and molecular detection by the PCR amplification of specific DNA from MmmSC, and supported by serological tests is one of the best methods for the diagnosis of CBPP.[31]

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed lung (LM, IHC)
- **Mycoplasmology** – effusion fluid in serum tube, lung, bronchial lymph node (MCULT, FAT, PCR).

DIFFERENTIAL DIAGNOSIS

A diagnosis based on a history of contact with infected animals, clinical findings, a complement fixation test, necropsy findings and cultural examination is necessary.

Diseases which must be differentiated from CBPP include:

Rinderpest Erosive stomatitis, dysentery, and erosions throughout the alimentary tract

Foot and mouth disease Salivation, lameness, fever, and vesicular stomatitis

Hemorrhagic septicemia Acute disease with death in 6 to 72 hours. Edema of the neck and brisket, lung lesions similar to CBPP. Culture of *Pasteurella* spp.

Theileriosis (East Coast fever) Coughing, nasal and ocular discharge, diarrhea, enlargement of peripheral lymph nodes, ulceration of abomasum. No lung lesions

Ephemeral fever Ocular discharge, drooling saliva, lameness, enlarged joints, self-limiting disease of short duration; most affected cattle recover quickly; fluctuating fever; secondary pneumonia may occu.

Pulmonary abscesses Large abscesses containing foul-smelling purulent material; may have total destruction of lung

Tuberculosis Tubercular nodules may resemble CBPP sequestra but they are degenerative cheese-like lesions, often calcified

Farcy Abscesses of lungs containing foul-smelling material and enlarged local lymph nodes

Actinobacillosis Generalized lesions of lung and other adjacent tissues

Echinococcal (hydatid cysts) Pulmonary cysts with a double wall and containing clear fluid, often calcified when old

TREATMENT

No therapeutic treatment is effective. Antibiotics can have no role in the eradication of CBPP either at the farm level, or more importantly, nationally and internationally. Antibiotics can alleviate the clinical course of the disease enabling some improvement in condition. For the individual farmer, particularly the nomad, this prevents the loss of, often, his only form of income and livelihood. However, a treatment strategy must be balanced against the difficulty created by subclinical carrier cattle spreading the disease across international boundaries which often results in explosive outbreaks amongst susceptible populations. In reality, antibiotics are used and thus advice is necessary about which ones are most effective.

An in vitro trial of five commonly used antibiotics on recent isolates of MmmSC found that tilmicosin and danafloxacin were effective both in terms of mycoplasmastatic, and mycoplasmacidal activity.[32] Florofenicol and tetracycline were intermediate, and spectinomycin was ineffective against some strains.

CONTROL

The major obstacles to the control and eradication of the disease are:

- Difficulty in controlling the movements of cattle, especially in sub-Sahara Africa
- Complications of applying quarantine and slaughter policies
- Lack of rapid pen-side diagnostic tests
- Ineffective vaccines
- Insufficient funds to implement control policies
- Civil strife and drought, which have an effect on the spread of the disease in Africa.

Social and civil disturbances interfere with effective disease control. Cattle may be stolen and sold far from their point of origin. Hungry soldiers disregard movement laws. Refugees fleeing war zones sell their cattle before moving, which changes the usual pattern of livestock movement. Farmers fleeing civil unrest may move their cattle to endemic areas and then return with them when the threat is over. This explains the spread of disease into Rwanda from Uganda and Tanzania in 1994. The indiscriminate movement of cattle by cattle traders accelerates the spread of disease. The movement of cattle from sparsely populated areas to densely populated areas is a major risk factor and trade depots and feedlots which receive cattle from other parts of the country regularly experience epidemics. When outbreaks occur, village traders commonly dispose of their animals to traders. It has been suggested that nomadism and pastoralism are major means of transmission of the disease from one area to another.

Control and eradication are applied to the individual herd and to the area with the goal of eradication in the country. The possible strategies used for control in affected countries or regions are:

- **Slaughter of all sick and in-contact cattle.** This requires full cooperation of cattle owners and an adequate and timely compensation system. This strategy is impractical in developing countries with a pastoral economy
- **Slaughter of all sick cattle and vaccination of in-contact cattle.** This strategy is used frequently and usually perpetuates the disease

- **Vaccination of healthy cattle with slaughter of sick cattle in an epidemic and revaccination of cattle at risk.** This method depends on the ability of the authorities to detect epidemics rapidly, most effectively, by abattoir surveillance and to maintain vaccination for at least 3 years. Vaccination in endemic areas must be done annually while newly infected areas require repeat vaccinations aimed at eradication of the disease after 3, 9, 21, and 36 months. Specific therapy is prohibited.

On a herd basis

When the disease becomes established in a herd the following measures may be adopted to prevent its spread.

Removal of sources of infection

Infected animals should be removed from the herd as soon as possible. The CFT is adequate to identify the infected animals and should be carried out in conjunction with clinical examination. Because animals in the incubation and early stages of the disease may test negative, it is necessary to have two negative tests 2 months apart before the herd can be classified as clean. After vaccination a positive reaction occurs; this usually disappears within 2 months but may persist for 5 months. All positive and suspicious reactors and clinical cases should be destroyed or transported under close control to abattoirs. Where this cannot be done without a chance of spread to animals along the route, destruction on the farm is necessary. Animals which eventually go to abattoirs should be kept under quarantine until slaughter, irrespective of their status.

In circumstances where a minimum of handling is desired, the herd may be blood tested and examined for clinical signs, and vaccinated all in the one visit. Animals which react to the test are then destroyed even though they have been vaccinated. The only difficulty that arises with this method is that cattle in the incubative stages of the disease may give a negative reaction to the test and, because of the serological reaction resulting from vaccination, retesting cannot be performed until 2 months later.

Hygiene

Any procedure which brings the animals together should be avoided. Passage through the milking shed, collecting for inspection, bleeding and vaccination all facilitate spread, especially in humid conditions, when droplet inhalation is more likely to occur. Strict quarantine of the infected and in-contact herds must be maintained until all residual infection has been eliminated – usually 12 weeks after the removal of the last reactor and/or clinical case is sufficient time. Animals in quarantine should be kept under constant surveillance so that clinical cases may be observed.

Vaccination

All effective CBPP vaccines have been based upon live versions of the disease-causing mycoplasma, either attenuated or not.[33] Current vaccine strains (T_1 44 and T_1 SR) for CBPP are made from freeze dried broth cultures of live attenuated *Mycoplasma mycoides* subsp. *mycoides* SC and are generally considered to exhibit poor efficacy and stability. Protection is low (only 30 to 60% of animals are protected), and short-lived (6–12 months), and repeated vaccination is necessary.[34] However, the poor efficacy of vaccines appears to be recent phenomenon because the vaccines used as early as 1852 and up until 1926 were efficacious although the procedure involved the implantation in the tail tip of serous fluid from diseased animals.[34] Recent experiences with the T_1 44 vaccine in Namibia showed that it was highly effective in bringing CBPP under control. The current vaccine is highly effective when administered as part of a well conducted vaccination campaign, in which high levels of coverage are achieved (in excess of 80%) and in which the vaccine is rapidly used following reconstitution (before a significant loss in titer occurred). If these conditions could be achieved over the entire continent, CBPP would probably be a disease of the past. The T_1 44 vaccine which is given subcutaneously has been successfully used to control CBPP in different regions of Africa and has advantages and disadvantages. A number of postvaccinal reactions may occur. Within two to four weeks following injection, an invading edema develops known as the 'Willems' reaction.[35,36] The incidence of these reactions varies from area to another.

The reversion to virulence of the T_1 44 vaccine has also been observed when it was serially passaged by endobronchial intubation resulting in the development of lesions of CBPP in animals which were infectious to in-contact animals. This suggests animals given the currently used vaccines (T_1 44 and T_1 SR) subcutaneously could be reservoirs for MmmSC and infect other animals in areas previously free of CBPP. Similarly, vaccination with the V_5 vaccine was abandoned in Australia when the prevalence of CBPP was sufficiently low, because the vaccine was responsible for erratic foci. In some situations, the T_1 44 vaccine induces a good immunity, especially when herds are revaccinated annually in which case the level of protection exceeds 85% which compares favorably with a number of other bacterial vaccines. The T_1 SR strain is completely devoid of residual virulence and the level of protection afforded seems to be similar to that provided by the T_1 44 vaccine after 3 months.

Recommendations to improve the efficacy of CBPP vaccines have been reviewed and include methods of preparing the vaccines, and reconstitution procedures and solutions.[34] The literature on the history of the vaccines has been reviewed.[37]

Inactivated CBPP vaccines have been field tested but results have been inconclusive.[38] Immunostimulating complex (ISCOM) protein subunit vaccines have been developed and early results are encouraging. The capsular polysaccharide (CPS) of MmmSC is an important surface antigen and pathogenicity factor previously known as a galactan. The immune response in mice of capsular polysaccharide conjugate vaccines against CBPP indicates that protection against MmmSC mycoplasmemia in mice is cell-mediated rather than humoral immunity.[38]

CBPP was successfully eradicated from Australia using the V5 broth vaccine, with no problems regarding efficacy or thermostability under field conditions.[11]

Vaccination is an effective procedure for control but its application is usually controlled by local legislation. All the vaccines in use are living preparations and their use is always subject to the suspicion that they may spread the disease. When tail vaccination with organisms of reduced virulence is practised, the possibility of spreading the disease is remote but because the possibility exists, vaccination is usually only permitted in herds or areas where the disease is known to be present. The value of calfhood vaccination is limited because arthritis, myocarditis and valvular endocarditis occur 3–4 weeks after vaccination of calves less than 2 months old. Vaccination of calves after this age is recommended because it avoids the occasional deaths which occur after vaccination of adults.

The vaccines available include pleural exudate from natural cases (natural lymph), cultured organisms of reduced virulence, and an avianized vaccine of low virulence. Vaccination is usually carried out by injection into the tough connective tissue at the tip of the tail with a high-pressure syringe. 'Natural lymph' is unsatisfactory because of the possibility of spreading this and other diseases and because of the severe lesions which commonly result. Severe reactions with this type of vaccine may cause sloughing of the tail and extensive cellulitis of the hindquarters, necessitating destruction or causing death of the animal. An intranasal vaccine avoids these sequels and appears to give satisfactory results. If animals which develop

a severe local lesion after vaccination are treated with a mycoplasmocidal drug, such as tylosin, the treatment will interfere with the development of immunity and animals treated in this way should be revaccinated.

In general, vaccines made from *M. mycoides* grown in broth culture cause less severe reactions but a correspondingly briefer immunity of about 6–10 months and require annual revaccination. The T1 strain broth culture vaccine is the one in most general use in the nomadic cattle herds of Africa. It has the virtue of long-term immunity, of at least 2 years' duration. Avianized vaccines have been developed which overcame the brevity of the immunity, increasing its duration to 3–4 years. These vaccines are the major types in use now and are capable of great variation in their virulence. In spite of increasing the attenuation, the use of these vaccines has been followed on occasions by severe local reactions and pulmonary lesions. This led to an investigation of the KH3J strain, which is less virulent than the standard V5 strain. A vaccine attenuated by egg culture but grown in its last passage in broth eventuated and eliminated the egg proteins from the vaccine which were thought to produce some of the local reactions. However, the more virulent vaccines are still in use and, provided tylosin is available to control undesirably severe reactions, are generally preferred. All vaccines against CBPP are susceptible to light and should be kept in a dark place.

On an area basis

The prevention of entry of infected animals into a free area is a difficult task. Only the following classes of cattle should be permitted to enter:

1. Cattle which have not been in an infected area nor in contact with infected animals for at least 6 months. This may be relaxed to permit entry of cattle going to immediate slaughter after a clinical examination and a period of 1 month in a free area
2. Cattle which have given negative reactions to the CFT on two occasions within the preceding 2 months and have not been in contact with infected animals during this period. These animals may or may not have been vaccinated. Less rigid measures than these will permit introduction of the disease.

When the disease is already present in an area, two methods of control are possible: vaccination and eradication by test and slaughter of reactors. The method chosen will depend largely on the economy of the cattle industry in the affected area. A vaccination program may be the first step to reduce the incidence of the disease to the point where eradication becomes possible.

In areas where farms are large, fencing is poor and the collection of every animal cannot be guaranteed, eradication of the disease by test and slaughter is impractical. Vaccination with culture vaccine can be practiced whenever the cattle are brought together. Animals moving out of or into infected areas, and groups of cattle which contain active cases, must be vaccinated. Moving cattle which develop the disease should be halted, clinical cases slaughtered and the remainder vaccinated. Results are usually good provided the vaccination is carried out carefully but some further cases due to prevaccination infection are to be expected. Extensive vaccination in Australia reduced the incidence of the disease to an extremely low level and complete eradication of the disease was achieved shortly afterwards. The residual problems were largely geographical and an annoying but low proportion of false-positive reactors to the CFT. Eradication was greatly facilitated by the use of the plate agglutination test in a mobile laboratory and autopsy of reactors 24 h later. Of great help also was the appointment of special meat inspectors to local abattoirs during the eradication program.

In countries where the cattle population is nomadic, control and eradication seems impossible by the conventional means described above. Annual vaccination of as many cattle as can be found has the capacity to reduce the occurrence of the disease to negligible proportions.

When outbreaks occur in small areas where herds can be adequately controlled, complete eradication should be attempted by periodic testing and the destruction of reactors, and in-contact animals should be vaccinated. To avoid unnecessary contact between cattle, retesting is delayed until 5–6 months after the first test when vaccination reactions have usually subsided. Under most circumstances all non-reactors should be vaccinated. This practice is particularly applicable in feeder cattle which will be slaughtered subsequently and when extensive outbreaks occur in closely settled areas where the chances of spread are great. Simple test and slaughter in these latter circumstances will be too slow to control the rate of spread. In either case the herd should not be released from quarantine until two tests at an interval of more than 2 months are completely negative.

In Portugal where CBPP is endemic in certain regions, for control purposes the country is divided into three regions: infected, buffer and disease-free. In the infected areas, cattle over 6 months of age are tested twice yearly. In the buffer region, serological testing is compulsory for at least 50% of all cattle. In the disease-free regions serological testing is reduced to 10% of all cattle. Seropositive cattle in the endemic zone are slaughtered; if these cattle have lesions, the rest of the herd is slaughtered and cattle movement is prohibited within a 2 km diameter of the farm. Restrictions are lifted on neighboring farms only following three consecutive negative CFTs done at 2-month intervals on all cattle. In the disease-free zones seropositive cattle are retested. The trend from 1990 to 1995 has been a reduction in the number of outbreaks.[6]

In Italy, control is based on abattoir surveillance and serological testing before movement of cattle. The policy of slaughter of both affected and contact cattle appears to have been effective.

Office des International Epizooties Plan for Eradication
